Introduction

This volume of Congress proceedings includes the full text or summaries of oral presentations in Sub-Plenary sessions received by 31 May 2000. Minor changes may have occurred since that date. The session moderator will mention them when opening the session.

The following Sub-Plenary sessions include posters:

Tuesday 8th August:

•A2 Sustainable management of natural resources. Fire and Forest

Wednesday 9th August:

•A5 Sustainable management of natural resources. Sustainable forest management and productivity

•B4 Forest and society needs. Evaluation of technologies for society needs

Corresponding poster summaries are not only in this volume; they are also published in the last section of the poster summary volume of the proceedings

Special thanks to authors for their contributions to the scientific programme of this Congress.

Enjoy your stay in Malaysia

Eric Teissier du Cros, Chairman of CSC

Abdul Rahim Nik, Chairman of the COC

Note: The full papers and summaries have been published as received from the authors and reviewers, respectively, who have sole responsibility for their contents

Abstract

There is now broad agreement amongst researchers that forestry activities have the potential to alter catchment water balances and thus change the amount and timing of catchment streamflows. Paired catchment experiments from around the world have provided a robust data base on which to found theories about the effects of forest cover on catchment water balances and runoff dynamics. However, it has been shown that different catchments respond to changes in forest cover in a variety of ways. Climate, topography, soils and the forest type each exert particular influences on the hydrologic function of catchments and their response to forest cover change. This review examines the findings of a variety of studies and seeks to develop generalisations about the effects of forest cover on catchment water balance and runoff dynamics. We focus on water yield or the amount of streamflow, streamflow seasonality and flow frequency, and the magnitude of peak flows.

There is strong evidence to show that forest cover tends to enhance evapotranspiration and reduce water yields, relative to what would arise from catchments under grass or crop cover. The extent to which yields are affected by forest cover change seems to vary primarily as a function of annual rainfall and forest type, and to a lesser extent by local climatic conditions. The greatest changes in water yield following forest disturbance tend to occur in the wettest areas, primarily because of the important effect of rainfall interception by forest canopies. Generally speaking, the lowest yields are generated by conifer forests, followed by evergreen hardwoods and then deciduous hardwoods. These differences are attributable to differences in the amount of leaf area and the effect that this exerts on transpiration and rainfall interception. There are some special types of forest in low radiation environments which tend to yield very high amounts of runoff, relative to the rainfall they receive, because of low evapotranspiration rates. Examples include tropical cloud forests and temperate native forests in the uplands and coastal areas of New Zealand. Alternatively, on the coastal margins in tropical areas, evapotranspiration rates are higher than normal because of advection of energy from the ocean, leading to lesser runoff from forests sited in these areas.

Some studies indicate that forest age also affects evapotranspiration and water yield, with old growth forests tending to produce more runoff than actively regenerating forest. Whilst the occurrence of this phenomena has only been conclusively demonstrated for some Australian eucalypt forest catchments, recent north American research has shown that photosynthesis and water use per unit leaf area decline as forest ages. These findings imply that catchment water yields should increase as forests age.

We review the fledgling literature linking forest cover to runoff seasonality and flow frequency. This is an important issue as the temporal distribution of flows has important consequences for the security of water for downstream enterprises (in the case of low flows), and the safety of dams, roads, culverts and bridges (in the case of high flows). Almost all catchment studies have noted that low, medium and high flows decrease as a consequence of afforestation, and increase as a result of forest clearance. However, low flows and high flows do not always change by the same amount as annual flows, with different parts of the streamflow range being more affected than others, depending on site factors such as soil depth and properties, and forest type.

We conclude our review by highlighting gaps in the field of research linking forest cover to catchment water balance and runoff dynamics.

Abstract

With the expansion of forest hydrology research from mid-latitudinal areas to tropical and boreal forests, a diversity of hydrological process patterns began to emerge that has since been tentatively explained along geographical lines. Our much improved knowledge of runoff generation processes, however, allows us to discard geographical straitjackets and explain the quite diverse hydrological functioning of forests world-wide in terms of those soil, meteorological, and geomorphological factors that control the movement of water on landscapes. Hence, we propose a functional approach to the classification of forest ecosystems based on those factors.

This approach entails a two-tiered screening of forested catchments based on adequate data. We first differentiate according to geomorphological criteria between catchments with low relief or wide valley floors and catchments of high relief that are deeply incised (e.g. small or no valley floors). The basic tenet underlying this differentiation is that groundwater plays a more important role in the former than in the latter. Next, we differentiate according to the interaction between soil and rainfall characteristics that controls the partitioning of rainfall into vertical and horizontal hillslope flowpaths, and therefore determines the degree of hillslope-channel coupling. High rainfall intensities, normalized to soil saturated hydraulic conductivity, or high rainfall amounts, normalized to depth to an impermeable layer, favor horizontal, near-surface hillslope flowpaths, and hence a tight hillslope-channel coupling; the reverse is true for low rainfall intensity or rainfall amount environments. This functional classification based on flowpaths that are controlled by soil, landscape and meteorological factors has necessary implications for stream water chemistry as it implies different kinds of water-regolith interactions in hydrologically different environments.

Our proposed evaluation and classification scheme is consistent for forested catchments across the spectrum of humid tropics, mid-latitudes, and boreal regions. In each case, we weigh our classification in each case by the quality of the published data. To avoid scaling issues, we restrict our survey to ‘small’ catchments; this restriction excludes hillslope- and landscape-scale studies.

We conclude our review by highlighting previously under-studied forest ecosystems and gaps in our process knowledge.

Abstract

High levels of sediment discharge into forest streams and rivers as well as resulting degradation of aquatic habitat have widely been blamed on intensive and extensive forest management activities. Additionally, reductions in site productivity of forest lands can also be related to accelerated erosion processes, both surface erosion and mass wasting. The burden of these environmental impacts that has been placed on forestry management may be overstated in many cases but, depending on the particular practice and region, may be partially or totally justified. In assessing the potential impacts of forest management activities, an important distinction needs to be drawn between surface erosion processes and mass wasting or landslide processes. This paper will attempt to link particular management activities with each of these erosion processes. We will focus on the Pacific Rim region because of its steep terrain, predominant forest cover, regionally active tectonics, high precipitation (total amounts and intensities) associated with mountainous and maritime zones, past and recent patterns of settlement, and widespread land use changes over the past few centuries.

In managed forest terrain where the infiltration capacity of soils is maintained, surface erosion is generally not a problem. Infiltration capacity of forest soils is reduced when soils are compacted or if organic horizons are removed in certain environments allowing the mineral soil to be exposed to forces of high intensity raindrop impact. Soil compaction related to forestry operations occurs on skid and haul roads, trails, landings, and other areas where heavy machinery operates. Excessive disturbance that exposes large areas of forest soil can be associated with certain types of ground skidding and site preparation practices. Other significant contributors to soil compaction and disturbance include intense grazing, recreational use, and residential development in forested areas. These impacts are magnified if they occur near stream channels and can generate increased peak flows, channel instability, and resultant high sediment loads. Riparian forest buffers around streams can minimize the sediment delivery to channels, promote infiltration and subsurface flow, and provide exchange sites for nutrients and pollutants. Forest roads and drainage systems in particular provide efficient conduits (as well as sources) for sediment delivery to streams during storm events. Short-term increases in surface erosion can result from burning and the creation of a hydrophobic layer in the surface soils. Surface erosion becomes a particular concern in steep terrain when agricultural or intense forestry practices are conducted which result in the removal or destruction of significant portions of the soil organic horizon. Such anthropogenic actions expose the more erodible underlying mineral soils to raindrop impact and, depending on soil and site conditions, may initiate rill and gully erosion on steep slopes. Modeling surface erosion in steep managed forest terrain is difficult because most databases used in the development of empirical models (e.g. USLE) have not historically included such sites and complex topography complicates the application of more theoretical models.

Factors that control the stability of steep forested terrain may be in a tenuous state of equilibrium that can easily be upset by human activities. Steep hillslopes with shallow soil mantles are typically unstable especially in regions of high precipitation and recent tectonic activity. In many of these areas worldwide, shallow landslides are the dominant erosion and sediment delivery processes. Timber harvesting activities in steep terrain can affect the stability of hillslopes by reducing the cohesion associated with tree roots. Rooting strength is typically at a minimum 3 to 15 years following clearcutting; however the recovery of rooting strength is dependent on the regeneration techniques used

at the site, available soil nutrients and moisture, and a host of other environmental and cultural factors. Additionally, the probability of a landslide occurring in a harvested site is partly controlled by local hydrogeomorphic and topographic attributes as well as influenced by silvicultural methods. All of these factors act together in establishing the conditions of site stability; however, an episodic rainstorm or snowmelt event must occur that generates a critical pore water pressure in the soil mantle to trigger the landslide. Deep-seated slope failures, such as rotational slumps and earthflows, are typically less associated with timber harvesting because tree roots rarely penetrate deep into the unstable soil mantle.

However, effects of roads and road drainage have been known to trigger or accelerate deep-seated mass movements by short-circuiting water to the failure surface. Progress is being made on developing predictive methods for landslides, especially for shallow mass movements, that are physically based and distributed. However, such models require rather intensive data inputs and may be difficult to apply in remote areas. Alternative approaches to landslide hazard assessment in more remote areas have been developed using digital terrain data, geological information, climatic data, land use maps, and other remotely sensed data. Successful application of such GIS-based models is contingent upon using terrain indicators that are closely linked with processes that control slope stability.

Abstract

Forest harvesting activities, such as road construction and the associated disturbance of soil and vegetation on logged hillslopes are widely considered as potential 'non-point sources' (NPS) of stream water pollution. Research over the past three decades has been conducted with the general aim of improving our ability to protect water resources in forested catchments. In many instances our knowledge is restricted because much of this work has focused on plot scale on-site soil erosion processes or subcatchment monitoring of turbidity or suspended sediment concentrations before and after a specific treatment. Both approaches have serious limitations that are commonly overlooked in our interpretation of the research findings and in assessing the most effective pollution control practices. The major aim of this chapter is to introduce a framework that investigates the potential impacts of forestry activities on water resources using concepts of sediment delivery and connectivity. The framework explicitly considers the transfer and delivery of material from a sediment/pollutant source to the stream network via processes of overland and channeled flow.

A state-of-the-art review of the international literature points to an abundance of data on processes and rates of sediment detachment and related on-site erosion impacts. These studies are unanimous in their findings; forest activities, in particular roading, track construction, cause increased soil compaction, decreased hydraulic conductivity, increased runoff and soil erosion at the point of disturbance. Roads and tracks are recognised as the dominant sources of both runoff and sediment and the general logged area occupying much of the catchment by area, is both a localised source and sink depending upon such factors as the degree of soil disturbance and the intensity and duration of rainfall. Studies on off-site impacts present no consistent message regarding post-logging sediment loads or the precise relationship to forestry-related disturbances on the hillslopes. In-stream data from paired catchment studies are best viewed as the summation of sediment detachment, delivery, storage and transfer processes and rates from the specific catchment outlet. The missing link between these two types of research approaches is quantification of the connection or delivery pathway between sources of sediment and the stream network. In developing this conceptual framework, we propose that the delivery and routing of sediment and associated pollutants from key sources such as roads, tracks, and general harvesting areas to streams depends upon, and reflects the interaction of two key factors. These are; (1) surface runoff rates at source, and (2) the characteristics of the delivery pathway, including the distance between runoff source and the stream network. Proximity to the stream network is well-represented using 'available hillslope length' as an index of overland flow path length. Recognition of the dominant runoff pathway over the dominant sediment source is an important distinction over previous approaches. The characteristics of the delivery pathway are broadly categorised as extensions of the stream network (new gullies) and diffuse overland flow pathways on vegetated hillslopes.

The second part of this chapter provides a structured consideration of source to stream connection by introducing a design approach that guides road or track drainage spacing for the combined inputs of rainfall intensity, distance to stream and road/track outfall gradient. This framework provides guidelines for road and track design in forestry environments with the objective of minimising the connection of road, tracks and other compacted areas to streams.

New Remote Measurement Tools in Forest Hydrology

by
A. Alexander Held
Remote Sensing and Spatial Analysis Group,
CSIRO Land and Water, Canberra, Australia
Tel: +61-2-62465718, Fax: +61-2-62465815,
E-mail: alex.held@cbr.clw.csiro.au

Abstract

Remote sensing data have traditionally been difficult to use directly for management purposes, or as inputs to hydrologic models. Correlation models are often required for the conversion from remotely sensed data to key variables used in forest hydrology applications, such as terrain attributes, vegetative cover, vegetation function, aerodynamic or canopy resistances, increasing the cost of data acquisition by remote measurement. The density of information provided by these instruments, however is unequalled, when compared to other spatial representations of landscape variables, often derived from point measurements.On board aircraft or satellite platforms, they provide catchment-scale or regional measurements with 100-percent coverage. Sensors used in aircraft usually offer higher spatial resolution, while their larger, satellite-borne counterparts are used for wider coverage and routine revisits.

A number of hydrologic models are currently using remotely sensed data as inputs in their vegetation cover sections. With further refinements, these types of models will soon be able to include more accurate forest cover information such as the spatial distribution of the different forest regrowth stages, currently being produced from multi-spectral satellite data. In addition, new systems are coming online, which offer more direct measurements of variables of interest and a capability for 'precision forest measurement'. These new sensors are also better calibrated and more sensitive for detection of increasingly subtle changes in the environment below.

Topographical data can now be collected by laser scanning systems and radar interferometers at sub-metre resolution and with high geopositional accuracy. Operational airborne laser systems in use today measure the distance between the aircraft and the ground directly, using very accurate measurements of aircraft position and fast digitising of the return light pulse, thus creating three-dimensional descriptions of the terrain below. In addition, prototype systems, developed by NASA are now capable of very high frequency digitisation of the return signal, hence providing the opportunity for detailed vegetation structure and biomass mapping. Spaceborne missions with laser profiling sensors onboard are already planned for deployment within the next 12 months. In addition to laser systems, radar interferometers allow for 'all-weather' topography, and soon vegetation structure mapping, using analogous methods to stereo photogrammetry, but using the microwave part of the electromagnetic spectrum. A spaceborne radar interferometer was deployed in early 2000 on the NASA Space Shuttle for global topographic mapping.

New imaging spectrometer systems, on the other hand, allow for more detailed chemical analysis of the objects below, and derivation of aspects of vegetation function. Using the principles of spectroscopy, traces of light reflectance from the vegetation or soil (termed spectral signatures) are matched against a 'spectral library' for pure specimens (termed 'endmembers'). This allows for use of new 'Imaging Specrometers' (also termed hyperspectral imagers), to create 2-dimensional maps of the presence and relative concentration of different compounds on the surface below. In other uses, specific regions of the plant reflectance spectrum are used for quantification of the composition of the samples, including nitrogen and water content. A number of narrow-band 'spectral indexes' have also been recently proposed, which are closely linked to pigment dynamics in plants, and in turn can be associated to their photochemical efficiency and stress levels. New forest growth and function models are expected to use this type of data as input or as validation of their sub-daily plant function predictions. In addition to highlighting new methodologies applied to traditional remote sensors, this review provides a technical background of new remote sensing systems, techniques and some examples of their use.

Keywords: Remote sensing, Forest hydrology

The Use of Stable Isotopes of Water and Carbon for Investigating Plant Water Use Strategies

by
Glen Walker[1], Michele Akeroyd[2] and Kate Nicholls[1]
[1] CSIRO Land and Water, PMB 2, Glen Osmond, SA 5064, Australia
[2]AFFA, GPO Box 858, Canberra, ACT 2601, Australia

Abstract

There has been an increase in the use of isotopes in determining the sources of plant water and the water use efficiencies of species and genotypes. Studies have encompassed a variety of plants including agronomic species (wheat, alfalfa, wheatgrass), mangroves, halophytes, deciduous trees and evergreen species. Increasingly, studies are integrating isotopes into ecological and water balance studies, of which the isotope component is only one part. Isotopes can provide information that can not be supplied by other techniques, provided appropriate care is taken with the errors and vagaries of isotopic techniques.

The principle of the stable isotope technique for sourcing plant water is the isotope composition in the plant conducting tissue is the same as that of the sources. Perhaps, the greatest potential source of the error with the technique is the extraction of water from soils. This can exceed the variation in ^{2}H and ^{18}O of water sources and hence make the technique unworkable. It is important that extraction procedures are verified, and inexperienced personnel receive training in specialist laboratories or alternatively have analyses done in those laboratories. It is also important how and where the plant sample is collected to minimise sampling errors and temporal changes must be considered in any sampling regime. There is a need to avoid evaporation on all soil, groundwater, rain and plant sampling. An intensive field study in SE Australia found that the difference between expected isotopic values of sources and that found in the plant xylem was less than 5‰ for ^{2}H and 1‰ for ^{18}O. This experiment was conducted over a range of extreme conditions and hence we believe that the method is robust.

Isotopes in the wood cellulose of tree rings can also provide a historical chronology of water use for trees. This can be useful in attempting to understand hydrological dynamics throughout the life span of the forest or understanding land use change impacts within the catchment. Unlike isotopic investigations of environmental and plant waters, there are small errors associated with the extraction of isotopes from the wood sample. However, there are a number of other limitations in using this approach such as 1) the degree of variability between plant physiological processes and the environmental variation of isotopes, 2) not all tree rings are grown annually, and 3) what are the age and population effects with regard to isotopic variability? These issues will be discussed in this chapter along with specific examples related to plant water sources and plant water use. Despite the possible limitations of this technique, it can provide a valuable insight into the longterm dynamics of forest hydrology.

The isotope method is an inverse method, i.e. the isotopic composition in the plant is used to infer information about the sources. It should be remembered that there is limited information contained in the isotope measurements. Hence, isotopes used by themselves represent a relatively blunt instrument. The integration of isotopes with other data such as piezometric data, transpiration fluxes, soil and leaf water potential, etc. allows more sophisticated interpretations of plant water use strategies. In particular, the use of isotope data to test the calibration and assumptions in a model that has been calibrated independently of the isotope data brings forth many possibilities. Models, whether conceptual or quantitative is a means of bringing prior knowledge into the interpretation of plant processes.

With the experimental basis described in this chapter, there are no reasons why isotopes can not be used more in agronomic, forestry and ecological studies. Isotopes allow measurements of processes that can not be obtained in any other way, provided some of the difficulties with the method are not

underestimated. The advances in soil moisture monitoring and transpiration measurements, as well as vegetation-soil models, together with isotopes, should see large advances in our understanding of plant water strategies over the next ten years.

Keywords: Water and carbon isotope, Plant water use

Hydro-Ecological Modelling of the Impacts of Environmental Change on Forested Ecosystems at the Watershed Scale

by
Fred G. R. Watson[1], Lawrence, E. Band[2] and Lars, L. Pierce[1]
[1]California State University Monterey Bay, Seaside, CA, USA
[2]University of North Carolina, NC, USA

Abstract

The past few decades have seen unprecedented public concern for the sustainability of terrestrial ecosystems over a range of scales. Remote sensing has alerted us to the extent to which we are changing the usage and cover of the land surface, and through both experiments and modelling at local scales, it is clear that these changes significantly affect water resources. Current concerns about watersheds have gone beyond water yield, and now include issues of water quality, sedimentation, wood production, fisheries, nutrient cycling, recreation, and biodiversity. Understanding human impacts on watersheds, including land use change, direct addition or extraction of water and chemicals, and flow path alteration, is critical. Most of our current knowledge about forest ecosystem processes is derived from plot scale studies, and models which look at one dimensional water, carbon, and nutrient cycling. However, most of our knowledge and experience in hydrology are based on applications at the hillslope to watershed scale, and on models which focus on runoff production and routing. The issues which we have defined require interactions between these two approaches. A convenient intersection of plot level and watershed scales occurs at the hillslope level. Hillslopes have closed boundaries (drainage divides), a lower absorbing boundary (stream channel), and fairly uniform slope and aspect. In this paper, we review current approaches which tightly couple carbon/water/nutrient cycling with hydrologic routing at the hillslope to watershed level. Such approaches address a range of watershed management issues including the effects of riparian buffer strips, silvicultural practices, road construction, forest senescence, acid deposition, and global climate change on water quantity, water quality, sedimentation, productivity, and nutrient cycling. Coupled approaches usually rely on established, pre-existing models as their basic components. Therefore, we also review the key lines of model evolution in the component areas of watershed hydrology, ecosystem growth, biogeochemical cycling, and sediment and nutrient transport. Linkages between these areas occur over varying spatio-temporal scales. A spatio-temporal framework is erected, and each modelled process and linkage is located within this framework. This facilitates a better understanding of the importance of coupled hydro-ecological modelling, particularly with respect to interactions which are only observed at long time scales (> 10 years). Case studies selected for closer examination include modelling the effects of forestry on water yield, modelling the effects of land use / land cover change on water quality and quantity, and modelling the effects of global environmental change on large-scale hydro-ecological and biogeochemical cycles. A number of important conceptual limitations to the advance of hydro-ecological modelling are discussed. Many long-term studies are limited by the lack of a universal, mechanistic understanding of the processes governing forest ageing. Scaling issues are also pertinent. Many established models do not adequately address the gap between the experimental scale at which physical governing equations were derived and the scale at which they are used to make predictions of watershed behaviour. There are also practical limitations, which do not necessarily require a fundamental advance in knowledge, just better technology. These include the low standard of software engineering in many models, restrictive spatial structures (e.g. grid cells), and a reluctance to apply existing landscape partitioning technology. In our discussion, we look to the future of hydro-ecological modelling. A greater level of model integration seems certain, but this must be accompanied by concomitant elucidation of the dominant governing forces if it is not to be lost in a miasma of improperly combined equations and computer code.

The Fire and Smoke Episodes of 1983 to 1998 in South East Asia: Ecological Background, Socio-Economic and Environmental Implications, and Challenges for Regional and Global Fire Research Programmes

by

Johann G. Goldammer
Fire Ecology Research Group,
Max Planck Institute for Chemistry
The Global Fire Monitoring Center / FIREGLOBE
c/o Freiburg University, P.O.Box, D-79085 Freiburg, GERMANY
http://www.uni-freiburg.de/fireglobe/

Abstract

The environmental and socio-economic consequences of application of fire in land-use systems and occurrence of wildfires in forests and other vegetation in South East Asia have long been ignored. Long-lasting regional smoke-haze episodes during the extreme droughts associated with the El Niño-Southern Oscillation (ENSO) phenomenon have occurred repeatedly between 1983 and 1998. The situation in 1998 triggered unprecedented awareness of the science community and on the political arena at national and international levels. This paper summarizes the state-of-knowledge on the fire environment in South East Asia, particularly basics of fire ecology, fire occurrence, and fire-generated smoke problems in SE Asia. It also provides a summary of international research and development projects and programmes.

Keywords: Fire ecology, Wildfire, Land-use fire, Forest conversion, Climate variability, El Niño-Southern Oscillation (ENSO)

Introduction

At the occasion of the IUFRO World Congress in Malaysia, a country embedded in one of the most diverse fire regions of the globe, this paper aims to provide a summary on the fire environment in South East Asia, particularly basics of fire ecology, fire occurrence, and fire-generated smoke problems in SE Asia. This paper is an updated and shortened version of earlier analyses of the author.

Fire has been present in the SE Asian biota since the Pleistocene. Long-term climate variability (glacial vs. non-glacial climate) and short-term climate oscillations caused by the El Niño-Southern Oscillation (ENSO) event have repeatedly created conditions that make even rain forest subjected to wildfires. The occurrence of wildfires is increasing with modern land-use changes. Forest degradation and repeated fires lead to the formation of fire climax grasslands of low productivity and short-return interval fires. In monsoon forests of mainland South Asia annual fires during the dry season have shaped the composition and productivity of this forest environment by selecting fire-tolerant species. Severe problems of land degradation (erosion, loss of nutrients) are the consequence of fires in these seasonally dry forests. Fire protection (fire exclusion) leads to a progressive development towards a more species-rich forest ecosystem. Fire climax pine forests are found in all SE Asian mountain regions. Burning of agricultural crop residuals, especially rice straw burning, add to the smoke generated by conversion fires and wildfires. These emissions influence the regional atmosphere and global biogeochemical cycles.

Fire in the Lowland Dipterocarp Rain Forest

Impacts of Climatic Variability on Fire Regimes: Prehistoric, Historic and Contemporary Events

It has been suggested that during the last Ice Age the drop of ocean water levels has caused the development of an overall arid climate at that time. Although palynological evidence from the tropical lowlands is still very scarce, it must be assumed that lowland vegetation was generally that of areas with a more pronounced dry season. First evidence of ancient wildfires in East Kalimantan was found by Goldammer and Seibert (1989, 1990). Radiocarbon (^{14}C) dates of soil charcoal recovered along an East-West transect between Sangkulirang at the Strait of Makassar, and about 75 km inland, showed that fires had occurred between ca. 17,510 and ca. 350 before present (BP). The fire dates between 1280 and 350 BP, as presented in the study, reveal that wildfires occurred not only during the dry Pleistocene, but also after the present wet, rain forest climate stabilized, at about 10,000 to 7000 BP. These fires can be explained by periodic droughts such as those caused by the modern El Niño-Southern Oscillation (ENSO) complex. The ENSO phenomenon is regarded as one of the most striking examples of inter-annual climate variability on a global scale. The event is initiated by the Southern Oscillation, which is the variation of pressure difference between the Indonesian low and the South Pacific tropical high. During a low pressure gradient, the westward trade winds are weakened, resulting in the development of positive sea surface temperature anomalies along the coast of Peru and most of the tropical Pacific Ocean. The inter-tropical convergence zone and the South Pacific convergence zone then merge in the vicinity of the dateline, causing the Indonesian low to shift its position into that area. Subsequently, during a typical ENSO event, the higher pressure over Malesia leads to a decrease in rainfall. The severity of the dry spells depends on the amplitude and persistence of the climate oscillations.

In the rain forest biome these prolonged droughts drastically change the fuel complex and the flammability of the vegetation. Once the precipitation falls below 100 mm per month, over periods of two or more weeks without rainfall, the forest vegetation sheds its leaves progressively with increasing drought stress. In addition, the moisture content of the surface fuels is lowered, while the fallen woody material and loosely packed leaf-litter layer contribute to the build-up and spread of surface fires. Aerial fuels such as desiccated climbers and lianas become fire ladders potentially resulting in crown fires or "torching" of single trees.

Peat swamp forests found in the lowlands of Borneo represent another fuel type. With increasing precipitation deficit and a lowering of the water table in the peat swamp biome, the organic layers progressively dry out. During the 1982-83 ENSO, various observations in East Kalimantan confirmed a desiccation of more than 1 to 2 m; preliminary estimates during the 1997 ENSO reveal that desiccation was less than 1982-83. While the spread of surface and ground fires in this type of organic terrain is not severe, deep burning of organic matter leads to toppling of trees and a complete removal of standing biomass. It is further reported that smouldering organic fires may persist throughout the subsequent rainfall period, to be reactivated as an ignition source in the next dry spell.

Long-lasting fires in coal seams extending to, or near, the surface are found in various rain forest sites in East Kalimantan and are another important natural fire source (Goldammer and Seibert 1989). It has been assumed that all of the ca. 150 coal seam fires known to be burning before the 1997-98 fire episode were ignited by the 1982-1983 wildfires. This was questioned by Goldammer and Seibert (1989), since there are numerous oral reports of burning coal seams made before in 1982-1983 drought. In the late 19th century the Norwegian explorer Bock (1881) reported that Modang people consider burning of coal seams going on "since the memory of man".

Goldammer and Seibert (1989) focused their research on dating ancient coal seam fires by investigating the "baking" effects of subsurface fires on sediment or soil layers on top of the coal seams. These effects of old, meanwhile extinguished, coal seam fires can still be seen today. Thermoluminescence analysis of burnt clay, collected on top of an extinguished coal seam in the vicinity of active coal fires, proved a fire event 13,200 to 15,300 years BP. It is assumed that ancient coal fires were ignited by lightning.

Historic and Modern ENSO Events and Wildfires

Berlage (1957) found that between 1830 and 1953, about 93% of all droughts in Indonesia occurred during an ENSO event. According to an evaluation of precipitation data since 1940 (Leighton, 1984), most of the 11 droughts recorded in 1941/42, 1951, 1957, 1961, 1963, 1969, 1972, 1976, 1979/80, 1982/83, and 1987 accompanied an ENSO. The worst droughts during that period were in 1941/1942, 1972, and 1982-1983, while the 1961 drought occurred independently of an ENSO event, and the 1965 ENSO did not cause drought in Indonesia. A recent thorough analysis of ENSO variations and drought occurrence in Indonesia and the Philippines are given by Harger (1995a,b).

The first documentation of the impact of an extreme drought in East Kalimantan is provided by Bock (1881). The Norwegian zoologist travelled through the lowlands of the Kutai district of East Kalimantan 1878 and reported drought and famine which had occurred in the year before his visit. He noted that about one third of the tree population in the forests around Muara Kaman in the Middle Mahakam area died due to the drought. More recent observations in various peat swamp forests of the Middle Mahakam Area of East Kalimantan confirm that significant disturbances of this ecosystem must have occurred around 80-100 years ago (Weinland 1983). The rainfall records of Jakarta (Java) 1877/78 explain these observations: between May 1877 and February 1878, rainfall in Jakarta was reduced by two thirds; a second severe precipitation deficit followed from July to December 1878 (Kiladis and Diaz 1986).

Bock (1881) did not report any forest fires. Nevertheless, there is evidence of historic forest fires in East Kalimantan by narrative tradition (Goldammer and Seibert 1990). In 1914-15, forest fires were again reported from Borneo. Published records were found for Sabah, where an area of 80,000 ha of rain forest and its superficial peat soil layer were destroyed by fire after an exceptionally dry period. This area now forms the Sook plain grassland of Sabah. Severe forest fires in Brunei following a drought of six weeks in 1958 were observed by Brünig (1971). Smaller fires in lowland dipterocarp forests and in *Dacrydium elatum* forests were recorded for 1969 and 1970 in Sabah and Brunei.

The Wildfires of 1982-83

The 1982-1983 drought in the "Maritime Continent" was the result of an extreme ENSO (Philander 1983). In north and east Borneo, the decrease in rainfall began in July 1982 and lasted until April 1983, interrupted only by a short rainy period in December 1982. The wildfire scene in Borneo in 1982/83 was set by a combination of the extreme drought and by numerous slash-and burn land-clearing activities, resulting in fires burning out of control. The extent and the immediately visible impact of these fires have been described by several authors and teams (summary and sources in Goldammer et al. 1996). It is assumed that the overall land area of Borneo affected by fires exceeded $5x10^6$ ha (Goldammer et al. 1996).

A series of studies on the regeneration of the fire-affected rain forest were conducted in the mid-1980's and reviewed by Goldammer and Seibert (1990). In 1988-89 a comprehensive research project on the cause and effects of the forest fires of the 1982-83 fire season in East Kalimantan was carried out by the Deutsche Gesellschaft für Technische Zusammenarbeit (GTZ) on behalf of the International Tropical Timber Organization (ITTO). The results are summarized by Goldammer et al. (1996). Within the study area (totalling $4.7x10^6$ ha) the actual area affected by fire was ca. $3.2x10^6$ ha of which $2.7x10^6$ ha were tropical rainforests. Forests on sites with low water retention capacity were most seriously affected by fire. This refers especially to peat swamp forests, heath forests (Kerangas), forests on limestone hills and rocks and all other forests on shallow soils. On the other hand, logged-over forests were particularly affected by fire, especially those growing on drought-sensitive sites. There is a close correlation between the year of logging and fire intensity. Especially forests which had been logged shortly before the fire event were very seriously damaged. Finally, forests in the vicinity of settlements and along rivers and roads were particularly affected by the fire. The analysis of the inventory results for different tree species allowed the following classification according to their sensitivity to fire. The results reveal that light-demanding species are promoted by fire (e.g., *Euphorbiaceae*). Fire-resistant species were also identified, e.g. Bornean ironwood (*Eusideroxylon zwageri*) and many others. Species suppressed by fire belong to the *Dipterocarpaceae* and other genera suppressed by fire are *Anarcardiaceae, Annonaceae, Burseracea, Fagaceae, Melastomaceae, Meeliaceae, Myristicaceae, Myrtaceae, Sapindinaceae* and *Sapotaceae*. It is concluded that biodiversity of fire-affected forests is considerably reduced with increasing fire intensity.

Damage of the Fire Episodes After 1982-83

During and after the ENSO and fire episodes of 1987, 1991, and 1994 only limited research has been accomplished on the extent and damage caused by fire and atmospheric pollution. The Indonesian Ministry of Forestry released some figures on the extent of burning during the 1994 drought. For the first time the government included burning activities other than uncontrolled wildfires into the statistics. According to the Ministry a total land area of ca. $5.1x10^6$ ha had been affected by fire, thereof

Traditional dryland farming	$2.8x10^6$ ha
Shifting cultivation	$1.5x10^6$ ha
Transmigrant farming	260,000 ha
Plantations	221,000 ha
Transmigrant settlements	39,500 ha
Reforestation areas	20,500 ha
Timber estates	17,000 ha
Natural forests	8,000 ha

The figures of the 1997-98 fire episode are currently being consolidated. Several approaches were undertaken to determine the extent of the 1997/98 forest fires in Indonesia using optical and microwave sensors. Some studies were based on the visual interpretation of multi-temporal SPOT quicklook mosaics, the evaluation of NOAA-AVHRR (National Oceanic and Atmospheric Administration - Advanced Very high Resolution Radiometer) and the combined use of ERS-2 SAR (European Radar Satellite-2, Synthetic Aperture Radar) coherence data and ATSR data. Liew *et al.* (1998) estimated with SPOT quicklook mosaics the total area affected by fire (burn scars) in Sumatra $1.5x10^6$ ha and $3.06x10^6$ ha in Kalimantan for the period January-December 1997. Fuller and Fulk (1998) estimated the area affected by fire $2.3x10^6$ ha on the base of NOAA-AVHRR data within IFFM GTZ NOAA\AVHRR processing window which did not completely cover Sabah and West Kalimantan. Moreover with the combined use of ERS-SAR and ATSR Antikidis et al. (1998) produced a first estimation of the forest surfaces burned in Central Kalimantan in 1997. Out of an area of $21.76x10^6$ ha analyzed a total of 588,000 ha forest were burned at that time. This number was corrected later to $1.8x10^6$ ha (Antikidis et al., pers. comm.).

The land area affected by fire in East Kalimantan has been assessed by the Integrated Forest Fire Management (IFFM) project (Hoffmann et al. 1999). The study used ERS-2 SAR (European Radar Satellite 2, Synthetic Aperture Radar sensor) radar images to disclose the size of the fire affected area for the entire province according to all land uses. The results of the inventory show that the 1997/98 fires affected a total of $5.2x10^6$ ha - corresponding to ca. 25% of the total land area of the province. Almost $2.3x10^6$ ha are located in natural forest concession areas, $0.4x10^6$ ha in protected forests, and 0.9 million ha 30 forest plantation enterprises and $0.7x10^6$ ha industrial crop plantations were affected. Almost 75% of the plantation areas (forest, oil palm, etc.), that were located within the 1997/98 fire zone, have been fire affected, a large number of them severely.

It should be stressed that many of the forests which had burned in 1982-83 or during one of the following ENSO droughts have been burned a second time in 1998. The consequences of repeated burns are detrimental because they are a key factor of the impoverishment of biodiversity in rain forest ecosystems (see also Nepstad *et al.* 1999, Cochrane *et al.* 1999, Goldammer 1999). The photographic documentation of rain forest degradation by two subsequent fires in the Bukit Soeharto forest, East Kalimantan, provide visual evidence.

Fire in Seasonal Forests

The occurrence of seasonal dry periods in the tropics of South Asia increases with distance from the perhumid equatorial zone. The forests gradually develop to more open, semi-deciduous and deciduous formations (e.g., moist and dry deciduous forests, monsoon forests). The main fire-related characteristics of these formations are seasonally available flammable fuels (grass-herb layer, shed leaves) which allow the spread of surface fires. Grass species, understorey plants (shrub layer) and the overstorey (tree layer) are adapted to regular fire influence. The most important adaptive traits are thick bark, ability to heal fire scars, resprouting capability (coppicing, epicormic sprouts, dormant buds, lignotubers, etc.) and seed characteristics (dispersal, serotiny, fire cracking, soil seed bank and other germination requirements). These features are characteristic elements of a fire ecosystem.

During the dry season the deciduous trees shed their leaves and provide annually available surface fuel. In addition the desiccated and dried grass layer, together with the shrub layer, add to the available fuel which overall generally ranges between 5-10 tha^{-1}. The fires are mainly set by forest users (graziers, collectors of non-wood-forest products). The forests are underburned in order to remove dead plant material, to stimulate grass growth, and to facilitate or improve the harvest of other forest products. The fires usually develop as surface fires of moderate intensity (usually less than 400 kWm^{-1}; cf. Stott *et al.* 1990), and tend to spread over large areas of forested lands. The tree layer is generally not affected by the flames, although crowning may occur earlier in the dry season when the leaves are not yet shed. In some cases fires may affect the same area two or three times per year, e.g., one early dry season fire consuming the grass layer and one subsequent fire burning in the shed leaf litter layer (Goldammer 1993a,b).

Dry deciduous forests and moist deciduous forests occur on ca. $250x10^6$ ha and $530x10^6$ ha respectively. No reliable information exists on the extent of recurring fires in these areas. It was estimated that in Myanmar between 3-$6.5x10^6$ ha of forests are annually affected by fire. A report from Thailand in the late 80s estimated an annually burned area of ca. $3.1x10^6$ ha, predominantly in dipterocarp monsoon forests. The affected area has diminished considerably since then: measures of fire protection have reduced the average area burned to ca. $1.5x10^6$ ha (unpubl. fire survey from Thailand, 1994). Analysis of historic information from British India reveals that during the last century and early this century almost all Indian deciduous forests were burned every year (Goldammer 1993b). Regional vegetation fire patterns in South and South East Asia recently have been described on the basis of satellite-derived information (Malingreau et al. 1998).

The ecological impact of the yearly fires on the deciduous and semi-deciduous forest formations is significant. Fire strongly promotes fire tolerant trees, which replace the species potentially growing in an undisturbed environment. Many of the monsoon forests of continental Southeast Asia would be reconverted to evergreen rain forest biomes if the human-made fires were eliminated. Such phenomena have also been observed in Australia where the aboriginal fire practices and fire regimes were controlled and rain forest vegetation started to replace the fire-prone tree-grass savannas. The fire adaptations and the possible fire dependence of economically important trees such as Sal (*Shorea robusta*) and Teak (*Tectona grandis*) have long been the focus of controversy regarding the traditional fire control policy in British Indian Forestry.

The fire climax deciduous forests are not necessarily in an ecologically stable condition. Long-term impacts of frequent fires lead to considerable erosion because of removal of the protective litter layer just before the onset of the monsoon rains.

Fire Climax Pine Forests in South Asia's Tropical Mountain Regions

In mainland South Asia and Insular SE Asia the pines (genus *Pinus*) are largely confined to the zone of lower montane rain forest. They are usually found on dry sites and prefer a slight to distinct seasonal climate. Most tropical pines are pioneers and tend to occupy disturbed sites, such as landslides, abandoned cultivation lands and burned sites. Besides the pioneer characteristics, most tropical pines show distinct adaptations to a fire environment (bark thickness, rooting depth, occasionally sprouting, high flammability of litter) (Goldammer and Peñafiel 1990). The tropical pure pine forests of South Asia, e.g., *Pinus khesyia, P. merkusii, P. roxburghii, P. massoniana*, most often are the result of a long history of regular burning. As in the tropical deciduous forests, fires are mainly set by graziers, but also spread from shifting cultivation fires and the general careless use of fire in rural lands. Fire return intervals have become shorter during the last decades, often not exceeding one to five years. These regularly occurring fires favour the fire-adapted pines which replace fire-sensitive broadleaved species. The increased frequency of human-caused fires has led to an overall increase of pines and pure pine stands outside the potential natural area of occurrence in a non-fire environment. In the mountainous zones of the tropics, fire also leads to an increase of the altitudinal distribution of pines, e.g., by expanding the mid-elevation pine forest belt downslope into the lowland Dipterocarp forest biome and upslope into the montane broadleaved forest associations, e.g., the mixed oak-chestnut forests. These tropical fire climax pine forests occur throughout submontane elevations in Burma, Thailand, Laos, Kampuchea, Viet Nam, the Philippines (Luzón) and Indonesia (Sumatra).

All over South East Asia fire climax pine forests potentially provide a high degree of habitability and carrying capacity for humans. If used properly in time and space, fire creates a highly productive coniferous forest, which grants landscape stability and sustained supply of timber, fuelwood, resin, and grazing land. However, together with the effects of overgrazing (including trampling effects) and extensive illegal (fuel)wood cutting, the increasing occurrence of wildfires tend to destabilize the submontane pine forests and result in forest depletion, erosion and subsequent flooding of lowlands.

Burning for Control of Weeds and Succession, and Disposal of Crop Residues and Waste

The burning of vegetation residues and the use of fire for weed control and other regular burning takes place all over SE Asia's lands which have been permanently converted into agricultural and pastoral land-use systems. Most striking is the burning of rice straw which contributes to seasonal haze in the region.

The total extent of agricultural residue burning is not known at present. However, some first estimates made for rice straw burning in Viet Nam show that ca. 20 x 10^6 tons of rice straw are annually burned in this country alone which contribute significantly to regional air pollution budgets (Nguyen *et al.* 1995).

Burning of household waste finally adds to the manifold open fires in the region. In these fires vegetation residues are increasingly mixed with other waste types, e.g. plastic materials, etc. Together with fossil fuel burning these emissions may also contribute significantly to regional smoke haze. These emission need to be included in regional assessments and mitigation strategies at national and regional scale. Priority must be given to exploring the specific emission characteristics of fires in primary and secondary rain forests, peatlands and peat-swamp forests, *Imperata cylindrica* grasslands, and rice straw burning.

Research Initiatives

Fire Ecology

Fire research in Indonesia and the mainland in the 1990s largely concentrated on fire effects on ecosystem properties and ecosystem stability. Much of this research has been analyzed by the author the late 1980s (Goldammer 1990). More recent research has been focusing on slash-and-burn agriculture and vegetation succession (Kiyono and Hastaniah 1997) and fire ecology research in South Sumatra (Saharjo 1997). The 1999 fire workshop in East Kalimantan (Suhartoyo and Toma 1999) and a recently published monograph on East Kalimantan's rain forests (Guhardja et al. 2000) provide the most recent update of fire research in the region.

The Underlying Causes of Fire Application

While many of the publications cited above contain information on fire causes, only few in-depth studies are available on the socio-economic and cultural aspects of managing the fire problem. The forest fire management system in Thailand has its strong base on a fire prevention approach which is being realized by a close cooperation with the local population. The same refers to the IFFM approach in Indonesia (Abberger 1996; see also the work of Otsuka [1991] on forest management and farmers in East Kalimantan). A basic study on the socio-economic and cultural background of forest fires in the pine forests of the Philippines was conducted in the late 1980s and reveals the usefulness of such surveys for further management planning (Noble 1990).

Despite of the initial efforts it must be stated that there is a tremendous gap of expertise and available methodologies of socio-economic and cultural approaches in integrating people into operational fire management systems.

Interdisciplinary Research: Coupling of Ecological, Atmospheric and Climate Research in the IGBP/IGAC SEAFIRE Programme

Estimates of the magnitude of tropical plant biomass burned in shifting agriculture, permanent deforestation, other forest fires and savanna fires revealed that the prompt (gross) annual release of carbon into the atmosphere from these fires may range between 1 and 4 billion tons. Though the amount of carbon remaining in the atmosphere (net release) is not known exactly, it is generally accepted that the annual net release of carbon into the atmosphere from plant biomass burned for permanent conversion of tropical forest into other land uses ("net deforestation") amounts to ca. 1 billion tons per year.

Although emissions from tropical vegetation fires are dominated by carbon dioxide (CO_2), many products of incomplete combustion that play important roles in atmospheric chemistry and climate are emitted as well. Much of the burning is regionally concentrated, occurring mainly during the dry season, and resulting in levels of atmospheric pollution that rival those in the industrialized regions of the developed world. Photochemical reactions, for instance, in the plumes of vegetation fires may be responsible for as much as one third of the global input of ozone into the troposphere. Recent observations of seasonally elevated levels of tropospheric ozone in some tropical regions, particularly over the southern tropical Atlantic Ocean between South America and Africa, have been explained by emissions from tropical wildland fires and subsequent photochemical processes which may play an important role in atmospheric chemistry over that large region of the Earth. The investigation of this phenomenon through an international fire research campaign has verified this hypothesis (JGR 1996).

Vegetation fires in South East Asia have additional implications which are not yet entirely understood. The global climate is determined critically by tropical convective air movements, leading to the injection of air masses into high altitudes of the atmosphere and their long-range transport and re-distribution. These global circulation patterns originate at the continental and oceanic surfaces with elevated temperatures. This "warm pool" of the globe is in the maritime continent of the equatorial region of Asia.

In the midst of the warmest region of the world, the Indonesian archipelago, extensive burning of vegetation (shifting cultivation, forest conversion burning, and other agricultural burning) takes place. Although the impacts of these fires on atmospheric chemistry have not yet been explored, it is assumed that two major patterns of emission distribution from vegetation fires exist:

i. During the "High Phase" (normal years) of the Walker Circulation low pressure is centred over the hot spots. Air masses with products from biomass burning (aerosols, trace gases) are carried to the high troposphere and exported globally.

ii. During the "Low Phase" the warm waters of the "warm pool" are transported to the eastern Pacific, and high pressure builds up over the Indonesian archipelago. A typical ENSO situation develops during which emissions from forest burning are trapped in the lower troposphere.

The last years with extraordinary fire activities in Indonesia were years characterized by the Low Phase of the Walker Circulation. The fire season of 1982-83 was characterized by escaped land-use fires which caused large-size wildfires on several million hectares. In the following years the situation was different. The smoke emitted from the Indonesian archipelago in 1987, 1991, 1994 and 1997 was not primarily caused by wildfires. The main sources were shifting cultivation, a traditional practice, but one that is rapidly expanding, and the systematic application of fire for converting primary and selectively exploited rain forests into plantation forests.

A systematic, quantitative and qualitative regional research approach is still missing. The first program which had been proposed in 1994 was the South East Asian Fire Experiment (SEAFIRE). SEAFIRE had been planned as a research activity under the scheme of the International Geosphere-Biosphere Programme (IGBP). The International Global Atmospheric Chemistry (IGAC) Project is a core project of

IGBP. One of the activities of IGAC Focus 2 (Natural Variability and Anthropogenic Perturbations of the Tropical Atmospheric Chemistry) investigates the impact of biomass burning on the atmosphere and biosphere (Biomass Burning Experiment [BIBEX]). However, the issues to be addressed by SEAFIRE did not receive sufficient attention before the 1997-98 fire episode. After 1997 numerous individual short-living research projects were implemented, all of which missed a concerted multi-institutional and interdsicplinary research opportunity.

A Program to Address ASEAN Regional Transboundary Smoke (PARTS) was initiated in response to the needs and assistance requested by the ASEAN Committee on Science and Technology, Sub-Committee on Meteorology and Geophysics (ASCMG). At ASCMG's 18th meeting (Bangkok, 1995) it was agreed to create a project on transboundary air pollution. The World Meteorological Organization (WMO), in conjunction with the goals of its Global Atmospheric Watch (GAW) program, in 1996 reviewed and evaluated National Meteorological and Hydrometeorological Services (NMHS) capabilities in detecting, monitoring and predicting the long-range transport of atmospheric pollution. Subsequently, WMO designed PARTS to improve the regional capabilities in satellite usage, modelling long-range transport of smoke, haze, and other pollutants, and to design and implement a monitoring strategy for the region.

Conclusions

The smoke-haze episode in Southeast Asia during the 1997-98 ENSO for the first time received high public and scientific interest at regional and global levels. However, the state of fire research in the 1990s reveals that causes and impacts of vegetation burning are well explored. The unchanged and dramatic situation of forest conversion burning and escaped wildfires calls for management-oriented research and appropriate response.

Abstract

Natural forests covers 47% of the total land area of Central and South America, almost all (95%) being tropical. Forest cover continues to decrease due to clearance for cropland, cattle raising, and the construction of roads, dams and other infrastructure. More recently, fire has become a major threat to natural forests throughout the region. In 1997-1998 fires raged through the forests of Brazil, Colombia, Mexico and many countries in Central America. Tropical forests are burning due to a number of interdependent natural and human-related factors that are often obscured by lack of information. Undisturbed rain forest is highly resistant to burning, but will burn during severe droughts, principally after it has been logged or otherwise disturbed. In the Brazilian Amazon a combination of logging and drought are increasing the flammability of large tracts of forests. Fire research in the Amazonia is in its infancy, and has eluded the priority-setting processes of the region's government research institutions. Economic and policy studies are urgently needed to document the costs of fire to landholders and society at large, to identify how land users can be encouraged to control and prevent fire damages, and to propose mechanisms by which the disparate public policies that influence deforestation could be integrated to favor a more sustainable and less fire-prone development pathway. Research is needed to determine which kinds of production systems are most likely to use fire, and which ones invest most in fire control and prevention both for fire risk assessment and for targeting governmental initiatives to reduce fire. Field studies of the causes of forest flammability could provide the basis for a regional early warning system of forest fire risk. One of the most serious impediments to fire risk assessment in tropical forests is the insufficiency of rainfall data collection. In the short term, an *El Niño Early Warning System* indicating impending drought episodes, could act as an effective substitute for a comprehensive fire risk warning system, giving landholders time to incorporate the prospect of severe drought into their land management planning. In the long term, research on fire behavior and its impacts on ecosystem processes, biodiversity, biogeochemical cycles, atmospheric quality, and local and global climate, as well as evaluation of damages and losses, are needed to establish management practices for the forests of tropical America. The probability of future forest fire disasters can only be reduced if the causes of hazard and risk are well understood and comprehensive strategies devised to address these causes.

Keywords: Forest fire, Rain forest, Brazil, Amazonia

Introduction

Natural forests cover 47% of the total land area of Central and South America, almost all (95%) being tropical. Forest cover continues to decrease due to clearance for cropland, cattle raising, and the construction of roads, dams and other infrastructure. More recently, fire has become a major threat to natural forests throughout the region. In 1997-1998 fires raged through the forests of Brazil, Colombia, Mexico and many countries in Central America. Tropical forests are burning due to a number of interdependent natural and human-related factors that are often obscured by lack of information. Undisturbed rain forest is highly resistant to burning, but will burn during severe droughts, principally after it has been logged or otherwise disturbed.

In the Brazilian Amazon a combination of logging and drought are increasing the flammability of large tracts of forests. Fire research in the Amazon is in its infancy, and has eluded the priority-setting processes of the region's government research institutions. Economic and policy studies are urgently needed to document the costs of fire to landholders and society at large, to identify how land users can be encouraged to control and prevent fire damages, and to propose mechanisms by which the disparate public policies that influence deforestation could be integrated to favor a more sustainable and less fire-prone development pathway. Research is needed to determine which kinds of production systems are most likely to use fire, and which ones invest most in fire control and prevention—both for fire risk assessment and for targeting governmental initiatives to reduce fire.

Fires in the Humid Neotropics

Fire is a fast and cheap way of clearing land, providing nutrient-rich ash to the soil and of reducing populations of weeds and pests. The use of fire makes economic sense when land and forests are abundant and inexpensive resources. Burning in the Amazon region today is primarily associated with the clearing of forests for agriculture, pastures, logging, and other purposes. By 1988 approximately 400,000 square kilometers (8% of the Amazon region) had been cleared, and it was increasing at a rate close to 35,000 square kilometers per year (Fearnside 1993). More recently it has been estimated that around 517,000 square kilometers of the Brazilian Amazon forests had been clear-cut and burned by 1996 (Nepstad et al.1998). Most of the deforested areas in the Amazon are maintained as cattle pasture. Large ranches account for 75% of the clearing for pastures and small farmers account for the remaining clearing. Usually pasture burns are done every 2-3 years (Fearnside 1993) and fire spreads from cattle pastures into surrounding forests where selective logging has occurred (Uhl and Buschbacher 1985). Fire is the quintessentially extensive land management tool of the tropics. However, fire is wasteful of nutrients and forests and it threatens investments made in agricultural and forestry production systems.

Three major types of fires have been recognized in the Amazon (Nepstad *et al.* 1999): i) Deforestation fires, associated with the clear-cutting and burning of standing forests for agriculture purposes (pasture formation, plantations, crops, etc.); ii) Forest surface fires, associated with standing forests, either primary or logged, where the fires burn through the fuel layer on the forest floor, and iii) Fires on deforested land, occurring in pastures, secondary forests, croplands, plantations and other vegetation on lands that had once been forested. Generally, deforestation fires and fires on deforested land are ignited intentionally as the main tool for land management, while forest surface fires may occur accidentally.

Deforestation monitoring by satellite is an important tool to study the length of human effects on the Amazon forests because it documents extreme forms of land-use, over large areas, and at relatively low cost (Nepstad et al. 1999). Clear-cut deforested land is easily distinguished from forest in Landsat TM images even years after the deforestation took place. However the scars left by fires in standing forests are harder to detect and much degraded forested areas in the Amazon are counted as closed forests on deforestation inventories (Nepstad, Moreira and Alencar 1999). According to Nepstad et al. (1999) estimated that selective logging severely damage 10,000 to 15,000 km^2 of forests per year and that this is not represented on the annual estimates of deforestation for the Brazilian Amazonia that is impoverished by logging and fire each year, and even less during years of severe drought. Despite an early report of the synergism between logging and forest fire (Uhl and Buschbacher 1985), little information is available on the areal extent of this very important alteration of Amazonian forests. We have estimated that approximately 200,000 km^2 of forest were at very high risk of burning by the end of the 1998 dry season, that is, forest that had depleted all of the plant-available water in the upper five meters of soil (Nepstad *et al.* 1999). This estimate is 10 to 15 times the total area deforested each year in the Amazon.

The largest ecological impact of fires on the Amazonian forest could be the replacement of vast areas of closed-canopy evergreen forest with savanna-like, fire-prone scrub vegetation through the synergistic effects of increasing drought and human land-use activities. According to Cochrane et al. (1999) the average rate and intensity of forest burning and deforestation in the Brazilian Amazon can be expected to increase as previously burned forest area expands. A positive feedback exists between forest fires, future fire susceptibility, fuel loading, and fire severity. First-time burns can be controlled and put out manually with minimal equipment, but fires in previously burned forest generally have fire line intensities that are beyond the limits of manual control. These fire-induced changes will take several years to occur but are likely to be irreversible under current climatic conditions. Effects on the regional climate, biodiversity, and economy are likely to be extreme.

Challenges to Research and Policy

Fire is a challenge to both research and policy because it is a very appealing land management tool in most of tropical America. It is an inseparable feature of the agriculture frontier in Amazonia, where land is abundant, but labor and capital are usually in short supply. Millions of farmers and ranchers ignite tracts of forest to release crop-fertilizing ash onto the soil, or to get rid of pasture weeds to favor grass production. The problem is that many of these fires escape their intended boundaries with large costs to land-holders and society at large. Solutions to this problem must therefore acknowledge that fire is currently a chronic, annual feature of rural Amazonia (Moreira 1999).

Solutions to the fire problem must harness the public concern that arises during "emergency" years, when severe drought and/or accelerated fire-dependent land-use activities greatly increase the occurrence of accidental fires during a particular period of time. The solution is to direct public concern into political processes that leads to a long-term approach that gradually decrease the use of fire by rural producers and increase landholder investments in prevention of accidental fire. Here we briefly discuss techniques and community-level approaches that are currently employed by Amazonian farmers and ranchers to combat accidental fire on their properties, and the research and education needs associated with the testing and dissemination of these approaches. Since many of the benefits of landholders' investments in fire prevention accrue to society at large, or to neighbors, strategies to reduce fire losses cannot rely on the enlightened self-interest of the landholder alone, particularly in the absence of effective mechanisms to enforce existing legislation. Instead, such strategies must place restrictions on the ways in which rural landholders use their land, and must provide economic incentives.

Fire Prevention and Suppression Techniques by Landholders

Effective techniques for preventing and controlling accidental fires in rural Amazonia are available and widely used, but the knowledge of these techniques resides among the farmers, ranchers and loggers who are faced with economic losses to fire every dry season. This "indigenous" knowledge of fire management techniques has received little attention by researchers, and remains to be tapped by government institutions responsible for defending public interests in Amazonian natural resources. This knowledge should be rigorously tested, documented and incorporated into training programs for extension agents, agronomists, foresters and other natural resource professionals (Nepstad, Moreira and Alencar 1999).

The first rule of fire prevention and control is that it is much easier and cheaper to prevent accidental fires from occurring than to put them out once they escape the limits of the intended burn area. Small, strategic investments made in fire prevention can thus avoid the need—and the expense—of assembling large groups of people and equipment to combat fires under emergency conditions. Cattle pastures are the most flammable ecosystems in Amazonia because forage grasses exposed to the full drying action of the sun are highly flammable (Uhl and Kauffman 1990), and the winds that sweep across large pasture clearings provide ample oxygen. Techniques for preventing and controlling accidental fire must remove at least one of these essential fire ingredients in order to be effective. The options for removing these ingredients are many, with varying requirements for labor, capital, and equipment.

Vegetation can be protected from fire by strips of land from which fuels have been removed. These "fire breaks" are the single most important technique for defending vegetation against accidental fire, but they are also the most expensive to implement. Small-scale rancher would spend half of his anticipated profits from cattle production in the manual preparation of fire breaks around a 100-ha pasture. Hence, education programs that encourage farmers and ranchers to invest in the preparation of firebreaks run the risk of encouraging practices that are not economically viable thus discouraging landholder investment in fire prevention (Nepstad *et al.* 1999).

Fire education campaigns should encourage those fire prevention and control practices that are relatively cheap to implement. One of the most underutilized, inexpensive techniques for containing fire is the back-burn, in which a fire line is ignited along the downwind border of an area that is being intentionally burned. This back-burn has the effect of widening the downwind fire break at a very low cost. Back-burning can therefore reduce the expense of preparing the downwind fire break.

The "cool burn", in which intentional burns are set when vegetation moisture content is high, or late in the day, as the relative humidity of the air begins to climb, may appear to be an inexpensive technique for reducing the risk of accidental fire. However, there is a large cost associated with it, in that less of the vegetation being burned is converted to ash. Farmers can suffer reduced crop harvests, for example, if large portions of their slash and burn plots fail to burn effectively.

Perhaps the most effective technique for controlling the spread of forest fires is the forest fire break line. Subsistence farmers across Amazonia control the low, slow-burning fires that spread into their forests by sweeping the forest floor free of organic debris along narrow trails that circumscribe the forest fire. These forest fire breaks impede the spread of forest fires at a much lower cost than military troops and water-bearing helicopters.

Local Governance among Neighbors and Farm Communities

The greatest challenge of fire prevention and control techniques is to reduce the amount of money, labor, and/or time needed to implement them. One of the most promising ways of reducing the costs of these techniques is through cooperation between neighboring landholders, or among members of farm communities. The types of cooperative agreements that can be made range from an agreement between two neighbors to notifying one another when an accidental fire is spotted, to a full-fledged community fire ordinance that defines the ways in which fire can be used by community members, and with penalty imposed for non-compliance. The easiest fire agreement to make is between two neighboring landholders with a common interest in reducing the occurrence of accidental fire (Moreira 1999). Such agreements take place informally between landholders across Amazonia, but their effectiveness in reducing accidental fire remains to be studied. Our findings indicate that this is virtually the only type of agreement that is made by large scale landholders, since they are rarely organized into close-knit communities as small-scale farmers frequently are. More sophisticated agreements between neighboring landholders can include the spatial planning of different agricultural systems to reduce fire risk (Nepstad, *et al*. 1999).

How to Encourage Investments in Fire Prevention?

Even the most remote farm communities in Amazonia have access to AM radio, and can be reached through educational radio spots. Educational handbooks are another tool by which successful approaches to the prevention of accidental fire can be disseminated. These dissemination efforts represent important research opportunities to measure the changes in farmer and rancher behavior that occur in response to information on fire. Of greatest interest is the long-term sustainability of any behavioral change. Educational campaigns may cause a temporary pulse in farmer investments in firebreaks, for example, which diminishes in subsequent years because of its considerable cost.

An additional constraint on the potential of education programs to reduce the occurrence of accidental fire is our lack of knowledge of the most cost-effective techniques and institutional arrangements for preventing and controlling accidental fire. The fire prevention and suppression techniques described above are being used in rural Amazonia, but their relative effectiveness has not been studied, nor have their costs and benefits been analyzed.

We do not know the circumstances under which it is economically advantageous for landholders to invest in fire breaks, fire surveillance, and emergency fire suppression plans. Such information is essential to enable public authorities to allocate scarce budgetary resources for fire prevention where they will be most effective.

There are no easy short-cuts around the formidable organizational and economic barriers that prevent groups of Amazonian farmers or ranchers from joining forces to reduce the occurrence of accidental fire on their land. Sometimes, a lack of leadership, low levels of community participation, and community instability may present the greatest barriers to the implementation of community fire regulations in communities across Amazonia. A single recalcitrant farmer who refuses to pay his neighbor for damages caused by an escaped fire can undermine a fire regulation that required repeated community meetings over several months to establish (Nepstad, *et al.* 1999).

The development of the capacity for local governance within a farm community is a long-term process, which can be accelerated through sustained inputs from dedicated, well-trained professionals, willing to spend much of their time working directly with communities under harsh field conditions. There is a severe dearth of such professionals in Amazonia. Many of the technical schools and university programs that are training agronomists and foresters have curricula aimed at industrial production systems, with virtually no training in the management of fire within agricultural or forestry production systems given. A new generation of extension agents and researchers is needed; one that is capable of integrating a variety of disciplines.

Community-based approaches to the reduction of accidental fire require more than just a new generation of multi-disciplinary, field-oriented extension agents and researchers. In addition, the economic and legislative context in which rural development proceeds also must change. Economic and legislative tools implemented by government can create an environment in which rural producers shift to agricultural systems that are less dependent upon fire, or are encouraged to invest in fire prevention techniques, and organize themselves to reduce the occurrence of accidental fire. We analyze here some of economic and legislative approaches to the reduction of accidental fire.

Economic and Legislative Tools.

It makes economic sense to use fire when land and forest is abundant and inexpensive. Fire is an intrinsic component of the current model of occupying rural Amazonia, in which natural resources such as land and forest are viewed as virtually unlimited commodities that can and should be mined. The long-term solution to the fire problem of Amazonia will depend upon the emergence of an alternative model for regional development that favors greater investments of labor and capital in smaller areas of land (Moreira 1999).

Public policies are important part of any strategy to address tropical forest fires. In the Amazon fire is not just another environmental issue, rather, it influences—and is influenced by—a broad spectrum of the region's rural development policies. As one of the essential tools of extensive land use, fire is at once both the cause and the result of a development pathway based on natural resource mining. Efforts to change the model of natural resource use from its current mining approach to a "sustainable" basis will require integrating Amazonian policies aimed at promoting economic development and settlement with those designed for conserving natural resources. In this sense, the cross-cutting nature of the fire problem represents an opportunity to reconcile interests in the region's economic development with interests in natural resource conservation. Policies are needed that provide incentives for increased agricultural productivity on deforested lands while at the same time reducing the availability of forested land. The key elements of this policy integration include land tenure, infrastructural planning, protected areas, and credit programs (Nepstad *et al.*1999).

Land tenure policies should be aimed at granting legal titles to land in the very early stages of frontier evolution. Land title given to settlers helps them acquire access to credit that they need to make investments in their land that create disincentives for fire use and incentives for fire prevention. Legal ownership of land also favors more intensive forms of land-use because it can decrease the risk of government appropriation and increase the confidence that benefits of investments in the land will accrue to the landholder. We interpret all government decisions to establish infrastructure in unsettled forest regions of rural Amazonia as *de facto* policy decisions to expand the agricultural frontier, indirectly exacerbating the Amazon fire problem. The construction of all-weather roads, electric power grids, waterways, railways, gas pipelines, hydroelectric dams and the concession of industrial mining permits brings people into remote forest regions, and brings new lands into the frontier and onto the land market. This frontier expansion drives down the value of land that is already accessible, and favors extensive forms of agriculture that give high yields on labor (or on the capital that is invested), but that require new cheap land to be economically viable (Schneider 1993). Infrastructure investments should focus on existing frontiers, where they can favor land use intensification.

Increases in the area of forest effectively protected from development also impedes frontier expansion. The Brazilian government's recent commitment to set aside 10% of the Amazon forest in strict protected areas could represent a substantial contribution to fire control efforts in the region. The requirement that 50% of private properties must be kept in forest reserves could also act to slow the rate of frontier expansion, if it were implemented. However, the current structure of this law results in severe fragmentation of forest reserves on individual properties; it would have much greater forest conservation value if each landholder's forest reserve were part of a large, consolidated forest reserve. Finally, agricultural credit programs should include technical assistance and other measures designed to promote the intensification of land-use systems by improving marketing facilities and by building the capacity of local institutions to engage in commercial enterprises.

Credit, subsidies, and tax breaks may represent the most direct way by which society can compensate private landholders for the added investments in fire prevention needed to defend forested areas. Economic policies are well known and frequently utilized instruments for influencing decisions by landowners, and they often have more far-reaching effects than legislation. The Amazonian fire problem is a particularly appropriate target for the application of such policies, since the brunt of economic damages associated with accidental fires falls on private landholders. Currently, none of the economic programs available to Amazonian farmers and ranchers are explicitly designed to reduce accidental fire Amazon (Nepstad, Moreira and Alencar 1999).

Rural credit policies should include support for investments in fire prevent and control techniques and equipment in their programs that finance agricultural and forestry activities. Such changes would be easy to make because these policies are legally autonomous. In the case of financial support programs directed specifically towards rural communities, could be designed to encourage the adoption of fire use regulations by funding community-level infrastructure and equipment needed to manage fire, and by covering the expenses of establishing and maintaining local organizations for fire prevention and control. For instance, in the Brazilian Amazon small changes could be incorporated into the fiscal and taxation policies that already exist for the region: Fire utilization should be prohibited in agricultural projects approved through the Amazonian Investment Fund. Businesses throughout Brazil that draw on this fund and enjoy income tax exemptions of up to 75% over a ten year period, could be threatened with removal of this tax holiday if they fail to exclude the use of fire from their enterprises. Tax exemptions on the purchase of equipment could also be used to encourage communities to adopt fire regulations, and to create volunteer fire-fighting brigades at the community or municipal level.

Fire insurance for farmers and ranchers who adopt fire prevention practices could also reduce accidental fire. Producers who invest in fire breaks, for example, could be compensated for damages associated with accidental fire through such an insurance program. Such a program would run the risk of encouraging accidental fires, and would have to be closely monitored.

These economic approaches to the fire problem could be used over the long term to encourage the substitution of fire-dependent forms of land-use with more intensive production systems on land that is already deforested. In the context of an overall policy reform that improves transport systems, energy supplies, health services and education systems in old frontier regions instead of encouraging the expansion of new frontier regions, these economic tools could be used to make agricultural intensification through agroforestry systems, cattle production intensification (Mattos and Uhl 1994), and forest management for timber (Uhl et al. 1997).

Fire Risk Warning Systems

The vast ecological and economic damages caused by accidental fires may decline if the region's land holders use fire less—and invest in fire prevention more—when the risk of accidental fire is high. Currently in the Amazon, every landholder is on his/her own in deciding what this risk might be, even though the interest in fire risk is very high. The ability to predict fire risk could also provide a powerful tool to reduce the occurrence of accidental fire. The personnel, vehicles and other resources that are necessary to implement legislation designed to prevent accidental fire are tiny given the magnitude of the Amazonian agricultural frontier, and predictions of the severity of fire risk in different parts of Amazonia could help government agencies decide where to invest their scarce enforcement resources, and when additional resources are needed.

In the case of Brazil it will take a major investment in fire research to develop fire warning system for Amazonia, similar to that already in operation in both the US and Canada, for instance. Fire warning systems in these countries are the fruit of decades of fire research and dozens of scientific careers that have yielded numerical models for the major fire-prone ecosystems that incorporate information on fire spread, fire energy release, ecosystem flammability, and human factors under a wide variety of climatic conditions.

In contrast, fire prediction is in its infancy in Amazonia. The first map that we are aware of that integrates data on rainfall, soils, and field measurements in Amazonian forests to identify areas of fire-vulnerable forests is the "RisQue" (described below). Its predictions are based on data from a mere 60 weather stations, compared to more than 1000 in the US! Many of the assumptions and algorithms used in the construction of RisQue must be verified in the field, and modified as new data arrive. Until a national fire research program is established within Brazil, fire prediction in Amazonia will depend upon models such as this (Nepstad *et al.*1999).

One promising approach to fire risk prediction in Amazonia would directly involve rural landholders. Farm communities and ranchers could calculate forest fire risk themselves once fire researchers have developed equations that describe the relationships between rainfall, soil water availability, and forest flammability for Amazonia's major forest and soil types. Fire risk prediction kits could be disseminated to rural landholders through rural extension programs, and would include rain gauges, rain data collection sheets, calculators and tools for sampling soil. Based on soil textural analysis, regional research centers could provide the appropriate equation for calculating forest fire risk, and extension agents would teach the landholders how to calculate fire risk with this equation using rainfall data input. This approach to fire risk would address one of the most serious impediments to fire risk assessment in Amazonia, the insufficiency of rainfall data collection.

In the short term, an "El Niño early warning system" could act as an effective substitute for a fire risk warning system. During most El Niño episodes, the surface temperatures of the southern Pacific Ocean begin to warm approximately six months prior to the onset of El Niño-related climate disruptions (such as Amazonian drought). Rapid dissemination of early El Niño signals would give Amazonian landholders time to incorporate the prospect of severe drought into their land management planning.

Predicting Future Burnings

Accidental fires in Amazonia may become worse in the future. El Niño events are associated with severe droughts across much of Amazonia, and have been more frequent in the last 15 years. The increase in El Niño events may be associated with the accumulation of carbon dioxide in the atmosphere (Trenberth and Hoar 1997), and could therefore represent the beginning of a long-term trend. Rainfall reductions in Amazonia are also a predicted outcome of Amazonian deforestation itself (Nobre et al. 1991, Shukla et al. 1990). Either of these trends would exacerbate the problem of Amazonian fires by increasing the susceptibility of forests, pastures and plantations to conflagrations.

Accidental fires may also increase in the coming years because of the expanding agricultural and timber frontier. As roads such as the Santarem-Cuiabá, the Manaus-Boa Vista, and the Acre-Pacific are paved, logging, colonization by landless poor, and large-scale forest conversion to cattle pasture by large scale landholders, will both increase the flammability of vast stretches of new forest, and introduce fire sources through traditional agricultural and pasture management practices. The prediction of future fire scenarios for Amazonia—and the influence of public policy change on them—is a crucial task for science.

One illustration of the potential application of science to environmental policymaking was the work of The Woods Hole Research Center (WHRC) and the Amazon Institute for Environmental Research (IPAM). In 1997/98, when forest fires became an important issue in the Brazilian Amazon, WHRC/IPAM scientists used accumulated knowledge on the dynamics of Amazonian fires to create a fire-risk prediction model (called "RisQue", from the Portuguese "Risco de Queimadas e Incêncios") that incorporates data on climate, soils, forest flammability, logging, and agricultural fires to predict future Amazonian fire regimes (Nepstad et al. 1998). The model played a pivotal role in raising worldwide awareness about the problem. The model was subsequently presented to Brazilian policymakers and general public and led to an overhaul of the legislation and policy approach to forest fires. This case presents evidence that both natural and social sciences can influence environmental politics/policy in positive ways. Further development of this model could provide a powerful tool for illustrating the impacts of current rural development trends in Amazonia.

Conclusion

Fire is deeply inter-woven into the cultural fabric of tropical America. It is the basic tool by which subsistence farmers survive in remote forest regions, and it is the means by which larger landholders claim and defend their property, and fend the regrowth forest from their sickly cattle pastures. Given the difficulty to implement fire-related legislation in the region, strategies to reduce forest burning must address the central role played by fire in the lives of forest residents and therefore there is no quick mechanisms for solving fire problems. The challenge is to find more effective means to support rural land-holders in their struggle to prevent and control unwanted fires. The solution will depend upon fundamental changes: reduction of the rate of agricultural frontier expansion and intensification of agricultural and forestry production systems where the frontier is already settled. It is through a dramatic reduction in the availability of new forested land that producers will use fire less, and invest more heavily in fire prevention. Extending new roads, waterways, and electric grids into remote forestlands will perpetuate the presence of fire in agricultural landscapes.

Farmers and ranchers throughout the region suffer substantial economic losses through fires that escape their desired boundaries, thus farmers, small and large, more than anyone else, want a solution to the fire problem. If the "supply" of virgin forest land ripe for colonization dwindles, farmers and ranchers must turn to their existing land for sustenance and wealth, investing in fire-sensitive fences, fruit trees, and forage grasses that create a powerful incentive to use fire less. This common interest in less fire, less smoke, and lower risks to investments made in the land, is the seed of solutions for the fire problem.

Abstract

National forest fire research programs have enjoyed a long and productive history in Canada, the United States, and Russia. These programs have traditionally addressed major and topical fire management issues, so have evolved in concert with, and in support of, changing fire management practices. Although fire research activities are carried out at academic and regional institutions in these three countries, research at the federal government level has been dominant, providing the much-needed stability and continuity required to build relevant and adaptable research programs. The recent collapse of the Soviet Union presented the first opportunity for Russian and western fire research scientists to interact openly and productively. Since 1992 organizational structures have been put in place to facilitate this cooperation, joint meetings and experiments have been undertaken, and a great deal of progress has been made on many fronts. With the growing trend toward international, cross-disciplinary approaches to global fire problems, it is anticipated that this cooperative approach to fire research between Russia and North America will continue to flourish.

Keywords: Forest fire research, Research institutions, Research history, Mandates, International collaboration.

Introduction

By the beginning of the 20^{th} century, forestry education and forest practices in Canada, Russia, and the United States were strongly influenced by European views of proper forest management. Fire was viewed as an enemy, something to be controlled and even eliminated where possible, replaced by intensive, structured forest management. Accomplishing this in Europe, however, proved much easier than in the vast boreal and temperate forests of both North America and Russia. Fire is both natural and essential to forest ecosystem composition, structure and function in these biomes, and suppression of all fires has proven neither physically possible nor ecologically desirable. Settlement and exploitation of these boreal and temperate forests led to the development of sophisticated fire management programs that have had great success in reducing the areas burned by unwanted fires in protected zones, even as the numbers of ignitions from human causes was often increasing. However, at least in North America, it is becoming apparent that in many ecosystems, economically feasible levels of protection may delay, rather than prevent, eventual fire impacts. This is evidenced, for example, by the buildup of fuels and, therefore, resistance to fire control, in many of the short fire return interval systems (such as ponderosa pine). While the suppression of fires that threaten public and industrial interests is a goal over much of North America and Russia, there are also large areas in northern Canada, Russia, and Alaska where values-at-risk are low and little or no forest protection takes place and fire is allowed to perform its natural role. For these reasons, forest fires continue to exert a significant influence on boreal and temperate forests in North America and Russia. Furthermore, the large magnitude of annual burning in temperate and boreal forests, and the predictions of global change models that boreal forests will see above average increases in temperature, suggest that it is critical to develop data and models for better prediction of the impacts of boreal forest fires on the global environment.

Coincident with the implementation and expansion of fire suppression capabilities there was a realization that effective fire control required an intrinsic understanding of the factors governing the incidence and behavior of forest fires, and forest fire research programs were undertaken to provide this information. Canadian and American fire research began in earnest in the 1930s, with similar research priorities and approaches. Just as operational fire management agencies in Canada and the U.S. have cooperated in sharing ideas and resources, the fire research programs in these countries developed through extensive exchange and collaboration. Contact with fire managers and researchers in the former Soviet Union was, until recently, sporadic and incomplete at best. Despite this situation, the Russian approaches to operational fire management and fire research have gone down some similar paths to those in North America. Expanding collaboration over the past decade has provided the realization that Russia and western countries, while poles apart ideologically during the Cold War and earlier, have much to offer each other in exchange of information and technology for fire management and in collaboration and information exchange in fire research. Differences in political history and in the development of fire management and fire research have also led to unique strengths in each country's research program that can be built on by collaboration.

This paper outlines the development of fire research programs in each country and shows how research has evolved to meet developing fire protection needs. It concludes with a summary of current collaborative research activities involving Russian and western fire scientists.

Recent Historical Forest Fire Research Directions

Russia

Early fire research activities in Russia were closely tied to operational fire problems, and have developed in conjunction with the evolution of fire protection methods and capabilities. In the early 1920s it was recognized that effective protection of the vast Russian taiga required aircraft, and research was focused in this area. Experimental aerial reconnaissance flights were undertaken sporadically, with the beginnings of a formal aerial protection program initiated in the early 1930s when organized, operational flights for fire detection and monitoring began in the central Urals, Siberia, and the Far East regions of Russia, under the All-Union Scientific Research Institute of Agriculture and Forestry Aviation, and later the All-Union Trust for Forest Aviation. This formalization of aerial fire protection led quickly to rudimentary attempts at dropping chemicals and water from aircraft and, in 1934 a smokejumping program was initiated. New bases were established across Siberia, and the program expanded dramatically after World War II using surplus military aircraft and demobilized paratroopers. Avialesookhrana - the aerial forest protection service - began using helicopters to transport firefighters and equipment (some mechanized) in the mid-1970s, and began to exert a major influence on the area burned throughout Russia, especially as regards suppression of human-started fires near settlements. By the 1990s the Soviet Union had amassed the largest firefighting system in the world. However, when the Soviet political system collapsed in 1991, budgets for fire control were greatly reduced. With these recent political and economic changes in Russia, the past gains in fire suppression have become difficult to sustain as the area receiving fire protection, the frequency of reconnaissance flights, and the numbers of fire fighters that can be hired and deployed have all decreased.

The development of forest fire research in the Soviet Union closely paralleled the expansion of fire control across the country. Within various forestry institutes, fire science developed through the 1930s, with emphasis on fire behavior, ecology, control and use. Although disrupted by World War II, fire research programs continued to expand, with sophisticated textbooks being produced, and a national system of fire danger rating (the Nesterov Index) being developed. Postwar reconstruction led to the development of three major institutions, under the auspices of the Russian Academy of Sciences and the State Committee on Forests, that have dominated Soviet/Russian forest fire research activities to the present - the Leningrad Forest Institute, the

Far Eastern Scientific Forestry Research Institute in Khabarovsk, and the V.N. Sukachev Institute for Forest Science in Krasnoyarsk. The Leningrad institute focused on forest pyrology in European Russia, specializing in aerial operations, including fire detection and weather modification (cloud seeding), fire retardants, and pumps. The Khabarovsk institute carried out research in the development of forest fire spread models, fire danger rating, and fire ecology of the forests in the Far East, while the Krasnoyarsk laboratory pioneered research in fire fundamentals and the fire ecology of Siberia. Major fires in 1972 brought a renewed commitment to fire research, with expanded facilities and financial support. In addition to continuing ongoing research, emphasis was placed on the development of fire-fighting equipment, particularly the conversion of agricultural and military machinery for this purpose. An emphasis was placed on theoretical modeling, including the development of a comprehensive mathematical model of fire behavior. Fire ecology research was also expanded across Siberia. Other centers of forest fire research have included Tomsk University (physical fire behavior modeling) and Novosibirsk (wildfire smoke chemistry and aerosols). The International Forestry Institute in Moscow has taken a leadership role in analysis of national fire statistics and development of a national system for satellite fire detection and other satellite applications. A number of technology institutes have been established and maintained by the Russian Forest Service, with a primary goal of developing new firefighting equipment and technology. The number of fire research publications increased dramatically, and fire research symposia were held frequently during the 1960s and 1970s. At this time the Canadian fire research community, although lacking direct contact with their Soviet colleagues, was acquiring and translating many Soviet fire research publications.

With the economic stagnation and eventual collapse of the Soviet Union in the late 1980s and early 1990s, funding for fire research dropped dramatically at the same time as fire suppression capabilities diminished. Research programs were cut, institutions stagnated, and those researchers who persevered worked for little or no salary. This was the situation when western fire scientists, following the "opening" of Russia to the west, began to interact and collaborate directly with their Russian counterparts in 1992.

Canada

In the early 1900s Canadian forestry practices were strongly influenced by European approaches to forest management. As a result fire was seen as an enemy and something to be eliminated from the forest whenever possible. Recognition of the folly of this approach was long in coming, but a series of catastrophic wildfires across Canada in the first three decades of the 20th century galvanized public opinion, and resulted in the birth of modern forest fire management. Although fire exclusion was still the policy of the day, there was a recognition that much more knowledge was required on the occurrence and behavior of forest fires if fire protection efforts were to be successful. The Canadian federal forestry service was responsible for fire protection nationally in the early 1900s, turning this responsibility over to provincial agencies by the early 1930s, and beginning to focus on the development of fire protection techniques. Beginning in 1925, a modest program of forest fire research was initiated by the Canadian government, and this program has developed and expanded to the present day. Although various provincial/territorial fire management agencies, and some universities, currently conduct some fire research, the Canadian federal government program has been by far the strongest, broadest, and most continuous commitment to forest fire research across Canada.

Early Canadian fire researchers began investigations into the relationship between weather and forest flammability, working primarily in Ottawa and the Petawawa Forest Experiment Station in Ontario, but expanding a network of field experiment stations into western and Atlantic Canada in the 1930s. Fire danger studies, including the conducting of numerous small-scale test fires in the field, resulted in the development of a national system of fire hazard rating which was implemented at that time, and which has survived many metamorphoses to form a part of the current Canadian fire danger rating system. While fire hazard research was a primary research thrust at that time, fire suppression research was also carried out, with the development of fire retardant chemicals and specifications and performance-testing procedures for portable fire pumps and accessories. The number of professional fire researchers in Canada increased gradually during this period, reaching a modest total of 8 by 1958. During this period, although visits were few, there was substantial correspondence and sharing of ideas with fire scientists in the United States, particularly in the area of fire danger rating.

A major expansion in Canadian fire research capabilities occurred in the 1960s, when fire research programs were established at federal regional laboratories across Canada (in British Columbia, Alberta, Ontario, Quebec, New Brunswick, and Newfoundland) to supplement the continuing fire research activities at the Petawawa Forest Experiment Station. The regional establishments provided continuous, rather than sporadic, contact with operational fire management agencies, and the development of broader research programs aimed at addressing fire agency requirements directly. During the 1960s the Forest Fire Research Institute was established in Ottawa to act as a focus for the federal fire research program, which was at its zenith during the 1960s and 1970s with 29 professional researchers working (with support staff) across the country. This period saw the increasing use of physics and laboratory studies to support a field program aimed at the development of a continuously improved fire danger rating system which included the prediction of quantitative fire behavior through empirical models based on an extensive national experimental burning program. The result is the Canadian Forest Fire Danger Rating System, completed in 1989, which is currently in use throughout Canada and in many other countries. During this period the evolution of computer technology, along with modern management science and remote sensing led to the development by Canadian fire researchers of sophisticated computerized fire management systems that revolutionized operational fire management in Canada. Integrating remote sensing for fuel type identification, the prediction of daily lightning and human-caused fires, fire detection planning techniques, resource inventories and fire growth models, these fire management systems were tested and implemented across Canada in partnership with fire management agencies, and have been exported internationally. Fire ecology research became a major research focus in the 1970s, particularly with respect to Canada's national parks where perpetuating natural forest ecosystems that include fire as an environmental factor is a priority, but a gradual decline in research resources prevented fire ecology research from becoming a sustained major research focus. Fire economics, as a component of a larger field of forest management economics, received some attention from the Canadian fire research community during this period, focusing on the impact of fire on timber supply and the determination of optimum expenditure levels in fire protection. At the same time, some fire suppression research, from equipment development and assessment, to formal studies of aircraft water/retardant bombing effectiveness was carried out over a number of years.

From this peak period, the resource level of Canadian fire research has seen a steady decline, consistent with a lack of funding support from the federal government to federal scientific research in general. In 1979 the Forest Fire Research Institute was disbanded, with much of its program, with staff reductions, being transferred to the newly reorganized Petawawa National Forestry Institute. In the mid-1990s, amid a general federal government downsizing, the Petawawa National Forestry Institute was closed, along with the regional laboratory in Newfoundland. Since that time, the Canadian Forest Service (CFS - the current federal forest research entity), scrambling to maintain a national scientific program in the face of diminished support, has developed a series of Science and Technology Networks designed to address cross-disciplinary forestry research priorities in an integrated fashion, making the most of continually dwindling resources. The Fire Research Network, one of 10 CFS S&T Networks established in 1995, has a research complement of 25 (16 professionals), located primarily at the Northern Forestry Centre in Alberta and the Great Lakes Forestry Centre in Ontario, with smaller components at Pacific Forestry Centre in British Columbia and the Laurentian Forestry Centre in Quebec. The current research objectives of the Fire Research Network are:

- produce the scientific understanding and decision support tools required to manage wildland fire within the context of sustainable development;
- form a foundation of knowledge to model fire behavior and fire effects at ecosystem and landscape scales, and establish a national decision support system t implement these models;
- construct tactical, strategic, ecological, and economic decision support tools and systems for use in fire and forest management;
- determine and assess the role of fire in relation to global change; and
- monitor fire weather, fire behavior, and fire activity on a national scale.

Research activities in support of these objectives are organized into five program areas within the Fire Research Network: Fire Environment, Fire Ecology, Fire Management Systems, Fire and Global Change, and the Role of Wildland Fire in Canadian Forests.

A significant but lesser volume of fire research has come from Canadian universities in recent decades, often in collaboration with federal and provincial colleagues, particularly in the areas of fire management systems, fire ecology, fire occurrence prediction, fire danger rating, and physical fire modeling. Most notable have been the University of Toronto and Lakehead University in Ontario, Laval University and the University of Quebec at Montreal in Quebec, Brandon University in Manitoba, and the Universities of New Brunswick, Alberta and British Columbia.

Over the past seven decades the fire research program of Canada's federal forest service, through many organizational changes and fluctuations in resource strength, has produced a continuous series of innovative products of practical value to fire and forest management in Canada and abroad. Fire research in Canada has largely followed the empirical method, primarily through extensive field observation and measurement programs, although theory has been linked with field results where possible. Successive research generations have expanded, and built upon, the progress of their predecessors as new information and technologies became available, but a strong sense of continuity has remained. There has always been a large amount of cohesion and collaboration within the Canadian fire research community, despite varying disciplines and locations, and this approach, combined with a close working relationship with operational fire managers across Canada, has been fundamental to the success of the program.

The United States

While early European settlers in the US often used fire to help clear land for homes, agriculture, and other purposes, by the end of the 1800s the effects of devastating fires on forests and on communities were converging with the opinions of some ecologists to embrace the idea that fire was bad both ecologically and socially. Fire destroyed valuable timber, interrupted natural succession processes, and caused tremendous loss of property and life in the early wildland-urban interface fires such as the 1871 Peshtigo and Humboldt fires in Wisconsin, where perhaps 2,250 people died. Although arguments about the usefulness and role of "light fire" and prescribed fire as management tools were to continue even to the present day, fire protection and suppression became the primary focus of fire management. This focus changed gradually as prescribed burning was increasingly advocated and used, beginning with policy changes allowing burning for specific purposes in the 1940s. In many cases, the National Park Service led the charge on implementing prescribed burning programs in the West (e.g. Sequoia-Kings Canyon National Park). However, outside of the South, the areas covered by these programs were often small. It has only been in the 1990s that a series of large and costly fires, the weight of scientific evidence on negative effects of fire exclusion on both ecosystems and fire hazard, and increasing concerns over management of fire in wilderness and wildland-urban intermix areas led the federal agencies to make major changes in fire management policies. As a result, there has been a dramatic upturn in the extent of fuel management and prescribed fire programs in agencies such as the USDA Forest Service and the Department of the Interiors

Bureau of Land Management (BLM) as well as a shift toward better integration of fire management into overall land management planning. Strategies and tools for addressing risks of increased vegetation buildup to forest health and to fire hazard and for monitoring changes and impacts of treatments will need to continue to evolve if land managers are to deal effectively with the large areas currently believed to be at risk of catastrophic fires. Throughout the changes in fire policy over the course of the 20th century, fire research programs provided support for improving operational capabilities of fire suppression, as well as the scientific foundation for changes in attitudes and policies toward wildland fire.

The beginnings of fire research as an independent area of investigation in the US might be traced back to 1898, when the first chief of what is now the USDA Forest Service requested a study of the effects of wildfires in southern California. The Transfer Act of 1905 provided the initial authorities for managing and studying fire, but interest in the study of fire accelerated after the devastating fires of 1910. This early research was carried out primarily in California by researchers and administrators in the Forest Service (FS). It consisted largely of case studies and retrospective analyses of fire statistics. In 1915, the Forest Service established a new Division of Fire Control, as well as a separate Branch of Research. In 1926 a national program of forest fire research was developed, and the California Experiment Station was established, with fire research as one of its areas of emphasis. And in 1928, the McSweeney-McNary Act gave the responsibility for all federal research on forest fire to the Forest Service. Early work focused on analysis of fire statistics, fire control, fire danger, and fire behavior, with the emphasis on developing better methods of fire suppression. This work laid the foundation for the 10 a.m. policy, established in 1935 (which called for fires burning the previous day to be extinguished by 10 a.m.). While this policy received strong political and popular support, some researchers and historical users of fire (e.g. in the southeastern US) questioned its wisdom as a blanket policy. Both Forest Service and university researchers continued studies on the effects of frequent “light burning”, although results from FS research were sometimes suppressed for several years before publication. University researchers at Washington, California, and Yale, along with the Tall Timbers Research Station in Florida were among the pioneers of fire ecology and the advocacy of a natural role for fire. Despite official policy, prescribed fire continued to be used in local areas, particularly in the short-fire return interval pine systems of the southeast and the west. The 1940s and 50s began to see increased use of prescribed fire as a management tool in some areas of the South and the West. During and after World War II, many of the federal fire research programs were focused on projects supported by the military, which addressed topics such as mass conflagrations from nuclear attacks; many of the results of these studies are still classified. But by the early 1950s emphasis in the Forest Service programs was returning to the problems of wildland fire prediction, behavior, and control with a great deal of emphasis on equipment and techniques for fire suppression, such as aircraft and fuelbreaks, and a lesser emphasis on the effects of fire on ecosystems. It was during this period that a large research program on delivery and testing of aerial fire retardants was begun; this program continues today as a development and application program supported by the Fire and Aviation operations branch of the Forest Service. Meanwhile, at universities and research institutes such as Tall Timbers, studies on the ecology of fire and its natural role were increasing.

In the late 1950s , after severe fire seasons in 1953 and 1955, federal support for fire research grew, and the FS ultimately received funding to build three major fire research laboratories in Missoula, Montana, Macon, Georgia, and Riverside, California. These laboratories initially focused strongly on developing models and tools to support fire operations (including fire behavior and fire danger rating systems), but programs increasingly focused also on the ecological and environmental impacts of fire, fire exclusion, and fire use. A major research program also was built in Arizona during the 1970s to address problems of fire ecology and management, and effects of fire on erosion and watersheds. A large research program was developed in the Pacific Northwest, focusing on slash burning, smoke, and forest fuels; and programs at the North-Central Forest and Range Experiment Station addressed social aspects of wildland fire management and atmospheric processes. Federal fire research programs, and fire research at universities, have seen great variability in funding support and capacity over the past 30 years. Decreases in funding for fire research in the 1980s led to closure of the Macon laboratory, numerous personnel transfers, and severe reductions in staffing or closure of programs at other locations. The trends in reduced staffing of FS programs have continued into the 1990s, with approximately a 50% reduction in permanent staffing for FS fire research programs between about 1985 and 1999. Currently over 50% of the fire research in the USFS is conducted outside the two main fire labs, often as part of interdisciplinary projects on silviculture or ecosystem processes. The smaller fire research programs in the Department of Interior, formerly located primarily in the National Park Service, have also been disrupted by major restructuring, and now reside in the newly-consolidated Department of Interior (DOI) research program under the US Geologic Survey (USGS). A number of universities, including the University of Washington, University of California, Northern Arizona University, Arizona State University, University of Montana, University of Idaho, Duke University, and University of Colorado have built strong research programs in various aspects of fire research over the last 20 years, with particular strengths in fire ecology, fire history, and remote sensing. Major accomplishments during the 1980s and 1990s have included development of the BEHAVE fire modeling system, the National Fire Danger Rating System, fuel models, the Incident Command System, models and data on fire emissions, systems for improved prediction of seasonal fire hazard, better understanding of fire meteorology, ecology, and the effects of fires on erosion, vegetation structure and dynamics, and nutrient cycling. Through the use of satellite data, coarse-scale maps of fire danger and other parameters are now available on the internet. A number of the systems developed by US fire scientists (such as the BEHAVE system, the landscape fire modeling system FARSITE, and the Incident Command System) are used widely outside the US. Fire research has a long tradition of close cooperation with users in research development and application. Much of the current fire research in the US is carried out in interdisciplinary teams that often include cooperators from federal, state, and local land management agencies, non-governmental organizations, universities, USFS, USGS, National Aeronautics and Space Administration (NASA), and Department of Energy scientists, and regulatory agencies such as the Environmental Protection Agency (EPA) and state air quality boards, and funding often comes from multiple sources. Establishment of the interagency Joint Fire Science Program in 1998 to provide scientific support for fuel management activities on federal lands, has provided a new source of competitive funding for applied fire science in a wide range of disciplines. Other aspects of research programs are being supported by NASA, EPA, and other agencies.

Several trends will strongly influence fire research in the US over the next five years. These include: increasing emphasis on integrating fire management into land management planning; recognition of fire's role in forest health and sustainability; the need to quantify the impacts of changing fire regimes on regional, national, and global carbon budgets; the need to understand and predict interactions of fire with other key disturbances such as global change, climate extremes, insect and disease, and harvesting and silvicultural systems; and the need to understand the social context of fire management. Addressing these issues will require integration of fire planning and economics, physical science, fire effects, ecosystem process, and social sciences research. Specific needs include:

- better quantification of the extent and severity of fire on the landscape, and its impact on ecosystem dynamics and carbon budgets;
- improved models and data on emissions and smoke dispersal for better air quality management and understanding of regional and global impacts of fire emissions;
- improved fire meteorology models and fire hazard prediction and mapping systems;
- tools for monitoring and modeling of the effects of vegetation/fuel management treatments on a landscape to national scale;

- modeling systems that integrate improved and validated fire behavior and fire effects models;
- integrated and consistent approaches to mapping and monitoring fuels and for modeling succession and fuel development over time;
- tools to evaluate the cost-effectiveness and environmental impacts of alternate management strategies;
- improved understanding and models of interactions between fire and other disturbances.

While planning and management tools for fire suppression activities will continue to be improved, the future of fire research lies in a shift of emphasis and expansion into research that will help managers and policymakers address key issues in landscape management, strategic planning, and influence of fire and fire management strategies on global and regional environments and on the sustainability of ecosystems to meet future needs for fiber, clean water, recreation, and other resources.

Current and Future Trends

As previously mentioned, early attitudes toward fire management in the US and Canada were shaped by management concepts from European forestry. International collaboration has played a key role in fire research and fire management for many years. Fire researchers and managers have long been involved in international activities, often in the form of technology transfer or training. These activities have certainly proved mutually beneficial, and will undoubtedly continue (e.g. US involvement in response to the recent fires in Indonesia; training programs on fire behavior modeling or use of the Incident Command System), but the most fruitful international work in fire research will continue to be that which involves true collaboration and mutual information exchange.

Over the past 20-30 years North American fire research has benefitted greatly from long-standing collaborations with researchers in countries such as Spain, Portugal, Australia, Germany, China, Japan, South Africa, Zimbabwe, Brazil, Honduras and Guatemala, Mexico, and France, to name a few. These collaborations have been critical in helping to develop a better understanding of fire behavior modeling, the role of fire, vegetation dynamics, fire management strategies, the influence of social and economic factors on fire use and suppression, and the interaction between fire and global change. Interest in remote sensing of fire has led to recent collaborations with scientists in the European Union.

Despite this history of broad international collaboration in fire research, for many years the extensive literature and experience of fire researchers in the former Soviet Union was largely inaccessible due to restrictions on travel and communication and to the strong language barrier. Direct collaboration between western and Russian fire scientists began in 1991 when, after the collapse of the Soviet Union and the relaxing of political tensions, the International Boreal Forest Research Association (IBFRA) was formed at a meeting of Russian, Canadian and American representatives in Arkangelsk, Russia. The Fire Working Group of IBFRA met for the first time in Krasnoyarsk in central Siberia in May 1992. The goal of this meeting was the development of a set of protocols and hypotheses that would guide future cooperative fire research initiatives between western and Russian scientists. In all, a series of 8 hypotheses were developed, dealing with fire behavior, fire ecology, ecosystem processes and response to fire, climate change and fire, and determining the spatial and temporal distribution of large fires. These specific long-range hypotheses envisioned international, multi-disciplinary research teams conducting a coordinated and sequenced series of experiments addressing these issues.

During the summer of 1993, the first international fire conference involving western and Russian fire scientists was held in Krasnoyarsk. This conference ("Fire in Ecosystems of Boreal Eurasia") attracted over 40 papers (presented by fire researchers from 9 countries) dealing with many aspects of fire ecology, fire behavior, fuels classification, fire meteorology, modeling, and global change - with emphasis on boreal Eurasia. The proceedings from this highly successful, groundbreaking conference were published as a monograph (see References). Following the

Krasnoyarsk conference, a field experiment, Fire Research Campaign - Asia North (FIRESCAN) was carried out under the joint sponsorship of IBFRA, the International Geosphere-Biosphere Program (IGBP), and the United Nations Team Of Specialists on Forest Fires. The aim was to conduct a high-intensity experimental fire under controlled conditions that would permit Russian and western fire scientists to compare research methodologies. This fire was thoroughly documented (e.g. fire behavior, fire effects, and smoke chemistry measurements) by Russian and western fire scientists, and the results published jointly. Followup measurements were made annually for 5 years by a joint team of North American, European, and Russian scientists.

A major focus of collaborative research between Russian and western scientists has been quantifying the extent and impact of Russian boreal fires. In 1993, NASA cooperated with Russian scientists in to establish ground receiving stations for obtaining NOAA/AVHRR data across Russia. Data on fire activity from the Krasnoyarsk station and from NOAA archives is being jointly analyzed by US, Canadian, and Russian scientists. With the diminished capacity of Russian fire protection, satellite monitoring of fires, particularly in the more remote regions of Russia, provides an essential capability. Recent emphasis on global change issues, including carbon budgets, have focused attention on the large carbon pool in Russian boreal forests, and the need project climate change impacts on this resource. IGBP high-latitude transects have been established in Siberia, Scandinavia, Canada and Alaska to investigate and determine how the terrestrial carbon cycle will be affected by the rapidly changing environment in these regions. As fire is the major disturbance regime in boreal forests, controlling ecosystem dynamics including carbon cycling, Russian and western fire scientists are planning interdisciplinary experiments along these transects, along with colleagues investigating many additional aspects of the terrestrial carbon cycle.

Another outgrowth of the 1993 activities has been the development of strong collaboration between Russian scientists, Avialesookhrana, the Russian Forest Service, the USFS, NASA, and the Canadian Forest Service in the Krasnoyarsk Region in a program of fire effects research that will combine experimental and remote sensing data to obtain better estimates of the extent of fires of differing severities in central Siberia, and of the impact of fire severity on ecosystem processes. The goal of this program is to better quantify the effects of fire on carbon cycling and sustainable management of pine forests in Siberia. The USFS is also collaborating with researchers, fire managers, and forest managers in Krasnoyarsk on a pilot demonstration program on the use of prescribed fire. Development of these programs has involved repeat exchange visits between the US, Canada, and Russia over the past several years.

The IBFRA Fire Working Group has also initiated studies into the suitability of the Canadian Forest Fire Danger Rating System for use in Siberia, and are jointly analyzing historical weather data for Siberia. In addition, support has been extended to the physical fire modeling group in at Tomsk University, including the translation of a Russian book on high-intensity fire modeling, and participation in a fire modeling conference in Tomsk in 1995. Russian fire scientists have also been sponsored to attend the ongoing (1997-2000) International Crown Fire Modeling Experiment in Canada's Northwest Territories.

In the summer of 1996 a major United Nations seminar, “Forests, Fire and Global Change”, sponsored jointly by the Russian Federation and the UN Team of Specialists on Forest Fire, took place in Shushenskoye in south-central Siberia. The goals of this seminar included assessments of the extent and impact of wildfires globally, the development of methodologies for collecting and archiving fire data at a global scale, and the development of mechanisms for expanded international cooperation in fire and disaster management. Holding this meeting in Russia demonstrated the important role of Russia in global fire management and further accelerated their involvement internationally.

Declining budgets, government downsizing, and a growing awareness that fire is a global force with multi-dimensional social and environmental impacts, have resulted in an unprecedented trend toward more cooperative fire research activities. International, cross-disciplinary collaborative investigations into common problems are becoming the means by which fire research programs are now being delivered. The International Geosphere-Biosphere Program has many Core Projects with fire research components operating studies and field campaigns in many regions of the world, including North America and Russia. The International Boreal Forest Research Association has a Fire Working Group conducting collaborative fire research programs in northern Canada, Alaska and Russia. The United Nations Team of Fire Specialists, and the International Union of Forest research Organizations (IUFRO) Fire Research Group are also actively involved in this modern, and growing approach to forest fire research.

International meetings, translations of Russian literature, and increasing exchange visits and research cooperation have opened up vast new opportunities for collaboration and information exchange between Russian fire research and the rest of the world since 1991. Collaboration in the international fire research community has grown tremendously in recent years. Some of the key areas of current cooperative research include active fire monitoring; remote sensing of burned areas; development and testing of fire behavior models, emissions, carbon cycle, and ecosystem process models; and use and effects of prescribed fire. While fire researchers and managers have long been involved in international activities, in the past these were often in the form of technology transfer or training. These activities have certainly proved mutually beneficial, and will undoubtedly continue (e.g. international involvement in response to the recent fires in Indonesia), but the most fruitful international work in fire research will be that which involves true collaboration and mutual information exchange.

Although fire management and fire research programs in Russia developed largely in isolation from similar programs in Canada and the United States, there have been many similarities in these highly-effective approaches. Now that isolation is no longer an issue, joint research programs have been accelerated and are proving quite fruitful. In a world where individual countries can no longer solve problems alone, and where a rapidly expanding capability to communicate and collaborate in addressing environmental problems that transcend borders already exists, this collective approach to fire research challenges can only continue to grow.

Abstract

This paper discusses and presents the underlying factors and the need for a coherent research campaign concerning forest fires in the Mediterranean Basin. With a very long history of human settlements and land use coupled with the climatic and topographical conditions, Mediterranean Basin has very distinct landscape patterns shaped by biotic and abiotic factors. Of the factors involved, forest fires human made or natural are among the most important ones. Fire in the region is of social, cultural, economical, historical and psychological origin. Yet, fire research has mainly concentrated on the prediction of fire behaviour and ecology, i.e., the immediate effects of fires on fauna, flora and soil. No genuine effort has been made to relate resulting landscape patterns with typical fire regimes to historical land use practices, and socio-economic, cultural, historical and political backgrounds of fires, nor is it clear how the changing land-use pattern would affect the vegetation types and fire regime, overall land management planning and the contribution of wildland fires to regional atmospheric chemistry.

To overcome the problems in such a complex region the Mediterranean Basin, a multi-national, interdisciplinary research effort dealing with a broad range of interlinked aspects of the fire problem is vital. Here, the concept and tentative framework of a such research exercise is presented.

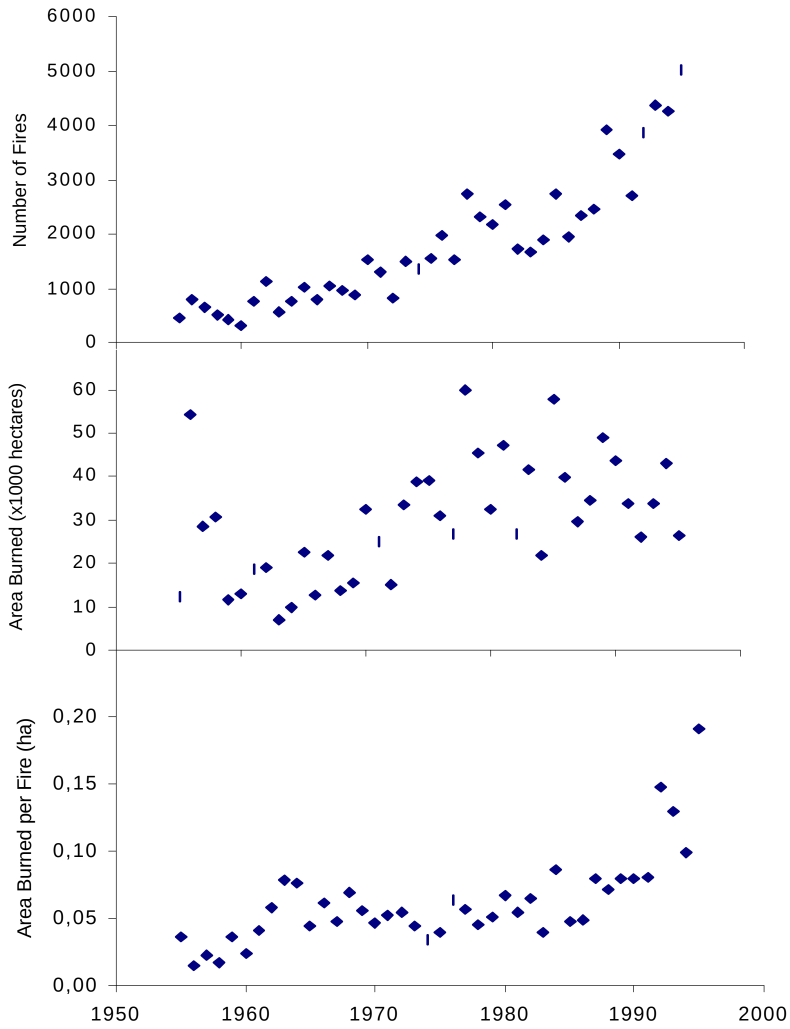
Keywords: Forest fire, Mediterranean Basin, Research

Introduction

Fire has been, still is and certainly will continue to be one of the great forces of nature in the Mediterranean Basin, and has a pervasive influence on its forests and their management, consuming hundreds of thousands of hectares of forest land annually resulting in billions of dollars in suppression costs and causing great damages in lost timber, real estate and recreational values, and even loss of life. Recent statistics indicate that the region is experiencing an ever increasing wildland fire problem. Supporting this statement is the fact that there are now an average of 50,000 forest fires per year in the region, consuming an area of 600,000 hectares, twice that of 1970s (Fig.1). While natural fires play an important role in many of the Mediterranean forest types, the increasing frequency of recent fires has transformed the fire from nature’s tool to nature’s threat, resulting in a dramatic decline in the quality of forests with the average fire cycle, in some localities, having been reduced to as little as 25 years (Alexandrian and Esnault 1999).

Fire in the region is of a very complex and multifaceted phenomenon involving social, cultural, economical, historical and psychological aspects, and marked by a prevalence of fires of human origin, with reliable estimates being up to 99%. However, fire protection agencies have evolved around an effective fire protection policy with a strong emphasis on fire control with little or no regard given to underlying causes of fires, and fire research concentrated mainly on the prediction and the immediate effects of fires on flora, fauna and soil.

Figure 1. Pan-Mediterranean fire statistics for the period 1955-1997. Source: Alexandrian and Esnault (1999).



Investigation of fire behaviour and fire impacts on ecosystems is undoubtedly very important. But knowledge about the human impact on fire and fire regimes, about the correlation of land use and fire regimes, about arson in relation to political and economic situations, about cultural, ethnological and psychological factors of ignition, about the history, the present and the future trends of those anthropogenic factors that determine fire regimes is essential. For effective and long-term prevention against wildfires, research must fill this gap in present fire ecology studies. It has to be made clear what the main determinating human factors are in producing high fire risk and uncontrollable fires.

"To address the complex and far-reaching issues related to anthropogenic impacts on fire regimes and ecosystem properties, formulation of a truly interdisciplinary approach is critically needed" (Kauffman *et al*. 1993). This calls for a genuine support and cooperation of nations and operational organizations to take it part in a multi-national, interdisciplinary research effort dealing with a broad range of interlinked aspects of fire problem.

The objective of this paper is to identify and present the underlying factors concerning forest fire problems in the Mediterranean Basin. To deal with the problem, the concept and tentative framework of a research exercise is presented.

A Retrospective Synthesis of Fires in the Mediterranean Basin

The Mediterranean Basin distinguishes itself from the rest of the world by its very long history of human settlements and land use with distinct climatic and topographical conditions. From the first hints of hunters (300,000 years ago) to our days many different cultures and civilizations (Persian, Egyptian, Hellenic, Roman, Byzantine, Islamic, capitalism, and international tourism) have established their typical land-use systems and therefore changed natural ecosystems completely. Fire was, in many cases, the only management tool by which the change in natural ecosystems was realized, and the evidence of anthropogenic ecosystem modification can be found up to the most peripheral sites of the region. "Europeans burned woods as well as heath and moor to improve pasture and range. ... They burned agricultural fields and gardens. Until very recently agriculture, after all, was rotational, either because it moved the farm through the landscape or because, in effect, it moved the landscape through the farm; both forms demanded fire. Europeans adapted slash-and-burn farming into slash-and-burn forestry. And so it goes" (Pyne 1994).

Fire has been identified as a natural process in dry and semi-dry landscapes which keeps vegetation forms in a dynamic equilibrium, guaranteeing the maintenance of biodiversity, the release of nutrients, and elimination of dead or otherwise not usable plant material. Since mankind learned how to handle fire, they have used it in many different ways: "Humans purposefully set fires to increase food choice, to facilitate the gathering of edible plants, and to attract and hunt games" (Perles 1977, cited after Trabaud *et al.* 1993). The domestication of animals and agricultural expansion promoted ignition in order to clear and fertilize wide areas. At the same time, biomass fuel was collected for heating and cooking. "The development of all human cultures was dependent on the free burning of vegetation and on the use of plant biomass to provide energy" (Goldammer 1993).

The introduction of exotic plant species and plantations, excessive wood cutting (deforestation) and increasing grazing pressure changed the natural fire regimes entirely. "Humans are a principal force that shape the size, frequency, and severity of fire on Earth. They directly impact the biota by accelerating, modifying, or excluding fire from ecosystems" (Kauffman *et al.* 1993). The cultivated and densely populated landscape ecosystems of the Mediterranean Basin have been in an equilibrium which was based on human activities. Two recent tendencies, which have started at almost the same time, have changed the existing "Total Human Ecosystem" (Naveh and Lieberman 1994) deeply and modified the artificial but well-balanced fire regime - the shift from burning wood to fossil fuel combustion, and urbanization.

As has been stated by Kauffman *et al.* (1993) "the shift from burning wood to fossil-fuel combustion has dramatically changed human society, the biota on Earth, and the chemical composition of the atmosphere". With the onset of the modern industrial age, the region has experienced an ever increasing influx of peripheral populations into larger cities resulting in the abandonment of traditional farming practices and the use of fires therein. This has led to an increase in the buildup of fuels and an expansion of fire-prone areas. The accumulation of fuel material in Mediterranean shrub and forest lands that was previously used for heating and cooking has increased the fire risk and the intensity of wildland fires. Coupled with the total fire control policy of the governments, this has also, in many parts of the region, resulted in a change in the vegetation types and, thus, fire regime. Moreover, afforestations with highly flammable pine and eucalyptus forests on former agricultural and pasture lands have increased fire hazard. Recently recreation activities, the development of urban sites in woodlands (tourism and residential housing), and the misuse of fire-setting as a political device have raised the probability of ignition. It is, however, not clear how the changing land-use pattern will affect the vegetation types and fire regime, overall land management planning, and the contribution of wildland fires to regional atmospheric chemistry.

The contemporary fire regimes of the Mediterranean Basin are entirely human-made. This is why "the protection against forest fires needs to recognize two facts:

(i) Fire is an integral factor of the Mediterranean ecosystems, because of the climatic and demographic conditions of this region.

(ii) The worsening of the situation has a socio-economic origin" (Vélez 1993).

Therefore, it is mostly astonishing that the eco-subsystem "society" is still treated marginally in both fire prevention policy and fire ecology research.

Fire Causes

The majority of forest fires in the region are caused by humans. Human-caused fires account for 95 to 99% of all fires, while natural agents are responsible for the remaining 1 to 5%. Human-caused fires can be examined under three broad categories – voluntary, involuntary, and unknown fires. The shares of each category differs from country to country and from region to region. When examined in detail, it is very obvious that fire causes are closely related with land management activities, standards of living and population dynamics (Bilgili *et al*., 1999). Thus, to better understand the underlying causes of fires, the subject should be examined in relation to these factors.

Land Use and Vegetation

Land use is the general term for human activities on earth surface. It includes agriculture, silviculture, pasture, settlements, networks of communication, recreation areas, and so on. Through using the landscape - extensively or intensively - mankind changes the land´s natural potential and with it also the natural fire regimes. The manner of land use is usually a combination of tradition and history, economic constraints, technical and financial possibilities, natural delimitations, cultural and psychological motivations, the means of land possession, and politics. Three main land use types prevail in the Mediterranean Basin, namely forestry, pastoralism and agriculture.

Of course the changing of natural fire regimes is very obvious in **forestry**. By planting or cutting woods, by collecting fuel biomass, by fighting wildfires, and by setting woodland on fire both purposely and accidentally, the natural equilibrium of the forest ecosystems has been disturbed and has been replaced by entirely human-made ones.

In the Mediterranean Basin **pastoralism** still plays an important role. Through setting fire to natural forest and brush humans gain pastorages, while repetitious grazing selects plant species and prevents maturation of vegetation. Overgrazing has been recognized as one of the most destructive processes to the Mediterranean environment. However, "animal grazing of the understorey vegetation, carried out in a rational way, constitutes a very efficient tool for eliminating fuel accumulation on the ground surface..." (Liacos 1988).

The third area-wide land use in the Mediterranean is **agriculture**. By clearing surface cover in order to receive arable lands, farmers stopped natural burnings and replaced them for occasional prescribed burns. The migration of the rural population from peripheral regions into cities and the abandonment of traditional agriculture have made possible the reinstallation of brush and forest lands - and with them the return of fire risk.

Forestry, livestock-farming, and agriculture - as area-wide activities - influence to a highest degree the actual fire regimes. These activities are dependent on social and economic factors. Determination and analysis of these factors should be a major task for the research community.

In order to approach economic and political factors of land use and fire regimes, the following questions should be answered:

- What are the future tendencies?
- What kind of socially acceptable land-use practices would keep the biomass fuel at acceptable levels of low fire hazard (e.g., prescribed burning, prescribed grazing)?
- What is the social and economical interest in existing vegetation (structure and species)?
- What is the fire adaptation of socially and economically desirable plant species?
- How did history and land use influence vegetation composition?

- What are the ethnic, cultural, and psychological motives behind the human creation of different vegetation formations?
- What could be socio-economically compatible alternatives of less flammable vegetation to the existing one?
- What kind of natural firebreaks are socially acceptable?
- What other interests besides the reduction of fire hazard could society have in vegetation pattern diversity (e.g., biodiversity, recreation activities, hunting)?

Only answering these questions will we be able to determine the human impact on plant composition and to give sound recommendations for a socially adapted but less fire-prone vegetation. The analysis of vegetation is also closely connected with the land use. As a result of investigation in the impact of land use on fire regimes, suggestions for less fire-favouring and more socially acceptable patterns of land use should be made. This could happen through both general and specific terms (e.g., national agriculture policy, land-use maps of a region), by consulting responsible institutions (e.g., the fire risk of different plantations), and by advising politicians (e.g., laws).

Population

Population and land use are correlated systems. Not only the quantity of human beings, but also their distribution and the quality of their action and interaction determine land use. Settlements and communication networks cover more and more of the earth's surface. Metropolitan areas expand while at the same time rural homes are mostly constructed within woodlands. The wildland/residential interface shows an increasing disaster risk. Investigations have shown "a significant conformity" of burnt areas "with the areas where an important, demographic unbalance has penetrated and become accentuated" (Delgado 1990).

The expansion of recreational uses in the forest - mostly in times of high fire risk - leads to an increase of potential ignition sources. This new tendency of residential urbanization and tourism in "natural" woodlands has risen the peril of careless ignition. Additionally, criminals have discovered in arson a means of reaching their aims (vengeance, delinquency, speculation). There is substantial evidence that social and political unrest leads to an increase of arson fires. Examples from Greece, Cyprus, and - recently - Algeria show that domestic political problems are well reflected by forest fires.

In order to effectively prevent wildland fires, the reasons why they exist and spread have to be clarified. Demographic and political analyses, inquiries in behaviour of individuals and societies, inventories of urbanization, and plans of development need to be carried out. This requires a broad cooperation of various social scientists and geographers. Moreover, the results of such a research should be prepared in forms not only suitable for integration into research models but also for teaching and raising public awareness.

Culture and History

"Wholesale anthropogenic modification of the biosphere did not begin with the industrial revolution or with the neolithic revolution but with the hominid revolution announced with promethean splendor by the capture of fire" (Pyne 1994, 1997). Being conscious of the importance of human impact on fire regimes, it is hard to understand why Mediterranean fire ecology research has neglected the cultural and historical aspect of the topic for such a long time. "An understanding of fire history is necessary to ascertain future effects of anthropogenic fire on the environment and atmosphere. ... Such studies should include the cumulative influences of past burning practices and current fire regimes, and they should seek to establish trends that can be projected into future scenarios for societies and the ecosystems they inhabit" (Kauffman *et al.* 1993).

The comparison of different eras and/or different cultures would help illuminate the human impact on fire. Questions should be asked and answered such as following:

- How did fire regimes change within key epochs (Roman Empire, Islamic expansion, end of pre-Columbian period, industrial period)?

What is the cultural impact on wildfires?

How do differing land-use systems affect fire regimes in naturally similar but culturally different landscapes? (e.g., Southern Spain and Northern Africa).

Research that seeks answers to such questions has to deal with a broad spectrum of scientific methods and strategies. Every data set - charcoal, fire scars, ethnographic accounts, forest stand structures, paintings, census statistics, literature, government reports, etc. - has to be taken into account (cf. Clark *et al.* 1997). Sophisticated technologies and traditional concepts as well as the natural and social sciences should be complementary. One of the biggest problems of such an investigation may be the exchange and accession of dispersed data.

Socio-Economics and Policy

"Forest fires are not an autonomous phenomenon, but a symptom of socio-economic problems" (Vélez 1993). Depopulation of rural areas, the relinquishing of traditional agriculture, pasture, and silviculture, recreational activities, urbanization, arson, and so forth are the results of the socio-economic situation that confronts the Mediterranean population, and these considerations must frame any policy of fire management. The governmental support of fossil energy, for example, has displaced traditional fuels which now remain in the forests. The subsidy of intensive mass production gives way to the abandonment of peripheral and multifarious agriculture.

A political decision might influence fire regimes in a way that can scarcely be foreseen when released. Goldammer (1988) lists some legislation and regulations related to forest fires. It is amazing how multiple are the direct impacts of policy on fire regimes. How much more involved must be the indirect impact, usually through the device of economic regulations. There should be analyses pointing out the effect of political decisions on fire regimes. Moreover, the causes of incendiarism have to be clarified and the motives eliminated. Social, political, and psychological analyses are needed and such scientists should work together with the fire ecological research community toward common solutions.

Research Needs: Rationale

In the last decades many efforts have been made in the Mediterranean to collect data regarding ecosystem response to wildfires as well as fire behaviour. Danger-rating systems have been installed; models for simulating fire behaviour and for detecting fire-prone areas (e.g., BEHAVE, CARDIN) have been elaborated. At the same time fire fighting techniques have improved, the amount of well trained personnel has increased, detection and monitoring networks have expanded, and aircraft, helicopters, and modern fire patrol vehicles have been made available. But "in spite of the efforts and expenditures on fire suppression, wildfires in the Mediterranean are becoming more frequent and devastating" (Naveh 1990).

Fire ecology research still concentrates on the natural causes of wild fires (climate and weather conditions, vegetation composition and fuel development, topography), on fire behaviour (simulation), and on fire impact on the ecosystem (monitoring of vegetation succession and soil characteristics, atmospheric deposition), whereas the social impact on the fire regime is treated marginally by researchers. This is an irony given the fact that fire conditions in the Mediterranean Basin are primarily anthropogenic.

In order to be able to predict fire regime tendencies, to detect fire-prone areas, to launch sound fire prevention measures, and to understand fire behaviour, complex models are required. A lot of investigation has been executed within this scope, and many different models are available. Most of them concentrate on those subsystems of the ecosystem that include biological and geographical data. Meteorological values, vegetation and fuel factors, and the georelief deliver the main input parameters for the common models (e.g., BEHAVE). But remembering statements made, for example by Vélez (1994) - "The forest fire problem has an essentially human origin component which has to be dealt by sociological approaches" - one can ask why so few models contain anthropogenic system parameters.

One problem is the incompatibility of the type of data required by mathematical models and the type of data delivered by sociologists, historians, and ethnologists. Another problem is the reluctance for interdisciplinary cooperation within the research community. Researchers nowadays tend to restrict themselves to details within their scientific scope and to consider every possible aspect of each detail. But the more perfect the subsystem models are, the greater the risk that they cannot be integrated into a general/complete system. More-over, the complete model has to reduce its level of quantitative characterization to the level of the least figured one (Leser 1991). One of the least figured systems in fire ecology is the human subsystem. Making other subsystems more perfect will not improve the complete model as long as anthropogenic factors remain neglected.

"A sizeable body of work on fire has concentrated on individual events and on the characteristics of the burning process itself; there is now a recognized need for assessments of the characteristics and effects of fire at hitherto unexplored scales. This calls for a better understanding of burning on regional and global scales, a better appreciation of historical changes that have affected the use of fire during various periods of human history, and, if possible, improved predictable capabilities to chart future trends and possible impacts" (Malingreau *et al.* 1993). "...Research is needed to develop fire models that link spatial scales. These models must be developed with the capacity to account for the evolution of changing cultural, economic, atmospheric, and biological conditions. ...Trade-offs of ecological effects, altered fire regimes, and ecosystem properties between the use of fossil fuels and the traditional role of biomass burning must be described. These include costs and benefits of land-use practices on the atmosphere, biota and humans at local, regional, and global scales " (Kauffman *et al.* 1993).

Politicians and managers ask for research that clarifies the reasons for the increase of wildfires and that is applicable and politically acceptable. They request background analyses and practical suggestions. Research results should lead to recommendations for application: Realistic recommendations for land-use systems have to be made. The way has to be shown by what political devices (e.g., laws, subsidies, education) the stated objective can be achieved. Key questions have to be asked and answered. By understanding the anthropogenic background of fires we will be able to think about solutions to the problem. This will enable managers and politicians to enact an effective prevention policy.

Moreover, international exchange and cooperation of fire research groups seem to be very unsatisfactory. Thus, efforts have to be made to promote international cooperation and exchange of knowledge and to compare different fire regimes created within the same ecosystems but with different land-use systems, and to analyze future tendencies. The concept presented in this paper shall be one step into this direction.

All these problems should not produce a hopeless feeling, but should be an encouragement to tackle the task. Anyway, before thinking of how to integrate anthropogenic data into a coherent and realistic operational system we should think of what parameters are needed in order to understand the human impact on fire regimes. The input data are derived from research results (i.e., model development), and there is still an immense scientific backlog of demand. "The body of knowledge currently available to address the human role in the use of fire has been driven by a variety of land-use, scientific, and cultural objectives. As such, there has been no overall strategy for data collection.... identification and investigation of the critical gaps in our knowledge concerning the human role in shaping fire regimes, ecosystem properties and climate are particularly important" (Kauffman *et al.* 1993).

Fire ecological research will have to include economical, social, cultural, historical, ethnological, and psychological factors of the "Total Human Ecosystem" (Naveh and Lieberman 1994). All the parameters that influence and interfere with fire regimes have to be investigated and analyzed. Efforts have to be made to investigate the impact of society on wildfires, to promote international cooperation and exchange of knowledge, to compare different fire regimes created within the same ecosystems but with different land-use systems, and to analyze future tendencies. High levels of interdisciplinary and international cooperation will be demanded - a challenge to the research community.

The System and the Model

At the Second International Conference on Forest Fire Research, Coimbra University, Portugal 1994, the first pan-Mediterranean fire research program was proposed (Goldammer 1995). Its interdisciplinary nature was expressed by its designation "**F**ire **I**nformation Systems **RE**search in the **S**ocio-**C**ulture, **H**istory, and **E**cology of the **M**editerranean **E**nvironment" (FIRESCHEME). FIRESCHEME was proposed to be a large research endeavor in the concert of a series of other programmes which address the role of vegetation fires in regional, subcontinental, continental, and inter-continental to global scales. FIRESCHEME was proposed as an international multi- and interdisciplinary project, which aims to illuminate the human impact on fire regimes in the Mediterranean Basin, in particular:

- History and prehistory of land use and fire
- Development and treatment of Mediterranean vegetation and potential natural vegetation
- Socio-economical, cultural, historical, and political background of fires
- Present state of vegetation as related to e.g., wildfire hazard, consequences of fire
- Contribution of Mediterranean wildland fires to regional atmospheric chemistry during the fire season
- Management practices.

The FIRESCHEME concept shall not only show the complexity and diversity of natural and anthropogenic fire regimes and fire impacts, but also contribute to the

- Development of a new valuation of Mediterranean fire
- Delivery of data to a Global Cultural and Historical Fire Model
- Contribution to a Global Vegetation Fire Information System (GVFIS) at the Global Fire Monitoring Center (GFMC)
- Delivery of data to regional and global atmosphere and climate models
- Improvement of operational fire management decision support systems.

The research must be supported and integrated by advanced methods and technologies used by the scientific disciplines involved, such as remote sensing and Geographic Information Systems (GIS). "We still need to develop more sophisticated answers to meet the needs in the coming decades. This may require rethinking some of our approaches, redesigning some of our methods, and reconstructing our research. Answers must become more realistic and non-deterministic; approaches more integrative and holistic" (Martin 1990).

FIRESCHEME will be a research activity coordinated with ongoing and planned regional fire research programmes under the umbrella of the International Geosphere-Biosphere Programme (IGBP) Core Project "International Global Atmospheric Chemistry (IGAC) with its Biomass Burning Experiment (BIBEX), IGBP-GCTE (Global Change and Terrestrial Ecosystems), IUFRO, and the International Boreal Forest Research Organization (IBFRA).

Operational Steps: Definition of Objectives, Planning and Implementation

The objectives of FIRESCHEME are not yet defined in detail. The definition will depend on the inputs and implementation capabilities of the research groups interested in becoming involved. The IUFRO Forest Fire Group (8.05) meeting at this World Congress is offering an opportunity to determine the first steps to be taken.

The finance component is still open. FIRESCHEME could potentially be financed following the example of STARE/TRACE-A/SAFARI (Van Wilgen *et al.* 1997, JGR 1996). That research campaign involved more than 150 scientists from numerous institutions of 14 participating nations. Each of the groups brought their own budget into the exercise and shared resources.

The organizational umbrella of the International Geosphere-Biosphere Programme

(IGBP) with its core projects, e.g., IGAC (International Global Atmospheric Chemistry Programme), GCTE (Global Change and Terrestrial Ecosystems), and PAGES (Past Global Changes), is offering structures and access for national funding.

In the case of FIRESCHEME, however, it is proposed to conduct the programme under the auspices of the European Forest Institute (EFI). An independent and non-governmental research body, EFI conducts problem-oriented and multidisciplinary forest research at the European level in order to serve the needs of policy-making and decision-making bodies in Europe. FIRESCHEME would include the North African and Near East regions because of their strong historic, cultural, and environmental links to the European part of the Mediterranean Basin. This should not discourage the fire research community to apply for sponsors through a Europe-oriented research facility. A relevant proposal needs to be drafted and submitted to EFI. A feasibility study would provide appropriate answers to the many open questions which remain after the founding of FIRESCHEME.

Call for Participation

Objectives and final achievements of FIRESCHEME depend highly on inputs and active participation of interested groups. In order to explain Mediterranean fire, FIRESCHEME requires a large variety of datasets, e.g., analyses of sea and lake sediments, alpine ice cores, pollen, charcoal, fire scars; anthropologic, ethnographic, socio-economic, and cultural accounts; historic and modern literature, paintings, and other artwork; reports from explorers; government reports, census statistics; historic and modern composition and distribution of vegetation; historic and contemporary land-use systems; regional climatology and atmospheric chemistry; etc.

With the use of modern technologies for describing the Mediterranean fire environment, such as remote sensing techniques, and advanced methods of processing large amounts of data and integrating information into systems like Geographical Information Systems (GIS), the research community will be able to create a highly interdisciplinary working platform.

Acknowledgements

The preparation of the initial FIRESCHEME concept was supported by Kai Schrader.

Abstract

This paper presents and evaluates the effects of fine fuel moisture content of forest floor fuels on fire occurrence in mediterranean ecosystems of Turkey. Fine fuel moisture contents were measured in an even-aged, fully stocked red pine (Pinus brutia) stand near Izmir. Three fuel samples were taken daily in the early fire season in June and once or twice a week thereafter. Fuel samples were weighed and oven-dried at 100^{o}C for 12 hours or until no change in weight was attained. Moisture contents were determined based on the weight difference between before and after oven-drying. Weather measurements were taken daily at noon local standard time from a nearby weather station located at Menderes Interantional airport. Measurements included temperature, relative humidity, wind speed and direction, and precipitation. Fire occurrence data during the study period were obtained from the Regional Forest Directorate in Izmir. Analyses showed that a close relationship exists between weather conditions and fire occurrence. Indexes generated from this study should be invaluable for fire managers in the region and other places having similar conditions.

Performance of the Monte Alegre Formula on Fire Danger Evaluation in Different Regions of Brazil

by
Ronaldo Viana Soares, Otávio Bezerra Sampaio
Federal University of Paraná
Curitiba, Brazil
Fax: + 55-41-253-2332.
E-mail: rvsoares@cce.ufpr.br

Abstract

The occurrence of forest fires is highly influenced by weather conditions. For that reason, fire danger rating indices based on meteorological variables are important tools to aid in planning and supervising fire control activities in fire protection units. Besides presenting a good performance, an index must be adapted to the local conditions, mainly to the available data for its calculation. That is why sophisticated indices that require data that is not easy to obtain cannot be used in developing countries, where meteorological and other necessary information are seldom available. The "Monte Alegre" formula (MAF) was developed in 1972 using meteorological and fire occurrence data of the central part of the State of Paraná , and has since been used by most forest institutions and companies in Brazil and other South American countries to predict fire danger. It uses only three variables: relative humidity (directly), number of days without rain and amount of precipitation (both indirectly), and can be easily calculated every day through the following equation:

MAF = 100 SUM FROM { n=1 } TO { n } 1 OVER H

where n is the number of days without rain and H is the relative humidity measured at 1:00 PM.

The performance of the MAF was evaluated in three deferent forest districts in the southeastern and southern regions of Brazil. Firstly, using a data set from the region where the index was developed (Cfa climate, according to Koppen's classification), its performance was checked. Results showed that 52.5% of the fires registered in that period occurred when the index indicated a very high danger; 31.7% when the danger was high; 13.8% when the danger was medium; 2.0% when the danger was low; and no fire was recorded when the index indicated no danger. Secondly, using data from a forest district in the southern State of Santa Catarina (Cfb climate), the MAF was compared to the locally used index, developed by the South Carolina State Department of Forestry, USA, (SCI) in the 1960s. By the MAF, 13.0% and 87.0% of the recorded fires occurred when the index indicated high and very high danger, respectively. When the SCI was used, 43.5% of the fires occurred when the danger was low, 26.1% when the danger was medium, and 30.4% when the danger was high; and no fire was recorded when the index was very high. Thirdly, using data from a forest district in the central region of the southeastern State of S o Paulo (Cwa climate) the performance of the MAF was compared to three other indices: Nesterov, Tellysin, and the Canadian Fire Weather Index (FWI). Three methodologies were used to test the efficiency of the indices: Mahalanobis distance, Friedman's test, and distribution of the occurrences through the danger scale of the indices. According to the Mahalanobis distance and Friedman's test, the FWI was more efficient but when the distribution of the occurrences through the danger scales was used, the MAF was more efficient in estimating the fire danger of the region.

Wildfire Occurrence in a Forest District and Other Brazilian Protected Areas

by
Ronaldo Viana Soares, Otávio Bezerra Sampaio
Federal University of Paraná
Curitiba, Brazil
Fax: + 55-41-253-2332.
E-mail: rvsoares@cce.ufpr.br

Abstract

Wildfire is a permanent threat to native and planted forests in most part of the Brazilian territory. Periodical dry seasons and abnormal weather conditions have induced to large and destructive fires from time to time. In 1998, for instance, an extremely large fire burned about 13,000 km2 of tropical forest and savanna vegetation in the State of Roraima, located in the Amazonian region. Despite the preoccupation with the tropical forests, data on fire occurrence in that ecosystem are not sufficient to make a good description of fire occurrence in Brazil. This paper presents the history of fire occurrence in the Agudos region, State of Sao Paulo, southeastern Brazil, from 1984 to 1995 and other protected areas throughout the country. The center of the forest district area is located approximately at 22 28'S, 48 59'W and 526m above sea level. The fire season in the region goes from June to November. There was statistical difference among the months of the year for both, number of fires and burned area. August, with 21.60%, presented the higher number of occurrences, and 76.36% of the fires occurred from June to November. September presented the largest burned area (28.49%), and 80.41% of the total area affected by wildfires burned from August to November. There was no statistical difference in the number of fires or burned areas among the days of the months and the weekdays, although Sunday, with 17.36% of the occurrences and Monday, with 24.86% of the total burned areas had presented the highest numerical values. However, significant difference was observed both, in the number of fires and burned areas, among the hour of the day. About 85.17% of the fires and 91.97% of the burned areas were recorded between 10:00 AM and 06:00 PM. The hour that presented the highest occurrence was 02:00 PM, with 17.20% of the recorded fires. Precipitation was the weather variable that presented the best correlation with fire occurrence. About 42.1% of the annual precipitation and 82.41% of the recorded fires occurred between April and October. August was the month with lower precipitation and higher number of fires. Data collected from protected areas in the Brazilian territory in 1994 and 1995 presents similar results showing that the history of forest fire occurrence is similar all over the country. September, with almost 30% of the recorded fires, was the leading month in fire occurrence, and 84.61% of the fires and 97.85% of the burned area were observed between July and October. Arson (41.40% of the fires and 11.81% of the burned area), Debris burning (32.26% of the fires and 79.55% of the burned areas), and Smoking (10.21% of the fires and 1.13% of the burned area) were the leading causes of forest fires.

An Analysis of Forest Fire Behavior Based on Estimation of Wind Direction and Wind Velocity at the Time of the Fire

by
Shoji Inoue
Ehime University, Tarumi 3-5-7, Matsuyama, 790-8566 Japan
Tel: +81-89-946-9875, Fax: +81-89-946-9875,

Website http://web.agr.ehime-u.ac.jp/

Abstract

Wind direction and wind velocity data are necessary to analyze the behavior of forest fire and its propagation. It is possible to obtain prevailing wind data from weather stations but not the characteristics of fire whirlwind at the site of the forest fire unless we measure it at the time of the fire.

This paper presents a procedure of estimation of wind direction and wind velocity from the stem-bark char remained at the forest fire damaged area. In this investigation, in order to clarify the relation among the factors affecting fire-scar of stem, wind tunnel experiments were carried out. And in order to establish how to predict the forest fire behavior, field experiments were carried out using opportunities of prescribed fire.

In the wind tunnel experiments, it was observed that the height of stem-bark char registered at the windward face of a stem is smaller than that of the opposite face of a stem under all the experimental conditions. Therefore, an estimate of wind direction from the remaining stems in a burned field can easily be done.

Further it was found that, the height of stem-bark char of windward face of a stem decreased as the wind velocity increased. The height of stem-bark char of a stem opposite the windward direction increased as the diameter of the stem increased. It was derived from these results that the magnitude of the difference in height of stem-bark char of windward face and opposite face of a stem was an important factor for estimation of wind velocity. From a viewpoint of field application, stem-bark char ratio of both faces of a stem tends to be significant as well as the difference in height of stem-bark char of both faces, because of the dissimilarity of scale in wind tunnel experiment and actual phenomena in the field. Dimensional analysis was carried out for the factors affecting the stem-bark char using the observations mentioned above. Based on the results of the study, the equations for estimation of wind velocity were proposed when the stem partially burned.

In the field experiments, first, the wind velocity calculated by experimental equations was compared with wind velocity observed in two prescribed fire sites. It was observed that the wind velocity could be expressed with a high accuracy by the above-proposed equations.

When the fire behavior was an upslope fire, the fire whirlwind directions estimated from the stem-bark char showed a fixed direction. Fire whirlwind direction agreed approximately with slope azimuth, in spite of a prevailing opposite wind direction. Further relationship between fire whirlwind velocity estimated by experimental equations and maximum slope gradient was investigated. However, it was not possible to recognize a relationship between them using individual data of slope angles and wind velocities estimated, which could be due to the differences in on-site condition of experimental logs. But, dividing the slope into ranges and taking mean values for gradient instead of individual values, it was observed that fire wind velocity increased as maximum slope gradient increased.

Forest Plantation Fire: the SAFODA Experience (Sabah Forestry Development Authority)

by
H.H. Liwangsa, N. Hajimasrie, Z. Saridi
Sabah Forestry Development Authority
Locked Bag 122, Kota Kinabalu, Malaysia 88999
Tel: + 88-751267, 752384.
E-mail: safoda@po.jaring.my

Abstract

The Sabah Forestry Development Authority (SAFODA) was enacted in December 1976, its objectives are to convert wasteland and marginal agricultural land to a highly productive forest plantation and to uplift the living standard of inhabitant through employment in reforestation and afforestation work related to forest plantation establishment. SAFODA has allotted 118,756 ha. of land throughout the state of Sabah for that purpose. By the end of July 1998, SAFODA has planted about 31,417 ha. of trees mainly *Acacia mangium* and 8,356 ha. of rattan. Other than pest and disease problems, fire is still the most dangerous phenomena due to its extensive negative impact toward certain ecosystems and has long been the major treat in forest plantation project. In 1983, it is recorded that about 5,565 ha. of the SAFODA forest plantation throughout the state of Sabah had been burnt and the latest occurrence was during El Nino 1998 period, which 3,818 ha. of plantation were totally burnt. The objectives of this paper are to highlight and share the experience of forest fire occurred in the Bengkoka Forest Plantation Project in Sabah, its also discuss the problems encountered, annual budget, fire fighting technique, material and equipment used as well as the future direction of research needs. Since 1983-1998 there were 124 fire cases in Bengkoka Forest Plantation Project caused by mainly farm burning, smokers, campfires and incendiary. Most of the fire occurred in March to October each year. It is also noted that one to five years old forest plantation is very severe to fire. Therefore, an effective forest fire management system is really needed to lessen these problems.

Natural Regeneration of Tectona Grandis and Gmelina Arborea After Fire in Ikrogon Forest Reserve, Cross River State, Nigeria

by
Daniel Otu
Nigeria
E-mail: drill@infoweb.abs.net

Abstract

Ikrigon Forest Reserve is a dry lowland rainforest, surrounded by a Derived Savannah and located between latitude 6.17 degrees north and longitude 8.36 degrees east. The total forest reserve area is about 600 hectares. The soil is loam to loamy sand with rock composition of mainly granite, quartzo-feldspathic biotite and hornblends-bearing gneisses, schists and magmites (Wright et al 1985).

Since the forest reserve is within a derived savannah, there is yearly fire occurrence which affects the natural and artificial forest in the area. At the plantation forest edge, bordering the savannah where principally *Gemlina arborea* (Gmelina) and *Tectona grandis* (Teak) are the planted reserve boundary species, there is annual seed dropping on the forest floor and the adjoining savannah area. This annual seed dropping has led to the natural establishment of seedlings of these plantation species on the frontiers of the adjoining savannah woodland. Over the years, the seedlings have grown under the strong competition induced by annual fire, spatial distribution of seedlings, nutrients, soil, water and sunlight.

The result of this situation is natural selection in which some seedlings have grown to poles and trees while others remain stunted as perpetual understory species due to lack of adequate sunlight and persistent annual fire. The litter drop of *T. grandis* is heavier than that of *G. arborea* and the leaves of the former wider in area than the latter. The leaves of *G. arborea* decay faster than those of *T. grandis*. The result is that there are more *G. arborea* seedlings on the forest floor than those of T. grandis. The perpetual persistent litter of Teak does not support profuse seedling production in Teak.

Data collected in mini-quadrats of 10 m by 10 m show an average spread of about 8,900 seedlings per hectare in Teak and 8,547 in Gmelina. There are also 494 trees established in one hectare of Teak and 567 in Gmelina. This means that the trees naturally establish themselves at an average espacement of 4.5 m by 4.5 m for Teak and 4.2 m by 4.2 m for Gmelina. It is also deduced that in Teak area, over 8,406 seedlings lose the competition battle due to annual fire, heavy leaf litter, root competition, and canopy closure of dominant trees. The maturity survival percentage of the species under natural and untended conditions is 5.6%. Similarly, in the Gmelina area 7,980 seedlings lose the attainment of mechartable size due to fire, competition for nutrients, sunlight, and weeds. The maturity survival percentage of Gmelina in the area is 6.6%. The heavy litter and canopy in the Teak area neither permits weed growth nor speedy development of seedlings. In the Gmelina area however, canopy is almost open thereby allowing for more Gmelina seedlings and weed growth. This is proved by the tree survival in the two plots assessed. The Teak plot does not therefore allow for encroachment of many indigenous species while the Gmelina plot does - especially weeds (Cromolena odorata).

Recruitment and survival is therefore based on the annual severity and time of occurrence of fires, competition for nutrients, sunlight, weeds, and canopy effects. Natural espacements for Teak and Gmelina seedlings on the forest floor are 1.06 m by 1.06 m and 1.2 m by 1.2 m, respectively. Also natural espacement for mature teak and Gmelina are 4.5 m by 4.5 m and 4.2 m by 4.2 m, respectively. The espacements exhibited by these tree species can scientifically influence espacement decision in plantation silviculture.

Impact of Fire on Forest Insect Species Diversity: A Study in the Silent Valley National Park, India

by
George Mathew, P. Rugmini, C.F. Binoy
Division of Entomology,
Kerala Forest Research Institute
Kerala, Peechi-680 653 India
Fax: + 0487-782249.
E-mail: libkfri@md2.vsnl.net.in

Abstract

The Western Ghats of India, which is the most imposing, but extremely threatened topographical, floristic and faunistic feature of the Indian subcontinent is one of the 18 biodiversity 'hotspots' of the world. Spread over an area of 175,000 sq.km. in six States, this mountain range extends more or less parallel to the west coast of Indian Peninsula from Kerala to Gujarat traversing a length of 1600 km. The Silent Valley National Park is situated in the Palghat District of Kerala State, between latitudes 1103' and 11015'N and longitudes 76023' and76030'E. As per the world classification of Udvardy, the area falls under the Malabar Rainforest Realm.

The total area of this forest is 90 sq.km. and accessibility to this area is restricted due to the steep slopes on all sides. The region is characterised by heavy summer rains and the mean annual rainfall is 4400 mm. The major forest disturbance is fire which frequently occurs during the summer season in the grasslands and spreads to the adjacent natural forests. As a result, several patches of natural forests get degraded leading to disappearance of many evergreen species. The 'gaps' thus formed in the forest due to burning are subsequently colonised by various secondary species that are found in the adjacent moist deciduous forests and grasslands.

The impact of fire on insect species diversity was studied in representative plots. Altogether. eight plots were taken along a transect in such a way that four plots were in the fire affected zone and the remaining in the unaffected forest patch. Plot size was fixed as 625 m2 and the distance between plots was 25 m. Data on vegetation and insects were collected from all the plots and from this, the species composition as well as the indices of diversity, dominance, evenness, species richness etc., were computed separately for plots in the fire affected and unaffected zones.

There were 3951 plants belonging to 130 species in the study area, of which 1608 plants belonging to 81 species were found in the undisturbed area and 2343 plants belonging to 109 species in the disturbed area. The diversity index for the undisturbed area was 3.66 and the value for the disturbed area was 3.55.

The floral composition in the disturbed and undisturbed areas was also interesting. While the undisturbed areas had good representation of primary species like Palquium ellipticum, Aglaia sp., Myristica dactyloides, Mesua ferrea, Cullenia exarillata, Holigarna arnottiana, Casearia bourdiloni and Persea macrantha, the disturbed areas had only poor represention of these species. More over, there was an invasion of various secondary species like Olea dioica, Scolopia crenata, Macaranga peltata, Zizyphus rugosa, Walsura trifolia, Celtis sp., Albizia chinensis and weeds like Clerodendron viscosum, Mikania micrantha and Lantana sp.

Altogether. 10451 insects belonging to 578 species under 13 Orders and 67 families were collected from the study area. Of these, 5781 insects belonging to 449 species were from the undisturbed area and 4670 species belonging to 417 species from the disturbed area. Thirteen Orders and 61 families were represented in the undisturbed area and 12 Orders and 60 familiesin the disturbed area. The species diversity index was 4.76 in the former and 4.65 in the latter.

Consequent to the changes in plant composition following forest disturbance, there was a higher representation of arboreal feeding insect families (Geometridae, Saturnidae, Cossidae etc.) in the undisturbed area where as herbaceous feeding families like Pyralidae, Noctuidae, Chrysomelidae etc., were very abundantly found in the disturbed area. The Orders Diptera, Lepidoptera, Coleoptera and Hymenoptera were the most dominant groups in both the areas.

The implications of forest fire on insect species diversity in the tropical forests are evident from the reduction in species diversity. As a result, several rare and endemic species are seriously affected and many are likely to be phased out unless urgent corrective measures are undertaken. A critical examination of species collected from the study area has shown a steady loss of arboreal feeding forms and abundance of weed feeding forms. Conservation strategies based on the findings of this study will be discussed.

Growth and Development of A Maritime Pine Stand After Fire

by
Angelo M. Carvalho Oliveira, Jaime S. Luis
Departamento de Engenharia Florestal, Instituto Superior de Agronomia
Fax: +351.1.364500.
E-mail: angoliveira@isa.utl.pt

Abstract

Three permanent plots, each with 1000 m2 were laid out in 1989 in a State managed pine forest in the northwest of Portugal. The plots, installed in 1989, are located on a natural regenerated pure even-aged stand of Maritime Pine (Pinus pinaster Ait.), after a forest fire in 1975. To decide about the most appropriate degree of thinning for this kind of stands two degrees of intermediate thinning were performed in 1992. In August 1993 a forest fire attained the three plots but it was decided to keep it to evaluate the impact of the fire on tree vigour, tree mortality, tree growth and yield and the occurrence of natural regeneration of maritime pine and other forest tree species.

At the first measurement, in 1989, each plot contained six tree rows, approximately four meters apart. Diameter measurements, at 1,3 meters above ground level, were collected for all trees within each plot, by taking the average of two caliper measurements. Tree height measurements were performed for sample trees only, ca. 40 in each plot, using an extending measuring pole. At the second measurement in 1992 tree height and breast height diameter were measured in the same manner. The height of the beginning of the crown was measured for all sample trees using a pole. The crown was considered to begin at the point on the tree stem where the first two green branches were detected. Furthermore, for all trees within the central four rows of each plot, four crown radii measurements, considering the greatest extension of tree crown, were made at approximately 90 degrees to each other. The overall plot dimensions and the spatial arrangement of the trees within each plot were measured using a extending tape. The corrected distance measurements, for the slope, together with crown radii measurements were utilised to construct crown maps of each plot.

In 1994, 1996 and 1998 tree height, breast height diameter and the height of the beginning of the crown were measured in the same manner, all the trees were examined in relation with the occurrence of pests or diseases and classified according their vigour. In 1998 new crown maps were realised and the natural regeneration was identified and counted in ten square plots randomly located , each with 1m2, in each plot.

The effect of fire on all the above-described parameters and their evolution in the last five years are reported in the paper/poster.

Abstract

It is difficult to assess and get general view of large scale forest fire with ground survey alone. Satellite remote sensing technique, which enable monitoring over a large area multi-temporally, were employed to map the extent and degree of the large scale forest fire occurred in East Kalimantan Province, Indonesia, between mid 1997 and early 1998. According to the report of Indonesian Government, this fire damaged more than 520,000ha of forest in this Province. Southern part of Samarinda, the capital city of East Kalimantan Province, was selected as a study site. The study site covers 24,1000ha, including Bukit Soeharto Education Forest (BSEF) and Sungai Wain Protection Forest (SWPF). Although BSEF and SWPF are both protection forests, they have different degree of protection level and different types of vegetation management.

Two change detection analysis methods, Normalized Difference Vegetation Index (NDVI) analysis method and Change Vector Analysis (CVA) method, were introduced to map vegetation cover changes caused by the forest fire, using 5 scenes of Landsat TM data (acquired on 1997/4/13, 1997/8/3, 1998/1/26, 1998/2/11, and 1998/3/31) and 3 scenes of JERS-1 OPS VNIR data (acquired on 1996/9/27, 1997/8/1, and 1998/6/5). Maps of detected change derived from NDVI analysis represented suitable results compared to CVA when using limited ground information, and were adopted as the maps of vegetation cover change in this study. From this satellite remote sensing data analyses, 26.8% of land area in the study area showed vegetation decrease from February to March 1998, which probably caused by the forest fire, and 11.8% showed vegetation increase from March to June 1998 by regeneration of vegetation after the forest fire.

A GIS database of this study area was newly constructed to find out the relationship between human activities and forest loss due to the fire. The database comprises spatial data such as 1) slope model, 2) basin/ridge model, 3) buffer zones representing human activity area, 4) boundary of the BSEF and SWPF, and 5) land cover map of the study area before the forest fire obtained from RS data classification. By overlaying vegetation cover change layers with other GIS layers, it was possible to assess the scale and degree of the forest fire in relation to human impact and vegetation management condition.

From February to March 1998, 54.8% of forest area in BSEF, where protection of vegetation by university had been not carried out sufficiently, showed vegetation decrease caused by the forest fire. While in SWPF, where sufficient vegetation protection by Indonesian Government had been carried out, 31.5% of forest area showed vegetation decrease in the same period. Furthermore, SWPF showed 6.1 times large vegetation regeneration area compared with BSEF after forest fire, from March to June 1998. By using 1 kilometer buffer zone of human activity area, where human impact to vegetation environment thought to be large, 65.1% in BSEF and 50.2% in SWPF showed vegetation decrease from February to March 1998. They suggest that the vegetation change of the study site caused by forest fire have strong relation to the conditions of vegetation management.

Sustainable Management of Natural Resources: Fire and Forests

by
I.D. Pande, S. Pande
Kumaon University
Glenthorn, Mallital, Nainital, India 263002
Fax: + 91-594236218

Abstract

Forests are not merely an economic resource but constitute an essential life support system, especially for the people living in mountainous or rural areas, Recurring forests fires cause considerable damage and degradation to forests and environment every year and more so in a cycle of four to five years. Ministry of Environment and Forest, Govt. of India, appointed a committee to assess the damage from forest fires in Uttar Pradesh (U.P.) and Himanchal Pradesh (H.P.) in 1995. This committee assessed direct economic losses to the tune off 139.3 million rupees, in U.P. alone during the Fire season of 1995. It also recommended that studies to make a scientific and comprehensive assessment of damage resulting from forest fires should immediately be undertaken by the Indian Council of Forestry Research & Education (ICFRE) and then the result of those studies applied in all states in evaluating the loss from the fire damage. These recommendations clearly reveal that research on Forest fires has seriously been neglected.

It is paradoxical that fire protection was one of the first tools of scientific forest management in India, yet research in forest fires has been a neglected field in this country. Although research on two other injurious agencies off forest viz. Diseases and Insect pests started long time ago, limited studies have been made on forest fires so far.

To estimate the true extent of fires losses, quantitative value has to be assigned to various impacts of forest fires. Forest fires are known to bring down considerably the various values e.g. productive, wildlife, aesthetic-recreational grazing, socio-economic & others. It is also essential to have a reliable data base to generate the desired type of information. Expenditure on fire control can be justified only up to an amount representing the savings or loss reduction which results from that expenditure. The more valuable the forest, the greater is the amount that it is worth spending to control fires. Research has to encompass all aspects of forest fire from pre suppression, prevention, detection, control, reporting, quantification and monitoring of losses. In the Himalayan region specific research is required towards cost effective & environment friendly hazard reduction methods e.g. some economically viable use for chir pine needles or some process to hasten its rate off decomposition. A modest beginning towards forest fire research has been made during the past two decades by adopting fire danger rating system for different type of forests, evaluating direct fire losses, designing statistical format for fire reporting for subsequent use in fire damage analysis. In view of the importance of the forests in Himalayan ecosystem forest fire problems of this area need prioritisation in the Forestry research agenda.

Abstract

It is proved that climate changes occur with extreme declination of seasonal weather variations and may cause large scale fire emergency situations (Stocks, 1993; Wein, Groot, 1996; Fosberg, Stocks, Linham, 1996). In the last years climate changes are vividly seen in the South of Siberia and the Far East and they are the cause of intensified spring and summer droughts. Due to these droughts such emergency situations often occur when forest and steppe fires become dangerous for inhabited localities and even inflict casualties. This work analyses the peculiarities of dangerous wildland fire development, the forecasting and possibilities of prevention emergency situations on the basis of vegetation fuel maps. Emergency situations take place when a strong fire threatens an inhabited locality or some valuable object.

The dangerous fire intensity depends on the mass of vegetation fuel burning down in flame regime in time unit per long meter (but not per square meter!) of fire edge. This mass depends on two factors: a) the stock of such vegetation fuel per unit of area and b) the speed of fire edge spread. If the speed of spread is large, the intensity of fire can be very high even under small stock of vegetation fuel. The presence of considerable stock of vegetation fuel burning down in the regime of smoldering (litter, peat, duff) decreases the intensity of flame burning. Fires become of high intensity and, therefore, of danger if they reach the so called phase of self development Firstly, it happens at the expense of their speed increase under potted spread with throwing about burning particles in front of the fire front. It is especially characteristic of explosive fires.

Ignitions in inhabited localities and industrial objects occur because of burning particles which are thrown about in front of a strong forest or steppe fire front. This usually happens in dry windy weather, therefore, ignition of separate dwelling houses and industrial buildings can spread over other buildings and objects. Burning particles can spread up to 500 meters distance and more. Due to this, strong vegetation fires can get over the rivers, unburned bogs and other obstacles.

The main way of protection objects against an approaching strong fire is preliminary backfiring. The history of very large forest fires (for example, fires in the Northern China in 1987) shows that such fires are able to spread freely over the area for a long time destroying inhabited localities and crossing the rives and roads which could be the best initial line for preliminary backfiring.

The list of problems on prevention of loss under the emergency situations, connected with wildland fires close to inhabited localities and others valuable objects, includes the following tasks: 1) showing up of inhabited localities which can be damaged under wildland fire (forest, steppe and so on); 2) elaboration of prophylactic measures on protection of such objects from wildland fires; 3) prognosis of possibility of wildland fire dangerous development, active near the inhabited locality or near the industrial object; 4) prompt, safe and reliable stoppage of dangerous fires with the least expense of strength and means.

The solution of enumerated tasks is possible on the basis of vegetation fuel maps usage and method on vegetation fires behavior prediction. Technology of vegetation fuel maps creation on the basis of forest inventory data and air-space information and method of fire behavior prediction are elaborated (Volokitina, Klimushin, Sofronov, 1995).

Seedling Survival, Mortality and Regeneration After Fire in A Tropical High Forest in Ghana

by
K. Owusu-Afriyie, Joshua Ayarkwa
Forestry Research Institute of Ghana
UPO Box 63, Kumasi, Ghana
Tel: +233-51-60123. Fax: +233-51-60121.
E-mail: forig@africaonline.com.gh

Abstract

Tropical high forests were previously thought to be immune to fire. However, studies and empirical evidence have suggested that fire might have played an important role in their evolution. Following the extensive bush fires throughout the tropics in 1982-3, fire has become a major issue impacting on the management of dry semi deciduous forest types of the tropical high forest of Ghana. Several hectares of intact forest have been degraded due to the combined effects of recurrent fires and logging.

Studies including prescribed burning have been conducted elsewhere with the aim of reducing the detrimental effects of fire on the forest, whilst promoting regrowth of woody vegetation. However, most of these studies have focused more on the savanna woodlands and transition zones and least on the tropical high forest itself. At present, data is not available for a systematic study of the influence of fire on seedling survival, regeneration and tree mortality following fire in the tropical high forest.

This study attempts to quantify the effects of early and late burning on the survival and mortality of seedlings and trees and regeneration after fire in a tropical high forest in Ghana. It has been observed that tree seedling survival and mortality and regeneration thereafter are greatly influenced by the time of burning,. Early or late burning is rather subjective and is determined by the prevailing weather conditions at the time of burning.

The implications for forest management in the dry zone of the tropical high forests are discussed.

About the Necessity of a New Approach to Estimating Forest Potential Pyrological Forests

by
A.P. Sapozhnikov

Abstract

Principles of forest protection from fires, the evaluation of their consequences and their elimination, as has been shown by the catastrophic fires 1998 in Khabarovsk Territory, Russia, are no longer the matter of any separate country or any of its regions alone. Catastrophic forest fires periodically appear in this or that region and not only in Russia. No atrocious forest exploitation can be compared with the pyrogenic consequences, because only due to fires in a very short period are possible irreversible disturbances and destructions of formed many centuries ecological connections and trophic chains on the vast territories. Besides, as a result of fires, the indirect consequences are possible which it is impossible to take into account immediately. For example, soils destruction on mountain slopes in the result of burned stand decomposition which could happen after 10 or more years after the fire. Experience shows that no country having large forest volumes located in insufficiently accessible areas (due to weakly developed road networks) is not indemnified from the development of fires up to catastrophic sizes with all ensuing global ecological consequences. The world community is not so much worried by the loss of raw potential of the forest lands as by those ecological consequences which follow mass deforestation of the territories. Among the most meaningful ecological consequences are soil erosion, low river water, the loss for a long period carbon sequestration functions and, as a consequence, contravention of climatic situation on the planet. Evidently, it is necessary to improve all facilities of forest protection from fires - from their forecast and inventory to elimination of their consequences.
One of the important aspects is the determination of fire cause needed both for current and retrospective analysis of succession dynamics. If earlier it had a specifically administrative meaning, then today the role of cause in determination of priorities in pyrologic territory organization, prophylactic work with the population, improvement of legislative and regulatory bases becomes more actual.It is evident, that both physically and economically there are no possibilities to fight all forest fires. In other words, it must be discriminatory relating territory and relating the value of forests. Such experience has been accumulated, particularly, by Canada. For Russia conditions, with its mammoth and hardly accessible territories, it is necessary to zone areas on a new basis - first of all according to forests ecological value, not only formally stated in the regulatory documents, but also actual, for example, according to carbon sequestration ability. The last could be estimated on green mass production and not only by the stand, but forest coenosis on the whole. According to these signs, the territory must be differentiated by zones according to prioritization of fire control active methods use under mass ignitions, similar to fires 1998, and according to the necessary expenditures for prophylactic measures. To prevent fires and decrease their destructive impact, especially in the forests of high ecological and social value, it is necessary to introduce a system of prescribed burnings with the elaborations of corresponding technologies and regimes relating to the concrete forest formations or even to economic groups of the forest types. Similar experience also has been accumulated by a number of countries.One of the most important moments of a pyrological situation estimation is forest fires registration system improvement. It must be not only forehanded and independent from any interests but accessible both for professional use and for informing of population. This will permit to exclude disinformation, and also will be a good foundation for arranging global monitoring of forest fires dynamics and their consequences. Realisation of this thesis is possible with the use of satellites. Besides all, it will permit to advance sufficiently the formed system of land and airplane protection of forests.

Influence of Bush Fires on the Dynamics of Dry Forest: Case of Degraded Forests in North-Benin

by
André Mahoutin Tandjiékpon
Unité de Recherches Forestières
INRAB
06 BP 707 Cotonou, Bénin
Tel: (229) 330662 Fax: (229) 330421
E-mail: (organization): inrabdg4@bow.intnet.bj

Abstract

The North-Benin is in the dry part of the country where dry season covers 6 to 7 months of the year with a rainy season of 5 to 6 months. The average temperature is about 27°C with the rainfall oscillating between 900 and 1200 mm annually. The vegetation is savannah type with low density of large trees. The main activities are agriculture, breeding and hunting. In this part of the country, bush fires are widely used by farmers, breeders and hunters for their activities. So, every year, many hectares of forests are burnt with consequence of gradual degradation of forestland. This attitude of populations has a sociological foundation, which is not easy to overcome. In order to appreciate the real impact of fires on natural regeneration of forest, an experiment was initiated in 1990 with objective to determinate the appropriate periods for fires use as a tool for forest management. For this purpose, five treatments have been applied on six different sites as following: a) use of "Early fires" (EF) on 11 November and 11 December; b) use of "Late fires" (LF) on 11 January and 11 February; c) no fire use (NF) as control. After some years of observation, the tests have been evaluated in 1996 and 1997 in order to appreciate the evolution of plots. The results appear that the LF is very damaging for young regeneration with about 95% seedling burnt causing in fact progressive genetic erosion and the destabilization of soil. On the other hand, the EF of 11 November stimulated more the natural regeneration with appearance of new species in the experimental plots. With this treatment, it has been observed a natural pruning of trees with best development of trunk. Concerning the protected plots, grass has grown with high concurrence to young regeneration and natural sowing and seedling. On these plots, it also appeared that the renewal of grass is low comparing to EF, the trees have developed large crown with big branches and the high accumulation of dead vegetation. The conclusion is that, fire is a real tool for forest management in dry regions when its use is well analyzed. For now, fire appears as the best tool to fight against the risks of uncontrolled bush fires in dry regions in regard to the context of socio-economic conditions of the populations concerned. The EF applied just at the beginning of dry season has a positive influence on natural regeneration and the reconstitution of dry forests for wood and fodder production as well for biodiversity conservation.

Abstract

Forests are managed not only for the production of wood, but also as a safeguard for environment. One of the main factors effecting forest degradation is forest fires and uncontrolled burning. Asean countries especially Malaysia and Indonesia were most affected by forest fires during July-November, 1997. The worst haze occurred in Sarawak, Malaysia when the Air Pollution Index (API) reached 800, exceeded the 500 danger level. Consequently the state was declared emergency by the government. This paper will highlight the capabilities of satellite image (NOAA-AVHRR and SPOT image) in monitoring forest fires. Observation and studies showed that the haze was caused by fires and burning. This paper also assessed the burned forest areas and the relationship between the number of hot spots and the severity of haze occurrence i.e. affected areas. The causes of forest fires were highlighted and management plan of forest fire control was proposed.

Effect of Fire on Soil Properties in Pine and Natural Forest in Sri Lanka

by
Ranjith B. Mapa
Department of Soil Science
Faculty of Agriculture, University of Peradeniya
Sri Lanka 94-8-388041
E-mail: 388041, mapa@agri.pdn.ac.lk

Abstract

Forest fires have become regular events in Sri Lanka due to intentional burning by livestock owners and hunters and practice of slash and burn agriculture (shifting cultivation). The foresters as a tool to eliminate undesirable weeds or dominant species in forests also use burning. In Sri Lanka other than the natural forest, part of the hill country is reforested using exotic species as Pinus and Eucalyptus. Much information is available on the regeneration of forests and regarding the change of the composition of vegetation after forest fires, its effect on soil properties have not been studied in detail. By studying the effect of forest fires on soil properties will help in understanding forest regeneration patterns and help in efficient management of natural and plantation forests. Therefore the objective of this study was to study the effects of fires on soil physical and chemical properties in a natural and pinus forest in Sri Lanka. These were studied at three stages, namely before the occurrence of fire, one day after fire, one and three months after fire.

This study was conducted in adjoining pinus and natural forest in the mid country of Sri Lanka. The soil profiles of the two sites were described using the FAO guidelines and the major soil horizons were identified. Soil properties as soil texture, acidity, total nitrogen, available phosphorus, organic matter and aggregate stability were measured. The area were burnt as usually done at the end of the dry season before the rains and similar measurements were conducted for soil samples obtained one day and three months burning.

More emphasis in this study was given to the determining of dry and wet soil aggregate stability, as soil erosion is one of the major problems in these sloppy lands. The dry aggregate stability was determined using dry sieving with a nest of sieves. The mean weight diameter and log standard deviation was obtained as aggregate indexes reflecting resistant to erosion by wind. Wet aggregate stability was determined by wet sieving using a single sieve technique. The percentage of the initial sample remaining after 18 minutes of sieving was used as the index showing the resistance to erosion by water. The results showed that the soil pH increased just after burning and again decreased to the original value after about three months. The increase was higher in the pinus plantation than in the natural forest. The increase was from 4.6 to 5.1 and is mainly due the basic nature of ash remaining after burning. Afterwards these bases are easily leached due to rainfall and the soil becomes strongly acidic as before. The soil organic matter content nitrogen decreased with burning which the most damaging effect related to the loss of biomass to the atmosphere. The available phosphorus increased significantly in the surface layers of natural forest due to burning. The available P increase from 40 to 62ppm in just after burning and decreased to 50 ppm after three months. The change in available P in pinus plantation was not significant.

The dry aggregate stability and wet aggregate stability decreased in the pinus forest with burning. In the natural forest the decrease in soil aggregate stability were not significant. These aggregates developed to the original size after three months of burning. This shows the vulnerability to soil erosion by wind and water in the pinus plantations during the first three months of burning.This study shows how the soil property change after burning in natural and pinus forests in the mind country of Sri Lanka. In both forest types the chemical properties changed significantly after burning. In natural forest the properties attain the pre-burning values in three months after burning while in pinus forest it took longer times. In the pinus forest the susceptibility to soil erosion increased during the first three months after burning when compared with the natural forest.

Abstract

The area of the forest stock in Russia, including forests transferred to the permanent use, according to the calculation made in January 1,1993 is 1180,9 million hectares. Burned-out forests, cuttings, swamps and hayfields are also included into this territory. Forests proper take the area of 705,8 million hectares; 507,7 million hectares are covered by coniferous species: larch (52%), pine (22,5%), spruce and fir (17,8%), and cedar(7,7%). Acerous leaves(needles) and timber of these species contain essential oils and colophony, that is why they are too flammable(susceptible to fire). Russian forests have a multiple-aged structure: undergrowth-22%, middle-aged-33%, maturing-11%, mature and overmature-34%. Formation of such forest structure was influenced by industrial cuttings; but the main factor of taiga forests formation is forest fires. According to the official statistics their number varies from 13,4 thousand (1987) to 31,3 thousand(1997); the area of forests, subjected to fires -from 569(1987) to 2450(1998) thousand hectares. Pine and larch forests of the North, Siberia and Far East, growing on the drained, rising grounds are mostly subjected to fires.

The average temporal interval, during which these forests may undergo low fires is 30 years. In the course of this period the critical amount of combustibles, able to catch fire in hot dry weather and keep burning, is accumulated under the forest canopy. Spruce young growth, which is a constant competitor to pine and larch, burns out in low forest fires. Dark-colored spruce-fir forests grow on the low areas with damp(moist) soils close to subsoil waters. That is why fires can hardly occur in these forests even in the short-term periods of drought. In case of fierce droughts, occurring every 70-90 years, when caught by fire spruce-fir forests burn out completely, without any young growth left. Due to this reason their further reforestation goes, as a rule, through the change of species, that is, at first, the process of regeneration of cutover stands by broad-leaved species (birch and aspen) takes place, and only then young spruce and fir sprouts start growing. In the light-colored coniferous 30 year-old forests low fires, which do not cause damage to them, prevail. These fires play the role of thinnings, by means of taking away weakened trees and those falling behind in growth, providing the rest of trees with optimum light condition and space for roots development. In the permafrost region of light-colored coniferous forests low fires destroy the mossy cover, warming overburden layers.

After fires the level of permafrost goes down, but the power of root layer increases, providing conditions for significant increment of trees. It is found out that successful reforestation of pine and larch can be possible only as a result of low fires, destroying thick mossy cover and debris layer. With the average interval between fires of 30 years and the mean age of mature and over-mature forest crops in the boreal forests of 150-200 years, every crop is subjected to low fire as many as 4-7 times during the period of its growth before it is completely replaced by young growth. Only top fires may happen on the areas covered by coniferous young growth, but they lead to the complete damage of the latter. By the way, pine undergrowth is mostly subjected to fires. Dead larch undergrowth cover burns out only in the periods of drought, accompanied by strong wind. Artificially planted even-aged coniferous crops seldom happen to grow till their natural decomposition.

On the contrary, wild multiple-aged forests, formed by fire during millions of years, not only survive in the temporal fire weedings, but even improve, becoming more fire-resistible. We have a powerful overland and aviation forest service, which protects forest stock territory on the area of more than 700 million hectares. With the help of aviation, tele-and infrared equipment, and data obtained from artificial Earth satellites, forest service detects and eliminates considerable number of forest fires in proper time. But we should admit, that these activities do not exert great influence upon the general amount of forest fires. On the

contrary, eliminating forest fires we favor the accumulation of combustibles under the forest canopy, which may cause destruction of the crop in case of fire. Every year in two or three regions of the country fire passes through the area of 1-2 million hectares. Coordinates of these regions, time of fires origin, their number and extent of the burned out territory are programmed by nature itself, but it is still beyond our capacity to make a prediction in advance. Specialists in the field of fire fighting assure, that fire behavior in the forest is unpredictable. It is necessary to carry out a thorough and detailed research of this natural phenomenon, to reconsider our hostile attitude to the fire and to start using it as an ally.

E-mail: gpeterson/rmrs@fs.fed.us

Abstract

This paper discusses social and economic aspects of management and conservation of forest gene resources. The goal is defined as sustainable use and development of forest gene resources toward sustainable improvement in the human condition through wise self management and wise environmental stewardship. A review of the kinds of human values that may be associated with or dependent on forest gene resources, including economic value, leads to identification of the boundaries of economic value as a necessary but not sufficient criterion. Social and ecological complexity, bounded human rationality, and institutional dysfunction stand as obstacles to achievement of the sustainability goal. The policy and management choices we make now will determine Homo sapiens' long-range alternative futures. Our choices include (1) guiding cultural and institutional evolution through a "new social contract for science," public education, and wise political leadership and (2) allowing the invisible hand of the macro processes of nature to take us where they will. The first is the recommended course, but governmental interventions must be evaluated carefully to ensure that the "cure" is not worse than the "disease." The paper closes with the proposition that while social dysfunction may be the proximate cause of our erosion of natural capital, it poses a more immediate threat to our well-being.

Keywords: Human values, Economic, Social, policy, Management

Introduction

This paper discusses social and economic aspects of management and conservation of forest gene resources. The first section defines "sustainability" and "forest gene resources." The second is a review of the kinds of human values that may be associated with or dependent on forest gene resources, including economic value. The third identifies the boundaries of economic value as a necessary but not sufficient criterion. The fourth reviews social and institutional obstacles to sustainable use and development. The fifth section reviews two long-range alternative futures that appear to be contingent on the policy and management choices that lie before us. The seventh section summarizes the arguments. The final section briefly recommends what this author believes we must do to enable sustained improvement of the human condition over time.

This paper assumes that the goal is sustainable use and development of forest gene resources toward sustainable improvement in the human condition through wise self management and wise environmental stewardship. "Sustainable use and development" means that use and development of forest gene resources can continue indefinitely into the future without foreclosing future options. "Sustainable improvement in the human condition" means that Homo sapiens moves continually toward a more benevolent future. The UNEP Global Biodiversity Assessment reviews the state of scientific knowledge about global biodiversity as of 1995 (Heywood and Watson 1995). The assumption that the criterion is human use and development requires examination of the question of "value" in some detail.

The Nature of Value and the Value of Nature

The Anthropocentric Premise

Prevailing sovereign authority defines the policy criteria. In a democratic society that policy is the collective will of the people, as expressed through their legal and political institutions, on those things to which they can agree. We thus accept human preference as the criterion by which to measure the value of nature. As stated by Santayana (1896):

> "We may therefore at once assert this axiom, important for all moral philosophy and fatal to certain stubborn incoherences of thought, that there is no value apart from some appreciation of it, and no good apart from some preference of it before its absence or opposite. . . . Or, as Spinoza clearly expresses it, we desire nothing because it is good, but it is good only because we desire it."

Human appreciation is multifaceted, however. In order to understand the meaning of forest gene resources to Homo sapiens, we must understand the various ways we humans appreciate those resources.

The Preferred versus the Preferable

Morris (1956) defines value at three levels: operative, conceived, and object. Operative value is the domain of the preferred as evidenced by what people choose (revealed preference). Conceived value is the domain of the preferable, i.e., what one believes one ought to choose. Object value is the domain of what is, in fact, preferable, given one's desired outcomes and the reality of cause and effect. People do not always choose what is good for them because of ignorance or irrationality. For example, in the years before medical science discovered our dependence on vitamin C, many people died of scurvy on long ocean voyages. They desired health and long life, but their ignorance of the need for vitamin C misled their preferences and choices.

Individual and Collective Preference

Institutions, laws, and governmental powers as expressed through whatever political and judicial processes of social choice exist in a given society define collective preference as the long-run value structure of society within which individual short run preferences express themselves. The two are not always in agreement (e.g., Hardin 1968; Sen 1977; Harsanyi 1955, Blamey 1995). The enablements, constraints, and incentives created by collective preference exert strong influence on individual behavior, however. If that institutional framework is dysfunctional, it will guide behavior away from sustainability.

Derived Value

Our preferences assign derived value indirectly to other things by functional dependence. Such derived value often is implicit and beyond awareness of the relationship that assigns the value, as illustrated by the vitamin C example. If human well-being depends indirectly on forest gene resources in addition to the obvious and direct linkages (e.g., forest product markets), ignorance will allow us to make foolish choices. Because of that problem, the precautionary principle (Taylor 1991, Haigh 1993) is finding application in policy around the world.

Normative Value

A conceived or held value advocated by one agent as a standard or norm by which to judge the desirability of something to a second agent is a "normative" value. Keeping and advocating that value account is the domain of scientific, educational, philosophical, and ecclesiastical institutions. When based on good science or cultural experience, it is an information system worth listening to by those whose rights and lives may be affected.

Held versus Assigned Value

Brown (1984) differentiates between held value and assigned value. A held value is an enduring conception of the preferable. Assigned values arise from preference relationships among things about which people make choices. Held values tend to guide behavior. Assigned values are the outcome of choice. The value classifications of Brown and Morris imply that sustainable use and development of forest gene resources requires people to desire sustainability, understand the impact of their choices, and choose to behave rationally.

Economic Value

Economic value is the amount of money (or other parameter of value in exchange) one is willing to trade for the thing in question, either as a buyer, seller, or loser and is a specialized member of the operative assigned value account. In a market economy, equilibrium between supply and demand assigns marginal market prices which individual producers and consumers then decide whether to accept, based on the economic value to them. Market prices are economically efficient only under perfect competition, the conditions of which are well known but rarely achieved. Economically efficient prices and the resulting allocation of resources are equitable only under the assumption that the existing distribution of income is fair.

Market prices fail to include the value of goods that are non-rival and/or non-excludable in consumption (e.g., public goods), are external to market transactions, or are non-priced for other reasons, such as government policy or cultural tradition (Friedman 1981, Randall 1983).[1] We therefore break the economic objectives of efficiency and equity into financial and total economic components. The financial component includes only direct revenues and expenditures and, in the case of equity, the financial impacts amplified through the economy. The total economic approach adds non-market values.

Forest gene resources generate economic value at several levels of concern: (1) the value assigned directly through commercially harvested and marketed forest products; (2) the latent commercial value assigned by undiscovered but potentially marketable products, the focus of bioprospecting (e.g., Sedjo 1992; Polasky and Solow 1995; Sedjo and Simpson 1995a,b; Simpson, Sedjo, and Reid 1996; Polasky et al. 1999; Sedjo 1999; Simpson and Sedjo 1999; Rausser and Small, In Press; Simpson, Sedjo, and Reid 1998; (3) the derived value assigned indirectly by the relationships by which things preferred by people depend on forest gene resources (Heywood and Watson 1995); (4) amenity use value realized through forest recreation and other forest-dependent activities (e.g., Rosenberger and Loomis 2000); and (5) passive use value, including existence and bequest value, people assign to specific species, places, or the wholeness of complex systems of diverse species (e.g., Krutilla 1967; Ciracy-Wantrup 1968; Krutilla and Fisher 1975; Bishop 1978; Randall and Stoll 1983; Walsh et al. 1984; Brookshire et al. 1986; Walsh et al. 1990; Cicchetti and Wilde 1992; Freeman 1993; Mazzotta and Kline 1995; Loomis and White 1996; Crowards 1997; Farmer and Randall 1998; Carson et al. 1999; Morton 1999). Perrings et al. (1995) provide a good overview of the economic value of biodiversity, including theory and method of measurement. Polasky et al. (1999) at http://arec.orst.edu/biodiv/ is a comprehensive bibliography on the conservation of biological diversity, including a section on economics.

Some of the values find expression as prices through commercial markets. Others are measurable in theory (but often elusive in practice) by non-market methods such as contingent valuation. Still others, such as derived values, may require derivation through processes by which they contribute to direct values.

Dejure and Defacto Value

Preferences based on legally defined rights justify dejure value. People may have preferences that are not based on sovereign rights or effective powers, however. Such preferences yield defacto values that are important to people, but policy, litigation, and markets generally ignore them until they find expression by effective legal, political, persuasive, or coercive means. If end states such as sustainability and biodiversity that some of us may hold as preferred states are not protected effectively as property rights, economic, political, and judicial processes will not defend them in the short term.

Intrinsic Value

Biologists and ethical philosophers sometimes refer to intrinsic value as independent of human appreciation. They may mean thereby conceived values they believe people ought to hold. Or, they may have posited a

[1]A good is non-rival when consumption by one person does not reduce the amount available for consumption by others. E.g., viewing a sunset. A good is non-excludable when the owner is unable to prevent others from consuming it, e.g., appreciation of the existence of a wilderness area. A good (or bad) is external when, as part of a market transaction, it impinges on parties other than those directly involved in the transaction, the affected parties are difficult to identify, and the affected property rights are difficult to defend.

philosophical criterion of value other than human preference, such as a philosophical maxim, or what they believe to be the preference of God, of nature, or of non-human species (Rolston III 1981, 1985, 1994). Intrinsic value thus defined is a normative concept.

The Boundaries of Economic Value

When measured and applied correctly, economic value answers important personal, policy, and management questions. Cost and revenue accounting helps private firms and government agencies evaluate financial efficiency and distribution. Economic efficiency analysis with non-market values included addresses the broader concept of aggregate social welfare. Economic impact analysis addresses the equity objective by showing how an action distributes priced and non-priced costs and benefits among people. There are, however, other important questions economic value does not answer (Peterson and Brown 1999). This section lists reasons why economic value seldom tells the whole value story.

Failure to Explain Why

Economic value does not explain the functions and services that cause a thing to have value. A simple nutritional metaphor illustrates the point. The economic value of a meal at a restaurant is a sum of money. The price thus defined does not explain "why" the consumer was willing to pay, and it does not tell the consumer what will happen to her if she eats the meal. To make an informed choice among alternative meals, the consumer needs the advice of a professional nutritionist. The nutritionist will decompose the meal into its nutritional components and explain what it will do to the person who eats it. Environmental policy choosers likewise need information about the specific consequences of alternative choices in addition to their economic values. As stated by Hicks (1956) ". . . We ought to think of the consumer as choosing, according to his preferences, between certain objectives; and then deciding, more or less as the entrepreneur decides, between alternative means of reaching those objectives." The demand that assigns economic value to goods derives from the objectives people want those goods to serve. Two different goods can serve very different objectives while having the same economic value.

Poorly Defined Goods

In order to make good choices between goods and money as required for economic valuation, people need clear and correct perception of the goods in question. "Forest gene resources" are not well defined goods that people can understand in terms of monetary exchange.

Inability to Measure Some Values in Economic Terms

Economic valuation of forest gene resources generally is not achievable when: (1) the question is loss (WTA); (2) there are no substitutes for the good in question that money can buy; (3) the state of the art is inadequate; and (4) application of available methods to meet reasonable standards of quality is too expensive. Monetary valuation of public goods and passive use values remains controversial (Mitchell and Carson 1989; Arrow et al. 1993; Cambridge Economics 1992; Portney 1994).

The Distribution of Income

Economic value carries an implicit assumption that the distribution of income is fair. Fairness is a political question that each person, nation, and society must answer in the way it finds acceptable. When applied blindly across significant income differences, for example, across rich and poor nations at the global scale, the assumptions that underlie economic value (such as "one-dollar-one-vote") beg political questions with which the affected parties may not agree.

Ignorance and Consumer Sovereignty

Economic value as defined under the market system is justified by consumer sovereignty, but consumer sovereignty fails when the consumers are not fully informed. We do not fully understand the processes by which human welfare depends on forest gene resources, and we do not experience the costs and benefits of our impacts on those resources directly and in understandable ways, especially when the feedback occurs far in the future. Thus, the boundaries of human knowledge and rationality distort economic value (Simon 1985).

Intergenerational Failure

Economic valuation represents the interests of future generations through application of a discount rate to predicted future outcome. Discounting presents at least four perplexing problems. (1) Uncertainty about the preferences of future generations. (2) Uncertainty about future consequences of present decisions. (3) Uncertain about what discount rate to use. (4) Violation of the logical basis for discounting. The discount rate is, among other things, a rent to cover the opportunity cost of capital. Capital is capable of growth through wise investment, and a given amount of capital is therefore worth more now than later. But consumption of natural capital by the present generation can produce one of at least three alternative futures: (1) It may be a growth producing investment that makes the future better off through increased natural or man-made capital. (2) It may cause the loss of unique resources and opportunities for which money and technology cannot compensate. (3) It may be hedonistic consumption of pleasure that returns nothing to the future but a historical memory of past pleasures enjoyed by others. Even the "precautionary principle" carries the dilemma that failure to invest natural resources now may deny capital growth that might have been created. For a rigorous review of discounting and intergenerational equity see Portney and Weyant (1999).

Cultural, Political, and Institutional Diversity

Not all nations and cultures agree that economic analysis is an important language by which to consider personal and public decisions. Even among industrialized nations, there is disagreement about the usefulness and appropriateness of economic quantification of human values, especially those values that are external to market transactions (Peterson and Hoekstra 1990, Shrader-Frechette 1985). Values must be expressed by the systems of logic and negotiation appropriate to each nation and society.

A related problem is that economic values imply political assumptions that may not agree with all cultural and institutional value systems. Economic value also depends on the institutional context (Bromley 1982). Different nations provide different institutional contexts, thus creating a perplexing noncomparability.

Failure to Represent the Full Public Interest

Available methods for measuring the economic value of non-priced goods and services generally focus on short run individual values and may not capture long run collective values that need to be expressed through legislative, judicial, or ethical channels as institutional guidelines and constraints (Hardin 1968, Harsanyi 1955, Sen 1977, Blamey 1995). If technical valuations are to be complete, we also need to include methods that place people in citizen roles, such as values juries (Brown et al. 1995) and citizen juries (Crosby 1995, Armour 1995), or a court of generations (Tonn 1991). Because of market friction, market prices may not measure efficient marginal values for the goods to which they apply.

Marginal versus Total Economic Value

A common problem in application of economic value is confusion of the value of a thing with the value of the function it performs. Economists are well aware of this question as the difference between marginal and total value. Popularized as the "diamonds and water paradox," it was the focus of considerable concern in the early evolution of economic theory (Silberberg 1978). We must not measure the value of global biodiversity as the economic value of a marginal change in the population of an abundant species. The value of such a marginal change is likely to be trivial, but the cumulative value of many marginal changes may be large. The total value of a nonmarginal change in something like forest gene resources that goes beyond the bounds within which the earth can sustain human life is the value of life itself. The ability of economic theory to clarify this question of marginal versus total value is a strength of the economic definition of value, not a weakness. We discuss it here only because confusion about the matter is common, and ignorance of the theory sometimes causes abuse of economic value in application.

The Need to Look Beyond Economic Value

In summary, economic value is a useful tool, but it cannot capture or adequately represent all the values affected by forest gene resources. Full understanding of the value requires that we understand and correctly apply economic value, including its limitations in application, and also look beyond this useful but narrow concept by explaining the ways human survival and quality of life depend on the condition of our forests. Rather than abandon economic valuation because of its imperfection, however, we need to improve the state of the art and the quality of public opinion by investing aggressively in research and public education so that technical information systems and political processes both can function more effectively.

Obstacles in the Path

The preceding sections on value discuss what we want to achieve, why we want to achieve it, and how we measure achievement. Under the assumption that sustainable use and development of forest gene resources is a desirable goal, the discussion now turns to obstacles that stand in the way. Those obstacles are complexity, bounded rationality, and institutional dysfunction.

Complexity

Nature is extremely complex and " Systems Ecology" is not yet a mature science. Unlike physics, chemistry, or mathematics, there is no refined foundation of systematic knowledge from which to build theories and models that can offer effective predictions of the long-term consequences of our personal and institutional choices.

Bounded Rationality

We humans are not perfectly rational and informed creatures. The conceived values we allege to worship in cultural and religious institutions too often fail to describe the operative values implied by our personal and collective choices. The causes include short-sightedness and irrationality, as well as imperfect information and limited cognitive capacity (Morris, 1956; Simon, 1985). The imperfection infects both collective and personal choice.

Institutional Dysfunction

Some of the most serious challenges confronting ecosystem stewardship are creatures of a dysfunctional institutional framework (Honadle, 1993; Hardin, 1968) at both national and global scales, including the price signals to which personal and collective choices respond. Successful ecosystem stewardship requires major institutional reforms (Honadle, 1993).

Present Choices and Alternative Futures

Present economic and demographic trends in the use and development of forest gene resources do not appear to be sustainable (Aplet et al. 1993). Ecological complexity, bounded rationality, and dysfunctional institutional incentives seem to be moving us toward bankruptcy of the natural capital those resources represent. Scarcity caused by depletion in the face of growing demand will drive up the cost and reduce availability of some species while reducing overall diversity. How and to what extent the future welfare of Homo sapiens at the global scale depends on the holistic diversity of forest gene resources and the role it plays in the ecological fabric of the earth's biosphere is largely unknown. Acceleration of global climate change through reduction in carbon sequestration is one potential outcome. Our future destiny may well depend on choices we make now. There are at least two plausible courses of action: (1) use reasoned choice to change personal behavior and the institutional structure of incentives through scientific research, public education, and normative persuasion and (2) let the "invisible hand" of natural "happening" determine the future toward which we move.

Self Direction through Reasoned Choice

If all nations were under dictatorship, changing personal behavior and the institutional structure of incentives would be simple in theory. The people in command could simply direct the needed changes, but it would not be in their short-term interest to do so because the incentives to which they would respond are all short-term and they probably would not know what the best course is. It would require very thoughtful and well informed statesmen to choose to serve the long-term welfare of global society, and they would have to believe that leaders of other nations would do likewise.

In a democratic society the problem is still more complex. Noble statesmen, if they could get elected, could make noble choices, but they would not remain in office long and the changes they make would soon revert. Politicians respond to their perception of the "will of the people" as read from polls and expressed through power politics. The masses and the power brokers respond to the existing institutional incentives. The outcome is a paradox to which there seems to be no easy resolution.

The answer, if there is one, would seem to be in a slow process of cultural evolution facilitated as suggested by Rivlin (1993) and Lubchenco (1998) by scientific exposure of the processes by which human welfare depends on forest gene resources and effective communication through public education of the knowledge thus obtained. Scientists also need to use that knowledge to identify available choices and predict the alternative futures contingent thereon. Raising the quality of public opinion through public education may allow the emergence of informed statesmen able to work effectively toward the needed institutional reforms. Tolstoy (1957) asks in *War and Peace* whether leaders cause revolutions or revolutions allow leaders to emerge. Truth probably lies in a middle ground where enlightenment produces potential leaders, allows enlightened leaders to emerge, and moves the masses to call for and accept the needed changes. Changing values, perceptions, beliefs, and behaviors through education and persuasion is not a quick or easy process. But, the institutional structure of incentives must change if we are to achieve sustainability, and there seems to be no feasible course other than slow cultural evolution through sustained education, normative persuasion, and effective political leadership.

Leave It to the Invisible Hand of Nature

Failure to orchestrate cultural evolution will leave human destiny in the apparently indifferent "invisible hand" of macro-system processes. The state and process of nature are the products of at least four forces: (1) the press of non-living nature toward more probable states as described by the second law of thermodynamics, (2) the synergistic force of non-sentient life that reduces entropy locally while increasing entropy globally by creating otherwise improbable states through blind variation and selective retention powered by energy imported from the sun or stored within the earth, (3) the force of reasoned choice by which Homo sapiens and other reasoning species (if any) attempt to organize nature (including self) into preferred configurations, and (4) the growth of human learned culture by accumulation of successful values and beliefs as captured in folklore, religion, language, social organization, political institutions, and written knowledge capital.

We humans have been so successful in our accumulation of culture and population that our impact on the planet we inhabit is no longer marginal. A recent paper in the National Geographic characterized Homo sapiens as the "Sixth Extinction" (Morell 1999). Apparently we are in a race between the self-regulating mechanisms in nature (Wynne-Edwards 1965) and the technology by which we construct and fortify artificial habitat. The critical question is whether we can, by reasoned action, gain control of the macro system effects of our increasingly disturbing presence. If we do not, then we will be at the mercy of complex spontaneous processes that eventually may impose Draconian impacts on us as the consequence of our accumulation of non-marginal disturbances. To allow ourselves to follow such an arbitrary course is reminiscent of the conversation Alice had with the Cheshire Cat in Wonderland (Carroll 1993):

> "'Would you tell me, please, which way I ought to go from here?'

> 'That depends a good deal on where you want to get to,' said the Cat.
> 'I don't care much where . . .' said Alice.
> 'Then it doesn't matter which way you go,' said the Cat
> '. . . so long as I get SOMEWHERE,' Alice added as an explanation.
> 'Oh, you're sure to do that,' said the Cat, 'if you only walk long enough.'

And, we might add, we must also LIVE long enough.

If we are lucky, the combined effects of technological innovation and automated cultural and biological self-regulating mechanisms will keep us on a safe course. But, relying on "luck" sounds dangerously close to turning our fate over to the second law of thermodynamics which erodes improbable states. Nature's indifferent "choice" of a course for us may not be quite as benevolent as what we might want. Is our capacity for reasoned choice a force toward our salvation, or is it the cause of the problem? Perhaps the outcome of the race will be determined simply by which force is stronger, the press of non living nature toward more probable states or the synergistic power of the unconscious life force on which our arrogant consciousness rides. Despite such troublesome questions, we have no choice but to continue to investigate our relationship with the earth and strive toward sustainability.

Summary

Social and economic considerations in the management and conservation of forest gene resources include (1) the human preferences and behaviors that determine how we use and impact those resources and how that impact returns to affect us, (2) the role of economic value as a necessary but not sufficient consideration, (3) social and economic factors that push us away from sustainability and toward environmental bankruptcy, and (4) the alternative futures that depend on the choices we make now.

Notwithstanding alternative views, this paper adopts the premise that the principal reason for concern about management and conservation of forest gene resources is the welfare of Homo sapiens. We are severely modifying our habitat and we need to learn how to sustain it so it can sustain us. In order to understand and change the choices that hurt us by hurting our habitat, we need to understand the values, beliefs, and incentives that motivate those choices. Areas of concern include the difference between the preferred and the preferable, held and assigned values, collective and individual preference, values the law recognizes as property rights and those it does not, direct versus derived values on which we depend in ignorance of the processes that tie us to them, normative and intrinsic values, and economic value.

Economic value is a particularly important, useful, and potentially dangerous way to define and measure value. It is a necessary but not sufficient criterion because the economic paradigm is not appropriate for some factors; where economic valuation is appropriate, the state of the art is often inadequate; and application of available methods to meet reasonable standards of quality is often too expensive. Furthermore, before they can decide the economic value of something to them, individual citizens and policy makers both need to know the outcomes of the alternative choices they face. If abused or misrepresented, economic value and the analyses by which it finds expression can mislead.

Whether the values and beliefs that motivate our personal and collective choices are right or wrong, three major problems not only obstruct achievement of sustainability, they tend to move us in the opposite direction. They are (1) inadequate understanding of the overwhelming complexity of the physical, biological, economic, and social ecological systems of which we are a part; (2) the bounded rationality by which we make short-sighted personal and collective choices; and (3) dysfunctional institutional incentives that motivate us away from where we need to go.

Forest gene resources serve human welfare through commercial harvest and marketing of forest products, but such activity too often is

not sustainable. There also may be potential but unknown products, such as medicines and other useful marketable chemicals, hidden behind our ignorance. Such things are the focus of the growing activity of bioprospecting. Through the processes of adaptation and evolution, successful forest species have had to solve many problems to survive. The solutions to those problems, such as resistence to disease and predators, may have useful human applications.

Forest gene resources also serve us by creating forested environments where we can find scenic beauty, recreation opportunity, or simply appreciation of their existence. But, their most important service, a service that we least understand, may be their holistic role in the fabric of global biodiversity, a role by which they help control global climate change, for example, through carbon sequestration. The value of species, if any, that are keystones in the ecological structure, may be infinite.
Present trends in the use and development of forest gene resources appear to be leading us away from sustainability. Two courses of action are available. One is remedial. The other, which is to continue on the present course, may be catastrophic. The remedial course includes two major components: (1) A more aggressive research attack on complex natural, social, and economic processes by which our choices disturb the environment and return to disturb us, together with more effective injection of scientific knowledge into the personal and public decision-making processes that affect sustainability. (2) Constructive modification through public education and political and judicial leadership of the institutional framework of dysfunctional constraints, enablements, and incentives that guide individual and organizational choices away from sustainability.

The laissez faire option, which is simply to let things continue to go the way they are headed, places us at the mercy of purposeless and indifferent macro-system resolution of four major forces: The entropy maximizing force of non-living nature, the synergistic force of non-sentient living nature, the cognitive force of micro-level sentient reasoned action, and the quasi-sentient force of macro-level cultural evolution. The unguided resolution of those forces may or may not promote sustained improvement in the human condition over time. Being indifferent, the resolution doesn't "care" what impact it has on us. It simply carries us along or discards us in the process of macro system evolution.

Is the "invisible hand" of nature leading us with blind wisdom toward sustainable improvement in the human condition or toward catastrophe? Will reasoned efforts to control ourselves and our habitat help or hinder our quest for sustainability? Those questions have plagued humanity without resolution throughout history and perhaps even before.

Specific Recommendations

The recommended course of action is, of course, the first one, the process of cultural evolution toward institutional reforms, facilitated by "a new social contract for research" (Lubchenco 1998), including public education and effective political leadership. The problem is complex, and I do not pretend to have definitive answers. Specific institutional reforms, such as taxation and regulation policies, use of macro-economic indices that more effectively reflect the cost of natural capital depletion, political campaign finance reform, international transfer payments to buy forest gene conservation, creation of institutions that help people cope more effectively with change, increased investment in public environmental education, etc. have been advocated by various authors, but government intervention in private affairs often has unintended consequences that can make the cure worse than the disease. We need to be sure that any reforms we adopt solve more problems than they create.

Depletion of natural capital is not the only serious problem we face, however. Without apology, I submit a trite but unpopular proposition: Social dysfunction is at least as serious a threat. In the opinion of this author, unequal distribution of power and wealth, institutionalized intercultural discrimination, neglect and alienation of children, and intercultural and interpersonal violence, among other things, constitute immediate global crises that threaten to destroy human civilization. They are also are among the factors that contribute to unwise environmental stewardship. Nature has recovered sufficiently from cataclysmic events in the pre-human past to allow Homo sapiens to emerge and worry about the ecological condition of the earth. Nature will recover and move on from whatever disturbances our temporary presence imposes. Perhaps we should spend a bit more time worrying about the socio-cultural condition of ourselves. Our first and foremost concern ought to be the sustainability of human life and quality of human life. Concern for the long term welfare of Homo sapiens surely must be the cause and justification for our concern for sustainability of the ecological systems in which we participate, and social dysfunction is at the root of the disturbances we impose on nature. . . But I am preaching a sermon we all know to be true and apparently can't (or won't) do anything about.

Abstract

The paper describes some work carried out at international level in the field of forest genetic resources. It points to the urgency to translate general principles and international agreements into operational national programmes aimed at the wise management of these valuable resources, the need to review national forest genetic resources programmes within the framework of regional plans and activities, and the desirability to develop an action oriented, country driven framework to ensure complementarity of action at global level.. Special reference is made to recent efforts by FAO and international and national partners to support and facilitate the elaboration and implementation of regional and sub-regional action plans for the conservation and sustainable use of forest genetic resources.

Keywords: Biological diversity, Forests, Forest genetic resources, Genetic conservation

Introduction

Forest trees play a vital role in many national economies and in the daily life of rural communities, as sources of timber, fuelwood, food, fodder, essential oils, gum, resins, latex, medicines and pharmaceutical products, shade, shelter, as contributors to soil and water conservation, and as repositories of ethical, aesthetic, cultural and religious values. Such goods and services are provided by a large number of genera and species of trees and shrubs and, to a large extent, different species are used in different countries and regions to satisfy similar needs.

Forests are arguably the single most important repositories of terrestrial biological diversity. As major constituents of forest ecosystems, trees and woody plants support the life of a wide range of other organisms both directly and indirectly. As long-lived, outbreeding, and generally highly heterozygous organisms, occurring in often variable environments in time and space, they have developed at times complex mechanisms to maintain high intraspecific diversity. Genetic variation is needed to ensure present-day and future adaptability of species to dynamically evolving environmental conditions and their continued evolution. It is also needed to maintain options and potential for improvement to meet changing end use requirements. The well being and continued ability of forest trees to provide goods and services are thus dependent on the maintenance and management of their genetic foundation. The actual and potential value of this genetic foundation is embodied in the concept of *forest genetic resources*.

Unlike most agricultural crops, in which genetic diversity can be sampled, collected, and relatively easily stored and conserved in seed banks, the long-term storage, maintenance and regeneration of collections of forest tree seeds present a number of specific problems. Forest genetic resources are most commonly stored, in the long term, in living trees. Land use practices and variations in forest cover, quality and composition thus have direct and decisive impact on the extent and patterns of genetic variation in forest trees. In most regions of the world, threats to the integrity of forest genetic resources have increased in the past decades, in the form of deforestation due to changes in land use, forest habitat destruction and alteration, inappropriate forest harvesting practices, atmospheric pollution, and climate fluctuations and change. A further threat to genetically diversified, local populations, which may possess special or valuable attributes, is posed by introduction of non-local forest germplasm for plantation establishment, which may lead to hybridization of local and introduced genepools and to various degrees of loss of local adaptation in subsequent tree generations.

Management of Forest Genetic Resources

The aims of genetic management are to safeguard the evolutionary potential of dynamically evolving ecosystems and species, and to ensure the enhancement and sustainable utilization of the genetic variation available to meet present-day and future human needs. The specific objectives of genetic management will change over time, as environmental, economic and social conditions and requirements continually shift. Attention should therefore not only be given to those tree species, populations and genetic traits which are considered useful today, but also to those of potential future economic, social and environmental value. Priorities for action will depend on value-judgements, and are usually to a large extent determined by the primary beneficiaries of the conservation effort. To ensure a holistic view, it is clear that dialogue and involvement of all stakeholders is of utmost importance in the planning and implementation of conservation programmes. Such dialogue should include government institutions, private owners, industry and national non-governmental organizations, academic and research institutions, and others, as relevant. Mechanisms must also be in place to ensure that needs and aspirations of local communities or other present-day primary beneficiaries of forest goods and services are duly considered.

As a first step in action towards genetic management, the level or levels targeted must be clearly specified. This is of utmost importance since it is possible to conserve an ecosystem and still lose specific species, and to conserve a species and lose genetically distinct populations, genes or gene complexes that may be of future value. Decisions regarding strategies and methodologies will depend not only on the biological characteristics, genetic variation and variation patterns of a given species, but also on the degree of knowledge available on its silviculture and management; its present use, importance and uniqueness in this regard; perceived threats; and, quite decisively, the institutional capacities in countries directly concerned, including infrastructure and availability of funding over time.

Conservation of genetic resources is used in this paper in the commonly agreed-upon meaning, *the management of human use of genetic resources so that they may yield the greatest sustainable benefit to present generations, while maintaining their potential to meet the needs and aspirations of future generations*. The two main strategies for the conservation of genetic resources, *in situ* and *ex situ* conservation, complement one another. *In situ* conservation implies the continuing maintenance of a population in its natural or original habitat, within the community of which it forms a part. *In situ* conservation of forest genetic resources is, in practice, carried out in forests experiencing varying degrees of human intervention, from strict protection to intensive management for specified goods and services. *Ex situ* conservation includes conservation as seed, pollen or tissue, and conservation of genetic materials in live collections such as plantations, arboreta and clone banks, or in especially established *ex situ* conservation stands.

National Programmes

Growing concern over long-term maintenance of health and overall productivity of forests and forest ecosystems, species and genetic resources, and over alterations in forests at the landscape level, have led in many countries to the elaboration of national policies or special programmes for the conservation of biological diversity, including forest biological diversity and forest genetic resources. In this respect, the preamble of the Convention on Biological Diversity, adopted in 1992, reaffirms that States have sovereign rights over their own biological resources, and that they are responsible for conserving their biological diversity and for using their biological resources in a sustainable manner.

National policies and programmes relating to forest genetic resources cover a wide range of activities, from conservation measures taken to protect rare and endangered species and populations and regulations governing seed collection and transfer in socio-economically important tree species, to comprehensive approaches to the management of ecosystems and forest genetic resources. Implementation of conservation programmes has been accompanied by increasing recognition of their cross-sectoral nature, and by recognition that institutional strengthening, awareness raising and technical considerations in the management of forest genetic resources are intimately related and mutually dependant. Integrated strategic approaches to conservation are therefore necessary at national level. As an example, field repositories of genetic resources include nature reserves and other protected areas; private and publicly owned, managed and unmanaged, natural forests and plantations; trees outside forests in agroforestry systems, along rivers, canals, roads and in homesteads; arboreta and botanic gardens; and field tests and trials established within the framework of selection and tree improvement programmes. The maintenance and management of an appropriate combination of these *in* and *ex situ* "genetic repositories", in a range of locations under diverse environmental, institutional and silvicultural conditions, constitute the most efficient way to conserve various levels of genetic variation, while providing a buffer against actual and potential risks. However, it also constitutes a major organizational, institutional and technical challenge.

With the above complexities in mind, considerations related to forest genetic resources have been integrated in a number of countries within wider frameworks, such as national forest programmes and biodiversity status and action plans developed within the framework of the Convention of Biological Diversity.

The national programmes provide the basic framework for action, however, programmes confined within the national bounderies have a number of limitations, as the natural distribution of many forest tree species spans across political borders. Furthermore, at times, tree species or given populations or provenances have become socially or economically important outside of their natural ranges, while they may be of minor, present-day importance in their countries of origin; such situations raise questions regarding responsibilities in conservation, especially when *in situ* conservation is seen as an imperative. A number of introductions, frequently of undocumented origin, have also evolved into land races, which are well adapted to environmental conditions outside of the species' natural range, and these land races are often of importance in genetic conservation activities; also this situation calls for collaboration between two or more countries.

It is widely acknowledged that the greatest number of plant species occurs in tropical areas. These areas frequently coincide with territories of developing countries with limited financial, institutional and manpower resources. In the field of genetic resources, funding for research and development is available primarily in developed countries, while needs are global; there is an increasing urgency to acknowledge the need to share responsibilities in genetic conservation. In this regard, access and transfer of genetic resources and property rights issues are increasingly debated at national and international levels, *i.a.* within the framework of the Convention on Biological Diversity, with the aim to promote both the conservation and sustainable use of these resources and the equitable sharing of benefits derived from them.

The above considerations have strengthened the international element in genetic resource conservation and use. It is increasingly recognized that, while the national programmes form the building blocks in the genetic conservation and while implementation of such programmes is the responsibility of the national governments, collaboration and support at international level is also necessary. International mechanisms can usefully help ensure that action taken by individual countries is complementary, compatible and mutually supportive. Through such mechanisms attention can also be drawn to conservation issues of global concern, and gaps in coverage can be identified, pinpointed and agreement reached on remedial action, while at the same time respecting national souvereignity and priorities.

Initiatives at International Level

The International Forestry Dialogue

Heightened political and policy level recognition of the importance of conserving forest biological diversity culminated in the discussions in the United Nations Conference on Environment and Development, UNCED, held in Rio de Janeiro in June 1992. A number of agreements were reached at UNCED and a number of action frameworks were adopted and subsequently ratified by countries present. Some of these agreements and mechanisms directly addressed the forestry sector, notably Chapter 11 of Agenda 21 of UNCED, "*Combating Deforestation*"; and the "*Forest Principles*"[1]. The adoption and subsequent ratification of the legally binding Convention on Biological Diversity (CBD) was also of major relevance to forestry, in particular as regards protected areas, *in situ* conservation of biological diversity and genetic resources, and access to genetic resources, their sustainable use and equitable sharing of benefits derived from them[2]. A work programme for forest biological diversity was adopted by the CBD in 1998, and is under further development. The work programme makes reference to forest genetic resources and integration of related concerns into sustainable forest management.

The intergovernmental policy dialogue on forests following UNCED has been largely focused on the discussions in the Intergovernmental Panel on Forests (IPF) and, subsequently, the Intergovernmental Forum on Forests (IFF), established under the United Nations Commission on Sustainable Development. Neither IPF nor IFF, which held its final session in February 2000, focused specifically on forest genetic resources in their programmes of work, however, related issues on the conservation, management and sustainable development of all types of forests, which were discussed in more general terms, were of major relevance to the subject matter.

Coordination of inputs and support by the international organizations to the international forest policy dialogue has been ensured over the years by the high level, informal Interagency Task Force on Forests (ITFF), established in April 1995[3].

In addition to the active collaboration with its partners in the ITFF also an all issues related to forestry and in issues in forest biological diversity and forest genetic resources, FAO collaborates closely in these latter fields *i.a.* with the United Nations Educational, Scientific and Cultural Organization (UNESCO), the International Plant Genetic Resources Institute (IPGRI), the International Centre for Research in Agroforestry (ICRAF), the World Conservation Union (IUCN), and the International Union of Forestry Research Organizations (IUFRO). This latter organization recently established a Task Force on the management and conservation of forest genetic resources, which bridges the work of all relevant IUFRO Divisions.

Crop and Forest Genetic Resources

Concerns related to crop and forest genetic resources have received public and political attention in differing ways. The Fourth International Technical Conference on Plant Genetic Resources, convened by FAO in Leipzig, Germany, in June 1996, endorsed a State of the World's Plant Genetic Resources report and adopted a Global Plan of Action for the Conservation and Sustainable Utilization of Plant Genetic Resources for Food and Agriculture. The present version of the Global Plan of Action, as endorsed in Leipzig, covers genetic resources of agricultural crops. While making reference to wild relatives of cultivated plants, often found in forest ecosystems, and to domesticated tree crops (fruit trees, rubber *etc.*), the Global Plan of Action explicitly excludes forest genetic resources.

In forestry, growing awareness of deforestation in the tropics and of forest and environmental degradation in both developed and developing

[1] The Non-Legally Binding Authoritative Statement of Principles for a Global Consensus on the Management, Conservation and Sustainable Development of All Types of Forests.

[2] Other legally binding conventions of relevance include the Framework Convention on Climate Change, and the UN Convention to Combat Desertification.

[3] Partners in ITFF include: The Food and Agriculture Organization of the UN (FAO), the International Tropical Timber Organization (ITTO), the Secretariat of the Convention on Biological Diversity (CBD), the United Nations Department of Economic and Social Affairs (UN-DESA), the United Nations Development Programme (UNDP), the United Nations Environment Programme (UNEP), the World Bank, and the Centre for International Forestry Research (CIFOR).

countries, has contributed to the development of a number of international initiatives aimed at the conservation of forest biological diversity (including wildlife) on the one hand, and the sustainable management of forests and woodlands and the biological diversity housed in them, on the other. Although the need for specific focus on the management of the forest genetic resources has received increasing attention over the past thirty years, there is to date no international equivalent in forestry to the Global Plan of Action, mentioned above.

At technical level, a Panel of Experts on Forest Gene Resources was established by FAO in 1968. The Panel regularly provides advice to FAO and, indirectly, to the world community, on programmes and priorities in the field of forest genetic resources. The work of the Panel complements that of the subsequently established FAO Commission on Genetic Resources for Food and Agriculture (CGRFA), which oversees the International Undertaking on Plant Genetic Resources and the Global Plan of Action. The mandate of the predecessor to the CGRFA, the Commission on Plant Genetic Resources, established in 1983, was expanded in 1995 to cover "*all components of biodiversity of relevance to food and agriculture*", including the fields of agriculture in the strict sense, domestic animals, forestry and fisheries. The work programme of the CGRFA will be correspondingly expanded in the future, in a step-wise manner.

In line with the recommendations of the Panel of Experts on Forest Gene Resources, FAO has developed a worldwide data base and information system on forest genetic resources (REFORGEN)[4]. The objective of REFORGEN is to make available reliable, up-to-date information on forest genetic resources for use in planning and decision making at the national, regional and international levels. The information system complements national work in this field, and information contained in the national databases and information systems, and other country-derived information, will be aggregated for use and easy retrieval through REFORGEN. As of March 2000, information from 146 countries and on more than 1600 tree species was stored in the system. REFORGEN is linked to the FAO global forest resources information database, which contains information on forest areas and trends. It complements databases on threatened and endangered plants (including trees) administered by the World Conservation Union (IUCN) and the World Conservation Monitoring Centre (WCMC), and the data base on protected areas held by the WCMC. A great number of other international, regional and national organizations and institutions have established data bases or developed Internet sites and search engines on forest and tree genetic resources. The challenge will be to ensure compatibility between the major data bases, and to establish links between them for easy retrieval and use of all available information.

Initiatives at Regional Level

Regional and Species-Specific Forest Genetic Resources Networks

Regional approaches to the conservation of the forest biological diversity and the forest genetic resources are especially useful in cases in which countries have comparable institutional conditions and similar ecological needs and requirements. The regional approaches have over the past years been complemented by the eco-regional approaches and, at times, by action focused on common priority species or groups of species.

A number of international and bilateral development agencies and NGOs working at regional level have incorporated activities related to the conservation of forest genetic resources with the wider forestry strategies coordinated or supported by them. The activities undertaken cover a wide range of forest genetic resources issues, from exploration, evaluation, genetic conservation and tree improvement, to the incorporation of genetic considerations with the sustainable management of forests and woodlands, and the development of common technical methodologies, specialized training and capacity building, and strengthening of national institutions.

[4] REFORGEN is available on-line at the FAO Internet Homepage on forest genetic resources, at: http://www.fao.org/forestry/FOR/FORM/FOGENRES/homepage/fogene-e.stm

In some regions, country-driven action has lead to joint development of collaborative programmes in the forestry and forest genetic resources, which has helped ensure coordination of work between neighbouring countries. At each of three Ministerial Conferences on the Protection of Forests in Europe (Strasbourg 1990, Helsinki 1993 and Lisbon 1996), a number of resolutions were adopted, including one resolution specifically focused on the conservation of forest genetic resources (Resolution S2, Strasbourg 1990). As a follow-up to this resolution, five species-specific networks were established within the framework of the European Forest Genetic Resources Programme (EUFORGEN), a mechanism which was established following the Strasbourg Ministerial Conference to support countries in the implementation of resolution S2, and which is coordinated by IPGRI with technical support from FAO. Thirty countries participated in the first phase of the EUFORGEN programme (1994–1999). Proposals for a second phase have been finalized, with continued attention to the development of methodologies and "best practice" in *in situ* and *ex situ* conservation of genetic variation in targeted pilot species or groups of species, to the exchange of reproductive materials for purposes of research and conservation, and to the exchange of information and know-how.

Other regional and sub-regional programmes and projects include, among others: (i) the South Pacific Regional Initiative on Forest Genetic Resources (SPRIG), which during its pilot phase (1997–1999) helped develop comprehensive strategies and coordinated action in five island countries; a second phase of the project presently in preparation; (ii) the Integrated Regional Strategy for Seed Procurement in Central America and the Dominican Republic, carried out by concerned countries with the support of the DANIDA Forest Seed Centre, with the aim to strengthen national forest seed programmes and to enhance sub-regional cooperation; (iii) the Tree Seed Centres' Network of the Southern African Development Community (SADC), which has been instrumental in supporting the establishment or the strengthening of existing national tree seed centres in twelve countries in Eastern and Southern Africa; (iv) the Central Asian and Transcaucasian Network on Plant Genetic Resources (CATCN-PGR), coordinated by IPGRI, which focuses on the conservation of genetic resources of crops and forest trees in eight countries of the sub-region, and which benefited during its establishment from the experience and assistance of the EUFORGEN programme; and (v) the newly established Sub-Saharan African Programme on Forest Genetic Resources (SAFORGEN), co-ordinated by IPGRI, aimed at strengthening national research institutes and regional forest research programmes in countries in sub-Saharan Africa.

Examples of species-specific networks include*:* (i) the FAO coordinated project on Genetic Resources of Arid and Semi-Arid Zone Arboreal Species for the Improvement of Rural Living, initiated in the early 1980s in collaboration with IBPGR/IPGRI, UNEP and, subsequently, the DANIDA Forest Seed Centre (DFSC). The project is aimed at the exploration, collection, exchange, evaluation and conservation of genetic resources of dryzone multipurpose species, with special reference to two genera identified at the outset by collaborating countries: *Acacia* and *Prosopis* spp. The DFSC and FAO, in close collaboration with cooperating countries, are presently reviewing experimental results and their implications based on in-country findings and overall results across countries and sites; (ii) the International Neem Network coordinated by FAO, aimed at characterizing the extent and patterns of genetic variation of *Azadirachta indica*, and to assist collaborating countries in Asia, Africa and Latin America to make appropriate use of the potential which this species offers in arid lands; (iii) the International Network for *Leucaena* Research and Development, LEUCNET, based at the University of Queensland, Australia; (iv) TEAKNET, focused on *Tectona grandis*, hosted by the Forest Department of Myanmar; (v) the International Network for Bamboo and Rattan (INBAR), and the recently established International Centre for Research and Training on Seabuckthorn (ICRTS), both headquartered in Beijing, China.

Cooperative tree improvement programmes are common in both industrialized and developing countries. While many of these have originally received inspiration and a "model" from North American forest industries tree improvement cooperatives, such as the one operating in South Eastern USA and based at the North Carolina State University in Raleigh, these programmes at times also involve several countries. In this, latter case, membership might be based on the geographical closeness or ecological similiarities in conditions of collaborators, or on common interest in given species or groups of species. Existing cooperatives have often been established with a broad perspective, including seed exchange and tree improvement as well as conservation of genetic resources. An example of such programmes is the Central America and Mexico Coniferous Resources Cooperative, CAMCORE, hosted by the North Carolina State University, USA, which deals with the exploration, collection and exchange, testing, improvement and conservation of conifers and some hardwood species originating in Mexico and Central America.

Regional Forest Genetic Resources Workshops and Action Plans

As evidenced above, a number of international organizations has involved, directly and indirectly, in programmes related to forest genetic resources, and a number of mechanisms is presently used to further action in this field. While this situation offers excellent opportunities to address the conservation and sustainable utilization of forest genetic resources drawing upon a range of expertise and interests, and focusing on a range of different perspectives and modes of action, the lack of a common, global framework makes it difficult to define overall priorities, to identify possible overlap, and to identify and address gaps in the coverage.

In 1997, the Thirteenth Session of the FAO Committee on Forestry, "agreed that there was an urgent need for concerted action to strengthen national, regional and international activities in the conservation and sustainable use of forest genetic resources, to help enhance country capacities and to support the exchange of information, experiences and know-how". The Committee, "recommended that efforts to explore, conserve, evaluate and better utilize forest genetic resources be continued and further strengthened in collaboration with national institutes and international governmental and non-governmental partners". Some delegations considered that FAO should, "pursue efforts to develop regional plans of action for the conservation and sustainable use of forest genetic resources as a first step to develop a global plan of action". The Committee, accordingly, advised FAO, "in conjunction with Regional Forestry Commissions, international partners and countries that requested it, to convene a series of regional and sub-regional forest genetic resources workshops". The overall aim of such workshops, in accordance with the Secretariat Note prepared to underpin discussions[5], was to support countries concerned to develop mutually compatible and complementary action plans which would contribute to ensuring that forest genetic resources were conserved and sustainably utilized as a basis for local and national development, including food security, poverty alleviation, environmental conservation, economic and social advancement and the maintenance of cultural and spiritual values.

The Committee acknowledged that national plans and programmes would vary according to local biological, social and economic environments and according to national needs and priorities. The purpose of recommended action was thus not the development of one, single model for conservation for all countries, but the elaboration of a framework for national action, valid at regional level and, to the degree possible, consistent among regions[6].

Following the recommendations of COFO, FAO in collaboration with the national and the international partners has, to date, helped facilitate the organization of two regional forest genetic resources workshops, which are mentioned below. In these country-driven and action-oriented workshops, countries concerned assessed the status of their forest genetic resources and relations between forest genetic resources programmes and other sectoral programmes and overall development plans; defined national priorities and requirements in the conservation, enhancement and sustainable utilization of the forest genetic

---

[5] Conservation and Sustainable Utilization of Forest Genetic Resources. COFO-97/5. Thirteenth Session of the Committee on Forestry. FAO, Rome 10-13 March 1997. FAO, Rome.

[6] The full report of the 13th Session of the FAO Committee on Forestry is available at: http://www.fao.org/forestry/fo/statbod/cofo/cofo97e.htm

resources; identified target species and genetic resources activities of common interest; and determined priority areas for future collaboration among countries in the region.

The first of these workshops, "*Conservation, Management, Sustainable Utilization and Enhancement of Forest Genetic Resource",* was organized by FAO in collaboration with IPGRI and ICRAF, in Ouagadougou, Burkina Faso, in September 1998. Following in-country consultation among institutions and stakeholders, thirty-five participants from fifteen countries and six international, regional, bilateral and national agencies met to identify the main components of a sub-regional plan of action on forest genetic resources for the Sahelian and North-Sudanian zones of Africa. A synthesis document on the state of forest genetic resources in the sub-region, based on national reports prepared by 18 countries, provided the background for discussions and for the sub-regional action plan. When fully operational, IPGRI's SAFORGEN programme, mentioned above, will provide a useful platform to help implement a number of the research activities identified in the sub-regional forest genetic resources action plan.

As follow-up to recommendations made by Heads of Forestry of Pacific Island countries and territories, a sub-regional workshop on forest genetic resources was convened in April 1999 by the Australian funded South Pacific Regional Initiative on Forest Genetic Resources project (SPRIG), FAO, the Forestry Division of Samoa, the South Pacific Community/UNPD Pacific Islands Forests & Trees Support Programme, and the South Pacific Regional Environment Programme. The workshop, which was the first of its type in the region, was attended by fifteen Heads of Forestry or their representatives. A sub-regional action plan on forest genetic resources was prepared, complemented by a sub-regional synthesis on status and priorities in forest genetic resources, based on reports from countries and territories concerned.

A workshop on forest genetic resources, which will cover twelve countries of the Southern African Development Community (SADC), is scheduled to be held in June 2000 in Arusha, Tanzania, with support from FAO and international partners. The sub-regional forest genetic resources action plan which is expected to be developed, will complement and strengthen action presently coordinated by a joint coordination unit for the SADC countries, and will be underpinned by an existing, dynamic SADC network of national tree seed centres.

Similar worshops are planned to be held in other regions, pending identification of international, regional and bilateral partnerships, and the identification of necessary funding. Priority will be given to those regions in which institutional networking mechanisms already exist, as this will facilitate both the development and the implementation of action plans on forest genetic resources. It is hoped that, ultimately, work will stimulate joint efforts at the global level, in line with the UN Secretary-General's vision that the United Nations should increasingly serve as a catalyst for collective action, both among its Member States and between them and non-state actors, including the private sector and non-Governmental organizations[7].

The flexible, country-driven, step-by-step process towards coordinated action in forest genetic resources described above, was noted and welcomed by the XI World Forestry Congress in Antalya, Turkey (October 1997), and by the 4th International IUFRO/FAO Consultation on Forest Genetics and Tree Breeding in Beijing, China (August 1998). Action is in line with, and complements, that of other initiatives presently undertaken at national, regional and global levels, such as the elaboration of National Biodiversity Status and Action Plans under the Convention on Biological Diversity (CBD) and the exchange and sharing of technologies, know-how and information to be implemented through the Clearing-House Mechanism of the CBD.

Concluding Remarks

While some natural and human-induced losses in biological diversity over time are inevitable, the diversity between and within forest tree species can be maintained at an acceptable levels and managed by a wide range of human activities. The intensively managed commercial plantations for timber production and wilderness conservation areas represent some of the extreme alternatives in a wide range of forest genetic resources management options. All options provide benefits to the human populations and societies, while helping to maintain and develop genetic resources of proven or potential value to the present and future generations.

Long-term political commitment at national and local levels is a prerequisite for the implementation of sustainable genetic management programmes. The need for cooperation between a range of national agencies and local communities within a country stems from the multidisciplinary nature of genetic resource conservation, its close links and inter-dependency with other fields of forestry and development programmes in general, and the scope, vastness and urgency of the problem. Forest genetic resources considerations should increasingly be integrated with silvicultural and forest management practices, and they should also form part of national and local strategies for the maintenance of biological diversity in and outside protected areas. The genetic conservation considerations should also be an integral part of tree improvement and breeding programmes.

Since genetic resources do not respect political boundaries, national efforts in their conservation and wise use, which must at all times form the basic building blocks of regional and global strategies, can be usufully complemented by international support and coordination to ensure complementarity and global coverage of action. Joining efforts across national borders will make best use of scarce resources and will help fill the considerable information gaps in the forest resources field more quickly. While countries have sovereign rights over their genetic resources, and should ultimately decide upon action and programmes, it is important to recognize that coherent action at regional and global levels will facilitate solving the problems in the longer term.

Abstract

The current levels of genetic variation, and the distribution of that variability within and between tree populations is due to hundreds of millions of years of interaction between the different evolutionary factors, mutation, migration, recombination, genetic drift and natural selection. Artificial selection, breeding, and silviculture have so far had minor genetic effects on most tree species. The same evolutionary forces go on dynamically changing the genetics of the populations.

We should not strive to maintain the current status, but the goal of gene conservation, be it *in situ* or *ex situ* will need to be to allow these evolutionary processes to continue. The biological characteristics of species will to a large degree dictate the possible approaches to gene conservation .While there is much variation between species of trees in their genetic characteristics, most tree species are characterised by an outcrossing mating system and high levels of inbreeding depression. This means that care must be taken to control and monitor the potential level of inbreeding in breeding and production populations. Most species also have high level of variability in the genome in general, and in important quantitative traits, even if the distribution of this variability may differ between traits. When the gene pools of the species are actively managed through breeding or silviculture, it will be important to be aware of the influence of the different evolutionary factors. These principles will be illustrated with examples mostly from temperate tree species.

Keywords: Gene conservation, Population genetics, Forestry.

Introduction

The title of this presentation is very broad. The population genetics principles underlying conservation of genetic resources are similar for all organisms. However, the priorities of gene conservation are different for instance in rare and endangered species or economically important species. Likewise, different groups of organism vary in the basic features of their biology, and thus different aspects of the population genetic processes must be emphasised. Here I will deal with forest trees, and will not consider the forest ecosystem with all its other species. Gene conservation of forest trees, as of other plant species, has several aspects (Frankel et al. 1995).

It has been estimated that among the 100 000 described forest trees species more than a thousand are endagered through forest management activities and many for other reasons (World Conservation Monitoring Centre 1998). Forest geneticists should contribute to identifying conservation priorities among such species. This is a task where the methods of molecular systematics are likely to be quite helpful (Crozier 1997; Soltis and Gitzendanner 1999). Molecular systematics methods can serve to identify ways to conserve the maximum amount of genetic information with the limited resources available.

Likewise, we should be able to point ways to utilise in a genetically sustainable way the resources of natural populations (Koski 1998; Namkoong et al. 1996). It is a demanding task to generate criteria that will identify the proper management methods for genetic sustainability, and the rules need to be applied in different ways in different environments.

Further, the genetic resources of domesticated species need to be conserved for the purpose of their continued ability to adapt to environmental conditions, and for the immediate needs of tree breeding and production populations. I will consider those populations that are close to the natural populations, and maintain the original breeding structure.

Conservation biologists often discuss evolutionarily significant units (ESU) and management units (MU) (Moritz 1994).

Evolutionarily significant units are due to long term genetic divergence, while management units owe their distinctness to a shorter history and still can continue gene exchange. It is obvious that the above description of the tasks of forest conservation genetics has to deal with both ESUs and MUs.

Forest trees share many biological features. They are predominatly outcrossing organisms with often large population sizes. Conifers form an important group of species with shared phylogeny and biological similarities. In contrast, angiosperm trees are spread all over the phylogenetic tree.

In the following, I will discuss different evolutionary factors, trying to emphasise the special features of trees relative to other species that have been genetically studied.

Quantitative Traits and Molecular Markers

Variation of most traits of adaptive or economic importance is governed my multiple loci, even if the exact number is never known. Many of these have been and are influenced heavily by natural selection. Currently we gain much information about the genetics of species through molecular markers(Savolainen and Karhu 2000). As I discuss the influence of different evolutionary factors, it will be evident that there are limits to the information that markers can provide. It requires careful consideration to use that information properly to make inferences about the variability and distribution of quantitative traits (Lynch 1996).

Evolutionary Factors

A classical listing of evolutionary factors could include mutation, recombination, mating system, selection and genetic drift and founder effects. For a review of the factors, the readers are referred to any current population genetics tesxtbook, such as Hartl (2000) or Hedrick (2000). For the purposes of this review, I will emphasize also the role of history, which then comprises the joint action of an unknown set of factors.

Mutation

Mutation is responsible for all the genetic variation, but its effects are normally seen only in the long term. However, in selection experiments running for a few tens of generations, such as can be carried out in model organisms, part of the response can be attributed to mutation (Falconer and Mackay 1996; Lynch and Walsh 1998). Understanding mutation rates is relevant for gene conservation for several reasons. First, mutation rates partly govern the rate at which populations or species diverge into evolutionarily independent units. Second, characteristics of deleterious mutation influence the behaviour of small populations where inbreeding can be high. Third, mutation rates influence the rate at which variation is replenished after genetic bottlenecks (Nei et al. 1975).

Direct estimates of mutation rate are not easily obtained, and they are only available for model organisms. However, the theory of molecular evolution predicts that at neutral sites of the genome, the rate of nucleotide substitution between two species will equal the mutation rate. This simple feature can be used to estimate the rate of mutation by comparing the divergence at the nucleotide level between species. Few such quantitative comparisons are available. They all show that compared to many other organisms, trees evolve slowly, and thus the mutation rates at individual loci per year are low. As most mutations are likely to occur at DNA replication, the per generation mutation rate in long lived species should be higher. A similar result seems to hold for both angiosperms (Frascaria et al. 1993) and conifers (Mikkonen, Dvornik, Sirviö, Savolainen, unpublished). In fact, the initial results on the low estimates of mutation rates are somewhat surprising, given the high levels of variation that have been found in many trees (Hamrick and Godt 1996).

In many cases, the parameter of interest may be the mutation rate per character or per genome. For instance, the genome wide mutation rate to deleterious genes governs the dynamics of inbreeding depression (Charlesworth and Charlesworth 1987; Lande et al. 1994). The level of inbreeding depression in conifers suggests that the genome wide mutation rates for deleterious genes are many times higher than in most other organims (Klekowski 1988; Koelewijn et al. 1999; Lande et al. 1994).

The rate of mutation is just one characteristic of deleterious mutation. Another issue of significance for conservation genetics is the size of the mutational effects, and their effect in heterozygotes. These two parameters can have a major influence on the fate of mutations in small populations (Hedrick 1994). These are difficult to measure, and there is no consensus on the size of effects even for model organisms (Keightley and Caballero 1997; Lynch et al. 1999). Unfortunately, no results on the size distribution of deleterious mutational effects are available for trees.

Recombination

New combinations of genetic factors can only occur at meiosis in double heterozygotes. The effect of recombination is to generate new combinations, but also to break up old combinations of alleles at different loci. This results in independent evolution of different genes. Unless there is some strong force, such as selection based on interactions between the two loci, alleles at the two loci will behave independently in a statistical sense. Alternatively stated, there will be no linkage disequilibrium between the loci. The potential for recombination is strongest where double hererozygotes are common and crossing over occurs frequently. Most, if not all trees are predominatly outcrossing. They also often have large effective population sizes (large numbers of trees participate in reproduction). Many genomes are known to be genetically large (with pine genomes about 2000 cM Sewell et al. (e.g. 1999). Tree population generate very efficiently novel combinations of alleles at different loci. Some rounds of recombination can regenerate allelic combinations efficiently, as long as the variation at individual loci is present.

Mating system

Many reviews show that the outcrossing versus selfing mating system is the most powerful single determinant of the level of variation in trees (Hamrick et al. 1992; Hamrick and Godt 1996). The average level of variation at marker loci for selfing plants is 0.12, for outcrossers 0.16, measured as expected heterozygosity at individual loci. The level of differentiation of populations for outcrossers is on average about 0.1, whereas for selfers it is 0.5, measured as F_{ST} (Hamrick and Godt 1996). Most trees are predominant outcrossers. Some eucalypts have rather high partial selfing (Moran 1992). The outcrossing rates of pines range from rare intermediate outcrossing rates of about 0.5 in oceanic islands of *Pinus radiata* (Savolainen, Moran and Bell, unpublished) to nearly complete outcrossing in some populations of *Pinus sylvestris* (Muona and Harju 1989). Fully outcrossing species have their genotypic frequencies in Hardy-Weinberg equilibrium. When there is some selfing, the genotypic frequencies at the seed stage deviate, such that there is an excess of homozygous genotypes (e.g.Yazdani et al. 1985). In many cases, the genotypes due to selfing are eliminated by inbreeding depression before the adult stage, and the adult genotypic frequencies are again in Hardy-Weinberg equilibrium.

Temperate and boreal trees, both conifers and deciduous species, are mostly wind pollinated. Earlier studies have shown that the genotypic distribution of such species is rather robust to many kinds of environmental change. For instance, changes in density following harvesting do not seem to have a major influence of reducing outcrossing (Neale and Adams 1985; Savolainen and Kärkkäinen 1992). However, many tropical species are animal pollinated, and in such cases the maintenance of the pollination system may be much more vulnerable to environmental changes that threaten the pollinators, even if they would not directly influence the trees (Namkoong et al. 1996). Lack of pollinators could in the extreme case lead to reproductive failure and reduced population size, as has been shown in mistletoes (Robertson et al. 1999), but it could also have more subtle genetic consequences. Fewer pollinators, perhaps in a reduced density of trees could lead under some circumstances lead to an increased level of self-fertilization, if the species is self-compatible. It could also lead to a much reduced effective population size.

Migration

Population geneticists prefer to define in detail their migration model, because the results depend on these specifications (e.g. Hedrick 2000). Classical models include the island model, where all subpopulations of equal size are assumed to be exchanging genes at an equal rate with all other populations. A more realistic version of this is the stepping stone model, where gene exchange is more likely between adjacent than more remote populations. A model relevant for species with very large distributions, such as Scots pine, would be an isolation by distance model, where gene exchange is limited between parts of the population. A more recent development is to consider migration in an ecological context, where populations can go extinct and the sites can be recolonised (a metapopulation) (e.g. Barton and Whitlock 1997). The genetic differentiation of populations for neutral genes depends on the balance of migration and genetic drift. Many wind pollinated trees have very low levels of differentiation (e.g. Muona 1990), mainly because of very efficient pollen flow (Koski 1970). The effect of much less gene flow through seeds is seen when differentiation of maternally inherited angiosperm chloroplast DNA is considered. For instance in European oaks, there is a very high level of divergence in cpDNA markers, whereas the nuclear markers are nearly uniform(Petit et al. 1997; Zanetto and Kremer 1995)].

In contrast, paternally inherited cpDNA markers of conifers are not quite as differentiated. The lowest level of divergence is expected when genes migrate through both seeds and pollen (Ennos 1994). Northern conifers often have very low level of differentiation at neutral markers, such as has been found in Scots pine (Karhu et al. 1996; Muona and Harju 1989), whereas animal pollinated e.g. *Acacia*s are be much more diverged (Butcher et al. 1998).

Genetic Drift

Genetic drift occurs in small populations, where the sampling effect can overcome the influence of other evolutionary factors. Genetic drift results in loss of variation within populations, and an increase in the differentiation of isolated subpopulations (e.g. Falconer and Mackay 1996). Overall, there will be a large decrease in the heterozygosity of the population. For a discussion of small population phenomena in a forest genetics perspective, (see Savolainen and Kuittinen 2000). The effects of drift cumulate over generations. In each generation, the variability, measured by average heterozygosity, is reduced by ($1/2N_e$). Thus, even a very small bottleneck for one generation does not reduce the average heterozygosity by very much. However, if the bottleneck is extended, then the effects are large even on average heterozygosity. Average heterozygosity is mainly influenced by common alleles, rare alleles make only a small contribution. However, bottlenecks have an immediate effect on rare alleles. The number of alleles is immediately reduced . After the bottlenceck, mutations start recovering variability. The dynamics of this process vary between different kinds of genes (Nei et al. 1975). The number of alleles recovers more rapidly than the average heterozygosity. Recovery of quantitative variation may be faster than variability at individual loci, because so many loci may contribute to this type of variation.

Genetic drift will be of little concern in economically important species, where populations are by definition large. However, founder effects refer to small population sizes when new populations arise e.g. through colonisation of a new area by a small number of individuals. These bottlenecks are often of short duration, but may have consequences for the genetic structure. Such effects could also be important if a breeding program is started with a very small number of individuals, as has repeatedly happened in the history of cultivated plants.

Natural Selection

Many of the evolutionary forces are expected to influence all genes equally. All loci have in principle the same effective population size, they migrate together in the same pollen grains or seeds. Selection may be very slight on large parts of the genome, such as in the nonfunctional parts of the DNA, and probably at introns, and at the nucleotide sites that do not change the amino acid in the protein

(Kimura 1983). In these areas, the patterns of genetic variation are likely to be governed by the balance of mutation, drift and migration. Natural selection, can however, give rise to a very different pattern of variation. The extensive provenance variation of pines is well documented in both Europe and North America. Traits related to adaptation to the local growing conditions have much variation between populations, such as cold tolerance in Finnish populations of Scots pine (Aho 1994; Hurme et al. 1997), or the timing of vegetative growth in the same populations (Hurme et al. 1997; Mikola 1982).

Similar strong differentiation has been found in several North American species, such as Ponderosa pine (Rehfeldt 1990). In some cases this genetic variation has been quantified as Fst for quantitative traits (or Qst), which is related to the analogous measure on single locus variation (see Prout and Barker 1993). In all trees studied so far, the quantitative trait Fst values have been considerably higher than at single, presumably neutral loci (Yang et al. 1996), and comparable work in Scots pine (Savolainen, Hurme, Repo, in prep.). For other species there may not be exactly similar quantitative resuls available, but the main conclusion remains the same. (Table 1)

Implication for Population Genetics of Trees

Inbreeding depression is high

Individuals due to mating between related individuals or selfs have low viability and fertility. This is due to homozygosity of deleterious alleles. Trees seem to carry many deleterious alleles at a large number of loci. Numerous studies have shown that most tree species have reduced viability and growth after selfing or other close inbreeding (reviewed in Williams and Savolainen 1996). This feature must be considered both in tree breeding and in the design of conservation populations.In natural populations, inbreeding may lower the viability of populations (Saccheri et al. 1998).

Genetic Equilibria are often Reached Slowly

Current population sizes, mutation rates and selection can account for many aspects of the amount and distribution of genetic variation of trees.However, empirical studies have shown that species with similar life histories and approximately similar current distribution areas (and hence effective population sizes) can vary much in the level of diversity.

The genus *Acacia* provides some good examples (Table 2). The average expected heterozygosity within populations ranges from about 0.02 in *Acacia mangium* to about 0.30 in *Acacia melanoxylon*, using the same set of marker genes (Moran et al. 1989). In fact, later work has shown that the level of variation found within individual populations of *A. mangium* is quite variable (Butcher et al. 1998). Similar findings have been made in the genus *Pinus*, where *P. sylvestris* is among the most highly variable species, and a rather close relative, *P. resinosa* is nearly devoid of variation at the isozyme loci (Fowler and Morris 1977) and most of the DNA markers studied (Mosseler et al. 1992). These markers behave as neutral markers, whose levels of variability are in principle governed by mutation rate and the genetically effective population size (= $4N_e$). Note that the genetic consequences of a long period of a reduced effective population size take very long to overcome. There is no reason to suspect that this anatomically similar plants would have very different mutation rates. Thus, we can only search for explanations in the history of the species, and conclude that after a glaciation related bottleneck, *P. resinosa* has not yet reached its equilibrium level of diversity. The implication for conservation biology is that even between closely related species, we cannot for certain predict the standing levels of variation, many species may be far from the equilibrium.

Table 1. Comparison of Fst statistics for marker loci and quantitative traits

Species	Average Fst for markers	Quantitative trait	Fst	Reference
Pinus contorta	0.02	Height	0.19 (largest)	Yang et al. (1998)
Pinus sylvestris	0.02	Bud set date	0.82	Savolainen et al. (in prep).
Quercus petraea	0.02	Bud burst	0.33 (assuming h^2 is 0.30)	Kremer et al. (1997)

Table 2. Genetic diversities at isozyme loci in *Acacia* species, following Moran (Moran et al. 1989).

Species	Expected heterozygosity
A. auriculiformis	0.084
A. crassicarpa	0.081
A. dealbata	0.085
A. decurrens	0.156
A. mearnsii	0.206
A. mangium	0.017
A. melanoxylon	0.300

Note that the levels of diversity found depend on what parts of the distribution, of the genome, are sampled. In a later study Khasa et al. (1994) found a somewhat higher diversity for *A. mangium*, and later work with RFLP markers also found more variation (Butcher et al. 1998).

Populations are Differentiated for Historical Reasons

Above I pointed to cases where natural selection has resulted in large genetic differences between populations. However, genetic differences will accumulate between isolated species or populations just due to mutation accumulation. This seems to be quite a slow process e.g. in conifers. Species of the genus Pinus diverged 100 MYA seem as diverged as some Brassicaceous species that have diverged less than 10 MYA((Savolainen et al. 2000, Mikkonen, Dvornik, Sirviö, Savolainen, in prep.). Such isolated populations can have a high level of genetic divergence overall in the genome. Many examples are provided by the glacial isolation and post glacial migration of trees. In Finland, the eastern and western populations of *Quercus robur* on the south coast may represent different colonizations (Ferris et al. 1998). Similarly, Petit et al. (1997) have recognised different glacial histories in other oak populations of Europe.

Another well documented case is that of Norway spruce, where the isozymes are slightly differentiated between populations, and still carry the footprints of the different refugia, in similar areas as the oaks (Lagercrantz and Ryman 1990). In this case, part of the variation in quantitative traits follows the differentiation of isozymes, and it is likely also a reflection of the historical patterns.

Such populations represent evolutionarily significant units, and will merit independent conservation, even if there are no apparent adaptational differences.

Trees have a Robust Genetic System

As described above, the genetic and life history characteristics make trees rather robust and resilient to genetic change. Many studies have found that different management practices have not had serious effects on the main aspects of genetic structure. This should be especially true if we consider natural regeneration after recombination, outcrossing and pollen migration have influenced the genetic structure of the next generation. Recently, Rajora et al. (2000) compared microsatellite allele distributions between a set of about 100 old growth trees, and those remaining after about 75 % of the trees were cut. They concluded that the potential for adaptation was seriously endangered by the reduced number of alleles. This conclusion seems quite exaggerated. It is self evident that highly polymorphic loci will be lost. The question can be answered only after studying the regenerated stand (which they did not do). Their own data suggest that there will be gene flow from other areas to replenish numbers of alleles, and recombination will provide new combinations of existing alleles. Further, microsatellites in trees have not been shown to be related to any functionally significant variation. The real issue is the genetic structure after regeneration. In fact, perturbing forest tree population may often have more significant consequences for other organisms than for the genetic structure of tree populations.

Implications for Gene Conservations

Below I present some general conclusions that can be drawn from considering the goals of conservation of forest gene resources and the evolutionary and life history characteristics of trees.

It is in general not possible to relate variability at neutral marker loci directly to population viability (Holsinger 1996). However, changes in variability of species may carry some risks.

It is important to identify the conservation needs with respect to the threatened tree species. Molecular population genetics and systematics can aid effciently in these goals.

Trees evolve slowly compared to many other groups of organisms. Nevertheless, during isolation genetically divergent units within species have evolved, and they merit individual consideration

Adaptive differences, such as those found between provenances of conifers from different latitudes can evolve rather rapidly due to strong selection. Their conservation is of extreme importance for immediate management concerns.

Many forest trees have a robust genetic structure. It is not necessary to conserve individual multilocus genotypes. Recombination, outcrossing and gene flow will efficiently generate new combinations.

Gene reserve populations help to maintain the genetic resources. However, in the domesticated and exploited species, also other populations, at different levels of management, can be managed in ways that can maintain the evolutionary processes. They can also contribute to the maintenance of the genetic resources.

Overall, the main conclusion is that conserving forest gene resources means maintaining the dynamic processess that generate and maintain it.

Abstract

Most forests must be used to satisfy the requirements of a growing human population wanting a better life. Forest management and silviculture affect gene diversity, positively or negatively, but almost all diversity may be maintained through a suitable combination of conservation areas and managed production forests. As long as due consideration is given to regeneration, most forms of harvesting have a limited effect on long-term diversity.

Regeneration is the key silviculture activity that determines the diversity of future forests and their capacity for sustainable production. Both natural regeneration and cultivation can produce new stands with acceptable diversity. Well-planned and implemented tree improvement helps maintain diversity and at the same time can provide more productive reforestation materials. Diversity patterns typically differ between production forests and conservation areas. Production forests have a simpler structure, less species and age class variation within stands. Much of the variation instead is among stands.

Many foresters do not fully understand the value of the genetic resources they handle. The scientific community must take the responsibility for making foresters more aware.

Keywords: Silviculture, Management, Genetics, Diversity, Regeneration

Introduction

Genetic diversity refers to the phenomenon that within a species all individuals are not identical by inheritance and consequently respond in different ways to their environment. The variation among individuals is not only genetic. Many characteristics like branchiness, stem form and diameter are strongly affected by the environment, for instance expressed as site fertility or stand density. In uneven aged stands older trees are typically taller and bear more fruit. In most cases one needs sophisticated genetic tests and analyses are needed to separate the effects of genetic differences from those caused by environmental factors.

In all forestry activities, regeneration in particular, the maintenance of genic (allelic) variations and systems of recombination should be considered. The desire of many conservationists to preserve all old trees (genotypes) of a forest is not the best option for future generations. Even trees get old and die, and their environment is exposed to catastrophic environmental changes, e.g. forest fires or flooding. Changes in species composition and genetic structures of protected areas depend on stochastic events and genetic processes. Through dynamic genetic improvement and gene conservation the genotypic variation can be produced as long as alleles are not lost from the population's gene pool. Active forest management with due consideration of genetic aspects is at least as effective a system for maintaining genetic diversity as increasing the volume of protected areas. This in no way denies the value of protected areas in ecosystem conservation.

Increasing human populations wanting improved living conditions put greater than ever pressure on the forests. More and more wood is needed for fuel and as industrial raw material. At the same time there is a strong call for setting land aside as reserves, where natural processes can go on with a minimum of human influence, or for recreational use. To make possible the production of more and more wood for human consumption at the same time as we want to set aside large areas for non-productive use, the productivity of the land used for wood production must be as high as possible. Tree breeding is probably, from the environment's point of view, the gentlest way we have of accomplishing this.

It is a fact that most forestry measures, like exploitation and regeneration activities, affect diversity. With a wise management it should, however, be possible to combine the use of trees for human benefits with the maintenance of genetic diversity needed for the long-term health and stable functioning of the forests.

The aim of this paper is to discuss the impact which various forest management and silvicultural activities may have on the genetic diversity of future tree generations. Relevant research on this topic is sporadic and scant, so we will have to present many hypotheses and urgent research needs.

It is crucial, however, to understand that exploitation of timber without concern for regeneration and sustainability has nothing to do with proper forest management and of course can cause large damage to genetic diversity. In situations where such activities go on, new legislation, setting up of supervising organisations, etc. must be considered. This situation falls outside the scope of this paper, however.

General

Genetic variation in adaptive traits is advantageous to tree species. It gives them the possibility to evolve and adapt to changes in the environment. The actual value of variability in morphological or so called neutral traits is not known, but can hardly be seen as disadvantageous.

Forest trees mainly exist as wild populations. Most species show a wide genetic diversity, which so far has not been greatly changed by man. The wide genetic diversity of most species of forest trees has been shown in field tests for adaptive traits and in recent years, through various forms of isozyme and DNA analyses, on molecular levels. The patterns of variability are important and studies have shown that genetic variation exists on several levels:

1. Variation among species
2. Geographic (provenance) variation within species
3. Variation among sites within provenances
4. Variation among individual trees within stands.

Conkle (1980) found that conifers rank among the most variable plants studied by the use of isozymes. As always there are exceptions. There are some essentially monomorphic species like *Pinus torreyana* and *Pinus resinosa* (Ledig and Conkle 1983; Fowler and Morris 1977). Certainly most hardwood species are also extremely variable.

In general, provenance and tree-to-tree differences make up the majority of the genetic variation within tree species in natural stands. Adaptive traits of major species with large continuous distribution show clinal patterns of variation. That is, the change in gene frequencies is gradual and proportional to gradients of respective ecological factors. So called neutral marker characters display less geographical differentiation. In a study of cone morphology in *Pinus* sylvestris (Koski 1970) 70-80 percent of the total phenotypic variance was observed to be within population, and this in a material from 40° N (Turkey) to 70° N (Finland). Often, the variation among trees in a stand itself can make up most of the total genetic variation within large regions. In terms of isozyme variation Muona and Harju (1989) reported that more than 98 percent of the overall variation in central Finland *Pinus sylvestris* was within stand.

This paper mainly discusses the direct effects of forest management and silviculture on tree species. It should, however, be emphasised that even if a species is not directly subject to forest operations, such operations may well have an indirect impact on the species. An insect or bat pollinated species may suffer, if the management operations somehow harm the pollinator species.

Appropriate forest management comprises all the activities that lead to sustainable production under ecologically acceptable conditions. Management has the fundamental feature that it deals not with single stands but numbers of stands over entire landscapes. It is a process that works over long times, at least in temperate forestry reaching 100 or more years. An almost unavoidable effect of forest management is a simplification of the structure of each individual stand. Age-class and species variation is reduced. But on a larger scale this is not necessarily critical for the genetic diversity. All stands in the landscape are normally not cut at the same time. On a landscape level the ecosystems vary considerably and so must the silvicultural systems do as well. Over a rotation age, in most forests the goals for forestry tend to change, as do standard forestry practices. In most cases neither a single management system nor a single regeneration material will be used on a landscape scale. Stands on different sites or of different age will be genetically different from each other. All variation does not have to be represented in each stand.

While there is a choice of methods to study and evaluate the effects of forestry activities on the genetic diversity within species, there are also ways to study the effects on species mixture compared to pure stands. Foresters get into problems when they have to study these two phenomena simultaneously. What is the relative value to overall tree genetic diversity of adding a new species compared to that of increasing within species diversity? We have no good suggestions.

The following discussion will concentrate on the effects of harvesting, regeneration and domestication on the genetic diversity of tree species. It must be emphasised, however, that almost any management activity implemented in the forests will affect the genetic diversity of the trees and stands. Drainage operations, often necessary before a harvest, can radically change the environment so entire ecosystems are destroyed or significantly modified. Fertilisation can change the species composition directly or indirectly, for instance by affecting the conditions of critical symbionts like mycorrhizae.

The paper does not in depth consider the situation in high yielding industrial tree plantations, often established with exotics and on non-forested lands. This is something that should be seen as a form of "agriculture" or tree farming rather than sustainable forestry.

Harvesting

Harvesting may cause the most dramatic and lasting effects on the genetic diversity of the forests. Certainly a clear-cutting followed by no regeneration activities would be disastrous for tree genetic diversity. But this is not forest management, it is simply a mining of a biological resource. In terms of proper forest management, harvesting is always followed by regeneration. The mode of regeneration, whether natural or artificial, has a fundamental influence on the way harvesting operations should be carried out. In natural regeneration, prerequisites of sufficient flowering and mating must be met. In artificial regeneration, a preceding harvest can be total, but a reforestation material of sufficient variability must be available.

The effects of thinning within a species can be expected to be dependent on the type of thinning. If a thinning from above leads to the removal of superior genotypes at a young age, before they have been able to pass on their genes, this would have negative effects.

An example of thinning regimes affecting the genetic composition of the remaining stand can be found in a study of a 70 years old *Picea abies* stand in Germany (Hosius 1993). Parts of the stand were thinned from above and parts from below and the trees remaining after the treatments were then assessed for variation at 5 allozyme loci. The results were not consistent over all the loci, but still indicate that the two thinning forms resulted in changes of the genetic composition of the remaining stands.

In mixed stands, it goes without saying that a thinning operation can lead to dramatic changes in species composition of thinned and non-thinned areas. One of the primary aims of thinning is after all to concentrate the growth to the best trees of the economically desirable species.

On larger harvesting areas certain land should be left with untouched forest. This can often be land which is, for example, too steep for easy logging or on wet areas along streams or lakes.

Regeneration

Forest managers often have a choice of methods with which to regenerate a stand or tree population after or in connection to the harvest. All methods will influence on the genetic diversity of the new stand in one way or another.

The choice of regeneration methods is not always wide. Species with short-lived recalcitrant seed are certainly hard to handle in plantations, because of the logistical problems in collecting, transporting and processing the seed in time to seed them in a nursery while the seed is still viable. This is a major problem with certain important tropical species like the dipterocarps. Natural regeneration is often not possible or desirable. The quality of the existing stand may be poor, a change of species desirable, or the circumstances too harsh for seed germination or seedling development. Many commercially important tropical hardwoods do not germinate and grow well in full light, but require an over-storey for a number of years. They would certainly not do well as plantation species after a clear-cut. With more and more genetically improved regeneration materials and expectations for higher yields the interest in using artificial regeneration is also increasing.

Today the importance of using adapted seed sources is well understood. This is particularly true for species of major economic importance. For them there is also sufficient knowledge about how to obtain satisfactory regeneration. The future existence of these species is rarely at risk. The situation of especially rare non-commercial species is much more difficult. They are often not the target of a harvest, but incidental felling or changes in the environment caused by the harvest of other trees may leave conditions under which the species cannot survive or reproduce. Even when the problem is understood, the lack of basic information about the silvicultural requirements of many minor species often makes rescue attempts in the form of for instance enrichment planting fail. Marginal population and rare species with no commercial value are the most sensitive to the negative effects of harvesting.

Natural Regeneration

Natural regeneration is based on the reproductive potential of the stand itself, as a rule on the seed crop. The number of seed and seedlings is normally huge, up to millions per hectare as reported already in early literature (Lönnroth 1925). At germination and seedling stages mortality is predominantly random. At later stages stabilising selection eliminates many extreme genotypes from the population.

The diversity and quality of the new regeneration will largely depend on the trees left by the forester to take care of the regeneration. The importance of using local seed sources and having natural selection working on a large number of seed should not be given too much importance. As already pointed out, in most species the within stand genetic diversity is very large, so adaptation in most cases cannot be very precise. Random effects probably have a much stronger influence than natural selection on which seed will grow and develop and pass their genes on to coming generations. Natural selection works very slowly over a number of generations, and it alters gene frequencies only if the selection pressure, i.e. the environment, has changed.

Relatedness is common in natural populations of some species, often occurring in neighbourhood patterns (Coles and Fowler 1976). Using related trees as parents in natural regeneration will lead to increased relatedness among the offspring, reduce its genetic diversity and at worst cause inbreeding effects.

The changes in tree genetics following a harvest operation can be studied in terms of selection intensity. Harvesting of a few individuals trees in a wind pollinated pine forest should have little or no effect on the future of the stand. The intensity of selection is very low and the trees that remain to reproduce the new stand will in all probability be able to regenerate a new generation very similar to that of an untouched stand. This can perhaps be understood by considering the effects of plus tree selection, where progeny tests have shown that very high selection intensity is required before any significant effects, at least on growth traits, are reached.

Harvesting and most silvicultural operations, affect the composition of the forests, typically simplify species and age structures and change the conditions for selection. Opening up a stand will obviously create problems for climax species and favour those that regenerate well in more light. If exploitation is intensive it can lead to species being almost eradicated from large areas. In this situation remaining isolated trees or small populations of trees may not be able to maintain sufficient variation for natural evolution. Genes or adaptive gene complexes will be permanently lost. High-grading, the removal of all commercially interesting trees of a species and leaving the worst ones to regenerate the stand will of course also have a negative dysgenic impact. *Cedrus libani* can serve as an example. In the past generation after generation of harvesting of the best stems without consideration for the future of the species left many populations of this wonderful species severely degraded. Fortunately, good cedar stands still exist at high elevations in Turkey.

Wickneswari et al. (2000) reported on the impact of logging in two forests in peninsular Malaysia. Single logging events in lowland dipterocarp forest in the 1950's did not cause adverse changes in genetic diversity of timber or non-timber species. On the other hand, immediate loss in genetic diversity was detected among adolescent and non-timber trees in a ridge forest after a single logging in 1996. The immediate losses in genetic diversity may be compensated for by an existing good seed or seedling bank in the stand or by migration from surrounding undisturbed forest areas.

Shelterwood harvesting is a partial cutting system, in many ways resembling thinning, but intended to encourage regeneration. Studies on shelterwood systems in *Pseudotsuga menziesii* in Oregon failed to find any clear differences in isozyme composition between the original stands and the regeneration following shelterwood cutting (Neale 1985). The explanations suggested for the similarity between the original stand and the offspring were high heterozygocity in the stands, high rates of outcrossing and a large effective population size in the parent generation.

Seed tree regeneration can be controversial from the point of view of genetic diversity. The problem basically comes from the fact that only few trees, , are left to take care of the regeneration, which samples poorly the variability available in the original stand. Studies on *Pinus sylvestris* in Sweden clearly demonstrate the importance of the density and numbers of seed trees left on the site. In a stand with 122 seed trees left per hectare the rate of selfing was 12 % rate whereas a stand with only 18 trees left per hectare had twice as much selfing (Yazdani *et al.* 1985; Yazdani and Lindgren 1992). In the stand with the low number of seed trees much of the regeneration did not come from the seed trees on the regeneration area but were thought to be from seedlings on the ground before the cutting or to be the result of immigrant pollen or seed.

In evaluating natural regeneration with seed trees, genetic factors like rate of inbreeding, selection pressure and gene flow must be considered together with other silvicultural issues. For example, the share of the overall regeneration that arises from the seed trees must be compared to that which has other origin, like small seed or small trees already existing under the original stand or starting from seed somehow transported onto the regeneration area from outside stands. Volunteers like this provide valuable added genetic diversity (Ackzell and Lindgren 1992).

In a Canadian study (Buchert *et al.* 1997) of seed tree regeneration in *Pinus strobus*, 54 loci were analysed in all seed producing trees. The study was carried out in very small stands, 0.7 ha, with some 100 seed producing trees before the harvest. Some 75 % of the trees were cut, leaving 25 seed trees. Certain effects were dramatic. 80 % of the rare alleles ($p<0.01$) were lost and allelic richness reduced by 25 %. Not all of this should be attributed to the effects of selection, however. As Mullin and Bertrand (1998) point out, in small population like the one studied, simply by sampling 25 trees out of 100, the probability of losing a gene with an original frequency in the population of $p=0.01$ is about 57 %. If instead 250 trees out of 1000 had been sampled, the loss would have been much lower. Buchert's *et al.* study found very little change in heterozygocity and no losses of common alleles ($p>0.05$). In a situation where a seed tree stand is surrounded by more trees of the same species, especially in wind pollinated species like pines, gene flow into the population from the surrounding stands can be expected to bring back many of the rare alleles.

Artificial Regeneration

Forest cultivation, through planting or direct seeding, has been successfully used for many tree generations in many species. It gives the forester a chance to select exactly the species and sources of the species he wants to use, whether they existed naturally on the forestation site or not. Artificial regeneration also lets foresters restore or introduce a tree cover to areas where forests have been destroyed or where forests have not existed naturally. For economical and silvicultural reasons, artificial regeneration is normally established by single species. Mixed stands will normally be the result only when there already exists wild seedlings or seed of other species on the planting site or other species naturally migrate into the plantation. This development is common in artificial regenerations of coniferous stands; broad-leaf species appear in abundance. According to most current silviculture instructions the species mixes should be favoured, which is enhances by the above mentioned spontaneous immigration.

Artificial regeneration also provides the opportunity to create new forests in situations where the environment has changed so rapidly that the local trees no longer are well adapted. This may well become very important with the possible dramatic climate changes the forests may have to face as the result of expected global warming. Without getting deeply into the question of exotics in forest plantations, it should be emphasised that there is little proof of local sources being better adapted to a changing environment than introduced ones (Mátyás 1995).

A major problem with plantations, especially in the tropics, is that there is sufficient experience in and knowledge about establishing plantations with a limited number of the existing species only. For the method to become more general, much more research by local foresters will be required.

Throughout seedling production genetic diversity among the seedlings can be lost. El-Kassaby (2000) describes how for example seed storage, extraction, seeding pattern and culling of seedlings all can lead to some, largely unrecognised, losses.

Modern nursery technology has developed to the point that a very high percentage of the seeds develop into a seedling. Using *Pinus sylvestris* in northern Sweden as an example, it only takes some 2500 seed to produce enough containerised seedlings in greenhouse nurseries to reforest one hectare with some 2000 seedlings/ha. To produce the same amount of seedlings of a bare-root stock on free-land nurseries, a slightly tougher environment, three to four times as a many seed are required. To produce an acceptable regeneration on a suitable site through direct seeding, to get an approximation of the number of seed that could re-establish the forest naturally, some 25-30 times as many seed are required. Some people have seen here a potential risk. The forest environment would select the very strongest of the seedlings from the multitude of seed in natural regenerated or direct seeded areas, whereas many of the seedlings produced in the favourable green-house environment would fail when they are planted in the harsh reality of the clear-cuts.

In a comparative study (Ackzell 1992, 1993; Ackzell and Lindgren 1994) looked into this but failed to show any negative results of the nursery environment. The study compared natural regeneration, high density sowing (50000 seeds/ha), and planting with *Pinus sylvestris* in Sweden. No positive effects were detected which could be attributed to higher selection or mortality among the seedlings produced from seed, either those from natural regeneration or direct seeding. The study also included comparisons of local seed and seed from two seed orchards. There was no indication of the local seed being better adapted than either of the orchard seed lots.

In artificial regeneration, the selection of seed source is of fundamental importance. The quality of the reproductive material determines, throughout the rotation, the survival, growth performance, and genetic diversity of the stand.

The adaptation of indigenous stands is inherent, but not always perfect. Thus, a local indigenous seed source is usually a safe choice. However, strictly local seed is not always available, and the concept of local seed needs to be defined. As mentioned earlier, studies on the genetic structure of many forest trees consistently show that genetic differentiation is not very fine grained. Therefore a local seed refers to seed from ecologically uniform area, i.e. what is often called a seed zone, breeding area, or region of provenance. It is impossible to give any universal geographic dimension, since e.g. both latitude and altitude, among other factors, will affect the size.

Non-local origins are sometimes more productive or otherwise superior to local ones. The justification of non-local origin must be based on empirical knowledge from provenance studies in the region of interest.

Domestication

Domestication is the process through which "wild" plants, after repeated selection and breeding operations, each modifying the genetic set-up of the trees, leads to cultivars and varieties, which survive in cultivation and under consistent control. Genetically improved reforestation materials are still very close to their wild relatives and far from domesticated crop plants like the cereals or potato.

There is a widespread opinion that tree breeding in combination with artificial regeneration has a negative effect on genetic diversity in the forests and often can lead to loss of adaptation. But, the opposite is closer to the truth. A phenotypic selection of potential parent trees to create a founder population is the normal first step in a breeding program. El-Kassaby (2000) summarises the results of a number of studies comparing heterozygocity measures between natural populations of 5 boreal conifer species and those found in seed orchards of the same species. His conclusion is that the amount of genetic variation found in natural populations was retained or increased during the phenotypic selection. There are many examples from other species to support this. Plus tree selection does not necessarily lead to reduced genetic variability and breeding populations at least as variable as natural ones can be formed.

Breeders also know how to maintain this diversity. In most breeding programmes a careful separation is made between long term breeding populations and short term multiplication populations. The long term breeding populations are typically managed to provide a potential for long term gains and a large gene pool diversity. So, requirements on trees to be included in the breeding population can be quite separate from those wanted in trees planted today. A typical tree improvement programme handles its breeding population by carefully controlling the number of selected parent trees, dividing them into a number of sub-populations kept separate and bred in ways which minimise the build-up of relatedness (Namkoong *et al.* 1988). The genetic variance of a well-composed set of breeding populations can be larger than the genetic variability of a single large population (Koshy *et al.*1998) and definitely larger than populations in nature, with uncontrolled pollination and seed dispersal. The described form of breeding programme, with separate sub-populations bred to minimise the build-up of relatedness, is probably the best form of *ex situ* gene conservation available.

From the breeding population is then selected a multiplication population, typically in the form of seed-orchards, in which seed of a number of selected trees, having the properties required for production forestry in a certain area or region, are mass produced for seedling production or direct seeding.

In this way tree breeders can provide for immediate needs in today's forestry and provide a potential to satisfy future requirements. It also opens up possibilities to prepare for expected changes in the environment. It is already today possible to prepare for global warming, by testing our trees in environments with a climate like what is expected as the result from environmental warming. A multiplication population can then be ready to produce seed for trees that will thrive in the expected warmer climate of an expected future. The method is already included in the Swedish breeding strategies for *Picea abies* and *Pinus sylvestris* (Danell 1993).

Seed orchards are set up with a selected number of trees from the breeding populations, the trees that most completely carry the characteristics wanted by today's foresters. El-Kassaby and Ritland (1995 a,b) carried out a study following the genetic variability, in terms of heterozygocity parameters, through to the process of a breeding program in *Pseudotsuga menziesii*. The study compared the original natural population, and then the breeding and production populations selected from it. The study also analysed a number of first and second-generation seed orchards. The findings were, that phenotypic selection can capture most of the genetic diversity in the species natural range and that breeding and production populations are as variable as the natural ones. The comparison of 12 first and 3 second generation orchards found very small differences between the two groups. This indicates that the variation will remain relatively stable over plantation generations.

On a single stand basis, a plantation from orchard seed is normally at least as variable as a natural stand. But, on a landscape level, widely used seed from a large productive orchard could well lead to a reduced genetic diversity in a species. Much works against this, however. Not all regeneration is from planting and many species are normally used. Orchards also have a limited life span often much shorter than a rotation, so over a length of time seed will come from different orchards.

Recent research, e.g. Rosvall 1999, demonstrates how breeding for increased productivity can be carried out for many generations at a very limited cost in the form of loss of diversity.

Clonal Forestry

Foresters working with artificial regeneration are often seen as stepping outside of what nature does. Clonal forestry has for instance been blamed for creating stands with a too limited genetic diversity, vulnerable to changes in the environment, or attacks from pests and diseases. But let us not then forget that Mother Nature herself for many species, like the aspens (*Populus tremula, Populus tremuloides*), creates monoclonal stands, when individual trees through sprouting regenerate considerable areas. Clonal propagation in itself does not increase the susceptibility of a genotype.

Clonal plantations established with clone mixtures can be made much more variable than natural stands. But how much diversity is wanted when it costs productivity, because when there is an increase in the number and diversity of clones, of course the share of better clones must go down? The question is difficult. To summarise a discussion by Lindgren (1993) about the number of clones that should be included in a mixture:

1. The more is known about a clone, i.e. the more it is tested, the more it can be used,
2. the more intensive the forest management system is, the lower the number of clones that can be tolerated, and
3. the shorter lived the species is, or the shorter the plantation rotation is, the lower the number that must be included.

Libby (1982) and Park *et al.* (1998) both set a moderate number, both give maximum number of clones to 25, as the number of clones that from a variety of reasons should be sufficient. Opinions still vary about the importance of planting the clones in mixtures or in mosaics of pure blocks. Economically there are certainly some easily seen advantages with pure blocks. On the other hand, if the clonal plantation for some reason is abandoned or forgotten and let regenerate naturally, the regeneration from the pure blocks, even allowing for some outside pollen, would have very large share of selfed seed, which is undesirable. Legislation controls the use of clonal plantations in several countries.

There is a potential risk that stands made up by clonal plantations begin to regenerate spontaneously by seed. In a computer simulation such an option might lead to inbreeding and genetic erosion, but in nature biological mechanisms (diociousness, self-incompatibility, and embryonic lethals) reduce the risks considerably.

Conclusions

Most of the world's forests must be used to satisfy the requirements of a growing human population wanting a better life.

Really large-scale forest protection cannot itself maintain all forest biodiversity, conservation must be integrated as a part in forest management.

Exploitation of timber without concern for regeneration and sustainability has nothing to do with forest management.

Any forest management or silviculture activity will have an effect on genetic diversity, positive or negative. The effects can be particularly adverse if population structures and genetic systems are violated.

Almost all diversity can be maintained through a suitable combination of conservation and production forests.

The diversity patterns will differ between production forests and conservation areas. Production forests have a simpler stand structure, less species and age class within stands. Much of the variation is instead among stands.

As long as due consideration is given to regeneration, most forms of harvesting have a limited effect on long term diversity.

Regeneration is the key silviculture activity that determines the genetic diversity in the future forests and their capacity for sustainable production.

Both natural regeneration and cultivation can produce new stands with acceptable diversity.

Well planned and implemented tree improvement programs help maintain diversity and at the same time provide more productive planting materials.

Many forest managers do not fully understand the importance of the genetic resources they handle. The scientific community must take the responsibility for making foresters more aware.

In dedication to the late Dr. Abdou-Salam Ouédraogo, who established and led IPGRI's Forest Genetic Resources Programme with remarkable vision, professional dedication, and a contagious enthusiasm from 1993 to 1999.

Abstract

The research programme of the International Plant Genetic Resources Institute (IPGRI) on *in situ* conservation of forest genetic resources (FGR) in the tropics is discussed. The introduction highlights the value of forest genetic resources, stresses the importance of their dynamic conservation and opportunities for fulfilling basic human needs, and refers to constraints and challenges encountered in tropical environments. In the context of IPGRI's overall objectives and modes of operation, the FGR research agenda in relation to *in situ* conservation is described and illustrated with recent findings and on-going research activities. Selected priority areas for research include: 1) finding methods to prioritise species, populations, and conservation activities, 2) assessing patterns of genetic diversity and threats, 3) understanding biological processes regulating genetic diversity, 4) assessing the impact of human activities on genetic processes, 5) understanding local use patterns and devising participatory FGR conservation schemes. *In situ* conservation is a complex task, requiring a multidisciplinary approach integrating socio-economic, ecological and biological aspects. The need for additional technical and scientific knowledge, regional collaboration, appropriate policies, public awareness, and commitment at national, regional and international levels to enable more effective *in situ* conservation programmes and promote sustainable livelihoods is emphasised.

Keywords: *Insitu* conservation, Tropical forest, IPGRI

Introduction

Tropical forests, where around half of the world's higher plant species occur, are the source of multiple and fundamental values. Forest ecosystems fulfil basic life-support functions including watershed protection and soil conservation, climate regulation, carbon sequestration, biodiversity conservation, and pest control (Salati et al. 1999); they also contribute to society's recreational and cultural well-being, and support religious traditions and practices. In addition, they provide local communities and national economies with a variety of goods including food, fodder, gums, fibre, fuelwood, timber, medicinal products derived from plants and animals, and play a primary role in sustaining their subsistence and socio-economic development.

Due to their interdependence, all levels of biological organisation, i.e. ecosystems, species and genes are important for biodiversity conservation and the maintenance of forest ecosystem stability and productivity. Ultimately, the capacity of plants to adapt to changing environmental conditions and to continue evolving is ensured through their intraspecific genetic variation. Genetic variation also constitutes the foundation for improvement and breeding programmes that aim at meeting society's changing needs. Forest genetic resources (FGR), or the present and potential value of the heritable materials contained within and among species, are therefore among society's most valuable intergenerational resources.

However, threats to forest genetic resources in the tropics have considerably increased in past decades. Severe and continuous rates of depletion of tropical forests have taken place with deforestation through conversion of forest to other land uses, forest habitat degradation and non-sustainable exploitation practices. Forest area in developing countries in 1995 has declined by 65 million ha since 1990 and by 9.1% since 1980 (FAO 1999). This has had a direct impact on the amount and patterns of genetic diversity in forest trees. Many populations and species possessing unique and useful properties are presently being lost, sometimes without having been identified and studied (Mittermeier et al. 1999). While degraded ecosystems may be rehabilitated albeit with great difficulty and at high costs, extinction of species or the loss of unique forest genetic diversity within species is permanent and irreversible, with significant potential impacts for development. Therefore, conservation and sustainable use of forest genetic resources has been and remains a pressing and vital requirement for all local, national, regional, and international stakeholders (Ouédraogo 1997).

The task at hand is not easy. Gene conservation strategies should not aim to conserve the genetic makeup of forest species as it stands today, but allow the maintenance of evolutionary processes which will allow species to adapt to future conditions (Eriksson et al. 1993, Namkoong 1986). In this respect, a primary issue is the definition of the amounts and proportion of genetic variation that should be maintained to allow species to do so (Palmberg 1999). At the same time, gene conservation programmes should help prevent or reduce genetic erosion and species extinction, as well as preventing strong directional change of the genetic composition of conserved populations (FAO 1993).

Conserving Forest Genetic Resources *In Situ*

Forest scientists and the wider conservation research community have actively worked at developing conservation and sustainable use strategies, while sometimes pursuing conflicting objectives and approaches. Conservation can be achieved *in situ* and *ex situ* (Ledig 1986), and the two should be implemented in a complementary manner. However, several advantages make the conservation of forest populations, species and genes *in situ* i.e. within their original/natural environment (Frankel 1976), the preferred method. This method permits the maintenance of basic evolutionary processes and provides breeders with a dynamic source of variation. It is particularly recommended for species that cannot be grown outside their natural habitats, including those requiring complex ecosystem interactions to subsist, and species with recalcitrant seed behaviour. Furthermore, *in situ* programmes for target forest species will often result in the protection of associated animal and plant species and whole ecosystems in which the species occurs. Lastly, *in situ* conservation allows resource utilisation. It can and should plan to purposefully associate the simultaneous, sustainable use of resources by various stakeholders, thus also improving cost effectiveness of conservation.

It is worth emphasising that conservation and sustainable use of forest genetic resources is not just a problem for the future. It affects millions of people now. Therefore conservation cannot be viewed separately from development or human needs and demands. Perhaps the greatest challenge of *in situ* conservation strategies lies in the fact they should reconcile conservation activities with immediate human needs, recognise the importance of different stakeholders as potential suppliers and managers of genetic diversity and the link between biological and socio-economic objectives.

Production of forest-derived goods and environmental services will require that basic genetic and silvicultural guidelines be incorporated in forest management prescriptions and interventions (Kemp 1992). Conservation of genetic resources through sustainable management is a primary necessity for the large majority of forest tree species, which are not used in plantation and domestication programmes (National Research Council, Board on Agriculture 1991). The role of local communities in the selective regeneration, dissemination and planting of forest germplasm should be further investigated.

Whereas the *ex situ* conservation strategy is well known, widely used and fairly well developed, relatively little action has yet been taken for *in situ* conservation especially of intraspecific diversity. This may be due to the prevailing attention given to *ex situ* methods, and a limited co-operation between breeders and foresters as well as conservationists. Furthermore, the early focus of *in situ* conservation has been on the establishment of protected areas systems for ecosystem and endangered species conservation with little regard to within-species diversity (FAO 1989). The awareness that the development of effective *in situ* conservation, management and sustainable use strategies needs to take the dynamics of intraspecific variation into consideration has grown steadily. However advances in developing *in situ* programmes are limited by the lack of understanding and scientific knowledge on the extent, spatial and temporal organisation of genetic diversity in forest trees, genetic processes and the impact of socio-economic activities on forest genetic resources.

Challenges of Conservation of Forest Genetic Resources In tropical Forests

While *in situ* conservation of forest genetic resources is a complex field, its progress has been relatively slower in tropical regions in comparison to temperate areas due to the following general constraints and challenges (Bawa 1997, Ouédraogo 1997):

- The large number of species to be studied, low infrastructural development of local institutions, the lack of a critical number of personnel and difficulty in meeting the high costs of training and research have contributed to the relatively slow progress in bridging considerable knowledge gaps in botany, plant taxonomy, biology, and genetics of tropical forest species;
- The diverse biological characteristics and ecological relationships including diverse pollinator requirements and interactions, highly variable tree densities and spatial distribution of species, mixed mating systems, variable phenological patterns, necessitate that conservation methods and strategies be tailored to individual species;
- Evaluation and comparison of morphological and heritable characters has only been undertaken on a few species. Similarly, the development of tools and biotechnologies to assess genetic diversity is recent and genetic markers need to be identified and characterised. Also, despite the new range of molecular techniques and simulation models for genetic conservation, there is a need to go beyond molecular markers data collection;
- Sustainable management practices have been limited in tropical forests due to the large number of species present, many of which are non-commercial, difficulties in regeneration of target species, fragility of soils, and difficulty of access;
- The restricted availability of economic options for development enhances poverty and leads to short-term perspectives in conservation and use practices. The development of strong partnerships of local communities, indigenous people and other stakeholders represents both a continuing challenge and a strong driving force for the implementation and adoption of effective conservation and use strategies;
- National policies and legal frameworks which are conducive to resolving problems of conservation and sustainable use of forest genetic resources are strongly needed, yet can be complicated by the variety of actors and interests, and the gaps between local and national laws.

IPGRI's Research Agenda for *In situ* Conservation and Sustainable use of Tropical Forest Genetic Resources

The overall mission of the International Plant Genetic Resources Institute (IPGRI) is to encourage, support and undertake activities to improve the management of genetic resources world-wide, as well as to help eradicate poverty, increase food security and protect the environment. The conservation and use of FGR is one of eight priority domains on which the Institute has chosen to concentrate its efforts (IPGRI 1999). The objective of IPGRI's Strategic Action Plan on Forest Genetic Resources is to ensure the continuous availability of forest genetic resources for future use through (1) strengthening institutional frameworks and contributing to international collaboration; (2) generating knowledge and developing appropriate methodologies; (3) devising and providing practical tools for measuring genetic diversity and for the improved conservation and use of FGR (IPGRI 2000). Reflecting IPGRI's overall mode of operation (Box 1), the Global Forest Genetic Resources Programme conducts its research agenda through partnerships with national programmes in collaboration with international research institutions.

Box 1: IPGRI's modes of operation

IPGRI works through partnerships, complementing its partners' resources with those of its own to provide a collaborative research and implementation effort that is highly cost-effective. Savings accrue through the sharing of staff time, laboratory and field facilities, and so on. In addition, technology and information are transferred to partners who might otherwise have limited access to them because of their own shortage of resources. IPGRI operates directly or as a catalyst on almost any part of the research and development process related to the conservation and use of plant genetic resources. With its partners, IPGRI identifies which points in the process would benefit most from its involvement and would bring maximum gains in terms of exercising the greatest leverage over the process as a whole. In this way, both partners optimise the impact from the resources they invest in the collaborative effort. In undertaking its programmes of work, IPGRI takes particular account of the way in which networks can support its activities ensuring that research is conducted cost-effectively, and that materials, methods, results and information are widely disseminated. It also places emphasis on research that is contracted with partners. Contracting research helps to ensure that projects are well designed and that the resources are made available for their implementation (IPGRI 1999).

The objective of this paper is to describe IPGRI's general research framework for the *in situ* conservation of forest genetic resources, incorporating effective gene management and sustainable use of tropical forests. The paper also illustrates achievements and ongoing research activities of the Programme. As a result of extensive consultation with and field experience of partners in FGR conservation and use including national programmes, advanced research institutions and international organisations, the Programme has identified the following priority research areas for the development of *in situ* conservation strategies (IPGRI 2000, Ouédraogo 1997).

- Information allowing selection of priority species;
- Patterns of species distribution, intra-specific genetic diversity and threats;
- Biological characteristics and ecological processes regulating genetic variation;
- Impacts of human activities on genetic processes;
- Local use patterns and participation in forest genetic resources conservation

Priority Setting

Tropical forests host a large number of species that are threatened or at risk of extinction. These species fulfil a variety of functions and services and their value is recognised by several user groups at different scales (local communities, private enterprises, national governments, international institutions). On the other hand, a large number of potentially useful species are little or unknown. Therefore, the amount of information needed in the ecological, genetic and socio-economic aspects of FGR conservation and use is considerable. This demands the most efficient use of the limited resources and time available. An important task, therefore, is the prioritisation of research activities.

A central goal of IPGRI's Global Forest Genetic Resources programme has been to provide national programmes with adequate tools to develop strategies and to identify priority actions for effective conservation and use of FGR. For this purpose, the University of British Columbia, Canada, in collaboration with IPGRI has undertaken the development of a framework for prioritising species, populations, and conservation management interventions integrating genetic diversity, threat and management data (Namkoong and Koshy 1999). This project involves the development of three major components. The project is assembling a classification system of threats, which includes their types, frequency of occurrence in species, impact, monitoring requirements and potential to cause genetic erosion in relation to ecological and reproductive characteristics of species.

Furthermore, information on field and laboratory techniques for estimating genetic diversity has been compiled. This manual provides guidance on the suitability of available tools for different geographical locations, species and other biological considerations as well as equipment, personnel and cost requirements and comparative advantages. Work is also in progress to develop the overall priority-setting decision framework which includes factors of the estimated state of genetic variations, threats, and opportunities for recovery and sustainability of the resource for production and conservation. The draft framework is being tested in a field study in Brazil and experimental results from its use will yield useful information for its further refinement and greater applicability.

Patterns of Species Distribution, Genetic Variation and Threats

Once priority species have been identified, the development of adequate conservation programmes will require information on patterns of species distribution, level and spatial organisation of genetic diversity, and threats. This information is widely lacking. IPGRI's programme therefore collaborates with national programmes to generate information for priority conservation species which are recognised as threatened and/or having current or potential socio-economic value. A summary of the results achieved so far is presented in Table 1.

The different information layers can be combined to provide a current assessment of genetic resources. This superimposition provides spatially explicit framework for *in situ* conservation by identifying optimum areas for conservation to be ranked according to the level of threats they are subject to and the genetic diversity they hold. Marginal and isolated populations that may possess unique adaptations such as drought resistance, tolerance to given soil conditions, insect resistance should be carefully considered for selection. Genetic diversity evaluation will be important for protected areas designed for biodiversity conservation, so their contribution to the conservation of intraspecific diversity will be realised (Box 2). This exercise should also reveal locations where extreme threat levels preclude *in situ* conservation. Identified populations should then be subject to *ex situ* conservation.

Unfortunately, full knowledge of the genetic structure of the species may not be rapidly available. Nor is phenotypic evaluation data except for a restricted number of species. Therefore, a number of conservation areas covering the main occurrences of the species as well as outlying populations will be needed in order to expect to capture a considerable amount of the species intraspecific variation.

The identification of priority genetic populations is greatly facilitated by computer technologies including Geographical Information Systems which can integrate multiple data layers and has various data processing and modelling capacities.

Biological Characteristics and Ecological Processes Regulating Genetic Variation

The dynamics of genetic diversity in forest populations is influenced by a variety of factors including reproductive biology, dispersal mechanisms, regeneration patterns and ecological relationships. Tropical forest species display wide variation in their biological and ecological characteristics that in turn have considerable implications for their conservation and management. Yet even for prominent species such information is scant and incomplete.

To cite only a few, numerous questions remain about the effect of variation in flowering density on the genetic quality of seeds, interactions between patterns of seed production and seed dispersal by frugivores, the dependence on pollinators and how changes in the frequency and composition of forest species influence them (Bawa and Krugman 1991). Therefore, in view of the existing variability, there is a need to examine how contrasting modes of distribution, pollination and seed dispersal mechanisms influence the amount and spatial organisation of genetic variation in species.

Table 1: Outputs of research activities undertaken by IPGRI's FR programme in collaboration with national programmes.

Species and locations	Research activities			
	Species-level information	Genetic diversity	Threat assessment	References
Lophira alata Cameroon	Ecogeographic surveys in 3 ecological zones, data collected on population history, density, and health status. GIS distribution map.			Eyog-Matig 1998.
Anogeissus leiocarpus Burkina Faso	Populations sampled throughout national distribution range, data on tree stand characteristics (density, soil type, association, land use, regeneration rates). GIS distribution map.		Local perceptions of threat status and conservation need through semi-structured interviews.	Nikiema *et al.* 1997.
Acacia senegal Burkina Faso	Ecogoeographic surveys conducted, data gathered on tree stand characteristics (density, soil type, association, land use, regeneration rates). GIS distribution map.		Local perceptions of threat status and conservation need through semi-structured interviews.	
Parkia biglobosa Burkina Faso	Populations surveyed throughout distribution range and samples collected for genetic diversity analysis. Data on taxonomy, phenology, reproduction biology, dispersal mechanisms.	Distribution of allelic frequencies through isozyme analysis, highly variable populations located.		Buitelaar 1996.
Vepris glandulosa Kenya	Ecosystem surveys, data on habitat characteristics, land use, conservation status. New population found during surveys.			Lengkeek 1998.
Phyllantus emblica India	Seven representative populations identified within 30 Medicinal Plant Conservation Areas.	Seeds collected for isozyme analysis		Shaanker and Ganeshaiah 1997.
Ochlandra scriptoria India	Distribution information gathered from local forest divisions. Spatial location of selected populations marked on a map.	Allele diversity studied through isozymes, highly variable populations located. No evidence of geographic segregation among populations.		Shaanker *et al.* 1999.
Bambusa arundinacea India	Data on actual distribution gathered from forest maps, historical sources, aerial photographs, satellite imageries. GIS distribution map. Bamboo densities in forest areas calculated.	Allele frequency assessed through isozyme analysis. Genetic segregation between populations from northern and southern districts.	Change in bamboo cover during 1935-1970 evaluated. 90% of bamboo lost in the Northern portion of BRT Wildlife Sanctuary.	Shaanker *et al.* 1998.
Santalum album India	Information regarding past and present distribution of sandal gathered from aerial photointerpretation and historical records.	Allele frequency assessed through isozyme analysis along a disturbance gradient. Undisturbed populations harbor higher level of genetic diversity.	Change in sandal cover during 1935-70 assessed through satellite imageries. Some populations totally lost, others disjunct. Large decline in quantities of sandal extracted from 1980 to 95, despite increasing value. Trend reflected in supply to local industry. Annual poaching estimated 100-500 tons.	Shaanker *et al.* 1999.
Cotylelobium melanoxylon Thailand	Populations surveyed in four sites, including a genetic resource area.	Higher genetic diversity found in a population located in a Genetic Resource Area, than in three natural populations.		Chaisurisri 1998.
Dalbergia oliveri Vietnam	Field surveys on taxonomy, morphology, ecology, distribution, regeneration rates, land use and protection status. Data gathered on species composition, ratio and relationship between species within each stand. Taxonomic studies showed that *D. oliveri* is synonym of *D. bariaensis*		Assessment of forest cover changes over 22 yrs comparing satellite imageries of two distribution areas. 8% average reduction of forest cover recorded.	Le and Nguyen 1999.
Xylia xylocarpa Vietnam	Field surveys on taxonomy, morphology, ecology, distribution, regeneration rates, land use and protection status. Data gathered on species composition, ratio and relationship between species within each stand.		Assessment of forest cover changes over a 22 yrs comparing satellite imageries of three distribution areas. Peaks of 35% reduction of forest cover recorded.	
Pterocarpus macrocarpus Vietnam	Field surveys on taxonomy, morphology, ecology, distribution, regeneration rates, land use and protection status. Data gathered on species composition, ratio and relationship between species within each stand.		Assessment of forest cover changes over a 22 yrs comparing satellite imageries of four distribution areas. Peaks of 20% reduction of forest cover recorded.	

Box 2: Assessing the effectiveness of protected areas for intraspecific genetic diversity conservation

In Southern India, levels of genetic diversity in sandal (*Santalum album*) populations were assessed along a gradient across a protected area, and surrounding buffer zone as well as highly disturbed area (villages and agroecosystems adjoining the forests). Higher levels of diversity found in the core populations than in both the buffer zone and disturbed areas indicate that protection has had a significant genetic diversity impact. The lack of difference between the latter zones revealed insufficient protection of sandal populations in the buffer area, as supported by a large proportion of small size class individuals, the extraction of sandal heartwood being selectively done on larger trees (Shaanker et al. 1999). In Thailand, genetic diversity estimates of *Cotylelobium melanoxylon* populations obtained with isozyme markers indicate that a genetic resource area (GRA) established locally for *in situ* conservation harboured higher levels of variability than observed in three other populations studied. Such methodologies are useful for testing and monitoring the effectiveness of protected areas in conserving valuable germplasm (Chaisurisri 1998).

These parameters have a direct bearing on the number and distribution of unrelated, inter-breeding individuals needed to constitute a viable genepool of target species. In order to promote applied and management-oriented research, the Global FGR programme has tended to handle research on these subjects in combination with the study of impacts of human activities described below.

Impact of Human Activities on Genetic Processes

The inseparable goal of forest genetic resources conservation is to sustain the economic development of local communities and nations in which they occur. Therefore, a major component and challenge of *in situ* conservation programmes is to understand the effect of human management and use activities on processes which regulate genetic diversity. Conservation strategies including sustainable management plans can then be developed. The most relevant anthropic activities including deforestation, forest fragmentation, selective logging, extraction of non-timber forest products all of which might have detrimental effects on forest genetic resources and yet the magnitude and dynamics of their effect remains poorly understood.

Forest fragmentation resulting from the conversion of forests to other land uses is a reality that increasingly prevails in most tropical countries and therefore represents a critical area of study. A central concern is that reduced gene flow and increased genetic drift in fragmented populations can lead directly to the loss of genetic diversity. In addition, decreased fitness as a result of increased inbreeding in fragments will reduce population viability and may lead particularly in combination with other consequences of small population biology, to extinction. Advances in our understanding of the impact of human activities on mating systems, gene flow and genetic diversity also rely on the development of variable genetic markers to estimate gene flow and effective population size in many species. Collaborative studies between IPGRI, and Universities of Costa Rica and Massachusetts are addressing several of these components, including the characterisation of genetic markers and the impact of forest fragmentation on the reproduction, gene flow of tropical dry forest species used for timber in Costa Rica (Box 3).

Box 3: Impact of fragmentation on the reproductive biology of *Enterolobium cyclocarpum* and on geneflow of *Carapa guianensis* in the Guanacaste National Park, Costa Rica

In a first study, a range of characteristics in *E. cyclocarpum* trees located in continuous forests and pastures was compared. Reduction of continuous habitat was accompanied by a decline in flower visitation rates and likelihood of pollination as well as fruit set, and seed production per fruit. Yet the fact that when pollinated, the number of flowers with pollen on their stigma and the number of pollen grains deposited were similar, and that more flowers are pollinated than fruits mature, suggest that factors other than pollination determine the likelihood of fruit maturation. As ways through which plants may regulate the quality of their progeny, competition among developing fruits and genotype interactions between paternal and maternal parents may be responsible for differential seed abortion. Because progeny vigour among seedlings from pasture trees was significantly lower than from continuous forests, it can be assumed that habitat fragmentation disrupted mechanisms regulating progeny vigour and quality, possibly through inbreeding. In this study, fragmentation had no effect on outcrossing rates. This study also shows the importance of isolated trees in fragmented landscapes for the movement of pollinators and gene flow, and the inferiority of seeds from fragmented sources for the establishment of commercial plantations (Rocha *et al*. 1999).

Another study has undertaken to identify and characterise Simple Sequence Repeats (SSR) loci in *Carapa guianensis* that may then be used to detect polymorphism in related species. Using these markers, the study also tested the effect of fragmentation on gene flow and differentiation among fragmented and continuous forest populations by comparing them among pre-fragmentation adult cohorts and post-fragmentation sapling cohorts. Genetic distances between adults and saplings were greater in populations in forest fragments than in continuous forest sites. Average allelic richness of the sapling cohort was also lower than in the adult population in the site subject to cattle ranching and selective logging, while the opposite was true in the untouched and selectively logged continuous forest populations. Also, the larger genetic distance among all cohorts than adult cohorts was mostly due to differences between the fragmented site and the two continuous populations. In conclusion, while selection during life cycles may need to be accounted for, this project suggests that fragmentation decreases gene flow and increase allelic diversity. Yet additional comparisons between finer population samples aiming at characterising paternity, mating systems and gene flow events will be needed to have a more thorough understanding of the complex changes induced by habitat fragmentation and degradation (Sanchez and Bawa 1999).

Science should also be able to provide forest managers with prediction tools for assessment of genetic erosion to optimise the management of fragmented forests. A collaborative project between the Centro Agronómico Tropical de Investigación y Enseñanza (CATIE), IPGRI and the Centre for International Forestry Research (CIFOR) in Costa Rica is attempting to identify conditions regarding species, fragment as well as tree characteristics which allow sufficient gene flow between fragments to counteract the expected effects of fragmentation-induced genetic drift. It also addresses how these conditions affect outcrossing rates and the effect of their decline on population fitness (Box 4). The research undertaken in Sumatra on *Scaphium macropodum* and *Fordia johorensis* indicates that high tree density in fragments for species considered can at least partially offset the loss of heterozygosity which may result from fragmentation (Sudarmonowati 1999).

The task of monitoring all biological and ecological interactions between species which are necessary to maintain evolutionary processes, is enormous and totally impracticable for highly diverse tropical forest ecosystems. Thus, research partners from Escuela Superior de Agricultura, University of São Paulo and Centro Nacional de Pesquisa de Recursos Geneticos y Biotechnologia - Empresa Brasileira de Pesquisa Agropecuária (CENARGEN-EMBRAPA) are focusing on the response to disturbance of 'model species' as representative of ecological/genetic guilds forming the forest community (Kageyama et al. 1998). Specifically, demographic (abundance, age distribution, mortality and growth rates) and genetic (expected heterozigosity, outcrossing rate, and spatial autocorrelation) parameters are monitored for a few model species (Box 5). Five groups of model species based on contrasted densities, responses to disturbance, canopy position and light requirements, as well as successional stage have been identified. Being highly dependent on these interactions, the stability of these demographic and genetic parameters would indicate the interactions of a considerable part of the community are maintained. It is hoped that data obtained from these few model species can then be extrapolated to the community

Research is also needed on the effect of other major human activities affecting forest genetic resources, including selective logging and extraction of non-timber forest products. By extracting well-formed trees of reproductive size, selective logging lowers the density of flowering trees, which can diminish pollinator densities and alter foraging patterns. When effective population size is reduced and includes a disproportionate number of poorer genotypes, the species may become less adapted to its environment (dysgenic selection) and inbreeding occurs (Murawski et al 1994). Similarly, the extraction of non-timber forest products depending on modalities and parts harvested may impede natural regeneration, reduce population size and density and result in inbreeding. Changes in genetic diversity should be examined under a range of different intensities, in order to determine critical levels that result in significant losses so that management guidelines on allowable harvesting intensities can be defined.

Local Use Patterns and Participation in Forest Genetic Resources Conservation

In the tropics, where the fate of forest populations and species is dictated by every-day activities of local communities to satisfy basic needs, a major objective of *in situ* conservation should be to reconcile conservation activities with immediate human needs. Historically, however, management of protected areas has often been under the control of national governments and local people have had to bear the costs associated with access restrictions. *In situ* conservation programmes should devise local participatory development schemes that ensure the sustainable management, production and conservation of forest genetic resources while providing benefits to local users. To implement such an approach, it is necessary to first identify human activities that have an impact on forest genetic resources and assess forest use patterns and socio-economic factors which influence them. It is important to disaggregate uses by user groups based on gender, age, ethnic group and relevant socio-economic parameters. In order to understand the underlying causes of forest use patterns, on the one hand, the contributions of timber and non-timber forest products to local livelihoods and regional economies need to be assessed. On the other hand, local forest management institutions as well as national forest policies should be identified and described and the ways through which they promote sustainability or degradation analysed. Patterns detected in the present should be understood dynamically in relation to changes in the historical past in land use, forest cover, demography, socio-economic trends, activities and policies. It will also be necessary to assess the possible costs of applying conservation-oriented management guidelines resulting from biophysical research and how to optimise benefits in order to promote participation (Boyle and Ouédraogo 1995).

Multidisciplinary research is therefore essential for addressing conservation challenges in tropical forests and is an integral part of IPGRI's strategy. Research objectives and activities listed above are currently being applied through participatory methodologies in a project on conservation and management of forest genetic resources in Brazil and Argentina funded by the German Ministry of Foreign Affairs. Participatory research is also undertaken in the Western Ghats province of Southern India with the Soligas, an indigenous forest-dwelling community and the University of Agricultural Sciences in Bangalore for the long-term monitoring and conservation of local FGR (Shaanker et al. 1998).

Box 4: Impacts of fragmentation on genetic diversity in riverine forests of Costa Rica

Over a 350 km^2 area in northern Costa Rica, thirty-four forest fragments have been selected, ranging greatly in population size, size, shape, composition, land-use type and spatial characteristics. More than 1000 individual explanatory data values have been collected, mostly at individual-tree level, for two species (*Anacardium excelsum* and *Plumeria rubra*) which represent contrasting seed and pollen dispersal mechanisms. Factors affecting gene flow in fragments are investigated using two large populations serving as putative 'sources' and a number of surrounding smaller fragments serving as putative 'sinks'. Genetic diversity is measured using RAPDs in pre- and post-fragmentation cohorts and the proportion of extrafragmentary pollen parents will be estimated in progenies. These data should lead to the identification of fragment, tree and species characteristics that contribute to a resistance to genetic drift due to a propensity to receive immigrant alleles. In addition, inbreeding coefficients and outcrossing rates are being estimated in all study fragments and related to potential putative explanatory factors. This information, together with measures that can be employed to reduce such risk, will be of direct interest to managers of forests and protected areas (Cornelius 2000).

Box 5: Strategies and parameters for *in situ* conservation of tropical forests in Brazil

Research is conducted in four fragments ranging in size from 2 to 70 ha located around the Rio Doce State Park in the eastern part of Minas Gerais State, which contains continuous primary forest. Fragmentation is primarily the result of forest clearing and eucalyptus tree planting for the charcoal supply of the heavy steel industry. Preliminary findings indicate that rare species in primary forests which become abundant after disturbance such as *Dalbergia nigra,* may lose polymorphism and heterozygosity probably as a result of fragmentation-induced genetic drift and become further impoverished in density and genetic diversity if selectively logged (*Cedrela fissilis*). In contrast, shade tolerant or climax species such as *Sorocea guilleminiana* which are not subject to exploitation are probably genetically well conserved even in fragmented lands. But fragmentation is likely to have a drastic impact on species that are rare in primary forests and absent in secondary (*Hymenaea courbaril*) to the point that they become absent in fragments.

The development of comprehensive *in situ* conservation programmes relies on the integration of the methodologies, tools and management guidelines resulting from the various research components described in previous sections. Successful integration requires strong collaboration between the various conservation-related disciplines as well as a co-ordinated approach between national, regional and international partners. The institutional capacity strengthening at the level of scientists, national programmes, and through linkages between conservation players, which IPGRI invests in through its research and co-ordination activities, is an important step in the development of these programmes (Box 6) (Ouédraogo 1997).

Conclusions

The effective conservation of forest genetic resources is complex and requires improved methods of establishing priorities and tested procedures for supporting decision making on species, populations and conservation activities. A balance should be sought between corrective measures to conserve species and populations directly threatened with extinction and preventive measures for maintaining the viability of useful characteristics in commonly used species.

There is a strong need to expand scientific research on the patterns and processes that regulate genetic diversity at both species and ecosystem levels as well as on the impact of human activities on these mechanisms. Efforts should be made to further assess and classify differences in biological and ecological requirements among tropical forest species and to test prediction tools for genetic impact assessment. Advances are also needed in the definition of critical use levels and the promotion of the genetic agenda in sustainable forest management.

Box 6: Capacity building and regional collaboration for effective forest gene conservation

Strengthening capacities of national programmes to assess, prioritise and meet their own needs for FGR conservation and sustainable use is a direct way of contributing to genetic resource conservation. The Programme actively pursues opportunities for promoting national agendas in forest genetic resource conservation by bringing together partners in national programmes to assess the state of forest genetic resources at the national level, establish species and research priorities and implement recommendations. The programme pursues similar prioritisation and planning approaches at regional levels in collaboration with partners such as the Food and Agricultural Organisation of the United Nations (FAO), the International Centre for Research in Agroforestry (ICRAF) and CIFOR. It supports and actively participates in the development of regional or sub-regional plans for the conservation, management and use of FGR, which is being spearheaded by FAO (Sigaud et al. 2000). It also provides assistance to the establishment of regional instruments for international collaboration towards the effective conservation and sustainable use of forest genetic resources. For instance, IPGRI has helped countries establish an operational framework for a Sub-Saharan African regional programme on forest genetic resources, SAFORGEN which will assist countries in developing concepts and methodologies, strengthen national capacities and promote information exchange on FGR. As countries enlist for participation, this programme will be a useful platform to carry out research activities listed in the sub-Regional Plan of Action on forest genetic resources for Sahelian Africa. IPGRI also promotes linkages between partners, co-ordination of FGR conservation activities and exchange of information in other regions depending on needs and demand.

Successful *in situ* conservation also depends on the integration of broader rural development objectives. Through the involvement of local people, forest use practices need to be carefully examined and the constraints to sustainable use of FGR need to be addressed through active collaboration with other forestry and agricultural development sectors. In this respect, policies should be scrutinised and adapted to participatory development for the sustainable management, production and conservation of FGR. Information flow on the values of FGR, and the biological, genetic and socio-economic requirements of conservation and strong linkages between stakeholders is essential to give forest genetic resources the high importance they deserve on the national and international agenda.

National programmes represent the foundation of any enduring effort in FGR conservation. However they are often insufficiently equipped for the task at hand and therefore need to be strengthened and supported. This requires a continuing commitment at the national, regional and international levels. Regional networking should be seen as a primary means of strengthening national capacities through scientific collaboration and the exchange of information and germplasm, while avoiding wasteful overlaps and enhancing co-ordination and complementarity.

Abstract

Globally, anthrogenically-linked atmospheric pollution by the greenhouse gases, such as carbon dioxide, ozone, nitrogen oxides and methane, are increasing in phase with increasing human population. In addition, the global climate is being impacted by the greenhouse-gas-induced changes in the balance between solar radiation absorbed by the earth and the radiation re-emitted into space. The increased radiative forcing caused by the greenhouse gases is causing a general global warming. In this paper, I will document previous air pollution-induced changes in forest tree populations, review the current predictions for genetic consequences of rising atmospheric pollution and climate change, and propose some genetic management strategies to minimize future impacts.

Keywords: Genetic structure, Gene conservation, Air pollution, Climate change

Introduction

Impacts of atmospheric pollution on forest tree populations have included increased mortality of sensitive genotypes (Karnosky 1981, 1989) leading to changes in population sensitivity (Berrang et al. 1986, 1989, 1991), changes in the ability of a given species to compete with other species (Miller 1973, Miller et al. 1996), changes in gene frequency and/or occurrence of rare alleles (Mejnartowicz 1983; Muller-Starck 1989; Scholz et al. 1989) and, in occasional worst case scenarios, localized population extinction (Kanak 1986). While many of the localized emission problems in developed countries have been decreased with improved technology, localized severe pollution problems with sulphur dioxide (SO_2) and/or heavy metals are becoming more common in developing countries. In addition, the occurrence of greenhouse gas pollutants, such as carbon dioxide (CO_2), ozone (O_3), nitrogen oxides (NO_x) and methane (CH_4), are increasing globally (Roeckner 1992). These anthrogenically linked pollutants are increasing at approximately the same rate as the world population in increasing. In addition to impacting forest tree populations directly, these increased levels of greenhouse gases are causing global climate changes including a general warming (Bloomfield 1992) which is expected to have major impacts on species ranges (Iverson and Prasad 1998).

The management of forest genetic resources for future generations of productive forests becomes an increasingly complex problem when as forests planted today will be facing very different pollutant and climate scenarios than under which they were originally selected (Ledig and Kitzmiller 1992; Karnosky and Scholz 1995). In this paper, I present some examples of adverse impacts of air pollutants on forest tree populations, review the current predictions of genetic impacts of global warming, and speculate as to the strategies for the genetic management of forest resources in the face of increasing pollutant loading and changing climates.

Sulphur Dioxide and Heavy Metals

The impacts of localized emissions of sulphur dioxide (SO_2) and/or heavy metals during the past few centuries on forest tree populations within a few kilometers of the emission source has been well documented (Mejnartowicz 1983; Prus-Glowacki et al. 1992). In developing countries these emission problems were gradually corrected by technological developments such as stack scrubbers and filters to reduce emissions and taller stacks to dilute emissions. More recently, the tremendous volume of sulphur emissions from burning high sulphur coal in former eastern bloc countries has created another intensive selection pressure on forest tree populations as vast areas of the Czech Republic, Germany and Poland (in the area known as the Black Triangle) were impacted by air pollution (Kanak 1986; Karnosky 1997). Even more recently and now projected to be the most difficult sulphur dioxide and heavy metal emission problem of the new millennium are the rapidly developing countries in Southeast Asia, Latin America, and South America (Hongfa 1990; Klumpp et al. 1999).

Adverse genetic impacts on forest tree populations attributable to emissions of sulphur dioxide have been documented by Mejnartowicz (1983) and Müller-Starck (1989). Similarly, adverse genetic impacts on forest tree populations attributable to heavy metal deposition have been documented by Prus-Glowacki et al. (1992).

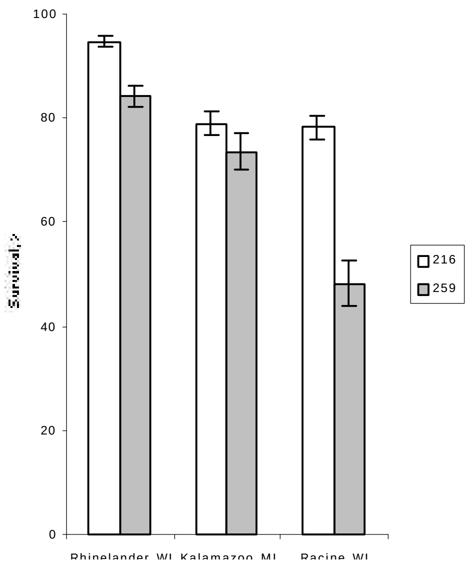
Ozone

The first and now most well documented case of adverse impacts of O_3 on forest tree populations occurred in the San Bernardino Mountains of Southern California where ponderosa pine was put under a competitive disadvantage because of its O_3 sensitivity compared to more O_3 tolerant species as a fir (Miller 1973; Miller et al. 1996). This was also one of the first cases of documented long-distance transport of air pollutants as the impacts were occurring hundreds of miles from the pollutant source (Los Angeles). The negative impacts of O_3 on other ponderosa pine populations in California have also now been described (Peterson et al. 1989; Patterson and Rundel 1995). In addition, a similar pattern of O_3 impacts on pine populations has been reported on the hillsides and mountains surrounding Mexico City (Hall *et al.* 1996). During a recent visit to Beijing, China, I found evidence of the impacts of O_3 on the lacebark pine in some of the most highly prized historical regions of Beijing (Figure 1).

While the selection pressure of O_3 on forest tree populations is thought to be quite low and the time of impacts are thought to be quite long (Parsons and Pitelka 1989; Taylor and Pitelka 1992), we have recently found evidence of a very rapid change in the intraspecific population diversity in trembling aspen under ambient O_3 in the southern Great Lakes region (Karnosky et al. 2000) We found evidence of an increasing mortality level among O_3 sensitive individuals over a five-year study along an ozone gradient from relatively clean air (Rhinelander, Wisconsin) to moderately high ozone (Kenosha, Wisconsin) (Figure 2). This study suggests that O_3 at moderate levels can be a strong selective force over the early regeneration period of a forest stand.

Figure 1. A dying lacebark pine in the old city center of Beijing, China. Needles showed classical O_3 symptoms including tipburn, chlorotic mottle, and premature abscission.

Figure 2. Survival of an ozone-tolerant (clone 216) and an ozone-sensitive (clone 259) trembling aspen clone planted in competition plots at low, moderate, and high O_3 sites in Rhinelander, Wisconsin, Kalamazoo, Michigan, and Kenosha, Wisconsin, respectively. The duration of the study was 5 years. (From: Karnosky et al. 2000).



Greenhouse Gases and Climate Change

The greenhouse gases including CO_2, O_3, NO_x and CH_4 are all increasing 1 to 2% per year (Roeckner 1992, Figure 3). With the exception of previously mentioned effects of O_3, little is known about the direct impacts of greenhouse gases on forest trees. Generally, trees respond favorably to elevated CO_2 (Ceulemans and Mousseau 1994; Norby et al. 1999), but since genetic differences occur in the magnitude of the positive growth response to CO_2 (Houpis et al. 1999), it is likely that elevated CO_2 will also affect tree-to-tree and species-to-species competition (Karnosky et al. 1999). In addition to the direct impacts of greenhouse gases on forest tree populations, these gases are contributing to a changing climate (Bloomfield 1992; Roeckner 1992, Figure 4). Since the climate is likely changing faster than trees can adapt or migrate, large scale impacts of climate change are predicted to occur (Iverson et al. 1999). These predictions must be tempered by the realization that large amounts of plasticity and adaptability occur in most forest tree populations (Loehle and LeBlanc 1996). However, there is little doubt that the mean summer and winter temperatures will be much warmer and the growing seasons will be longer towards the end of the rotations of trees planted today than they are at the time of planting (Rehfeldt et al. 1999).

Nitrogen

As with elevated CO_2, trees respond generally in a positive manner to elevated nitrate additions as nitrogen is often a limiting factor to growth (Norby 1998). However, excessive nitrogen deposition can lead to nitrogen saturation levels at which time several negative impacts can occur such as increased fine root mortality, increased susceptability to low temperatures in the autumn due to the nitrogen fertilization effect which tends to keep conifers from properly winter hardening in the autumn, and increased nutrient leaching from foliage and soils (Norby 1998, Sogn et al. 1999). High elevation spruce-fir populations are especially susceptible to the adverse effects of elevated nitrogen deposition as has been reported in both the United States (Aber et al. 1989) and Europe (Grennfelt and Thörnelöf 1992). Silver fir, a species of depauperate genetic variability (Ziegenhagen et al. 1995) is a particularly sensitive species to environmental stresses such as excessive nitrogen deposition.

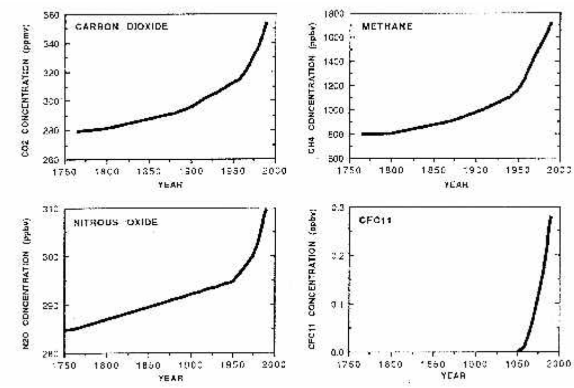

Figure 4. The IPCC global temperature record and a set of predicted temperatures. (From Bloomfield 1992)

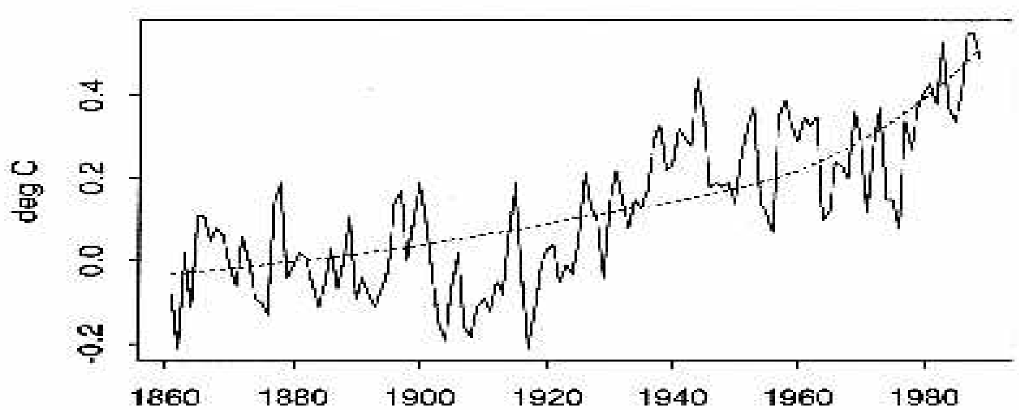

Management of Genetic Resources for Future Forests

Tree breeding and genetic selection has generally involved either plus tree selection followed by progeny testing or provenance testing followed by progeny testing of superior phenotypes. Then, seed orchards have been established and rogued to provide the seed for the next generation. This process has continued with advanced generation selection and breeding in a few commercially important tree species. In all facets of these programs, selection is done based on the conditions prior to selection and for the most part these selections are not done on the basis of predicted pollution and climate scenarios that will be in place during the rotation of the commercial forest. Screening and selection of genotypes suitable for future pollution and climate scenarios is generally thought to be nearly impossible because of the complexity and cost of such programs. Thus, an alternative strategy in which a wider genetic base is maintained in our breeding population is essential for developing future forests (Namkoong 1991). Maintaining large amounts of genetic diversity will increase the probability that adequate adaptability is maintained to meet rapidly changing environmental conditions (Gregorious 1986; Müller-Starck 1989).

Alternative strategies are also needed to insure that gene banks, clone banks, seed zones, seed collection areas and other "in situ" conservation strategies are maintained in multiplicative manner such that the changing pollution and/or climate scenarios will not result in the loss of such collections from single vulnerable test sites. Given the past several decades of "laissez-faire" attitude towards traditional genetic field trials and field conservation efforts, this need to conserve forest genetic resources in multiple amounts may help genetics regain prominence amongst the forestry community.

Knowledge Gaps and Conclusions

Population changes due to air pollution or climate change are difficult to detect because of the many years or decades needed for responses to occur. However, such long-term studies are needed to document impacts of air pollution and/or climate change on biodiversity. In the short-term, studies of competition in impacted areas around point source pollutants and along pollutant or temperature gradients are valuable substitutes for long-term studies. Recent findings with competition between clones of trembling aspen differing in O_3 tolerance suggests that the establishment phase of forest regeneration is a vulnerable time for sensitive genotypes. Population changes in relation to global warming will be particularly difficult to detect but will likely occur at the margins of species ranges. New and innovative ways to conserve forest genetic resources "in situ" are needed in light of the ever-changing global climate.

Abstract

Forest sustainability refers to a forest's long term, unfailing capacity to grow, reproduce, and to deliver all of the essential ecological and economic services that human expect from it, while coping with myriad environmental vicissitudes, not the least of which are rapid global climatechange and chronic herbivory. As global temperatures rise along with carbon dioxide, there will be inexorable and unpredictable changes in the community structure of native insects which live on and in trees. This will very likely lead to new "pests", more frequent outbreaks, and higher ambient levels of herbivory. Throwing yet another wildcard into the mileu, the continuing influx of exotic herbivores caused by expanding world trade and travel, are leading to an ever burgeoning list of exotics inforests.

Their impacts on forest sustainability are particularly worrisome because they have historically had substantial and long-lasting negative impacts on biodiversity and forest productivity. The next millennium will bring many new challenges to land managers whose responsibility it is to ensure sustained outputs from the world's forests.

Abstract

Pine wilt caused by pine wood nematodes, which is endemic to North America. In 1999, pine wood nematode, is a devasting epidemic disease of pine forests in Japan and which has already spread to East Asia, including China, Taiwan, and Korea, and *Bursaphelenchus xylophilus*, was discovered in Portuguese forests. If it were to become established in the pine forests in Europe, it could become one of the most serious threats to coniferous forests worldwide. The objectives of this paper are to clarify the wilting mechanism of the disease and to consider control measures.

Keywords: Pine wilt disease, *Bursaphelenchus xylophilus*, Pine wilt mechanism, Epidemic disease, Disease control programme

Pine Wilt Disease in the 20th Century

Since the end of the Second World War, pine wilt disease, incited by pine wood nematodes, has caused the total loss of 28 million m^3 of timber in Japan. Presently, losses due to the pine wood nematode amount to some 1 million m^3 of timber annually. Initially, the disease was recognized as an epidemic in 1905 in the major port city of Nagasaki, located in Kyushu in southern island of Japan. Since then, pine wilt disease spread from many port cities in western Japan both before and after World War II. In 1950, Dr. R.L. Furniss of General Headquarters (GHQ), who belonged to the bureau of Entomology and Plant Quarantine of the USDA, made recommendations to develop a pine bark beetle control program in order to control this disease. Owing to Furniss's recommendations, pine timber losses fell to 200-300 thousand m^3 annually. However, for reasons which remain unclear, pine timber losses again increased from the late 1970's, reaching 2.4 million m^3 in 1979, an amount equivalent to the timber required for the construction of 160,000 wooden houses in Japan. The susceptible species are Japanese black pine (*Pinus thunbergii*) Japanese red pine (*P. densiflora*) and *P. luchuensis*, which are also the most predominant pine species in Japan.

Until now, more than two thousand papers have been published on pine wilt disease. The causal agent of the disease, the pine wood nematode *Bursaphelenchus xylophilus*, was recovered from dead Japanese black pines in 1969 and was determined as the causal agent of pine wilt disease by innoculation experiments in 1971. In 1979, the pine wood nematode was discovered in Missouri, USA, by Drs. V.H. Dropkin and A.S. Foudin. Most pine species in the US seem to be moderately resistant to the pine wood nematode. Following an investigation of pine wilt disease distribution, the pine wood nematode was determined as being endemic to the US, and had seemingly been introduced into Japan in 1905. In recent years, pine wilt disease has spread to Nanjing, China in 1982 on Japanese black pine and southern red pine (*P. massoniana*), to Taiwan in 1985 on *P. luchuensis* and Japanese red pine, to Pusan, Korea in 1988 on Japanese black pine and Japanese red pine, and to Lisbon, Portugal in 1999 on maritime pine.

The pine wood nematode has been found in many pine species in Asia, North America and Europe. In addition to these pine species, it is also naturally found in diseased Eastern larch and European larch (*Larix* spp.), balsam fir (*Abies* spp.) and both blue and white spruce (*Picea* spp.), Atlas cedar and deodar cedar (*Cedrus* spp.) in North America.

Meanwhile, a closely related pine wood nematode, *B. mucronatus*, is found in declining pines, and is distributed over a geographically wider area than *B. xylophilus*. The hosts of *B. mucronatus* are *Pinus* spp. in Japan, China, Korea, Russia, France, Austria, Italy, Finland, Sweden, Norway, and Canada. In addition to *Pinus* spp., *Abies* sp., *Cedrus* sp., *Larix* sp. and

Pseudotsuga sp. are its host trees in the US and the former two in Japan. In 1989, Dr. G.de Guiran proposed that, based on hybridization and phylogeny of the pine wood nematode, the Japanese and American strains of pine wood nematode are derived from common stock originating in western Europe.

Pine Wilt Disease Control Program

Before the discovery of pine wood nematode as the causal agent of pine wilt disease, control methods based on the recommendations of Dr. Furniss consisted mainly of felling damaged pines, de-barking and burning. These measures immediately proved effective against the disease, however, in practice, they required a huge input of manpower. With the high level of economic growth in the 1960's, felling and burning were replaced by the spraying of BHC insecticide for the direct control of "Matsukuimushi", a general term covering more than 70 species of pine bark and wood borers which were thought to be concerned with pine wilt disease. Since 1971, when BHC was banned, other organophosphate insecticides having a shorter residual activity, such as fenitorothion (sumithion), have been used. Following the discovery of the pine wood nematode as the pathogen responsible for pine wilt disease, the Japanese pine sawyer, *Monochamus alternatus*, one of the "Matsukuimushi", was determined as a vector of the nematode. Accordingly, control measures were redirected to the destruction of the Japanese pine sawyer by the spraying of insecticide. A large scale, 5 year control project for pine wilt disease was initiated in 1977 by the Special Law in Force. It was characterized by implementation of aerial spraying to prevent Japanese pine wood sawyer maturation feeding. In spite of many efforts, severe damage was not completely controlled and the disease spread widely from the southern to the northern part of Japan, with the exception of Hokkaido, the northern island of Japan. The reasons for complete control failure are thought to be 1) the limitations of aerial spraying, 2) too great a reliance on the Special Law in Force, and 3) those people concerned not recognizing the severity of the threat to pine forests. In 1997, the Special Law in Force came to an end without a significant outcome even after 3 revisions and enforcement for 20 years since 1977. Currently, annual timber losses still amount to 1 million m^3, a similar level to the period immediately following the Second World War.

Wilting Mechanism and Environmental Conditions

Pine wood nematodes introduced into the shoots of young pines during maturation feeding of Japanese pine sawyer migrated rapidly into the whole trunk of pine trees at a maximum speed of 40-50 cm a day. The nematode density is very low at an early stage of disease development, often as low as a few nematodes per 100 gram fresh weight of wood, even following highly concentrated inoculations. After the entry of pine wood nematode into living pines, a slight reduction in the flow of oleoresin exudate is observed as a unique symptom at an early stage of the disease. This is due to the movement of pine wood nematodes through resin canals at early disease development and epithelial cells around resin canals are destroyed. Nematodes then eventually move from rays to tracheids through pits. At the same time, enhanced ethylene production is observed 2-3 days after invasion by pine wood nematodes. While the exact mechanism remains unknown, this increase, soon after infection, seem to be incited by the excretion of a considerable amount of cellulase by the nematodes.

As a general rule, symptom development may be divided into two stages following invasion of the wood by nematodes, namely an early stage and an advanced stage. In the early stage, cytological changes in the xylem parenchymatous cells occur, and these are soon followed by cavitation and embolism formation within a number of tracheids. Such internal symptomatology is induced not only in compatible but also in incompatible combinations of pine and nematode isolates. However, growth of the nematode population in living wood under conditions unfavorable to the nematode is not assured, even if a high concentration of nematodes is inoculated. Therefore, this stage is considered to be latent, that is, denaturation of parenchymatous cells by nematode invasion results in cavitation and embolism of some tracheids.

At the onset of the advanced stage of disease development, visible symptoms are expressed as a severe reduction of the oleoresin exudation rate, and chlorosis of 2-3 year-old needles, accompanied by a decrease in transpiration. Furthermore, cambial death and cavitation occur within a large part of the outer xylem and result in a water deficiency which induces a decrease in both transpiration and photosynthesis in leaves, accompanied by a further increase in ethylene production. At this time, other pathophysiological phenomena are observed, for example, electrolyte leakage from pine tissues occurs, and a number of abnormal metabolites such as benzoic acid are produced. From the onset of water stress, the nematode population begins to increase in remarkably close correlation with time.

In terms of pine wilt disease development, the water status of pines plays a very important role in the pine-nematode relationship. Experimental results suggest that pine seedlings do not wilt solely by virtue of the number of nematodes existing under conditions unfavorable to them, such as a well-watered environment. On the other hand, inoculation of a low density of nematodes was lethal to water-stressed seedlings. Empirically, pine wilt disease seems to occur more frequently and to be more destructive in summers with little rainfall. At present, surface tension of sap are examined in relations to the cause of cavitation during disease development of pines.

Present Pine Wilt Situation and Threat of Epidemics

Control measures against pine wilt disease are aimed at breaking the pine-pine wood nematode-pine sawyer disease triangle. Present control measures consist for the most part of aerial spraying of insecticides effective against pine sawyer as a preventative of disease, spraying of insecticides on timber damaged by infestation, and trunk injection of chemicals active against pine wood nematode. In spite of various efforts, the total amount of pine timber lost to the disease is not decreasing. A further environmental factor discussed, which may influence the incidence of pine wilt disease, is some effect of acid precipitation. I believe this arises in part from discontent regarding incomplete control of pine wilt disease despite many years of concerted effort. Furthermore, pine wilt disease has the potential to become a major threat if it were to be exported to European countries as in Portugal, particularly as increasingly warm and unusual weather conditions are expected in the near future.

In conclusion, pine wilt disease, which is endemic to North America, has already spread to East Asia, including China, Taiwan and Korea. If it were to become established in the pine forests of Europe and/or Siberia, it could become one of the most serious threats to forests worldwide in 21st century.

Abstract

The atmospheric environment in many forested regions of the world is changing. Levels of tropospheric O_3 are generally increasing and higher seasonal sums of O_3 are anticipated with warmer summers. In developed countries, anthropogenic emissions of SO_x have decreased dramatically in the past decade while emissions of NO_x are stable or increasing. The acidification potential from acidic deposition remains nearly constant. Nitrogen saturation is an increasing threat to the sustainability of some essential ecosystem processes. In developing regions of the world, emissions of SOx and NOx are expected to increase dramatically within the next 50-100 years. Coincidentally, the global climate is changing. The frequency of extreme climatic events appears to be increasing against a backdrop of a general global warming trend. Concentrations of atmospheric CO_2 continue to increase with modelled predictions suggesting significant forest fertilization while empirical evidence points strongly to a significant offset due to O_3 and N saturation. Stratospheric ozone depletion has resulted in large increases in biologically-effective UV-B radiation reaching forests. Reports and predictions of increasing forest growth due to increasing CO_2 should be considered a shorter-term phenomenon. Investigation of forest air pollution case histories reveals indications of increased levels of environmental stress on forest growth and essential cycles such as water, carbon and nutrients. Current research indicates that climate change may lessen or enhance air pollution effects. In this paper, we review the evolution of approaches used to investigate air pollution effects on forested ecosystems and propose the essential elements of a new integrative concept.

Keywords: Forests, Forest health, Global change, Air pollution, Climate change

Introduction

Forests internationally are growing in a changing atmospheric environment. The major components of this change that now, or are expected to affect forest health at regional, national and multinational scales include increasing tropospheric ozone (O_3) concentrations, increasing carbon dioxide (CO_2) concentrations, and acidic precipitation. Actual and potential impacts of these have been investigated to varying degrees and risk analyses have been completed, again at varying levels of resolution. Increasing levels of ultraviolet-B radiation (UV-B, 280-315 nm) resulting from stratospheric ozone depletion are a serious threat over the medium term, but the risks to forests are unquantified to this point. At a more local scale, emissions of sulphur dioxide (SO_2), fluoride (HF), heavy metals, fine particulates (< 2.5 um dia.) and a number of other pollutants will continue to affect forests in the downwind vicinity of point sources, particularly in developing or rapidly-industrializing regions of the world.

Against this backdrop of changing atmospheric chemistry, there is clear evidence that the world's physical (temperature, precipitation patterns) climate is changing and the consensus view is that anthropogenic influences are implicated (IPCC 1995). The most damaging aspect of climate change is thought to be the increasing frequency of extreme events, rather than the general increase in mean temperature. Coupled with atmospheric change and climate change, additional pressures are being exerted by changing forestry practices and patterns of land-use.

Together, atmospheric change and climate change, along with increasing demands (practices/land-use) upon the forest resource, are now considered the three key factors comprising the global change threat to forest health and sustainability. Considerable scientific effort world-wide, particularly in the northern hemisphere countries, has been devoted to the enhancement of our understanding of forest responses to global change at the process, organ, system, stand and ecosystem levels. In many cases, value-added has been achieved through development and use of new forest indicators and mathematical models that have greatly increased the ability to predict and prepare for the consequences of global change. Much work, however, remains to be done, especially in the area of scaling up to the landscape in the context of multiple stressors and in the transfer of knowledge from developed country programs to those of developing countries. Here, respected international NGO's like IUFRO (and, in particular, its SPDC) and multilateral processes like the Montreal and Helsinki Processes have leading and pivotal roles to play.

It is impossible to review in the allotted space for this paper, all the literature on global change effects on forests. Therefore, we shall concentrate below upon a presentation of the major atmospheric change issues as they are known or predicted to affect international forest health. This is accomplished in the context of air quality trends, state of effects science, current risk analysis, and uncertainties in our understanding.

Global Change and Forest-Health

Tropospheric Ozone

Tropospheric O_3 is a secondary air pollutant formed in the atmosphere under bright sunlight from the oxidation of the primary pollutants oxides of nitrogen (NOx) and volatile organic compounds (VOC). Ozone is the most prominent of many secondary pollutants formed, including nitric acid vapour (HNO_3), peroxy-acetyl-nitrate (PAN), aldehydes and others. Its photochemistry has recently been comprehensively reviewed by Finlayson-Pitts and Pitts (1999). Ozone is the most pervasive of all air pollutants affecting or potentially affecting global forests. Levels appear to have been about 10-15 ppb a century ago, compared to 30-40 ppb measured as "background" around the world today (Finlayson-Pitts and Pitts 1999). National daily maximum 1 hour O_3 concentrations in the US have decreased by about 10% since 1987 at 194 rural monitoring sites (EPA 1997). Average numbers of days per year (1986-1993) exceeding the 82 ppb 1 hour National Ambient Air Quality Objective (NAAQO) in Canada were 18 or less. Systematic monitoring throughout Europe began only in the late 1980's and trends are less certain (Matyssek and Innes 1999). There are no clear trends in alpine regions with episodes in northern and central regions occurring downwind of industrialized areas. Much of Europe's forest is exposed to O_3 levels above 40 ppb in excess of 10,000 ppb hrs, the threshold believed to be associated with significant reductions in tree growth (Fuhrer *et al*. 1997). Analysis by Stevenson *et al*. (1998) of past and future O_3 concentrations indicates that much of the world forest area will be regularly exposed to concentrations above 50-60 ppb by 2100. Fowler *et al*. (1999) have calculated the forest area at risk, assuming risk occurs at concentrations > 60ppb. In 1950, O_3 exceedance is largely restricted to the temperate latitudes and extended to 1.7 x 10^6 km^2, or 9.2% of the temperate and subpolar forest (Table 1). In 1970, 6.3 x 10^6 km^2 or 18% of the world's forests was exposed to phytotoxic O_3 concentrations, of which only 2/3 was in the temperate and subpolar regions. By 1990, almost 25% of the world's forest was exposed with a significant increase in the tropical and subtropical forest area to 3.0 x 10^6 km^2 (Table 1). In 2100, an astonishing 49.8%, or half of the world's forests, some 17.0 million km^2 will be exposed to damaging O_3 concentrations, or 6 million km^2 tropical and subtropical, and 11 million km^2 in temperate and subpolar regions (Fowler *et al.* 1999).

Increasing Sulphur Dioxide Concentrations and Acidic Precipitation

While emissions of sulphur (S) have declined significantly in North America (-25%) and Europe (-48%) since the early to mid 1980's (Fowler *et al*., 1999) due to enactment of strict pollution control strategies, those of all pollutants, including S, in the rapidly developing economies of south and east Asia, as well as Africa, South and Central America have been increasing quickly to the point where Southeast Asia now emits more S into the atmosphere than either Europe or North America (Galloway and Rodhe 1991).

Acidic precipitation arises from the oxidation of sulphur dioxide (SO_2) and nitrogen dioxide (NO_2) in the atmosphere to form sulphuric and nitric acids that are deposited onto forests via precipitation (rain, fog, cloud) or by dry deposition (gases, vapour). Organic acids play an important role (Finlayson-Pitts and Pitts 1999) and deposition may occur close to the point or area source as well as over long-distances of 1000 km or more. Fowler *et al.* (1999) have estimated the area of global forests at risk from acidification (> 2 keq H^+ ha^{-1} yr^{-1} as S). There is a predicted 624% increase in area of global forest at risk between 1985 (0.28 million km^2) and 2050 (5.9 million km^2), the majority of the increase being in sub-tropical and tropical forest regions (0 km^2 in 1985; 2.3 million km^2 in 2050) (Table 2). Many developing countries are already experiencing significant acidification problems (Innes and Haron 2000).

Table 1. Global forest area at risk to surface ozone concentrations > 60 ppb.

	Potential area of exceedance		
	all foreststropical + subtropical		temperate + subpolar
1860		no exceedance of 60 ppb	
19502	2.1 x 10^6 km^2	0.5 x 10^6 km^2	1.7 x 10^6 km^2
.%	6.3	2.9	9.2
1970	6.3 x 10^6 km^2	1.9 x 10^6 km^2	4.4 x 10^6 km^2
%	18.5	12.1	24.1
1990	8.3 x 10^6 km^2	3.0 x 10^6 km^2	5.3 x 10^6 km^2
%	24.4	19.1	29.1
2100	17.0 x 10^6 km^2	6.0 x 10^6 km^2	11.0 x 10^6 km^2
%	49.8	37.9	60.2

Reproduced from Fowler et al. (1999).

Table 2. Global forest area predicted to receive in excess of 2 keq H^+ ha^{-1} yr^{-1} as S per year and be at risk from acidification.

	Potential area of exceedance		
	all forests	tropical + subtropical	temperate + subpolar
1985	0.28×10^6 km^2	0	0.28×10^6 km^2
%	0.8	0	1.5
2050	5.9×10^6 km	2.3×10^6 km^2	3.6×10^6 km^2
%	6.0	4.4	7.3
% change 1985 to 2050	624	-	376

Increasing Carbon Dioxide Concentrations

Emissions from fossil fuel combustion and deforestation have been rapidly increasing CO_2 concentrations in the atmosphere (Schlesinger 1997). Concentrations have risen from about 280 ppm in the pre-industrial period to approximately 360 ppm today, with doubling anticipated by 2050-2100. On the one hand, global forests have considerable potential to reduce the anthropogenically-driven increase in CO_2 as they are generally (C3 system) carbon-limited at current atmospheric concentrations (Drake *et al.* 1997). However, significant knowledge gaps remain, especially in light of known potential of other air pollutants such as O_3 to reduce productivity gains under enriched CO_2 atmospheres (Karnosky *et al*. 2000). In addition, the role of long-term adaptations to higher CO_2 concentrations is unknown. A considerable literature is available on tree/forest response to enhanced CO_2 (Saxe *et al*. 1998; Norby *et al.* 1999).

Increasing Ultraviolet-B Radiation

Ozone (O_3) is the most important trace constituent in the stratosphere. Although present in relative concentrations of less than a few ppm, it is an extremely efficient absorber of highly-damaging UV at altitudes between 10 and 50 km. Biologically-effective UV-B that damages plant DNA and essential physiological processes is absorbed by O_3 with an efficiency that increases exponentially with decreasing wavelength (Tarasick and Fioletov 1997). Anthropogenically-induced stratospheric O_3 depletion was first confirmed over Antarctica in the early 1980's but has since been identified elsewhere, with peak depletions in the spring of 1993 over Canada reaching 30% at 16 km (Tarasick and Fioletov 1997). Measurements point to resultant large increases in ground-level UV-B radiation at high- to mid-latitudes of both hemispheres during 1979-1993 (Madronich *et al*. 1995). Further increases are expected to occur until at least 2050. Effects on photosynthesis, growth and biomass, vigour and the DNA of sensitive tree species are predicted in the next 100 years, although the magnitude of risk to global forests remains unresolved (Percy and Gordon 1998).

Interactions of Atmospheric Change and Climate Change

There are many known interactions between atmospheric pollution and climate change. For example, sulphate and nitrate particles and other fine particulate can act as condensation nuclei, increasing the formation of clouds. The incidence of clouds has an impact on global temperature. In relation to the impacts on forests, there are a number of important interactions. The occurrence of drought reduces the uptake by trees of gaseous pollutants. However, the exposure of trees to pollutants prior to drought may reduce the stomatal control of the trees, making them more drought-susceptible. These, and many other interactions, means that climate change and pollution must be considered together when examining the effects of global change on forests.

What is Forest Health?

Perhaps the most logical task beginning the discussion, is the definition of forest health. The Oxford Dictionary (Hawkins 1983) defines *health* as "the state of being well and free from illness...". While this definition is anthropocentric, it does relate, at least in part, to trees. However, as with the extension of human health to the health of cities, there are major problems in extending the concept of health from single trees to forests. To the best of our knowledge, at this time there remains no universally-agreed upon definition of *forest health*, or what constitutes a *healthy forest (*Edmonds *et al*. 2000). Certainly, resilience to disturbance(s), proper ecosystem functioning, productivity and a certain state of biodiversity must be considered some of the major attributes that would constitute a *healthy forest*. There also exists some confusion over the international usage, sometimes simultaneously, of the terms *forest health* and *forest condition*; the latter term was initially adopted as it was believed to be more appropriate to the descriptive measures used in many forest inventories. In contrast, the term tree health was considered to be best used in relation to the degree to which pathogens were disrupting normal tree processes.

O'Laughlin *et al.* (1994) defined forest health as "...a condition of forest ecosystems that sustains their complexity while providing for human needs." In the context of forest response to atmospheric change, the sustaining of ecosystem function is especially important when one considers that stress responses are not monotonic and usually begin with sensitive individuals and proceed from leaf to branch, to tree, and then to stand and ecosystem levels (Hinckley *et al.* 1992). Clearly, process-oriented and pattern-oriented considerations are essential to any definition of forest health. A recent summary of the divergent definitions of forest health, with their implicit assumptions, can be found in McLaughlin and Percy (1999). Here, we choose to discuss global change impacts on forest health from the ecosystem-based perspective, believing it to represent best the underlying values that contribute to a healthy forest. For the purposes of the following discussion, therefore, we use the perspective of McLaughlin and Percy (1999) who defined forest ecosystem health as "*The capacity to supply and allocate water, nutrients and energy in ways that increase or maintain productivity while maintaining resistance to biotic and abiotic stresses*."

How Are Impacts of Global Change on Forest Health Monitored?

Forest health has been continuously measured subjectively or quantitatively, at single points in time or over many years, and at stand to regional to national and international scales for several hundred years. During the past 20 years, considerable development in North America and Europe has occurred in the indicators being employed, techniques used to assess forest health or condition and in monitoring network design. Concepts of decline have been expounded (Manion and Lachance 1992) specific to individual forest declines, whether due to single or multiple agents. The most complete review of international forest health status and assessment was compiled by Innes (1993) and the reader is referred to this volume for a detailed presentation of international forest health in the early 1990's, as well as a summary of assessment methodologies. However, we would point out that since this compilation, the concept of forest health has continued to evolve and now, as our definition above suggests, encompasses the forest ecosystem as a whole. In this paper we shall focus upon programmes in North America and Europe.

Specific recognition of the policy requirement to monitor health effects of global change was evident in North America in the early 1980's, coincident with growing concern over the impacts of acid rain. It was then that the rationale and approaches for the North American monitoring programs changed due to studies that indicated that widespread changes in forest condition could be occurring in North America and Europe (Rehfuess 1981; Ulrich 1984; McLaughlin 1985). Prior to then, monitoring was largely restricted to assessment of tree and soil conditions in the vicinity of large, stationary point sources of sulphur dioxide (SO_2) and other gaseous air pollutant emissions. The extensive studies (Freedman and Hutchinson 1980 a,b) carried out in the Sudbury, Canada, area reporting on increasing degrees of forest decline and ecosystem modification with proximity to a nickel smelting complex represents the most noteworthy example. For O_3, the excellent long-term studies of Miller (summarized in Miller and McBride 1998) initiated in the late 1950's and reporting on tree condition and ecosystem shifts in the Southern California Air Basin is the classic example of earlier work. Substantial impacts on forests are still being noted around point sources today and have been described by Innes and Oleksyn (2000).

North America

The Acid Rain National Early Warning System (ARNEWS) was initiated in 1984 and consisted of 150 rectangular, 10m x 40m plots with 2m x 2m subplots stratified by forest region. Representing one of the best and most comprehensive forest health monitoring programmes conducted to date, soil samples, foliar samples for nutrient analysis, and radial growth measurements were collected every five years adjacent to the plot (soil) or from numbered off-plot trees (foliage, increment cores). Indicators were sampled on all plots at varying frequencies (Table 3). Foliar symptoms, hardwood seed crop, pest conditions (type of foliar insect/disease, woody tissue insect/disease and severity) and tree condition (mortality, live crown height, crown damage, needle retention) were measured seasonally and/or annually. Regeneration, saplings and ground vegetation (mosses, herbs, shrubs) were assessed biennially (D'Eon *et al.* 1994).

In the United States, the Detection Monitoring component of the US Forest Health Monitoring Program (FHM) was implemented in 1996 (USDA 1996) on about 40% of approximately 4000 forested plots in the lower 48 states. A spatially and temporally systematic sample has been based on a national hexagonal grid (27 km between grid centres). The plot size and sampling frequency format (Table 3) results in all circular 1 ha plots being sampled every 4 years with annual estimates of change being derived from smaller subplots (Smith and Mangold 1996). This design yields: 1) a base-line condition the first year; 2) a direct measure of 1-year change for sub-plot samples after two years; and, 3) a direct measure of 4-year change after five years.. Indicators (Table 3) being measured in Detection Monitoring include lichen communities, ozone bioindicator plants, tree growth, crown condition, damage, mortality, regeneration, vegetation structure and plant diversity.

In 1988 the Canadian Forest Service and USDA Forest Service joined with state and provincial departments to establish the North American Maple Project (NAMP). NAMP consisted of a network of 233 sites extending across the natural range of sugar maple (Millers *et al.* 1991). Sites were five-plot clusters of 20m x 20m plots. Variables assessed annually included defoliation, tree vigor, new damage to boles and crown condition (dieback, transparency).

These systems were designed to address unique agency mandates and have individual strengths and weaknesses in monitoring forest health response to global change. Alone, none has enabled policy makers to relate effects to causes with the required degree of scientific certainty. Also, re-ordering of priorities and shifts in resource allocations have resulted in the phasing out in 2000 of ARNEWS in Canada. The Canadian Forest Service aims to replace it with a new Three-Tier Strategy (Percy 1999), combining national-level assessment, case-studies and long-term ecosystem-level monitoring and research. In the United States, shifts in FHM have witnessed an increased emphasis upon data collection for carbon stocks inventory and the extension of the programme to a variety of different countries and issues (such as forest cover in the mountains of East Africa).

Europe

During the 1970's, concerns about freshwater acidification, particularly in Scandinavia, led to the United Nations Economic Commission for Europe (UN/ECE) initiating the Convention on Long-Range-Transboundary Air Pollution (LRTAP). Several impacts studies were started under the auspices of the LRTAP Convention. With the establishment of the International Cooperative Programme on Assessment and Monitoring of Air Pollutant Effects on Forests (ICP Forests) and a similar programme within the European Union, forest condition has been monitored using harmonized methods and criteria since 1986/1987 (UN/ECE 1994). In contrast to ARNEWS, Level 1 monitoring was carried out over an extensive area using a systematic sampling design (16 km x 16 km), but with a low-intensity of observations on a fixed number of trees per plot (Table 3). Crown condition was assessed annually in all plots, and the presence-absence of easily-identifiable damage such as biotic or climatic stress was assessed in many. A portion of the UN/ECE plots was also sampled for soil condition and foliar element concentrations. In 1994, a programme of intensive monitoring (Level II) was instituted on a much smaller number of plots. Level II features monitoring of factors believed to be affecting forest health including bulk deposition and soil chemistry, but still contains no detailed assessment of the incidence of pests and disease. A third level (Level III) has been called for, but never implemented, although its functions are largely duplicated by a small number of catchment studies set up under the International Cooperative Programme on the Integrated Monitoring of Ecosystems (ICP Integrated Monitoring).

State of Science on Forest Health and Future Prospects

North America

Air pollution is an important component of the atmospheric environment in which North American forests grow. McLaughlin and Percy (1999) have recently reviewed forest health as reported through national-level networks and through detailed analysis of the four most-important air pollution-forest case studies. Mortality in northeastern hardwood forests in the early 1980's was linked to acid rain, although sugar maple condition has improved (Stoyenhoff *et al.* 1998; Hall *et al.* 1998) while rainfall acidity remains largely unchanged. Analysis of soil buffering has correlated exceedance of S/N critical loads with branch dieback (Arp *et al.* 1996). Tree response has been primarily linked to soil sensitivity to acidic deposition (including N saturation). Acid rain is known to have caused the loss of soil base cations resulting in reduced Ca, Mg and K concentrations in sugar maple stands (Foster *et al.* 1992). Circumstantial relationships between increased seasonal O_3 exposure and increased crown transparency have been noted. In coastal birch forests field studies have documented a correlation between H^+ ion and NO_3 in fog with leaf browning (Cox *et al.* 1996) in an area that also receives significant O_3 from urban conurbations to the southwest. Fog frequency itself may also play a key role in modifying leaf surface properties and consequential enhancement of pathogen infections (J. Skelly, personal communication).

Table 3. Comparison of the United States Forest Health Monitoring Program (FHM), the Canadian Acid Rain National Early Warning System (ARNEWS), the North American North American Maple Project (NAMP) and the Eurpoean (UN/ECE ICP) forest health Level 1 monitoring programs.

B: bioindicator plants
P: passive O_3 monitors.
X: not assessed
M: modelled from regional networks; no on-site monitoring
I: instrumented
L: lichens

Winter injury was first observed in the late 1950's on red spruce growing at high elevations, resulting in decreased radial growth/increased mortality in both cloud and O_3-exposed mountain forests, as well as fog - and O_3-exposed coastal forests (Jagels *et al.* 1989; Johnson *et al.* 1992). Experimental studies, however, have not been able to reproduce symptoms at ambient levels of acid exposure. A summary of research on decline of red spruce is available (Eagar and Adams 1992). Dendro-climatological analysis (Cook and Johnson 1989) has shown that growth decline was associated with increased sensitivity of trees to winter (northern Appalachians) and warmer late summer (southern Appalachians) temperatures. Field studies have further shown reduced net carbohydrate production in foliage, reduced photosynthesis, and increased respiration (McLaughlin *et al.* 1993).

Growth declines in un-managed south-eastern pines were reported in the early 1980's by Sheffield and Cost (1987). Fox and Mickler (1996) have compiled a summary of forest characteristics, biotic and abiotic stresses along with the results from a large number of integrated field and experimental research projects. Ozone is known to significantly increase effects of soil moisture stress on stem growth of loblolly pine (McLaughlin and

Downing 1996). Somers *et al.* (1998) were recently able to correlate visible O_3 injury with radial growth of individual yellow-poplar trees. Acidic deposition effects in the short-term are not expected to be significant (Teskey 1995) in the southern pines and the main effects are expected to occur through primary impact on nutrient cycles.

Since at least the mid 1950's, much of the mixed conifer forest in Southern California has been exposed to some of the highest concentrations of O_3 in North America. The detrimental role of N deposition is also well established, and is unique in that most occurs in dry form as acidic vapor, gaseous and particulate species. Deposition as high as 25-45 kg N ha^{-1} yr^{-1} has resulted in localized N saturation (Bytnerowicz and Fenn 1996) affecting ponderosa and Jeffrey pine ecosystems. The complete history of the multi-disciplinary case study in the San Bernardino Forest has been published (Miller and McBride 1999). Uniquely, effects from foliar level to successional stage have been documented. Concentrations of 50-60 ppb O_3 were sufficient to cause foliar injury, early needle loss, decreased nutrient availability, reduced carbohydrate production, lower vigor, decreased height/diameter growth and increased susceptibility to bark beetles (Miller et al. 1982). It is interesting that under diminishing annual average O_3 concentrations, Miller *et al*. (1989) have reported an improvement (1974-1988) in the foliar injury index.

Europe

Spiecker (1999) has recently summarized growth trends in European forests and reports an increasing (management practices) growth trends (wood volume, up to +50%; height, up to +5 cm) in southern regions of northern Europe, most regions of central Europe and in some parts of southern Europe. No clear trend was evident in the most northern regions, in rare cases in central Europe and in some areas of southern Europe. Decreasing growth trends were found in cases where “extreme growth conditions such as intense exposure to pollutants (O_3, SO_2, N) or exceptional climatic conditions (drought, storms etc) occurred” (Spiecker 1999), such as close to Monchegorsk smelter on the Kola Peninsula of northern Russia. Air pollution is clearly affecting forest health and productivity in a number of regions such as the Kola Peninsula and parts of eastern Europe, although the evidence of continued impacts elsewhere is much more circumstantial. An exception is the evidence of ozone injury to trees in several central and south European countries, including Greece (Velissariou *et al*. 1992), Italy (Busotti and Ferretti 1998), Switzerland (Skelly *et al.* 1999) and Spain (Skelly *et al*. 1999). Elsewhere, ozone concentrations may be impacting tree health, and acidification has caused the disruption of ecosystem functions in a number of more sensitive forest ecosystems (e.g. Van Breemen and Van Dijk 1988). An additional, but localized, problem is the very high levels of ammonium deposition that occurs in some areas of the Netherlands and elsewhere (van der Eerden *et al.* 1998; Van Dobben and Ter Braak 1998). The abundance of nitrogen has severely disrupted the more sensitive components of the forest vegetation, in some cases resulting in the loss of species from particular areas.

A distinct deterioration in forest condition has been identified for seven of the most frequent tree species and importantly, distinct regional differences were observed at the European scale (Muller-Edzards *et al.* 1997). For many Level I plots, the analysis that was undertaken was unable to explain the deterioration through site factors such as altitude, location and climate. In parts of central and eastern Europe and in the Iberian Peninsula, clusters of plots (in areas of significant S and O_3 pollution) had crown condition deterioration which could not be explained by stand characteristics. However, there were also other clusters of plots with deteriorating crown condition (in areas without significant S and O_3 pollution) that were not explained by stand characteristics, suggesting that the problem is still some way from explanation.

Forest dieback due to air pollution in parts (1.1 million ha or 2.8%) of the 39 million ha of forest in 13 Central and Eastern European countries is mainly concentrated, but not restricted to the so-called “Black Triangle” (Czech Republic, Germany and Poland) (EC 1999). Air pollution is considered the most important anthropogenic factor (others are grazing/pruning, war in Bosnia and

Herzegovina, and fires) affecting CEEC forests. It remains the most important stress factor for forests in the central region (Czech Republic, Slovakia, Poland). Country emissions of SOx have decreased considerably (up to 50%) between 1980 and 1994, while only moderate decreases in NOx and ammonium were recorded. Ammonium emissions in Poland actually increased 7-fold (EC 1999). Average defoliation levels in Poland, the Czech Republic, Slovakia and Bulgaria are the highest in Europe. In Albania, Bosnia and Herzegovina, Estonia, Hungary, Latvia, Lithuania, FYRO Macedonia, Romania, Slovakia and Slovenia, low defoliation levels are typical.

Modelled estimates showed that calculated critical levels were exceeded at 20% of the plots for SO_2 and approximately 90% of the plots for O_3. Exceedance of critical threshold values for acidity and N occurred at 10-25% of the plots, although the thresholds related to effects on ground vegetation rather than crown condition (Muller-Edzards *et al.* 1997). While the atmospheric concentrations of sulphur and nitrogen can be correlated with increased foliar S and N contents (Innes 1995), it has been difficult to draw similar relationships with crown condition, and by far the clearest and most severe impacts have occurred amongst the ground flora, with substantial changes in species composition being recorded in some areas (Brunet et al. 1997). Although a number of correlation studies have been undertaken between forest condition and environmental variables, including pollution, major difficulties have been encountered with the interpretation of the results due to the large number of confounding factors (Muller-Edzards et al. 1997). It is possible that the more detailed environmental data that will be collected in the Level II plots will help resolve this problem, but it is likely that substantial problems will remain associated with the scaling of these individual case studies to wider areas.

Innes (1993) has pointed out that just because visible injury to foliage from air pollution is not recorded in national-scale monitoring programs, we should not assume that injury is absent. This is one reason behind the UN/ECE decision in 1995 to institute more intensive monitoring (Level II) to provide detailed surveys of soil, foliage and deposition and to allow for investigation of correlations between forest condition data and stress factors in Europe. Certainly, O_3 concentrations in many regions of Europe today are sufficient to adversely affect tree growth (Matyssek and Innes 1999). The sampling design, however, may be inappropriate to allow for analysis of such relationships, particularly in relation to the numbers of trees assessed per site.

Air Quality Standards, Guidelines, Critical Levels and Policy Concerns

North America

Canada and the United States differ in their approach to air pollution regulation. In Canada, the federal government sets (not legally enforced) National Ambient Air Quality Objectives (NAAQOs) on the basis of recommendations from the Canadian Environmental Protection Act/Federal-Provincial Advisory Working Group on Air Quality Objectives and Guidelines (Table 4). NAAQOs are designed to provide protection to human health, vegetation, animals and materials. In the United States, the US Environmental Protection Agency (EPA) is responsible for setting National Ambient Air Quality Standards (NAAQS) for criteria pollutants (Table 4). Unlike the Canadian NAAQO, the NAAQS are legally enforced. Primary standards are designed to protect human health; secondary standards to protect welfare including vegetation. NAAQS are based upon extensive consultation, scientific review and are examined by the Congressionally-appointed Clean Air Scientific Advisory Committee prior to recommendations being made to the EPA Administrator. Unfortunately, it is not meaningful to compare NAAQO with NAAQSs due to the differences in units of measurement (SO_2, O_3, NO_2), as well as form and level of standards/objectives.

Europe

In Europe there are UNECE, World Health Organization (WHO) and European Union (EU) limit values and critical levels published for O_3, SO_2 and NOx. The UNECE and WHO critical level for forests that is not to be exceeded for cumulative O_3 exposure over a growing season is 10 ppm hours in daylight hours over 6 months (April-September) (Table 4). This critical level is designed to indicate where there is a risk of growth losses associated with ozone. It is not designed to protect vegetation, and visible injury is known to occur at concentrations below the threshold (VanderHeyden *et al*. 2000). In view of this and a number of other difficulties, a "Level 2" standard is being considered. This will take into account species phenology, differential species sensitivity, climatic factors and a number of other variables.

The UNECE and WHO critical level for SO_2 forest exposure is defined under an annual or winter mean of 20 ug m^{-3} or 15 ug m^{-3} in "harsh climates". The EU lists 20 ug m^{-3} for all ecosystems away from the vicinity of sources (Table 4). The NOx level is listed as the annual mean of sum of NO and NO_2 concentrations (ppb), expressed as ug m^{-3} based on conversion for NO_2 and listed as 30 ug m^{-3} by all agencies.

Although direct comparisons between forest responses to different air pollution climates in Europe and North America cannot be made (Percy *et al*. 1999), in part due to centuries of forestry practices and land-use policies, clearly there is a need to standardize approaches to air quality standards and critical levels. Given the significant differences in factors (climate, latitude, elevation, disturbance history, species, genotype etc.) which combine to affect the magnitude and direction of stand or ecosystem response, perhaps it is time to converge upon a single form for an index which is most scientifically-defensible and has some biological base to it. The level within the form can certainly be adjusted then to account at the regional and national level for some of the confounding or predisposing factors. The Level 2 standard being considered for O_3 in Europe seems to be one such approach and needs to receive greater attention in North America.

New Approaches to Meet Policy Requirements

Utilitarian approaches commonly used to assess forest health are likely inadequate for the detection of future change and elucidation of the roles of natural and anthropogenic stressors. Integrated approaches linking process-oriented empirical studies (FACE) with pattern-oriented monitoring along defined pollution gradients (clones; ecological analogues), ecosystem-based research on essential cycles (calibrated watersheds) with new approaches to monitoring will be required if the interactive effects global change (air pollution + climate change) on forest health and sustainability are to be understood in the 21st Century.

One new forest health approach to addressing the policy requirement for enhanced linkage of cause and effect in a timely fashion is represented by the new CFS Three Tier Strategy. This design (Table 5) comprises elements of the North American and UN/ECE experience in that it integrates new approaches to national-scale forest health assessment with process research. Essential elements defined are : 1) a national-level synthesis of forest health stratified upon an national forest inventory inventory grid (Tier 1); 2) for health problems reported under Tier 1, and once spatial and temporal extents have been elucidated, individual shorter-term, multi-disciplinary case-studies to identify cause-effect linkages (Tier 2); and 3) longer-term ecosystem-level monitoring and research at the watershed level and beyond to support activities under Tier 2 and monitor policy performance (Tier 3). Tier 1 data will be collected under cooperative arrangements with provincial agencies by supplementing existing inventory and protection mandates with some health variables.

Table 4. Air quality objectives, standards, guidelines and levels for protection of forests.

	Ozone	Sulphur dioxide	Nitrogen oxides (Nitrogen dioxide)	Suspended particulate matter PM 2.5[3] PM10[4]
Canada NAAQO[1]	1 hr 82 ppb 24 hrs 25 ppb annual 15 ppb	1 hr 334 ppb 24 hrs 115 ppb annual 23 ppb	(1 hr 231 ppb) (24 hrs 106 ppb) (annual 53 ppb)	24 hrs 120 $\mu g\ m^{-3}$ annual 70 $\mu g\ m^{-3}$
United States NAAQS[2]	8 hrs 0.080 ppm	annual 15 $\mu g\ m^{-3}$ 2 4 hr 65 $\mu g\ m^{-3}$	(annual 0.053 ppm)	PM2.5 annual 15 $\mu g\ m^{-3}$ 24 hr 65 $\mu g\ m^{-3}$ PM10 annual 50 $\mu g\ m^{-3}$ 24 hr 150 $\mu g\ m^{-3}$
UNECE	10,000 ppb h in daylight hours over 6 months	annual 20 $\mu g\ m^{-3}$	annual 30 $\mu g\ m^{-3}$ (from annual mean sum of NO and NOx ppb)	
WHO	10,000 ppb h in all hours over 6 months	as for UNECE	as for UNECE	
EU		20 $\mu g\ m^{-3}$ (away from vicinity of sources)	30 $\mu g\ m^{-3}$	

[1] National Ambient Air Quality Objectives (NAAQO) are defined in terms of maximum desirable, maximum acceptable and maximum tolerable levels. Maximum acceptable levels are listed and considered to provide adequate protection against adverse effects on humans, animals, vegetation, soil, water, materials and visibility.
[2]National Ambient Air Quality Standards listed are Primary Standards. All values are means.
[3] PM2.5 : particles 2.5 µm in diameter and smaller
[4] PM10 : particles 10 µm in diameter and smaller

The Canadian Forest Service will provide national synthesis, quality asurrance, indicator performance evaluation functions. Selected ARNEWS monitoring indicators are combined with new indicators, such as needle surface wax chemical characteristics used to relate tree condition with "pollution climate" (Cape and Percy 1998), while broadening the forest values being assessed to include measures of resilience, biodiversity and essential cycles. An example of national-level forest health reporting combining essential elements of the three tiers and addressing a range of ecological and more anthropocentric forest values can be found in the first overview report on Canadian forest health (FHN 1998).

It is abundantly clear that existing air quality standards, objectives or guidelines do not afford an adequate degree of protection to sensitive trees and plant communities. This is not unexpected as most were designed to protect human health, and are more tools for regulators.

Table 5. Essential features of the new Canadian Forest Service Three Tier System for integrated forest health monitoring and research.

Tier	Objective	Duration	Stratification	Outcomes	Key Components[1]
One	Synthesis of national forest health	continuous on 10 year cycle 10% plots per year	statistical grid system (20 km x 20 km)	assessment trends health index	site quality pest condition stand integrity structural diversity species diversity wildlife trees coarse woody debris natural disturbance seral stage
Two	Case studies of cause-effect	< 5 yrs	gradient stand-level geographical region	cause-effect linkage critical loads/levels indicators	crown condition insects/diseases foliar condition increment soil indicators physiological indicators biochemical indicators site instrumentation deposition pollutant concentrations

[1]At time of writing, key components of each tier are still under discussion

Considerable effort over the past 15 years has been devoted, particularly in Europe under UN/ECE auspices, to the development of critical levels (SO_2, O_3) and loads (S, N, heavy metals) for the protection of forests.

This work is now at a relatively advanced stage, and detailed maps of exceedances are available for most countries. The maps have been extremely useful for decision makers in choosing which sources address first, and have enabled a more cost-effective, scientifically based approach to pollution control (Bull and Fenech 2000). It seems likely that this is one of the most cost-effective ways of reducing air pollution impacts on forests.

Abstract

The widespread bush and forest fires that occurred in Indonesia between April and October 1997 caused extensive episodes of haze or smoke throughout the region, particularly in Indonesia, Malaysia, Singapore, Brunei and parts of the Philippines and Thailand. Satellite imagery analysis has revealed that most of the fires started in the plantation areas in Borneo and Sumatra as a result of burning for land clearing and preparation for agricultural practices. The dry conditions in Southeast Asia resulting from the 1997 El Niño - Southern Oscillation (ENSO) climate phenomenon exacerbated the problems and made forest fire control more difficult. At least three combustion processes with specific characteristics were identified, namely, flaming, smoldering and mixed. More than 1,000 fires affected an estimated 300,000 ha or more, with some estimates extending to 800,000 ha. The question of biodiversity loss has yet to be assessed. The severity and extent of the smoke haze pollution were unprecedented and the region experienced extended periods of high particulate levels and severe reductions in visibility. The haze pollution also resulted in considerable health impacts to the people although the long-term health effects are yet to be determined. Long- and short-term implications of visibility reductions during the haze period on the survival of light-demanding and shade-tolerant species on the forest floor and their potential to shift species compositions in forest ecosystems due to changes in ecophysiological processes are also discussed.

Keywords: Forest fire, Haze, Health Impact, Haze particle, Forest Ecosystem, Ecophysiological processes.

Introduction

The recurrence of widespread bush and forest fires in Indonesia in 1997 caused extensive, although as yet unquantified, economic, social, and environmental impacts in Indonesia and its neighboring ASEAN countries. Fires occurred in Kalimantan, Sumatra, Java, Sulawesi and other islands. Satellite imagery analysis has shown that most of the fires started in plantation areas of Indonesia as the financially cheapest means for land clearing and preparation. The concurrent dry conditions in Southeast Asia resulting from the 1997 El Niño - Southern Oscillation climate phenomenon exacerbated the problem and made forest fire control more difficult. The area affected by burning is related to the length of the dry season. According to the ADB Report (1997), since 1987 the affected area has increased with each successive extended dry period (e.g., in 1987 (49,000 ha), 1991 (119,000 ha), and 1994 (162,000 ha)). In 1997, more than 1000 fires affected an estimated 300,000 ha or more, with some estimates up to 800,000 ha. Consequently, there was a widespread accumulation of haze or smog that covered neighboring countries and caused widespread economic, social and environmental impacts. The regional haze seriously affected Indonesia, Malaysia, Singapore, Brunei and parts of the Philippines and Thailand. It has been estimated that the regional haze crisis resulted in a one-percent reduction in national economic growth in some affected countries. Tourism in the region has been severely hit. The World Health Organization has predicted that the haze will result in lung ailments and breathing discomfort for about 20 million people in the region. Malaysia, Singapore, Australia, Japan, USA, and other countries as well as international organizations have provided rapid material support and technical assistance to Indonesia in combating the fires and assisting in relief efforts for the affected populations in Sumatra and Kalimantan. In short, the haze episode that occurred in the region from July to the end of October 1997 is on record as one of the historical air pollution disasters of the world, affecting nearly 300 million people over an area exceeding 2 million km^2. The incident has left a legacy of impacts on human health, the economy, the ecology, and on political systems as well as many more that need to be determined and investigated for the benefit of mankind.

Nature of Forest Fires

Within a framework of technical cooperation between the Government of Malaysia and the Republic of France, a team of multi-disciplinary remote sensing experts coordinated by MACRES (Malaysian Centre for Remote Sensing) was assigned to work on the 1997 forest fires and smoke haze. The study utilized high spatial resolution SPOT satellite data and low-resolution satellite images (NOAA-AVHRR satellite) for the purposes of disaster prediction, early warning, and damage assessment in the Southeast Asian region (Mahmood and Bolhassan, 1998) with special reference to Banjarmasin (Kalimantan) and South Sumatra. In the case of the maximum development of fires in Banjarmasin, the total area burnt by 7 August 1997 reached 50,550 ha, representing approximately 20% of the study area, whilst a total of 1,380,814 ha in South Sumatra accounted for 14.6% of the study area (9,415,375 ha). Mahmood and Bolhassan (1998) also pointed out that the burnt areas affected two land-cover types. In cultivated areas, fires exhibited geometric boundaries following the limits of the fields and of the deforested areas. This is considered to be the normal process of field clearing before cultivation. In natural vegetation areas, the fire patterns were more complex, and followed roads and tracks.

Analysis of the fires demonstrated that fire patterns could be broadly related to different vegetation structures. The direction of fire propagation seemed to be related to openings in the natural vegetation, such as drain channels, tracks and roads. Fire propagation followed the natural pattern of networks, such as rivers, sparing dense forest patches. In areas dominated by agricultural activities, natural vegetation, sparse forests and bushes border the river networks, and are connected by patches of dense forest cover. In this situation, the fire patterns followed these lines of natural vegetation, resulting in the propagation of fires over long distances. Wind direction plays an important role in determining the direction and extent of the spread of fires in these areas.

Brunei Darussalam

Vegetation fires occur in Brunei Darussalam during dry spells. As recorded by the Fire Department, there were a total of 740 reported cases of vegetation fires in 1997 between the months of January and October, which destroyed around 878 ha of vegetation cover. This is significantly more than what had occurred during the whole of 1996, when there were only 470 reported cases of vegetation fires destroying 474 ha of vegetation. The highest reported occurrences of fires were from May to September. The cause of the majority of the fires was unknown. Of those fires for which a cause was known, the most important source was open burning activities. Local vegetation fires are probably the major contributor to occurrences of localized haze in the country. However, in 1997, there were only a few incidences of vegetation fires that were of significance for the development of haze.

Indonesia

The results of actual and on the spot field inspections in Riau on 24 May and 23 August 1997, Jambi on 13 September 1997, South Sumatra (in Central Kalimantan) on 16 September 1997 indicate that ground and forest fires first originated from new investments in the agribusiness, especially large scale plantations violating bans on land-clearing fires issued by the Ministries of Agriculture, Forestry, Transmigration and the Settlement of Forest Squatters in effect since 1995. In addition, there was a lot of small-scale burning by individuals for agricultural purposes; this has become habitual each dry season in anticipation of the rainy season. As the conditions were extremely dry, fires set to clear land developed into uncontrolled wildland fires.

Hot spots in Sumatra and Kalimantan increased from February until July 1997. In August these hot spots tended to decrease at night and increase again during the day. This was an indication of controlled burning. Data in September indicated that hot spots were seen both day and night, implying that the fires were out of control.

Smoke pollution affects human beings by causing health problems and a rising number of cases of asthma, pneumonia, upper respiratory tract infection, eye irritation, diarrhoea and DHF has been identified. It was anticipated that all these effects would combine with the other normal effects of the prolonged dry season and with disturbances to air, land and river transportation routes.

Of estimated 121,626 ha of forests burned, 22,816 ha had being due to burning for land clearance, 10,103 ha due to fires spreading out of control and 88,707 hectares of existing plantations. In addition, 731 ha of food crops and horticulture were burned in South Kalimantan, Central Kalimantan, South Sumatra and Riau, consisting of 209 ha of rice crops, 1.5 ha of second crops and 520 ha of horticulture. At least 88 of 300 houses located on a 300 ha piece of land that was once peat soil were burned at the Sinunukan Transmigration settlement in South Tapanuli, North Sumatra province, and 149 houses were burned on a 800 ha piece of land at the Peat Soil Development Project at Muara Dadahup and Lamunti, Kuala Kapuas, Central Kalimantan. At the same time more than 268 houses were destroyed by fire on 800 ha of peat soil at the former Pegambit 2 transmigration settlement area, Pulau Laut Timur, Kota Baru, South Kalimantan.

Accordingly, 96,693 ha of forests were burned, consisting of 10,552 ha of protected forests, 70,259 ha of productive forests, 3,896 ha of natural conservation forests, 5 ha of provincial recreational forests and 35 ha of other natural forests. The Timber and Plantation Estates (HTI) suffered an estimated loss of Rp 45.7 billion. There was a decrease in income originating from the airline business, plane passengers, landing fees, and the directing and parking of airplanes due to the 1,037 flights that were cancelled at 11 airports in Sumatra and 2,027 other cancelled flights at 12 airports in Kalimantan.

The end of the transitional period between the dry and the wet season in Indonesia was accompanied by a change in wind directions and an increase in humidity and was helpful in slowing down the burning process. The winds that were first blowing towards the west and then turned on Sumatra to the north (similar to the pattern in Kalimantan) changed direction from the northwest to the south (Indian Ocean). This change in wind direction improved the air quality in Singapore and Malaysia. Following this, Malaysia lifted the emergency conditions in Sarawak.

This situation was followed by relatively heavy rainfall in several areas including Riau, South Sumatra, West Sumatra, Lampung, Jambi, West Kalimantan, Southeast Kalimantan, South Kalimantan and several areas in Java. The rainfall extinguished several hot spots in some areas and reduced smoke pollution. Visibility increased to more than 600 meters, which in turn resulted in the reopening of several airports that had stopped operations. However, some resumed operations in part only.

Malaysia

The haze episode in Malaysia was primarily due to the exceptionally high concentration of suspended particulates in the air. Smoke from ground and forest fires from Sumatra and Kalimantan, Indonesia aided by westerly and south-westerly winds caused serious reductions in visibility and high suspended particulate levels below PM_{10}. Malaysia experienced serious health, ecological, economic and political impacts during the period mid-July to early November 1997. Following the haze episodes of the 1990s, Malaysia established the National Haze Committee to examine the sources, preventive measures and responses needed.

The Haze Action-Lines (HAL), which use the PSI-based Air Pollutant Index (API), were drawn up to provide a coordinated response during haze episodes. These however mainly targeted the control of domestic sources and the actions taken are only effective if local sources are involved. In this connection, the HAL provided a good basis for the National Disaster Relief Committee to adopt a threshold enabling environmental emergency to be proclaimed after taking into account political and economic considerations. For example, instead of accepting 300 as the hazard level, 400 was adopted to close schools and 500 to declare an emergency for people to remain indoors.

The data collected during the episodes are being analyzed. Generally, East Malaysia experienced higher peak PM_{10} particulate levels than other parts of Malaysia – in September 1997, there were 10 days when concentrations exceeded the health standard, eight days when they exceeded the extremely unhealthy level and six days when they were extremely hazardous. In West Malaysia, the Klang Valley had more than 2/3 of the month of September above the threshold for health effects, but the peak values remained lower than the extremely unhealthy (300) level, with only one area (Gombak) crossing momentarily above 300 on 20 November 1997.

The good air quality normally prevailing throughout the country was adversely affected in 1997, largely by the forest and peat fires in the region (DOE, 1997b). All the 29 (CAQMS) stations, except the latest one in Miri, Sarawak, which came into operation only in October 1997, recorded hourly measurements of PM_{10} exceeding the MAQG of 150 g m^{-3}. Exceedances occurred for up to 15% of the year, about 1300 hours in Kuala Lumpur, and the two other most affected places were Klang (12%), and Gombak (10%). Although the hours exceeding the acceptable level were less than those in the Klang Valley, Kuching recorded about 8% exceedance, and registered the highest API ever recorded in Malaysia (839 over a 24-hour average on September 23rd, 1997). The maximum API values registered at other places in the country were less than 460. In atleast 5 of the 22 stations, sulphur dioxide concentrations were also high, and exceeded the acceptable level for 16% of the time at the Prai Industrial Estate in Pulau Pinang. Four other affected areas were Pasir Gudang-Johor (2%), Kajang-Selangor (0.4%), Johor Bahru-Johor (0.2%), and Shah Alam- Selangor (0.1%).

During the haze episode, the authorities and the public and private sectors were concerned about the synergistic effects of the pollutants. Of particular importance, particulates combining with SO_2 can be fatal, as experienced during the London smog of early December, 1952. During this period, there were 4000 deaths associated with concentrations of sulphur dioxide reaching almost 0.75 ppm (Awang, *et al.*, 1998). Fortunately, such an episode did not develop in Malaysia. Ozone (O_3), a secondary pollutant, particularly affected those places within highly urbanized valleys, namely Selayang-Gombak (1.3%), Kajang (0.7%), Shah Alam (0.6%), Kuala Lumpur (0.2%), Klang (0.1%) as well as Johor Bahru (0.1%), Ipoh (0.01%) and Pasir Gudang (0.01%). In Kuala Lumpur, but not the other stations, the measurements of CO and NO_2 exceeded the acceptable levels for 0.2 and 0.01 per cent of the time, respectively. These were due to motor vehicle emissions.

With the cessation of the El Niño conditions, the overall conditions improved in 1998, except at a few places during the early parts of the year that were adversely impacted by local peat-forest fires in Miri, Sarawak. Thirty per cent of the time in Miri, the measurements of PM_{10} exceeded the acceptable concentrations of 150 g m^{-3}. Exceedances also occurred at Kota Kinabalu (0.4%), Sibu (0.3%), Seberang Jaya (0.3%), Gombak (0.3%), Pengkalan Chepa (0.1%) and Kota Bahru (0.02%). Other places, though not adversely affected by particulates, continued to register SO_2 measurements that exceeded the acceptable level of 0.04 ppm averaged over 24 hours, namely, Prai Industrial Estate (5.1%), Prai Seberang Jaya (3.1%), Johor Bahru (2.35%), Pasir Gudang (2.0%) and Nilai 0.2% (all in the % of total monitored time).

The Philippines

As reported in the weather observations prior to the September haze intensification, light haze observations could be traced back during the summer months to September 12. As there is only limited information related to forest fires in Indonesia, the intensity of the haze is unknown. However, as the wind was coming from the southwest, it is likely that the source of haze particles during this period was not very intense.

The 4:30 am 24-hour weather forecast for September 12 indicated that typhoon *lbiang* was heading toward Japan-Taiwan area. Although typhoon *lbiang* did not have a direct impact on any part of the country, as it entered the Philippine Area of Responsibility (PAR) it enhanced the Southwest Monsoon flow. Consequently, on September 13 (8:00 am), the horizontal visibility in Zamboanga City was reduced to 5 km. The enhanced Southwest

Monsoon may have carried the smoke from the forest fires in Kalimantan, Borneo, to Zamboanga City, causing the reduction of visibility in the area. Incidentally, after almost three hours, rainshowers occurred that cleansed the air, eventually improving visibility. This scenario prevailed until September 17, 1997.

On September 18, a cyclonic circulation developed west of Mindoro. The system further enhanced the Southwest Monsoon flow although the effect was only in the Visayas and Mindanao including Metro Manila. The 20 km visibility over Zamboanga was again reduced to 6 km, a condition that persisted for 18 hours. This was followed by a 2 km improvement in visibility. The fluctuations in horizontal visibility in Zamboanga City may be due to the occasional precipitation in the area. The minimum visibility recorded in the area was 4 km (September 22, 2:00 pm). At 8:00 pm the same day, the visibility observed in Metro Manila was only 5 km.

The worst effects of haze were in Puerto Princesa. From September 21-29, the minimum visibility fluctuated between 2 and 5 km. The fluctuation may have been attributable to the wind direction and precipitation in the area, although the wind speed ranged from calm to 5 m s^{-1}. There were three sources of haze particles, namely: Indonesia (the north of Sumatra), South Borneo, and Buru in the Molluccas area. However the source of the haze affecting the country was Kalimantan in South Borneo. Based on the analysis, it was also there that the largest fires occurred. The fire in Borneo may have intensified on September 21, so that a combination of the extensive production of haze particles and the existence of a low pressure system west of Mindoro resulted in the haze occurrence in some parts of the country becoming very alarming.

This claim is supported by the 8:00 am satellite imagery for the period September 23-26, 1997. The satellite pictures also revealed the extent of haze that spread in the region during the intensification period. In all five stations under study, the greatest impact of haze was found in Puerto Princesa and Zamboanga.

From the beginning of the critical period, PAGASA released haze information and a bulletin to the Chair of the Task Force Haze and to the media. The first haze bulletin was released on September 25, 1997.

Starting on September 27, the wind direction in Zamboanga City started to shift from the southwest to the northeast while at the other four monitoring stations, the shift occurred in the early part of October. The wind shift gradually diminished the effect of haze in the country, and the southeasterly wind diverted the haze particles to the Malaysian Peninsula. Also, during the haze dissipation, there was occasional precipitation in the affected areas that cleared the atmosphere of the haze pollutants. This resulted in the improvement in horizontal visibility in the affected areas. During October, a light haze was observed although this gradually diminished, particularly in the latter part of the month.

Singapore

Satellite pictures showed some hot spots and smoke plumes in Sumatra and Kalimantan in late May, and again in mid-July. The hot spots appeared on intermittent occasions, and the accompanying smoke plumes were fairly localized. There was little impact on Singapore's air quality at that time.

The hot spots became more persistent after mid-July and began to show some effect on Singapore's air quality in August. This effect became significant in late August, and the air quality measured by the 24-hour Pollutant Standards Index or PSI went into the 'unhealthy' range for the first time on 13 September 1997. From August 1997, the 24-hour PSI readings had remained largely in the 'moderate' range (i.e. between 51 and 100). There were, however, 12 days when the readings went into the 'unhealthy' range; the highest reading recorded was 138 on 19 September 1997. During the 1994 smoke haze episode, Singapore's air quality went into the 'unhealthy' range on 17 occasions. Therefore, in terms of the deterioration in air quality, the impact in 1997 was not worse than that of the 1994 episode.

In addition to the daily announcement of the 24-hour PSI at 4:00 pm, the Ministry of the Environment also decided to provide hourly air quality updates based on a three-hour PSI. This was in response to public requests for more current air quality data. The hourly updates were released between 6:00 am and 10:00 pm each day. Whenever the three-hour PSI exceeded 100, health advisories were also issued. This information was made available to the public through the media, a haze info-line, and a PSI web-page on Internet.

Meteorological Factors in Relation to Haze Episode

During the cloud seeding operations conducted between September and November 1997 by the Malaysian Meteorological Service Department and the Royal Malaysian Air Force (Lim and Ooi, 1998), the haze appeared to be well mixed from the ground up to the haze top. The maximum observed haze height in the region (Peninsular Malaysia, Sarawak, Southern Sumatra and Kalimantan) varied from 7,000 to 14,000 feet, with the maximum thickness observed on 23 September 1997 corresponding with the highest air pollution index ever recorded. Lim and Ooi (1998) also observed that in association with the strong positive anomaly in sea level pressure particularly over the eastern Indonesia – northern Australia region, equatorial southeast Asia was dominantly influenced by southwesterlies and southerlies in the lower troposphere. In addition, south-easterly winds in the southern hemisphere in September 1997 were particularly strong compared to the same month in 1996. This led to the penetration of southeasterlies far northwards into the northern hemisphere, replacing the normal southwesterlies from the Indian Ocean and the Bay of Bengal. Geographically, both Peninsular Malaysia and East Malaysia lie at the downstream end of the southeasterlies which transported smoke particles from the forest fires in southern Sumatra and Kalimantan. Consequently, the steady and strong southeasterlies during the month of September 1997 culminated in the most severe haze event encountered, and by November 1997, the appearance of easterlies had virtually cleared the haze in Malaysia.

The study also revealed that a major El Niño event began in March 1997 (Lim and Ooi, 1998). The event, which was regarded to be equal or worse than that which occurred in 1982-83, was expected to fade away by June 1998. Being close to the core of the El Niño activity, Indonesia normally experiences a precipitation deficit from June to November associated with such an extreme El Niño situation (WMO, 1990). Climatologically, the southern parts of Sumatra and Kalimantan have rainfall peaks in the months of March/April, followed by a relatively dry period from June to September. Therefore, land clearing and open burning are usually carried out there after the peak rainfall period. Unfortunately, the major El Niño event in 1997 not only reduced the rainfall, but also caused a severe and extended drought, resulting in biomass burning becoming uncontrollable and extensive, especially when peat fires were involved. This major El Niño event also led to significant low-level wind anomalies favourable for the mass transport of smoke out of the southern parts of Sumatra and Kalimantan towards the Malaysian and the South China Sea region.

The severe haze episode had significant impacts on the global radiation received, which in turn, further stabilized the atmosphere. A closer examination of the temperatures during normal and hazy days revealed that the temperature in the layer between 700 and 600 hPa underwent stronger diurnal variation on hazy days. This phenomenon reflects the result of radiation heating during the day and radiation cooling during the night in the vicinity of the haze top, and the equivalent potential temperature structures on hazy days were relatively more unstable as compared to normal days.

Physico-chemical Characteristics of Haze

Scanning electron microscope (SEM) analysis of haze particles showed that majority of these particles were smaller than 2.5 m in diameter and were in the form of liquid droplets (Dzulkefly *et al.*, 1998). The percentage of particles less than 5 and 2 m were about 30% and 20% of the inhalables, respectively (Sulaiman *et al.*, 1998). Based on elemental analysis, the particulates contain amongst others Na, K, Ca, Pb, Al, Mn, Zn, Cu, Fe, Cd, Ni, Si, Ti and V (Wood *et al*. 1998). Polycyclic aromatic hydrocarbons (PAHs) concentrations, being the sum of concentrations of nine major non-alkylated compounds (fluoranthene, pyrene, benzo(e)pyrene, benzo(a)anthracene, chrysene, benzofluoranthenes, benzo(a)pyrene, indeno(c,d)pyrene and benzo(ghi)perylene) were predominantly present in the particulates (Zakaria *et al*., 1998), confirming that biomass burning due to forest fires was the main source of the haze.

Ayers *et al*., (1997) focussed on the haze event that occurred in Southeast Asia in September 1994. Their study showed that the general chemical nature of the haze aerosol at Petaling Jaya was that the PM_{10} component consisted of approximately 25% inorganic components, 25% elemental carbon and 50% organic material. Acid ammonium sulphate was the major component in the inorganic fraction. Even the "background" levels of PM_{10} at Petaling Jaya, at around 50-60 g m^{-3}, were primarily due to anthropogenic emissions. If forest fires were the primary cause of the three-fold increase in PM_{10} loading during the extremes of the haze event, then the aerosol composition data during that period would be dominated by biomass burning components. Tracers included in the samples were elemental carbon, aerosol potassium and gaseous NO_2. The time series of aerosol components indicated a correlation with the PM_{10} series during the haze event, suggesting a definite smoke component. Moreover, the time series of traces not related to biomass burning, such as sulphate and lead, showed significant correlations with PM_{10}. The study suggested that there were a number of different source-receptors (including a biomass-burning source) modulated by local and regional meteorology. Consequently, interpretation of the haze peaks in terms of a variety of strong local sources will be very difficult. In addition, Ayers *et al.,* (1997) concluded that smoke from fires at the two locations (Sumatra and Kalimantan) specified in the model was predicted to have reached Petaling Jaya during the haze event period although the temporal pattern of the modelled smoke transport to Petaling Jaya was not identical with the PM_{10} record. It was anticipated that the two fires may have played a part in the extreme haze peak near mid-September, but did not play a major part in the extreme PM_{10} peaks at the height of haze event at the end of September.

In another study, the DOE together with MMS (Malaysian Meteorological Service) and DANCED determined the origin, formation and composition of aerosol haze in Malaysia (DOE, 1997a). Approximately 200 representative samples collected by the MMS for total suspended particulate and PM_{10} measurements during the haze episode in 1994 and in the non-haze years 1995 and 1996 were analysed by Particle Induced X-ray Emission at the National Environmental Research Institute (NERI) in Denmark. The objective of the study was to apportion the sources of the 1994 haze episode, based on two mechanisms that have been proposed for the explanation of the haze episode. The first mechanism relates to the more stable atmospheric conditions that exist in the dry season. This would allow the rather continuous emissions from traffic and industry to build up high local concentrations of pollutants, which could explain why the heavily industrialised Klang Valley was often more polluted than other parts of the country during haze episodes. However, it does not explain why some localities with little traffic and industries such as Kuching in Sarawak, in some years were polluted with suspended particulate matter at levels of the same magnitude as in Klang Valley or even higher. The second mechanism relates to fire in South Sumatra and Kalimantan forests, which occur almost every year in the dry season, and in some years tend to get out of control.

The results of the analysis ruled out the first mechanism as there was a poor correlation with lead (Pb), the marker for local pollution. Conversely, the good correlation with sulphur supports the causal relation with forest fires or other biomass burning, as sulphur and potassium are the essential constituents in biomass. The SPM/sulphur ratios found at geographically widespread locations in the Peninsular Malaysia (Penang, Kuantan, Klang Valley and Johor) were very much the same, corresponding to almost constant contents of sulphur in the SPM (mass ratio 7-8%). This points to a common origin (and/or type) of source, perhaps the reported forest fires in South Sumatra. The high levels found in the

Klang Valley could be due to the combined effects of the geographical vicinity of the source area, an unfortunate position in the prevailing direction of wind flow, and perhaps some trapping of the biomass burning plume in the valley. The sulphur content found in Kuching was markedly lower (4%). This pointed to a different biomass burning source, probably fires in Kalimantan.

Effects on Agricultural Crops and Forest Species

Although growth limitations of agricultural and forest species due to air pollution in mid-latitude countries have been well documented (Awang, 1979), there has been no documented evidence that such problems exist in the region. The atmospheric pollutants that have the greatest potential for affecting the growth of crops and trees are oxides of sulphur, nitrogen and photochemical oxidants such as O_3 and peroxyacyl nitrate. As mentioned earlier, concentrations of these pollutants are frequently above the levels that could alter the biochemical and physiological processes of sensitive crops.

Measurements have shown that during the haze episodes, O_3, TSP and particulate matter with a diameter less than 10 m (PM_{10}) are the major atmospheric pollutants that might potentially affect the growth, development and yield of agricultural crops due to O_3 phytotoxicity and reduction in light intensity. It is important to emphasize that although the haze episode was a temporary phenomenon, it coincided with a critical stage of development of sensitive crop plants as the growing season of many major cash crops in Malaysia takes place between July and August. The observations also suggest that there were strong daily variations among the pollutants. Although the concentrations of oxides of sulphur and nitrogen were low, it is always possible that the combined presence of these two pollutants with O_3 may have a different effect and could have a significant impact on growth and performance of agricultural crops and forest species.

Impact of 1997 Haze Episode On Human Health in Malaysia

The major air contaminant during the 1997 haze period in Malaysia was suspended particle matter, whereas gaseous pollutants were not significantly different from normal days. During the period, PM_{10} concentrations rose beyond the MAQG (1989) level in almost all areas that were monitored. They increased 4-fold in the Klang Valley, and by up to 20 times in Kuching. Simultaneously, Hospital Kuala Lumpur recorded an increase in cases of upper respiratory tract infections (URTI), asthma and conjunctivitis; three diseases directly affected by the haze. The increase in asthma cases was found to have a two-day lag behind the Malaysian API as reported by the Ministry of Health Malaysia in 1998. However, no changes were observed for mortality cases during the haze period.

For respiratory diseases, Selangor recorded a significant increase in the total number of cases during the September haze period. Asthma cases increased from only 912 in June to more than 5000 in September 1997. The total number of Acute Respiratory Infections (ARI) cases increased from about 6000 to more than 30,000 during the same period. However, the number of cases gradually decreased towards the June value as the concentration of PM_{10} began to decrease after September. In Kuching, Sarawak, a significant increase in the number of these cases was also observed due to extreme API readings during the last half of September 1997. However, when the air quality was almost back to the values of a non-haze period in October, the incidence of the cases returned to normal. The trend indicated that short-term exposure to high levels of PM_{10} is detrimental to human health. However, the effect is apparently reversible, and no increase in mortality was reported during the period.

Besides respiratory diseases, there was also a significant increase in conjunctivitis during the haze period. In Selangor, the total number of cases increased from 207 in June to 3496 cases in October 1997. The same trend was also observed in Sarawak. In addition, the daily incidence of conjunctivitis in Sarawak during September was positively correlated

with the API (representing PM_{10} concentration).
The data suggest that the adverse effects of haze on human health could be attributed to the elevated PM_{10} levels in the ambient air and are not likely to be due to other pollutants. Despite the reversibility of the acute effects, it is believed that exposures to haze may have a long-term effect on the community.

Besides the health data, a spirometry study done on sixteen-year old school children in Kuala Lumpur (KL) also revealed that long term exposure to a relatively higher PM_{10} concentration led to decreased lung functions and increased prevalence of respiratory symptoms. The school children in KL were naturally exposed to 103.27 g m^{-3} ambient PM_{10}, while the control group (matched for age, gender, height, weight and smoking habits) was naturally exposed to only 47.35 g m^{-3} PM_{10}. Significant reductions in spirometry parameters such as the vital capacity (VC), forced vital capacity (FVC) and forced expiratory volume (FEV_1) were observed in the KL school children.

A higher prevalence of respiratory symptoms was observed in the Kuala Lumpur school children population; the most commonly reported symptoms were chest tightness, followed by breathing difficulties, morning phlegm and coughs. In both groups, females were found to be more susceptible to the exposure, showing a higher percentage in the prevalence of the respiratory symptoms. The results suggest that prolonged exposure to a relatively high concentration of PM_{10} (even though below the set safety limit) is associated with reduced lung function and increased respiratory symptoms in school children.

There is ample evidence to suggest that the most susceptible group to exposure to air pollutants are the elderly and very young children, while youngsters are among the most resistant. However, the Kuala Lumpur study clearly indicated adverse effects of the exposure on the 16-year olds (the most resistant age group). In addition, a preliminary survey carried out among secondary school children in KL and Klang revealed that less than 50% of these school children went for medical treatment each time they fell sick. Therefore, the total number of respiratory cases reported in the clinical health data is likely to have underestimated the degree of adverse effects caused by the haze on the community.

Although analysis of the health and spirometry data revealed that short-term exposure to very high PM_{10} led to increased cases of related diseases, the effect was apparently reversible. Nevertheless prolonged exposure to PM_{10} even below the MAQG could reduce the lung function and increased the prevalence of respiratory symptoms. The studies conclude that the concentration of PM_{10} and the period of exposure may determine the nature of the adverse effects to human (Awang *et al*., 2000)

Conclusion

In conclusion, the haze episode was caused by forest fires and the nature of habitat damage and impacts on human and environment were similar throughout the region. As far as economic impacts are concerned, the haze episode caused considerable losses both directly and indirectly to the impacted countries.

Abstract

Tree diseases have greatly influenced the activities of humans. This is commonly experienced in forestry where the occurrence of fungal diseases limits the planting range of a specific species or clone. In agriculture, tree diseases have necessitated the use of expensive chemicals and the development of complicated management and quarantine practices to limit losses. Diseases have greatly influenced trade and export routes, with many countries not accepting any fruit or plant material from countries where a specific disease occurs. Diseases have also had a devastating impact on native forests. Examples such as Chestnut blight and Dutch Elm Disease in Europe and the U.S.A. and Phytophthora root rot in Australia are but three examples. As our environment is placed under more pressure from the increasing human population and its activities, so the impact of tree diseases is likely to increase in importance and severity. Only with careful management and a strong vision for forest protection will we be able to ensure the survival of this important resource.

Keyword : Forest pathogens, Forest protection.

Introduction

The fact that pathogens and particularly fungi cause diseases of trees was discovered relatively late in the history of plant pathology. Indeed it was only in the late 19th century that Robert Hartig showed that wood decay is caused by microorganisms (Hartig 1874). Hartig, who is generally recognised as the "father of forest pathology" subsequently proceeded to describe a wide number of diseases of forest trees. To our knowledge, there were no records of forest tree disease epidemics prior to this time.

Foresters generally recognise that diseases and pests cause significant damage to trees. Here, their focus is typically linked to losses in yield and productivity of plantations or managed natural forest. In the developed world, the general public is aware of tree diseases, especially where these have reached epidemic proportions, and have consequently been the focus of considerable media coverage. In less developed countries, the importance of tree disease can fade into relative obscurity, although small-scale and subsistence farmers often depend heavily on their tree crops.

The impact that tree diseases have on society is hugely underestimated. Indeed, it is our contention that this lack of comprehension resides not only amongst the public at large, but that it extends much further and exists even among professional foresters. This situation most likely arises from the fact that tree diseases are hugely complex, and the impacts are poorly understood. Only when tree diseases start affecting food or some other scarce commodity does publicity relating to the problem increase and people become aware of the impact that pathogens have on their lives.

In this brief communication, we hope to illustrate some of the many ways in which tree diseases are impacting on global society. While some of these tree diseases are relatively well recognised, others are somewhat obscure, and have hardly been considered. We, furthermore, contend that there are emerging trends linked to tree disease that are likely to result in significant disease epidemics in natural stands of woody plants in the future. It is our hope that by illustrating some of these problems, both professional foresters and the public will take notice of them. In this way, it might be possible to reduce negative impacts on ecosystems that appear to be threatened.

Well Recognised Epidemics

During the course of the 20th Century, diseases of forest trees have resulted in numerous ecological disasters. It is impossible to treat all of these comprehensively in this brief presentation. Thus, a selected number of examples that illustrate the trends have been chosen.

A relatively large number of tree disease epidemics in Europe and North America caused by pathogens of Asian origin emerged early in the 20th Century. There can be little doubt that these diseases resulted from increased trade between Northern Hemisphere countries. A lack of knowledge of the threat of introduced tree pathogens into native forest environments was clearly to blame for the tragic losses that emerged. Chestnut blight, caused by *Cryphonectria parasitica,* has all but eliminated the American chestnut as a major forest species in North America (Anagnostakis 1987, 1988, Carefoot and Sprott 1969, Hepting 1974, Schumann 1991). Dutch elm disease caused by *Ophiostoma ulmi* and more recently *Ophiostoma novo-ulmi* has devastated native elm in Europe and North America (Brasier 1990, Gibbs 1978, Schumann 1991). Likewise, white pine blister rust caused by *Cronartium ribicola* has had a dramatic impact on native white pines in North America (Liebhold *et al*. 1995, Peterson and Jewell 1968, Ziller 1974). These three diseases are now known to have originated in Asia. They were accidentally introduced into Europe and North America, bringing them into contact with tree populations related to their native hosts, but that lack resistance to invasion (Anagnostakis 1987, 1989, Brasier 1990, 1995, Hoff *et al*. 1980, Kaneko *et al*. 1995, Milgroom *et al*. 1992). The result has been epidemics that, despite significant investments, could not be contained.

There are more examples of tree pathogens introduced from East to West than in the opposite direction. This could reflect greater levels of trade between Asia and Europe/ North America. It is also possible that tree diseases in Europe and North America have received more attention than in Asia. Certainly one disease originating in North America and that has a dramatic impact on native Asian forests is pine wilt caused by the pine wood nematode*, Bursaphelenchus xylophilus* (Kiyohara and Tokushige 1971, Mamiya 1983, 1987, Wingfield 1987). This disease was recognised in Japan early in the 20th Century, but its cause was only elucidated in the 1970's (Mamiya 1987, Kiyohara and Tokushige 1971). Upon its discovery in the United States, pine wilt was thought to represent an emerging new epidemic (Dropkin and Foudin 1979, Dropkin *et al.* 1981), but it was later shown that the nematode is native to North America where native pines are resistant to infection (Wingfield 1983, Wingfield *et al*. 1984, 1986).

The best known example of a forest disease of native tree species that has been introduced into a Southern Hemisphere country, is Jarrah dieback in Southern and Western Australia. This disease is caused by the notorious root pathogen *Phytophthora cinnamomi* (Colquhoun and Hardy 2000, Podger *et al*. 1965, Shearer and Tippett 1989), which is believed to have been introduced into Australia from Papua New Guinea (Old *et al*. 1984, Zentmeyer 1988). It is believed that *P. cinnamomi* was most likely introduced into Australia by early European settlers who brought fruit trees and other garden plants to the country (Colquhoun and Hardy 2000). Although *P. cinnamomi* is best known for Jarrah die-back it affects more than 2000 other native Australian tree species resulting in major changes to the native ecosystem (Colquhoun and Hardy 2000, Weste and Taylor 1971, Weste 1974, Shearer and Tippett 1989).

Emerging Epidemics

All plant pathologists and breeders are familiar with the famous examples of epidemic diseases of forest trees. What is less commonly recognised, is that there appear to be a large number of new and emerging tree disease epidemics in many parts of the world. As mentioned previously, the best recognised and apparently most devastating tree disease epidemics have occurred in boreal forests of the Northern Hemisphere. Shared genera of trees and the movement of wood and plant products have apparently driven this process.

Countries of the Southern Hemisphere tend to be typified by a considerably wider diversity of forest trees than is found in boreal regions. It is possible that this diversity has accounted for the lack of disease epidemics equivalent to those that have occurred in the Northern Hemisphere. However, is less recognised that related families of woody plants are also found on different continents of the Southern Hemisphere. The spread of pathogens of these trees between Southern Hemisphere continents could lead to serious disease epidemics. Trade and tourism, and thus the movement of plant material between countries in the Southern Hemisphere, are increasing rapidly. This increases the likelihood that epidemics similar to those that have occurred in the Northern Hemisphere will emerge in analogous situations in the South. We might, therefore, predict that epidemic diseases of trees in families such as the Myrtaceae and Proteaceae, will emerge in the coming years.

The Role of Exotic Plantations

Plantations of exotic tree genera such as *Pinus*, *Eucalyptus* and *Acacia* have been established in many countries in the tropics and Southern Hemisphere. These plantation areas have increased dramatically in extent during the course of the last Century and now cover at least 20 million hectares. Diseases caused by both exotic and introduced pathogens have caused and will continue to result in significant losses in these plantations. Fortunately, the diversity in the tree species planted has generally lowered the risk of total destruction.

Evidence from forest plantation situations has led us to believe that there is an increasing movement of forest pathogens between countries of the Southern Hemisphere. Development of exotic plantations has substantially increased the movement of forest products such as seeds, and to a lesser extent timber, between Southern Hemisphere countries. This exchange, as well as that linked to other trade and tourism activities is leading to the introduction of pathogens into new areas.

Establishment of plantations of exotic trees has led to some fascinating, yet disturbing developments linked to the emergence of new pests and diseases. For example, pathogens of native plants have developed the capacity to infect exotic plantation species. One of the best examples is the rust pathogen *Puccinia psidii* that is native on Myrtaceae in South and Central America. In the 20th Century this rust fungus suddenly appeared on various species of exotic *Eucalyptus* spp. planted in South and Central America (Coutinho *et al*. 1998). This disease now threatens plantation *Eucalyptus* in other tropical and sub-tropical countries. What is of greater concern is the fact that there are no rust diseases of *Eucalyptus* in Australia, which is the origin of most species in this genus and a centre of diversity for this family (Eldridge *et al*. 1993). *Puccinnia psidii* clearly presents a considerable threat to Myrtaceae in Australia and perhaps in other parts of the world. The magnitude of this threat has recently been recognised by pathologists. Consequently, an intensive research programme supported primarily by Australia and including South Africa and Brazil has recently been launched to gain a more comprehensive understanding of the problem.

Another disease of increasing importance in *Eucalyptus* plantations is *Coniothyrium* canker, caused by *Coniothyrium zuluense* (Wingfield *et al*. 1997, Van Zyl *et al*. 1998). This disease was discovered for the first time in sub-tropical regions of South Africa where it has caused considerable damage. The origin of *C. zuluense* is unknown, but the pathogen has recently been discovered both in Thailand (Van Zyl *et al*. 1998), Argentina and Uruguay (Wingfield, unpublished). Introductions of this pathogen into South America are thought to have originated through trade in seed, possibly with South Africa. If *C. zuluense* does not naturally occur in Australia, it is likely to be a significant threat to trees in that country. Furthermore, nothing is known regarding the host range of this pathogen, and any number of genera or species of Myrtaceae in various parts of the world could be threatened by it.

Plantation forestry based on exotic species is evidently resulting in significant increases in the inoculum load of important tree pathogens. Many examples could be used to illustrate this point, but perhaps one that is most topical currently is pitch canker disease of pines. Pitch canker, is caused by *Fusarium subglutinans f.sp. pini* and has been known in the South Eastern USA since early in the 20th Century (Dwinell *et al*. 1981, Hepting and Roth 1946). Very recently, pitch canker has appeared in the South Western United States where it is associated with a severe epidemic on *Pinus radiata* (Correll *et al*. 1992, McCain *et al*. 1987). The disease is now thought to have originated in Central America (Owen and Adams 1999, Viljoen *et al*. 1997) and has been introduced into Thailand (Kobayashi and Muramoto 1989) and South Africa (Viljoen *et al*. 1994, 1995), apparently on seeds from

Central America. Outbreaks of the disease have also occurred in Japan (Muramoto and Dwinell 1990) and more recently in Korea (Lee, unpublished). As additional outbreaks of this disease occur, the likelihood that it will be introduced into new environments increases. Its impact could be devastating, both for commercial forestry in countries such as Chile, Australia and New Zealand, and also in native stands of pine elsewhere in the world.

Multifaceted Nature of Losses

The impact of diseases of trees is multifaceted and many aspects are easily overlooked. The importance of tree diseases is generally linked to direct financial losses incurred by them. There are many diseases of trees grown in plantations, both caused by native and exotic pathogens, that have led to dramatic losses in timber and fibre production. The impact of diseases of plantation-grown trees is usually reduced through a series of management strategies. These include efforts to reduce inoculum build-up, avoidance strategies linked to the deployment of disease tolerant planting stock and, less commonly, chemical control. The establishment of a reasonably wide diversity of species in plantations clearly reduces risks.

The extent of the impact of epidemic losses to native species due to diseases such as Dutch elm disease, chestnut blight, *Phytophthora* root and collar rot and others is almost impossible to comprehend. When a tree species is eliminated from the landscape, losses extend far beyond those that are obvious, such as the value of the timber and perhaps fruit. These trees provide niches for great numbers of animals and plants, many of which probably can not exist without them (Carefoot and Sprott 1969, Colquhoun and Hardy 2000, Liebhold *et al*. 1995). Because ecological impacts of tree disease epidemics have hardly been evaluated, and is little understood, their significance can hardly be evaluated.

Death of shade and ornamental trees is felt directly by the public. These losses are, however, not only emotional and linked to the aesthetic value of the trees, but property owners and city councils are often forced to incur considerable expense to remove dead and dying trees, which have become hazardous (Schumann 1991, Templeton *et al*. 1999). Trees also often have religious or cultural significance and their loss can be deeply felt by the public. An example of this situation is in the death, due to pine wilt, of ornamental pines growing around religious shrines in Japan. It is perhaps this aspect of the pine wood nematode that is most strongly felt and recognised by the Japanese public. Similarly, *Seiridium* canker that is causing devastation to Cypress (*Cupressus* spp.) in southern Europe has had a tremendous social and cultural impact. Apart from its great economic importance to Mediterranean countries, Cypress trees are considered by many to be sacred trees (Graniti 1998).

Future Prospects

Forest and shade trees form a hugely important part of modern life. Their role is multifaceted and often greatly underestimated. Most people recognise the value of trees for the production of solid timber products, paper and fruit. Their role in shade production and as ornamentals is also generally appreciated. However, few people recognise the importance of trees as carbon sinks or in terms of their importance in global biodiversity.

Based on current trends, it is most likely that increasing numbers of tree disease problems and epidemics will mark the 21st Century. This is despite the efforts to preclude the introduction of pathogens into new areas through quarantine. Although this view might be somewhat pessimistic, we are inclined to suspect that while these efforts must be encouraged, they will not be particularly successful. Trade and tourism in the emerging 'global village' will dominate and the capacity of pathogens to adapt and to damage trees will lead to tremendous challenges.

Efforts to deal with tree diseases during the course of the past Century have been noble, yet relatively minimal in relation to the extent of these problems. In the future, we would hope that significantly increased support will be offered to pathologists, entomologists and biotechnologists to enable them to offer the world novel solutions to diseases of trees. Education of the public as to the importance of tree diseases, and the rapidly growing numbers of forest bio-invasions, will hopefully also help to reduce their impact.

Abstract

Sustainable development has become the umbrella objective for forest management in many countries of the world, and managers are increasingly faced with the challenges of balancing environmental and economic health in their forest management and resource utilization decisions. It can no longer be assumed that abundant raw materials are available simply for the taking. Changing times require that we change how the forest resource is managed and used. As we look to the future, we must develop a better understanding of the complex interactions of wood use and the resultant social and ecological considerations. This paper addresses the value of wood in human societies, provides a brief review of the world's forest cover, discusses worldwide links and expectations, makes the case for forest products technology, discusses global trends in forest products, discusses future supply and demand for industrial roundwood and wood products, and examines ways to meet future challenges.

Keywords: Forest management, Sustainable development, Forests, Value, Forest products technology

Introduction

A world without forests would be a world that is completely alien to the one we know today. Forests provide a wide range of benefits at the local, national, and global levels. Some of these benefits depend on the forest being pristine or subject to minimal interference. Others can only be realized through well-planned disturbances such as harvesting for wood and other products. The shrinking forest base and growing human population have heightened the challenge for forestry and forest products utilization to produce the needed types and quantity of trees and to prevent conversion of forestland to nonforest uses.

The concept of sustainability is central to sound forest management, and defining what it means is the subject of much current debate. Sustainability in all of its facets—ecological, economic, and social—is important today and will become increasingly important for stewardship of the world's forests. The benefits of forests are wide-ranging and diverse. These benefits include clean air and water, productive soils, biological diversity, goods and services, employment opportunities, community benefits, recreation, animal habitat, and naturalness. Forests also provide intangible benefits such as beauty, inspiration, and wonder.

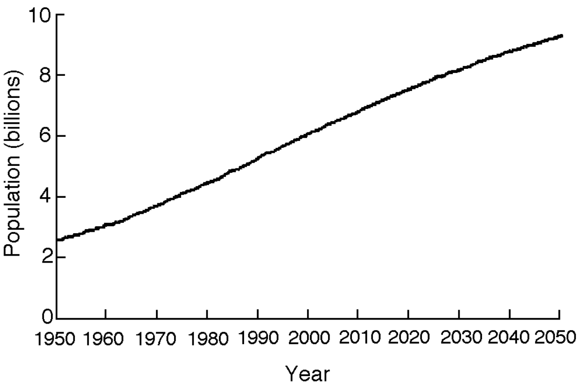
This paper will address the value of wood in human societies. It will provide a brief review of the world's forest cover and discuss worldwide links and expectations, make the case for forest products technology, discuss global trends in forest products, discuss future supply and demand for industrial roundwood and wood products, and examine ways to meet future challenges.

Value of Wood in Human Societies

A critical consideration in any discussion of future industrial raw materials demand is human population growth. All projections indicate a continuing increase in global population in the future. One way to view this is that a child born today will live in a world where the population will double during his or her expected lifetime. The greatest growth in population is likely to occur where the standards of living are also expected to show the greatest rise. The result is a world economy that will grow even more rapidly than the population. This means that demands for resources, which are already high on a per capita basis, will rise even higher.

The historical record of world population growth is dramatic (Fig. 1). World population doubled between 1850 and 1950 and then doubled again between 1950 and the present (Bowyer 1995). During each of the next four to five decades, global population is expected to increase by approximately 900 10^6. These figures make it dramatically clear that the world of tomorrow will place even more pressure on forests and forest resources.

Figure 1—World population 1950–2050 (From Youngquist and Hamilton 1999).



Tremendous quantities of wood are consumed each year throughout the world. Schulz (1993) reports that the world harvests approximately 3.5 10^9 m^3 of wood annually, with slightly more than half of this used as fuelwood. Approximately 63% of the annual harvest is comprised of hardwoods, which are mostly used for fuel in the developing countries of the world. The world's softwood use is primarily industrial.Sutton (1993) reports that the global per capita consumption of wood is approximately 0.67 m^3 per year, a figure that has remained largely unchanged since 1960 (Schulz 1993). This means that growth in world wood demand is closely following the growth in world population. With the assumption of a continuation of per capita consumption trends, population increases alone will add approximately 60 10^6 m^3 annually to world wood demand (Bowyer 1995).

The World's Forest Cover (FAO 1999)

Information on the status of the world's forests, their extent, location, type, and condition, is important for efforts to improve forest management worldwide and for assessments of the ability of the forest to provide the goods and services demanded of them. The area of the world's forests, including naturally occurring forests and forest plantations, was estimated to be 3,454 10^6 ha in 1995, or about one-fourth of the land area of the Earth. About 55% of the world's forests are located in developing countries, with the remaining 45% in developed countries (Fig. 2). The world's forests are almost equally divided between tropical–subtropical forests and temperate–boreal forests. Only about 3% of the world's forests are forest plantations. The remaining 97% are natural or seminatural forests. Data published in FAO (1997) provide a picture of the trends in forest cover for a 15-year interval (1980–1995) and allow a comparison between the 1980–1990 and 1990–1995 periods.

Between 1980 and 1995, the extent of the world's forests (including both natural forests and forest plantations) decreased by some 180 10^6 ha, or about 5% of the total forest land base. There was a net increase of 20 10^6 ha in developed countries but a net loss of 200 10^6 ha in developing nations. The change in forest area by region between 1980 and 1995 is shown in Figure 3.

Between 1990 and 1995, there was an estimated net loss of 56.3 10^6 ha of forests worldwide. This represented a decrease of 65.1 10^6 ha in developing countries and an increase of 8.8 10^6 ha in developed countries. Although the global loss of forests was very high, the figures suggest that the rate of deforestation might be slowing.

Figure2- Forest areas by main regions in 1995. (From FAO 1999)

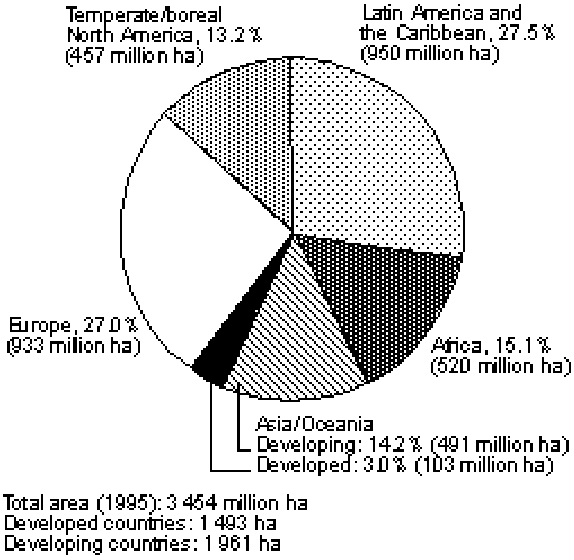


Figure 3—Forest area in 1995 as compared with 1980 (From FAO 1999.)

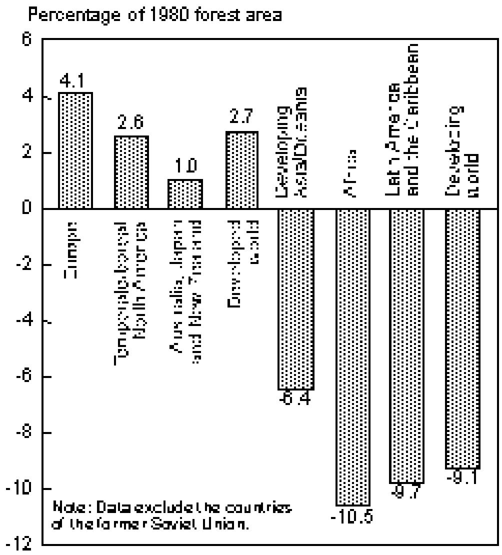


The estimate of forest cover change in natural forests of developing countries (which is where most deforestation is taking place) was a loss of 13.7 10^6 ha of forests per year between 1990 and 1995 compared with a 15.5 10^6 ha loss per year during the decade of 1980 to 1990. The major causes of change in forest cover in the tropics appear to be expansion of subsistence agriculture in Africa and Asia and large economic development programs involving resettlement, agriculture, and infrastructure in Latin America and Asia (FAO 1996). The net increase in forest area in developed countries is largely a result of afforestation and reforestation, including natural regrowth on land abandoned by agriculture. This increase has more than compensated for the clearing of some areas of forest in various developed countries, which is mainly due to urban expansion and infrastructure development.

The Approach to Environmental, Social, and Economic Concerns

Environmental, social, and economic concerns must be considered together. Ecological sustainability must provide a foundation upon which forest management worldwide can contribute significantly to economic and social sustainability. Conservation and wise management of forests can promote sustainability by providing for a wide variety of uses, values, products, and services and by enhancing society's capability to make sustainable choices. In a like manner, social and economic sustainability provides a foundation for ecological sustainability by broadening forest management perspectives through improved standards of living.

When the concept of sustainable development was presented in 1987 by the United Nation's World Commission on Environment and Development (United Nations Commission 1987), attention shifted to environmental concerns. However, the concept was one of balance—the environment and the economy cannot be treated separately. Material needs must be met in ways that preserve the biosphere, and concern for the biosphere must recognize material needs. Another important concept imbedded in this strategy is recognition of both the short and long term. The Commission's report clearly stated that sustainable development is "development that meets the needs of the present without compromising the ability of future generations to meet their own needs."

Worldwide Linkages and Expectations

The question of conservation and utilization of forest resources must be balanced and is at the very essence of the work of all of us who are concerned with the management and utilization of natural resources for sustainable development. The discussion of conservation and utilization must focus on how the needs for conservation and utilization can be combined harmoniously to derive the maximum benefits for present and future generations.

Finally, the theme of worldwide linkages and expectations means that the way that wood is processed and used must be developed in a global context to achieve success in sustainable development. Local decisions on timber harvest and use have clear implications for other countries. In developed countries, with rising demand, local decisions not to harvest create a higher economic incentive to harvest elsewhere. In countries where natural forests are not managed for regeneration, short-term harvest decisions can affect the availability of all forest resources in the long term.

The Case for Forest Products Technology

Given this changing context, what roles will forest products play in relationship to forests and forestry? In our opinion, forest product technology will play a central role in meeting these challenges for the following reasons:

Management is and will continue to be necessary to achieve desired forest conditions.

Management that includes wood removal is a cost-effective way to achieve ecosystem health.

Wood technology will help provide choices for the management and use of the forest.

Sustainability must recognize the interdependence of the environment and the economy.

Management for wood fiber will maintain prominence but not dominance.

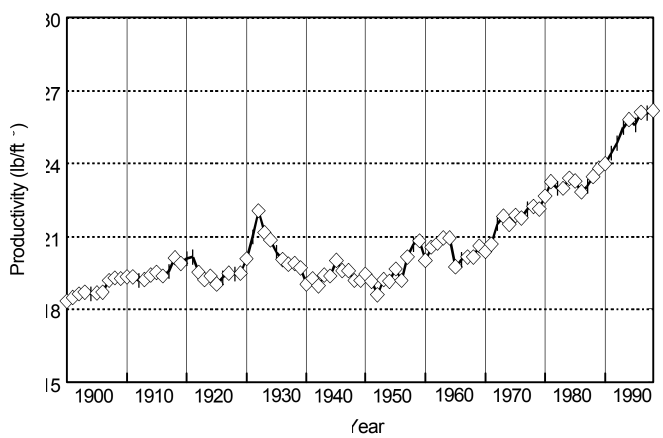
We need to understand and embrace the values the public is not willing to forego.

Forest products can help forest lands compete economically, thus making their conversion to nonforest uses a much less viable option.

Conservation of wood fiber, not competition of wood with other raw materials, must be the focus of wood products research.

A brief historical review is appropriate as one way of pointing out how a decline in wood resource availability can be at least partially offset by increasing efficiencies in the use of the wood resource. For example, in the United States, product output per unit of wood input has risen by about 40% during the past half century (Fig. 4) (Ince 2000).

Figure 4 – U.S. Product output per roundwood input (From Ince 2000)



Global Trends in Forest Products (FAO 1999)

To meet the needs for wood and nonwood products and, at the same time, fulfill demands for environmental and social services from forests is a challenge now facing the forest sector. Efforts to find an acceptable balance between production and protection and between use and conservation drive much of the debate surrounding the forest sector today.

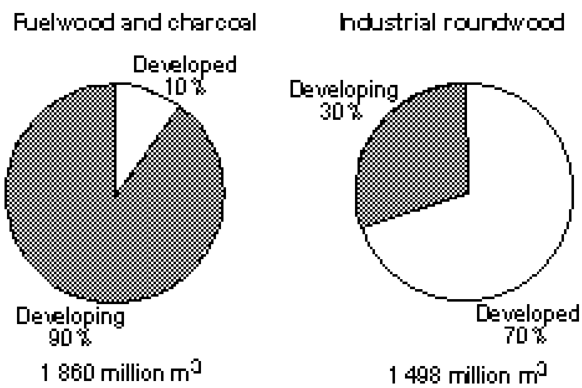
The overall patterns of production and consumption of wood products are very different between developed and developing countries. Developed countries account for 70% of the total world production and consumption of value-added industrial wood products. Developing countries, on the other hand, produce and consume about 90% of the world's fuelwood and charcoal, which are the major household energy sources in many of these nations (Fig. 5). More fuelwood and charcoal are consumed each year in the world than industrial roundwood. Demand for fuelwood is expected to continue to increase at a rate of about 1.1% per year between now and 2010, while demand for industrial roundwood is expected to increase at a rate of about 1.7% per year during the same period.

Factors that are expected to influence the ability to meet increasing demand include increased sources of wood (e.g., plantations and trees outside forests), technological improvements in wood processing, which will increase the efficiency of raw material use, and increased use of recovered and nonwood fiber. Trade will continue to help balance geographical wood deficits in one place with surpluses elsewhere.

While wood is the predominant commercial product from forests, increased attention is being paid to the actual and potential economic role of nonwood forest products (NWFPs). The importance of NWFPs to household and local economies, particularly among the poor in developing countries, is increasingly recognized, as is the need to consider them in forest management planning and in forest policy in many countries.

Wood energy is another area that is raising new interest. While fuelwood and charcoal remain significant sources of energy in developing countries, especially for domestic use, their potential to contribute to the modern energy sector as an alternative to fossil fuels is being investigated in several countries.

Figure 5- Production and consumption of wood products in 1996 (From FAO 1999).



Trade and Trends in Forest Products (FAO 1999)

According to the United Nations Food and Agricultural Organization, growth in the production of tropical forest products has slowed during the past 3 to 5 years. The export of most products has followed a similar trend; export volumes of tropical logs, sawn wood, and wood-based panels have decreased. Some of the trends reflect major structural changes that are unlikely to be reversed, while others are a response to normal short-term changes in market conditions. Factors influencing the changes include

- increasing domestic consumption in important developing producer countries;
- reduced harvest levels because of both environmental concerns and export market conditions;
- a shift in exports from logs, and to a lesser extent sawnwood, toward export of higher value products; and
- most recently, marked reductions in demand in Asia, especially in Japan.

Certification for sustainably produced forest products continues to be a high profile and often controversial subject in the forest sector. In addition, initial efforts are being made to extend certification to nonwood forest products, which will raise new issues. Certification systems are based on evaluating the standard of forest management being practiced.

Accurate statistics on the area of forests and volume of wood certified are difficult to obtain, and the figures are often difficult to interpret. The Forest Stewardship Council (FSC) reports that about 10.3 10^6 ha of forestland have been certified by FSC-accredited certifiers. It is significant that 90% of this area is in temperate developed countries, largely in Europe and North America. Sweden and Poland alone account for 58% of the total. Only a minor part is in tropical countries, where the problem of deforestation is greatest. The volume of certified wood involved and the volumes entering or about to enter the market are unknown but are still insignificant in global and regional terms. The area of forests certified is not a sound indicator of the volume of wood entering the market, since parts of the certified areas may not be of harvestable age, may not contain commercial species, or in extreme cases may not even have trees growing on them.

Certification efforts are being made at many levels. International efforts include those of FSC and the International Organization for Standardization (ISO). Regional initiatives include those of the African Timber Organization (ATO) and the European Union's Eco-Management and Auditing Scheme (EMAS) and Eco-Labeling Scheme. Countries with national programs include Brazil, Canada, Finland, Ghana, Indonesia, and Sweden. In the last 2 years, there have been many new initiatives and a number of additional forests have been certified or are in the process of being certified. Among importing countries, interest continues to be greatest in Europe, especially Germany, the Netherlands, and the United Kingdom. The exporting countries showing the most interest in certification are those whose main export markets share European countries and to a lesser extent the United States; hence the considerable effort Canada, Finland, Indonesia, Malaysia, and Sweden have put into developing national certification systems.

Future Supply and Demand for Industrial Roundwood and Wood Products (FAO 1999)

FAO has recently completed two new global supply and demand studies: the Global Fiber Supply Model (GFSM) (FAO 1998b) and the Global Forest Products Outlook Study (Whiteman 1999). A major and more detailed forestry sector study for the Asia and the Pacific region has also recently been produced (FAO 1998a). Rather than dwelling too intently on market forecasts, which are vulnerable to macroeconomic shifts (such as those recently experienced in Asia), these new studies focus more on the likely policy implications of forest product market developments. The following text briefly describes the main market developments that are expected in the future and discusses the implications of these developments within the context of sustainable forest management.

Future Forest Product Production and Consumption by Region

The current and projected level of wood production and consumption in 1996 and 2010 is shown by region in Figure 6. From 1996 to 2010, global industrial forest product production and consumption are projected to increase at an annual rate of about 1.7%, from 1,490 10^6 to 1,870 10^6 m^3. Thus in 2010, output will be about one-quarter higher than it is at present. It will, however, only be about 10% higher than the peak in production (1,700 10^6 m^3) around 1990. Growth will vary between regions, with Asia and Oceania likely to show the highest rates of expansion. Slow growth in consumption is expected for Africa and South America, and slow growth in both consumption and production is expected for North and Central America. North and Central America will, however, remain by far the largest producing and exporting region in the world. Europe, Asia, and North and Central America will account for about 85% of production and more than 90% of consumption in 2010 (roughly the same share as in 1996). However, within this group, it is expected that during this period of growth, a small share (about 5%) of global consumption will shift from North and Central America to Asia.

Future Forest Product Production and Consumption by Product Category

Current estimates and future forecasts of global forest product production and consumption by product category are shown in Table 1. As in the past, the market for paper and paperboard is expected to have the most rapid growth, at an annual rate of 2.4%. In contrast, production of pulp for paper is expected to grow by only 1.1% per year, reflecting an expected increase in the recycling of recovered paper in the total fiber furnish in the future. Moderate growth is expected in solid wood product consumption, at annual rates of 1.1% for sawn wood and 1.3% for wood-based panels. Most of the growth in the production and consumption of wood-based panels is expected in the reconstituted wood panels sector rather than the plywood sector.

Forecast Wood and Fiber Production Compared with Production Potential

A comparison of projected roundwood production levels in the Asia and the Pacific region with production (or estimated biological) potential shows that, in general, future wood demand could easily be met within the region. In certain countries and for certain types of wood (e.g., sawlogs), however, supplies are going to become increasingly scarce in the future.

FAO does not yet have sufficient data to make an accurate assessment of the production potential for the whole world. The Global Fiber Supply Model (GSFM), for example, covers a large part of the world but excludes the important contribution of trees outside forests. However, GFSM can be used to compare projected levels of production (Fig. 6) with supply potential from the forest and from recovered and nonwood fiber sources across some regions (Table 2).

As Table 2 shows, forecast production levels are well within the projected limits of production potential in South America and Oceania but approach the limit in Asia and exceed it in Africa. The results of the fifth European Timber Trends Study (Joint ECA/FAO Agriculture and Timber Division 1996) suggest that Europe should also have adequate wood supplies to meet production requirements in the near term. However, two points are worth noting. First, the GFSM projections should be considered as the absolute maximum amounts. The cost of accessing increasingly marginal areas, which are included in the GFSM analysis, may prevent the total potential supply presented in Table 2 from being realized in the near future. Second, it should be remembered that, while supplies may be plentiful at the broad regional or country level, there may continue to be local scarcity, which could put forestry policy makers under pressure to release natural forest resources for timber harvesting.

Figure 6— Forecast industrial roundwood production and product consumption in 1996 and 2010 (From FAO 1999).

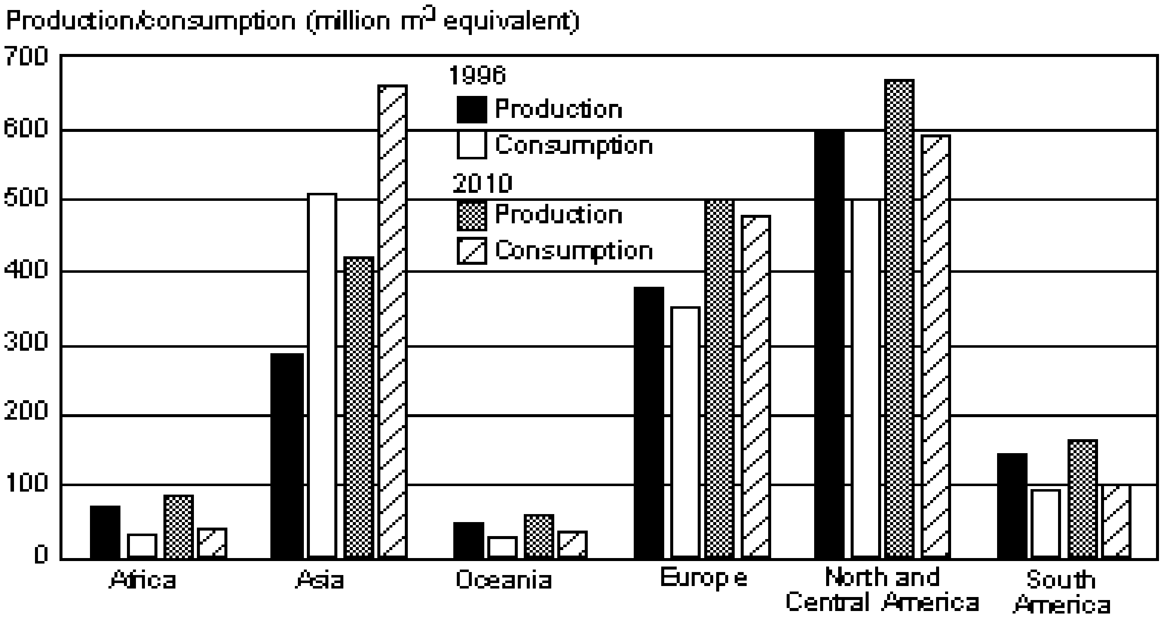


Table 1—Current and forecast global forest production/consumption by product category, 1996 and 2010[a]

Product	Production/consumption 1996	2010	Total growth 1996–2010 %	Annual growth 1996–2010 %
Industrial roundwood (million m^3)	1,490	1,872	26	1.7
Sawnwood (million m^3)	430	501	17	1.1
Wood-based panels (million m^3)	149	180	20	1.3
Pulp (million tones)	179	208	16	1.1
Paper and paperboard (million tones)	284	394	39	2.4

In regions such as Africa and Asia, where supplies (particularly of large logs) from forests are coming under pressure, consumers of wood and fiber will increasingly have to look to other sources to meet the demand (as they already do in Asia) if they do not wish to overexploit their forests. Another, perhaps more likely, alternative is that the markets for forest products will continue to move in the direction of substitution of other wood-based panels and engineered wood products for sawn wood and plywood. Wood-based panels and engineered products can be manufactured from small-sized wood or nonwood substitutes.

In summary, the supply and demand analysis carried out by FAO suggests that the capacity of the forest and other sources of fiber will be sufficient to meet demand for the near future. However, the situation will vary among countries and regions. Africa and South Asia will continue to need to use a wide range of nonforest supply sources to meet their consumption demands. The demand for higher quality sawlogs will also approach or even exceed the production capacity of forests and plantations in Africa, Southeast Asia, and the Pacific Islands.

Table 2— Forecast production potential from forests and recovered and nonwood fibre sources and forecast production of wood and fibre in 2010 (million m^3 equivalent)[a]

	Forecast production in 2010			
Region	Industrial roundwood	Recovered and nonwood fibre	Total	Total potential fibre availability in 2010[b]
Africa	84	2	86	81
Asia	421	222	643	729
Oceania	54	0	54	80
Europe	502	133	632	893
North and Central America	658	147	805	835
South America	153	2	155	225
World total	1,872	506	2,375	2,843

[a]From FAO 1999. [b]From GFSM (FAO, 1998a) or official government estimates.

However, it is expected that product prices will not rise significantly during the projection period. Many of the world's regions have ample or excess wood product manufacturing capacity. The current worldwide economic slowdown has further mitigated pressure on consumer prices for the time being. In selected cases, there may be upward pressure on the prices of certain types of roundwood (typically the higher grades), but price increases will be restrained by the availability of lower value wood and nonwood substitutes. Trading patterns are not expected to change significantly, apart from the continuing trend toward more in-country processing of wood raw materials. This should lead to less trade in semiprocessed and commodity-grade wood products and more trade in higher value products.

Possible Future Market Developments

Wood Supply

The sources of wood and other fibers used in production are likely to change in the future. It is expected that in most countries, there will be a move away from the use of forest resources for wood and fiber production and towards a greater reliance on other sources of supply. The greatest change by far will be the increased use of wood processing residues and recycled fibers in the product input mix. The use of such secondary sources is likely to continue to expand in the more developed parts of North America, Europe, and Asia, while trees outside forests are likely to have an increasingly important role as forest resources decline in some of the less developed regions of the world.

Within the forest, supply patterns are also likely to change in the future. The next decade or so will see large areas of commercial short-rotation plantations (for pulpwood) become available in the southern hemisphere. Greater areas of older plantations established for the production of sawlogs will also start to be harvested in countries such as Australia, Chile, New Zealand, South Africa, the United Kingdom, and the United States. These plantations will provide the greatest share of the expanded wood production potential expected in the future. In contrast, very few countries are likely to be able to expand production sustainably from the natural forest without considerable investment in silviculture.

Greater areas of natural forest are likely to be legally protected. Many of the areas that are likely to be chosen for preservation are not currently harvested and are considered unexploitable for economic reasons (physical constraints, transport limitations, low timber value). A decrease in harvesting intensities in the exploitable natural forest would have a greater impact on future supply potential than would an increase in the amount of legally protected forests.

Technological Change

Technological change has been incorporated in this supply and demand analysis only in the pulp and paper sector, where it has been assumed that current trends in the use of recovered paper in the total fiber furnish will continue in the future. For example, 1 ton of paper and paperboard in 1970 was made up of more than 80% wood pulp. By 1997, this figure had dropped to 56%, and by 2010, it is expected to fall to below 50%. This trend is partly a result of the increased use of recovered paper but is also a result of shifts in market shares, whereby the proportion of printing and writing papers (which have a lower fiber content) in the overall market has increased and is expected to continue to do so.

Other technological changes that are not included in the model may also occur in the future. First, improvements in harvesting practices could increase log recovery and reduce logging residues in many of the world's forests. Many developing countries have substantial room to increase their log recovery rates. Even a modest increase in log recovery rates in countries with high annual felling levels could increase production and contribute significantly to meeting the projected growth in industrial roundwood demand.

More efficient conversion and use of mill residues and better mill recovery rates have significant effects by reducing the amount of roundwood required to manufacture products. In addition, residues could be used more effectively to meet the demands of other wood processors. Not much is currently known about the utilization of mill residues outside a few of the large developed countries. However, it is suspected that large volumes of residues are wasted or left unused. As FAO (1998a) has shown, all of these sources could make a significant contribution to wood supply.

A third technological change that might occur is a move towards greater use of reconstituted panels because of two factors: upward price pressure resulting from the increasing scarcity of large-diameter logs and technological developments in construction and other wood-using industries, which would allow the use of such products where only plywood or sawn wood are currently used. This shift will also have the effect of extending the use of resources (recovery rates for reconstituted panels are typically higher than for sawn wood and plywood) as well as providing a ready market for residues from other industries.

Technological developments in wood processing continue to keep pace with market, environmental, and raw material resource trends. The increased production of reconstituted panels such as oriented strandboard and medium-density fiberboard and developments in the manufacturing of engineered wood products will continue to increase the efficiency of using more diverse raw materials. Engineered wood products increase opportunities for using small-diameter logs of lower quality and less-used species. The use of microprocessors in almost every step of the production cycle increases product quality and minimizes the amount of residues generated. Much of the technological development in wood processing is currently concentrated in industrialized countries, and the extent to which the technologies are used in nonindustrialized countries is not known. Wider adoption of current technologies and development of new ones that increase processing efficiency could help slow the increasing demand for raw materials to supply finished wood-based products.

Use of the Changing Wood Resource

Tomorrow's wood product manufacturers will face a distinctly different resource than that available today. The character of the wood supply varies with the forest management regime. Plantation-grown trees are likely to be single species, even age, even size class, relatively uniform, and genetically improved. Trees produced under sustainable forestry principles are likely to be more diverse—of mixed species, uneven aged, and mixed size classification. As the concepts of sustainable forestry and sustainable development move into practice, industry will most likely find itself needing to utilize a much more diverse raw material supply than it has in the past. In contrast, industrial processes and products usually benefit from a uniform, stable raw material supply because they can be optimized more readily. In addition, product variability is generally reduced and processes are more stable with a uniform supply. With a more diverse raw material supply, new technologies will be needed to overcome the problems of product and process variation. Today, technologies such as composite products, nondestructive evaluation, mechanical grading systems, and engineered wood products play an increasingly important role in adapting to a changing timber resource.

Composite technologies are generally more flexible in type and quality of material used than are solid lumber wood products. One composite experiencing remarkable growth is oriented strandboard (OSB), a product made from wood particles aligned to obtain the best engineered properties. OSB is being used as a replacement for plywood because of the difficulty of getting veneer-grade logs and because it can be made from a variety of tree species and size classes. OSB now represents more than 25% of the structural panel market, and the demand continues to grow. The raw materials for many OSB manufacturing plants in North America are underutilized species like aspen and yellow-poplar.

Another technology that has allowed the use of different tree species and size classes is nondestructive evaluation (NDE) technology. NDE can be used to determine the stiffness and strength of individual pieces of lumber, reducing dependence on visual grades (which are species dependent) in favor of mechanical grading (which is species independent). Mechanical grading can allow a wider range of species to be substituted for structural applications, as long as certain stiffness and strength requirements are achieved. Mechanical grading uses static bending techniques, vibration techniques, or stress waves to determine stiffness. Research has demonstrated a direct relationship between the bending stiffness of lumber and its bending strength. The only way to determine the actual bending strength of a board is to break it. Since that is not practical, the next best available method is to measure the board's stiffness, compute the modulus of elasticity, and then predict the bending strength. Such procedures produce a mechanically graded lumber that is accepted by regulatory agencies and all major building codes, provided that production follows approved grading agency certification and quality control procedures.

Meeting the Challenge

Forests are being squeezed between expanding needs and a shrinking resource base. The pressure being placed on the resource also pushes technological developments to help divert those pressures. Historically, technology has aided conservation by making more efficient use of resources. That trend will need to accelerate to meet the challenges of today and tomorrow. Key areas for research and development are use of the changing wood resource, extension of the resource, and environmentally friendly technologies.

Sustainable development must be based on the interdependence of the environment and the economy. Wood technology is essential to this integration. Some specific areas for research and development include

determining new, more efficient, and environmentally friendly ways to extract, reduce, and convert virgin wood raw materials to useful products,

developing technologies to allow the re-use of materials and products to the maximum extent possible,

making sure that the latest technologies for extracting, reducing, converting, using, and re-using wood raw materials are transferred to developing nations as quickly as possible,

developing methods to ensure that renewable resources of all kinds, e.g., wood and agricultural crop residues, are converted to value-added uses like advanced consumer and engineered wood products, and

developing technologies that do not produce harmful by-products during the manufacture of wood products.

This list represents just a few of the areas that hold promise for advancing wood utilization activities to meet the needs of society while keeping a well-tuned balance between the ecological, economic, and social aspects of sustainable forest management.

Principles of Timber Harvest Planning

by
Klaus v. Gadow

Institute for Forest Management, Büsgenweg 5,
37077 Göttingen, Germany
E-mail: kgadow@gwdg.de

Abstract

The purpose of timber harvest planning is to anticipate the future in a systematic way and threby reduce uncertainty. Numerous techniques have been proposed for ensuring sustainable timber yields and for evaluating alternative scenarios of forest development. Some of the techniques are limited to applications in simple forest production systems while others are suitable for any type of forest management, including selective harvesting systems. An important aspect of sustainable forest management is risk analysis which involves the evaluation of potential hazards for a given forest area and reference period.

Keywords: Risk analysis, Continuous cover forest.

Types of Forest Management

According to the statistics issued by FAO (1997) the world forest area in 1995 amounted to about 3.4 billion ha. The biggest share of this area is situated in South America and within the borders of the former Soviet Union, with over 800 mill. ha in each region. Forest areas of well above 500 mill. ha are found in each of the three important forestry regions Asia (including East South Asia), Northern and Central America and Africa. The forests in Europe, described in greater detail by Kuusela (1994), cover an area of about 146 mill. ha.

Comprehensive forest area statistics have been made available for some time, but very little is known about the distribution of forest management types. A traditional view of a managed forest is that its development follows a perpetual series of growth cycles which are defined by the rotation. A cycle begins with the establishment of the young trees and ends with the harvest of the mature ones. Intermediate thinnings may improve the value of the final crop. Productivity is measured in terms of the total volume produced, or the mean annual increment at rotation age (MAI_R). Sustained yield control is based on the model of the *Normal Forest*, and the present value of a specified silvicultural program is equal to the sum of the annual net incomes, discounted to the age of establishment[1]. The forest area is not continuously covered by trees and we may thus refer to such a forest as a *rotation management forest* (*RMF)*. Rotation systems with fast-growing timber species and intensive silviculture are found in the Southern hemisphere (Chile, South Africa, Australia, New Zealand), in the South-Eastern United States, in many parts of Asia and in some European regions. The management of plantation forests is comparable to that in agricultural production systems with short rotations, intensive pruning and thinning, fertilizer application, use of clonal seedlings, integrated timber processing plants and sophisticated information technology (Fig. 1).

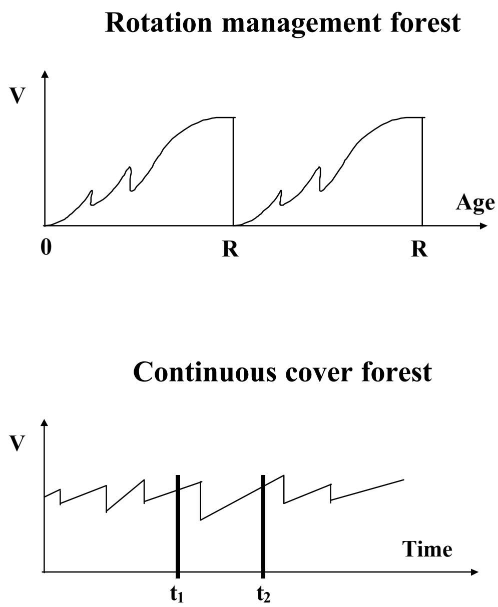
A second type of management which we may call *continuous cover forest* (*CCF*) is not uncommon in tropical regions and in Central Europe, where its importance and prevalence are currently increasing[2]. This type is characterized by selective harvesting of individual trees and for this reason the silviculture is appropriately known as *forest gardening*[3]. Forest development has no beginning or end. The forest remains in a state of undefined age, oscillating about a specified level of growing stock. Harvesting operations may take place at regular intervals and the distinction between thinnings and final harvests is not clearcut. Age-based measures of forest production and valuation, such as mean annual increment or age-based net present value, cannot be used and new simulation techniques for generating forest development

[1] for details concerning the economic criteria refer for example to Clutter *et al*. (1983) and Chang (1998).
[2] large areas which might be classified as *CCF* are not managed in a systematic way. Timber may be cut for construction or fuel, shifting cultivation and wildfires may be common and timber volumes are declining because no efforts are made to regenerate exploited forest areas.
[3] a translation of the French *jardinage*.

paths are required for evaluating future scenarios.

Examples of this type are the so-called *Plenter* forests found in France, Switzerland, Slowenia and Germany, some forests in the *Northern Hardwood* region of North America and the famous *Knysna* forests of South Africa. Low intensity systems of forest management are usually found in regions controlled by timber processing companies requiring more or less regular raw material supplies and large timber reservoirs are found in the coniferous forests of the boreal region and in the evergreen multi-species forests of the tropical and subtropical regions.

Figure 1. A rotation forest develops through a succession of growth cycles defined by a rotation (left). Age and rotation are undefined in a continuous cover forest and the growing stock oscillates about some desired level (right).



Sustainable Harvest Control

To sucessfully maintain an industry based on timber products, forest planning must ensure that there are always stands at the right stage of development and in sufficient number to yield the desired product mix coming from the forest. This problem has been addressed using a variety of methods. Some of the techniques are limited to the use in even-aged forests while others are suitable for any type of forest management.

Scenario Methods Suitable for Regional Resource Forecasting

Harvest planning is based on techniques which define a sustainable harvest on the basis of available growing stock volumes and growth rates. Quite useful, though not very sophisticated, are scenario methods based on age class simulation. The algorithm presented in Fig. 2, for example, may be used to simulate the effect of a given harvest level on the development of the age class distribution of a regional timber resource.

Obviously, the method involves considerable aggregation over growing sites, forest types and management regimes, and the predictions have to be interpreted with the necessary caution. However, an age-class simulation is often the only feasible way to predict the dynamic development of a forest resource for large timber growing regions.

Another highly aggregated approach involves the use of *area change models* which predict transitions of forest age class vectors through time. These methods have been used especially in Japan (Konohira and Amano 1986) and to a limited extent in Europe (Kurth *et al.* 1987; Kouba 1989). One of the most prominent applications is Suzuki's *Gentan* model which predicts the transition of a given age class vector through time (Suzuki 1971; Blandon 1985). The transition probabilities are not independent of the age class vector and this seems to be one of the problems associated with the use of area change models (Randall and Gadow 1990).

Planning Methods Suitable for CCF Systems

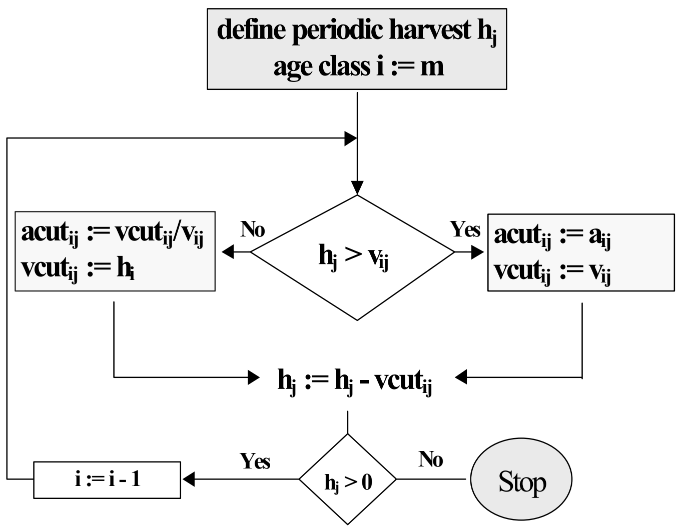
Various techniques have been devised for controlling sustainable harvests in continuous cover management systems. To ensure sustained production levels, a common method involves regular visits to a given area, recurring at discrete time intervals, and to harvest any accumulated surplus growing stock at each visit. Assuming a cycle of n years it is possible to map the progression of harvest locations and the change of the state-space distribution of forest states after each time step. The optimum state may be defined on the basis of a desirable diameter distribution after harvest (Susmel 1980, Virgilietti and Buorgiorno 1997) or a desirable basal area distribution after harvest (Hansen 1987; Gadow and Bredenkamp 1990, p. 111 et sqq, Seydack *et al*. 1995).

Sustainable management of a continuous cover forest may imply maximizing volume or value production while maintaining the forest in a steady state. The theoretical basis for this process is given by a linear transition matrix approach which assumes that each tree in a finite number of size classes has a known probability of moving to another class, which depends only upon its current size. During a given time step a tree may either remain in its class, grow into a higher class or die. The objective of an optimization model may be to maximize the total harvested volume, or timber value, during each cutting period while satisfying the equalities and inequalities derived from the transition matrix and specific steady state conditions (Buongiorno and Michie 1980; Rautiainen 1999).

Planning Methods Suitable for Any Management System

A managed forest typically consists of a discrete number of geographical units known as compartments. Each compartment develops over time in response to forestry operations such as plantings, prunings or removals of varying type and intensity. If appropriate tools are available, specific treatment schedules can be generated for a given compartment. A scenario of forest development represents a specific combination of treatment schedules for the different compartments within a specified forest area.

Figure 2. Algorithm for age-class simulation with flowchart (left) and abbreviated pseudocode (right). a_{ij}=forest area available in age class i (i=1..m) and period j (j=1..n); v_{ij}=timber volume available in age class i and period j; $vcut_{ij}$=timber volume harvested in age class i and period j (m^3); $acut_{ij}$=harvested area in age class i and period j (ha); h_j =specified harvest volume for period j (m^3).



For each harvest period *j*, do:
For each age class *i*, starting with the oldest one, and while h_j>0, do:

a) Calculate the available growing stock volume v_{ij} ;
b) if h_j v_{ij}, then harvest the entire growing stock available in age class *i*; else harvest only h_j m^3;
c) *subtract the volume harvested from* h_j

A scenario model thus embraces all the possible treatment schedules for all the compartments within the forest. The aim of forest management is to find the optimum combination of treatment schedules over all compartments. Various techniques have been developed to achieve this objective. The most popular method is constrained optimization which has been used for about three decades, after the basic structure was developed by Ware and Clutter (1971) which later became known as the Model I

In practice, the different silvicultural regimes are mutually exclusive. Only one regime per stand is possible. This limitation cannot be imposed in the Model I formulation, unless an integer solution is sought which would be prohibitive in terms of computer time. Various solutions have been offered to overcome the shortcomings of LP in timber harvest scheduling[4].

Risk Analysis

There is a wealth of harvest control techniques for calculating sustainable harvest levels, but a shortage of methods for evaluating sustainability under risk. *Risk* has been defined as the expected loss due to a particular hazard for a given area and reference period (United Nations 1992). An *expected loss* (*r)* is the product of the *damage* (*s)* expressed in monetary terms and its *probability* (*p*). *Risk assessment* is a formal procedure for quantifying risk with regard to the damage potential including all the possible threats within a given hazard domain. An example is the *hazard chain* in a spruce forest, presented in Fig. 3. A *risk evaluation* is concerned with the economic evaluation of potential threats and benefits while *risk management* includes specific strategies and actions for reducing risk (Hollenstein 1997).

A potential hazard presents a risk if it occurs with a probability greater than zero and if its occurrence will cause damage to a valuable object. The probability of occurrence of a given hazard factor may be defined by a probability distribution depicting the frequency of certain events on the basis of previous observations. Kouba (1989), for example, used the Weibull function for modelling spruce forest survival, assuming a variety of hazards and their cumulative effect.

$$\max Z = \sum_{i=1}^{I} \sum_{j=1}^{J_i} c_{ij} X_{ij}$$

subject to

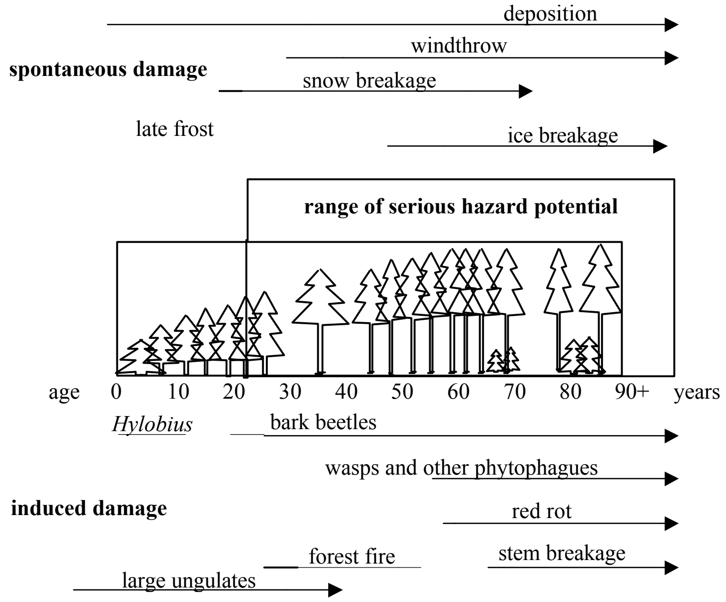
$$\sum_{i=1}^{I} \sum_{j=1}^{J_i} a_{ijpt} X_{ij} \le M_{pt}, \quad \forall p,t$$

$$\sum_{j=1}^{J_i} X_{ij} = A_i, \quad \forall i \text{ and } X_{ij} \ge 0$$

where

I=	number of compartments
J_i=	number of treatment schedules for compartment i (i=1..I)
X_{ij}=	area of compartment i managed according to treatment schedule j (ha; j=1..J_i)
a_{ijpt}=	amount of item p produced or consumed per ha in period t
M_{pt}=	total amount of item p produced or consumed in period t
A_i=	area of compartment i

Figure 3. Example of a hazard chain, - the potential hazards during the life of a spruce forest (Otto, 1994).



Discussion

The classical models of forest development are based on scenarios that evaluate alternative timber harvesting strategies and their effect on the future development of the resource. Harvest scheduling has always been a central issue in forest management, but harvest scenarios do not necessarily produce feasible plans. Felling volumes are often specified and, by some magic, assumed to be available at the prescribed time. To ensure that forest management scenarios are feasible, greater emphasis needs to be placed on models that predict potential hazards.

Abstract

A few Southeast Asian countries, particularly those from the everwet region like Indonesia and Malaysia that are endowed with timber-rich dipterocarp forests, dominate the international tropical timber trade. Many of these countries are quite dependent on the timber revenues, and so managing these natural resources on a sustainable basis is of high national importance. In this brief review, the state of forest management and product development in the region is given.

Attempts at sustainable management of natural forests have had a long but variable history in the region. The management systems were based on systems developed in European forests and subsequently tested in India and Burma. In the early part of the century the demand for timber was mainly domestic, and only the heavy and durable hardwoods were exploited. Management systems were developed to improve the poles, and subsequently the young regeneration of such species. With development of preservatives and mechanization of saw-milling, the number of species that can be utilized expanded, and the need to harvest large volumes in a unit area increased. A well renowned uniform tropical silvicultural system was developed to manage these timber-rich forests. Today, most of these forests have been exploited or converted to agricultural use. Forestry was relegated to the hills which are poorer in timber, and management problems more complex. Selective felling systems based on diameter limits became standard practice throughout the region. However, heavy logging damage to the residuals makes the system bicyclic instead of being sustainable. This, and concern for loss of these species rich ecosystems has brought about new ideas in management of tropical forests. There has been a departure from the concentration on yield management to practices that are holistic, and which encompass concern for biodiversity, socio-economic issues, environmental protection, etc. Today, foresters in the region are grappling with certification matters, "green timber" issues, carbon sequestration, minor forest products, and benefits to forest dwellers. The future of natural forest management would probably give less emphasis to timber production.

With the forecast that natural forests will play a lesser role in timber production, interest in plantations has grown in recent years. While there has been a long history of plantation trials, few successful models exist in the everwet region of Southeast Asia. Earlier attempts to produce fast growing exotic hardwoods for general utility timber saw massive failures. But small pockets of successes do exist and are now being expanded. There has been a swing in favor of planting indigenous species and mixtures of such species, out of consideration for biodiversity and pest problems in plantations. Research into high yielding clones, mass propagation using biotechnology, appropriate silvicultural practices, etc. are paving the way rapidly. All these spell a bright future for timber plantations in the region. In the next decade or so, the dream of capturing the high productivity in the everwet tropics may be fulfilled.

Product development is critical in furthering the effort towards achieving sustainability of resources. This area too has progressed with great strides and bounds since the beginning of the century. From utilizing a narrow group of highly durable heavy hardwoods, research in preservation techniques have made the majority of the big trees in the forests potentially usable. This saw the utilization swing from a handful of species at the beginning of the century to almost

300 species at the end of it. Other improvements in technology too have totally changed the processing and utilization of wood. Development of panel products, utilization of wood waste, developing technology with low environmental impact, laminating technology, etc. have resulted in better utilization of wood resources, leading to reduction in resource demands, and sustainability of the resource.

Keywords: Humid tropics, Sustainable production, Natural forest, Plantation forest, Forest products

Introduction

Sustainable production of tropical forests is no longer a subject of concern for foresters. The continued perpetuation of these forests has become an international issue, and is a much-debated subject these days. Well above that, sustaining the many benefits of tropical forests is a matter of survival for the millions of people in the tropics. In this respect, perhaps the issues and problems of management of the humid forests of Southeast Asia deserve a separate treatment of their own. This is because the tropical rain forests of the region are unique in several respects. Firstly, the timber-rich family Dipterocarpaceae dominates the region's humid forests. It therefore comes as no surprise that this region is the biggest player in the export of tropical timber in the world market. Easily 75% of the tropical hardwood logs traded in the world markets originate from the region (Nectoux et al. 1991). Next, the rate of deforestation is a shade higher in the region than that observed in the American and African tropics. Some of these forests are indeed among the richest in terms of biodiversity, and so their conservation is of a very high priority. Besides all the above, some important forest management practices were initiated in the region, and they hold a special place in the development of tropical forestry globally.

Which are the humid forests of Southeast Asia? The perhumid forests of the region are centered in the Malay archipelago, that include Sumatra, Peninsular Malaysia, Borneo Island, most of Sulawesi and the Philippines. The rain forests also penetrate into continental Asia, where they occur in the wetter and less seasonal parts of Myanmar, Thailand, Cambodia, Laos and Vietnam. All these areas enjoy a wet climate, with no regular dry season, or of only a few months' duration. In areas with longer annual dry season, tropical seasonal or monsoon forests occur.

Having recognized that many of the countries in the region are quite dependent of forest produce both as a source of foreign exchange as well as for survival, it is critical that the forest produce is managed on a sustainable basis. Besides management of natural forests, there is also the issue of plantations. For a long while, it has been argued that with such good growing climates, plantations would provide a superior means to supply timber for the overgrown timber industry. Their sustainable management is another equally important factor for the economic well being of this region. The same would also apply to the downstream industries, which provide considerable amount of employment opportunities for a large percentage of the people in the region.

Considering the above it is important to look at the issues of sustainable production of the natural forests, plantations and the industries in the region. However, treating a region as diverse as Southeast Asia may not be easily amenable for the present. With such enormous differences in the history of management, economic development, land-use patterns, and population demography, it will be no where possible to review all the issues thoroughly. What we have therefore adopted is to provide some of the important developments in the three areas, and use them as means to generalize for the development overall in the region. These models are applicable for many parts of the region, and they may be used for further developing the forest resources in each of the countries in Southeast Asia.

Sustainable Production in Natural Forests:

Certification

The byword in forest management these days is achieving Certification. This is a market movement whereby consumers are demanding that forests be managed on a sustainable basis before the products are sold. For attaining sustainable management, several international (e.g. ITTO Year 2000 Objective) and non-governmental agencies (e.g. Forest Stewardship Council's C&I) have promulgated a set of guiding rules, called Criteria and Indicators against which the forest management will be evaluated. These Criteria and Indicators represent a holistic approach, and takes into consideration aspects of forest management that include continuity of production, environmental protection, conservation of flora and fauna, and socio-economic benefits.

Reduced Impact Logging

To meet these stringent requirements for Certification, a number of forest management practices have to be improved. One of the first moves in the last decade in this direction was introduction of the practice now called Reduced Impact Logging. The issue to be addressed is logging damage. Heavy skidder-crawler tractor machines are used to harvest timbers. These machines, when used without supervision, cause enormous damage to the young regeneration, older residuals and the soils. Furthermore, many of the standing residuals become injured, and they succumb to the wounds and this mortality may persist for almost two decades following logging. Overall, as a consequence of using such damaging harvesting machinery, the negative impacts are numerous, and include:

- the second and future crops are heavily destroyed;
- soil damage is extensive and area for forest regrowth declines;
- erosion increases by many folds, waterways become silted, freshwater sources are destroyed;
- biodiversity, both flora and fauna decline.

Research in Kalimantan, Sabah and Peninsula Malaysia has come up with reduced impact logging techniques. Basically it involves logging guidelines for implementing good management practices, which include specifications for pre-harvest planning, vine cutting, felling, skidding, and post-harvest site closure. Pre-harvest planning entails preparation of 100% stock map of harvestable timber, including streams, road buzzer zones and sensitive areas. Roads and skid trails are located on ridges to avoid steep grades, facilitate uphill skidding, and minimize skidding distances. The positions of roads and skid trails are preplanned, so that only the least minimum is required for extracting timber. Directional felling of trees was employed to minimize damage to residuals. Further, the bulldozer skidding was limited to slopes of less than 35° only, blading of skid trails was restricted, and the practice of balding off of surface soil and sidecutting were controlled. As a result of all these strict guidelines, the damage to the forest was considerably reduced (Table 1).

The improvements to existing practices have resulted in considerable reduction in damage to the residuals and the environment. Today, for achieving forest management certification, RIL practices are obligatory. The additional costs for implementing RIL is calculated at US$ 4.50/m^3, about 10-15% increase over normal direct costs of harvesting and delivering logs to the log pond. But the indirect savings of lowered environmental impact, less loss of biodiversity, lower loss of soil nutrients, better future crops, etc. may far exceed the small additional costs incurred for practicing RIL.

Table 1. A comparison of damage resulting from conventional and reduced impact logging.

Effects	Conventional Logging	RIL
Proportion of area with soil damage	0.17	0.07
Skid trail density (m/ha)	199	67
% skid trails with subsoils exposed	87	38
Proportion of trees killed during logging	0.41	0.15
Density of undamaged seedlings (5-20 cm dbh)	49	104
Residual stand damage (%)		
Seedlings	33	18
Saplings	35	20
Poles and trees	40	19
Tree damage based on injury (%)		
Light	12	7
Heavy	29	12
Opened area (%)		
Caused by felling	11	8
Caused by skidding	9	5

Improved Harvesting Techniques

While the practice of RIL is a major development, it is merely an improvement and better implementation of existing practices. There are several researchers in the region who are looking at improving the harvesting techniques. Three improvements to the skidder-tractor systems are being tested. They are the helicopter system, mobile skyline yarder, and the long haulage ground cable system. Helicopter logging trials have been conducted in Sarawak. A heavy lift helicopter was used by Samling Sendirian Berhad to harvest dipterocarp forests (FAO 1999). The Boeing Chinook helicopter with a load carrying capacity of 12,700 kg was used. This translates into an annual extraction capacity of about 250,000 me, but in actual production it was about 100,000 m^3. The average payload for each trip to a landing was 5.8 m^3, and a typical tree produced a payload of about 7 m^3. It could yard up to 5 km, but the average extraction distance was 2 km. The damage to residual trees is limited to what occurs during felling, and soil damage is almost non-existent. The logging costs using helicopters ranged from US$60 – 70 per m^3, compared to about half using crawler-tractor systems. Besides this, the helicopter system has several other limitations:

i) because of its high costs, extraction of only a few valuable species is possible;

ii) maintenance and logistical problems are enormous to overcome under tropical conditions;

iii) the timbers cause too much torque, and spin a lot, resulting in their ejection often;

iv) the system allows free ranging, and theft outside the compartment cannot be controlled; and

v) the risk of accidents is too high, and it is becoming difficult to obtain insurance policies for such operations.

Similar conclusions were made from helicopter logging trial in Papua New Guinea (Blakeney 1994). Cheaper low impact logging systems are currently being investigated in Peninsular Malaysia. They include the Mobile Skyline Yarder (Sasaki et al. 1999) and the Long Haulage Ground Cable System (LHGCS) (Shamsudin et al. 1999). The LHCGS is a combination of a metal-fiber glass skidding cone attached to the front of a log, which is then hauled to the main road using a cable operated by a tractor. The system does not allow the tractor to free range in the forest. The cone allows logs to move over the ground unhindered by other logs, stumps, rock, or other obstructions. Practically no damage is caused to the soil, and damage to trees is only limited to a narrow corridor about 2 m wide from the valley to the main road. Both the low impact harvesting systems are being improved and their productivity is being improved. These systems are obviously much cheaper, and a small to medium-sized concessionaire can cheaply and easily operate the LHGCS. The technology is low-end and can be easily acquired as well. Overall, these systems offer the best promise as harvesting systems for tropical forests. If Certification is ever to be achieved, it seems like these systems have to be incorporated in all forest harvestings. Modifications of the systems can also be employed in plantations.

Nutrient Losses and Harvesting Cycles

The damage to the soil, in terms of soil erosion, water quality and nutrient dynamics has been extensively investigated (Zulkifli et al. 1998). Controlled selective logging experiments indicate 2-fold increases in the exports of Ca and Mg and 3-fold increase for K. The losses from timber extraction of 40 m^3/ha for Ca, Mg and K are 115, 13 and 44 kg/ha, respectively (Nykvist 1994). The recovery rates as a result of atmospheric and weathering inputs appear to be 35-90 years for Mg, 20-35 years for Ca, and 10-50 years for K. Under these circumstances, the estimate of a 30-35 year cutting cycle for dipterocarp forests appears rather too short. A more conservative one would be closer to 55 years for selective felling. However, if the improved harvesting systems become ubiquitous, then a 35-year cutting cycle may become a possibility.

Enrichment Planting

Enrichment planting has become a standard silvicultural practice to ensure regeneration poor sites are restocked with valuable timber species. Besides this, large tracts of logged forests are completely degraded – soils are compacted and/or highly eroded, with practically no tree vegetation able to colonize such sites. Such areas can measure up to 40-50% of a logged site. Fires have become frequent occurrences, and the areas that need rehabilitation planting are increasing. Vast sums of money are expended to restock the poorer forests, and rehabilitate the degraded sites. Enrichment planting has become the standard practice. However, in the majority of cases, the performance of enrichment plantings has been dismal to downright disasters. The problems are mainly due to the following:

i) the forest canopy closes too fast, and the plants stop growth, and eventually fade away;

ii) the sites are too compacted, and the root systems are not able to penetrate deep enough to receive adequate water and nutrients;

iii) heavily eroded sites are nutrient-poor, making growth difficult;

iv) the species chosen is unsuitable for such planting conditions; and

v) occasional drought spells wipe out the weakened seedlings.

New methods are being tested in Peninsular Malaysia, which appear quite promising (Raja Barizan *et al*. 1998). Tall seedlings/saplings of 1–2 m in height were used instead of the conventional seedlings which measure only about 10 cm in height. The tall seedlings, although more expensive both to raise and plant, have an advantage over the fast growing pioneer vegetation and climbers that proliferate in the forest immediately upon logging. The tall seedlings are able to out-compete the weeds, minimizing additional revisits and treatment costs. Where the soils are completed eroded or compacted, big planting holes, 1 x 1 x 1 m are made. This is done using a mechanical augur mounted on a small tractor. The soils are loosened before the planting is done, and fertilizer is added. First of all, the big holes allow deep root penetration, and this boosts the overall early growth of the plant. Such big holes contain a lot of moisture, which can sustain the plant during an unexpected drought. Finally, wild boars were a big nuisance to the seedlings, and many were bitten or pushed over. This was overcome by placing a barbed wire tower built around the base of the tree. All these measures have given meaning and success to the much-maligned enrichment-planting programme.

Village Model Forests

Forest dwelling communities are usually left out of the logging concessions, and the profits derived from such activities do not reach them.

Under these circumstances there was no compelling desire on the part of forest denizens to retain the forest, and quite often they converted them for agriculture. Realizing this, there have been moves in several Southeast Asian countries to introduce community forest management systems whereby the profits from logging accrue to the villagers. One such trial in Laos has developed a scheme to develop such a village forestry concept (Bonita 1997). Under the scheme a village forestry association was formed, and each village of about a hundred households is given about 2,000 ha to manage. They operate on a 5-year cutting cycle, removing only 1 – 2 trees/ha (Table 2). Heavy machinery are avoided, a lorry-winch system is used for extracting the trees along small tracks, and a lot of manual labor is employed in the harvesting operations. Under such systems the damage to biodiversity, soils, and waterways are minimized, and the minor forest produce is not compromised. The incentive to retain the forest stands is very high because of the labor opportunities and logging profits. Other countries like Vietnam and Cambodia are also looking into such schemes.

Forest Plantations

Forest plantations on the other hand is not new in concept and practice in the tropical region. However, interest in forest plantations in the past lacked the required impetus. It has vacillated quite a bit, influenced by only a few successful models in the tropics. Interest in forest plantation is now becoming more intense, being influenced by the fear of impending timber deficits in the future.

What Tree to Plant

The choice of species to plant depends initially on the end-use, or the environmental role of the plantations. Once the species has been chosen, it will dictate the silvicultural requirements, management and utilization of the crop. Switching to species halfway through its rotation incurs massive costs, that of cutting immature crop and planting the new ones. When choosing the species, the following basic questions must be answered: What is the purpose of the plantation? What species will readily grow in the available site? What relevant species are suitable and potentially available?

Table 2: Village timber management system compared with concession-based timber management system (Bonita 1997).

System elements	Village forestry	Concession-based forestry
Setting	50,000 ha, operated by 25 village forest associations; average 2,000 ha per association	50,000 ha, operated by a single concession
Cutting cycle	5 years	50 years
Compartment size	2,000/5=400 ha	50,000/50=1,000 ha
Cut per ha	5.8 m3	58 m3
Trees per ha	1-2	6-10
Openings in stand	Ca. 200 m2/ha	Ca. 2000 m2/ha
Logging methods	Labor intensive	Mechanized
Regeneration method	Natural regeneration	Natural regeneration augmented with enrichment planting
Forest protection	Easy	Difficult
Biodiversity conservation	Well conserved	Substantial loss
Soil and water conservation	Less erosion and sedimentation	More erosion and sedimentation

Once the end uses have been clearly defined, the specific choice of species for the plantations is narrowed down to select a number. Often foresters speak lyrical of the virtues of indigenous species, and otherwise of the exotics. Indigenous species are supposed to be more 'resistant' to local conditions. This may be a reaction to the predominance of a few species, mostly exotics that have dominated plantations throughout the tropics (e.g. tropical pines, eucalypts, acacias, yemane, teak and mahagony) to the neglect of some promising indigenous ones. The well-known exotics, on the other hand, have an accumulated knowledge of decades of research and should be exploited as well. The argument favouring indigenous species may also be spurious, because boundaries of a country are geopolitically determined and are not related to plant distribution. There are pros and cons about indigenous and exotics species. For example some of the tropical indigenous species like the merbau, chengal and balau produce excellent, highly durable, fine grained timbers with uniform colours. However, none will match the exotic cabinet quality species like teak, mahagony and khaya species as they fetch premium prices for special furniture and internal decorative work. Therefore restricting to only the indigenous species of the country limits the species choice for plantations.

Some important biological advantages are present with indigenous species, though. They therefore deserve more attention: It is possible to predict their performance in plantations based on their performance in natural stands; the species fills an existing ecological niche – it may therefore be less susceptible to disease and pests, since the natural enemies are already present; and the timber is well known to local industries. Major success with indigenous species are *Eucalyptus deglupta* in the Philippines and Papua New Guinea, *Pinus merkusii* in Indonesia, *Araucaria hunsteinii* and *A. caunninghamii* in Papua New Guinea and *Tectona grandis* in India, Thailand and Myanmar.

Exotics on the other hand provide a greater selection of species. The exotic, like *Hevea* is often free from disease and pest, for the early years at least. This could mean the natural predators and controlling agents are also present. The exotics in monoculture are often susceptible to massive uncontrolled attacks once a severe pest adapts to the exotic or natural disease and pests are unfortunately introduced (Tho 1979).

As a basic guideline species selection for plantation in the tropic should be classified into three classes. These categories would be:

Species for Pulp and Paper Production

Here species that have very fast growth habits and produce a large biomass within a short rotation of around 6-8 years should be considered. These would include exotic species like *Acacia mangium, Paraserianthes falcataria*, Pine spp and indigenous species like *Macaranga* spp.

General Utility Timbers

There is a huge demand for general utility timber for industrial purposes. They go into core of plywood, and make up the major constituents of fibreboard, particleboard, interior construction wood and other low-grade use. Several species have been identified for this purpose and include *Shorea* spp (light red meranti group), *Hopea* spp., *Dryobalanops* spp., *Endospermum malaccense*, *Hevea brasiliensis* etc. These species will have a rotation of around 30-35 years.

High Quality Timbers

High quality timbers will be grown for veneers, paneling, furniture etc. Suitable species will include *Tectona grandis, Azadirachta excelsa, Araucaria, Dyera costulata, Swietenia* spp., *Khaya* spp., etc. The rotations under full plantation conditions would be kept short, at around 20-25 years.

Production of High Quality Planting Materials for Plantation Programmes

Tree Improvement Programmes

A tree improvement programme involves all practices designed to produce genetically more desirable trees. It is important that any tree improvement programme is planned and coordinated in accordance with the purposes and priorities of national tree planting programmes in such a way that emphasis is placed on species for present or expected future importance and duplication of trials is avoided.

The objective of any tree improvement programme should be made clear and well defined before the programme is initiated.

The purpose of a tree-improvement programme is to optimize one or more of the following points

1. the quality of the end use as timber, fuelwood, fodder, shelter, etc
2. survival (adaptation to climate and environment)
3. resistance to pest and diseases
4. growth rate

Wrong selection as to growth rate will give less favourable results, while wrong selection as to adaptability, resistance and, possibly even more, end use may result in greater loss or even complete disaster.

A tree improvement programme is usually divided into different stages:

1. selection of desirable species
2. selection of desirable provenance within a species
3. selection of desirable families and individuals within a provenance
4. control breeding including recombination and hybridization.

Clonal Forestry

Marker Aided Selection

Conventional tree breeding for forest trees is a slow process when valuable traits are successfully improved. Traditional selection is based on phenotypic analysis, where efficient selection is possible only halfway through the rotation period. Methods to allow efficient selection at earlier age would allow increased gain per unit time.

An attractive alternative to expensive and time-consuming field trials is to take a small sample from each individual and look for the presence or absence of specific genes. This is especially important for traits that are not visible until the tree has reached maturity, for example wood quality. Most of the traits selected for in breeding programmes (so called quantitative traits) are regulated by several genes. The strategy is to use molecular markers for genomic sequences responsible for the expression of quantitative traits to make early selection.

Several approaches have been taken for identifying molecular markers linked to traits of interest. Molecular markers have for example been used to analyse the genetic basis for height growth and yield in eucalypt and pine (Sara von Arnold et al, 1998). Molecular marker maps are now available for several forest tree species and strategies are under development for using marker aided selection in the breeding of forest trees. It is expected that the incorporation of molecular markers in conventional breeding programmes will potentially result in significant genetic gains.

Vegetative Propagation through Macro and Micro Propagation Techniques

The possibility to propagate trees vegetatively creates significant advantages both for the deployment of selected genotypes through mass propagation and for capturing and enhancing the genetic gain in the breeding programmes. To ensure that maximum gain is achieved, of environmental factors on field performance of each genotype tested. Today the most common way to propagate plants vegetatively is through cuttings. However, large-scale cutting propagation is only possible for some tree species due to problems with rooting, ageing of mother trees, survival of cuttings and high costs. Tissue culture techniques and especially somatic embryogenesis can overcome some of these problems. From each seed an embryogenic callus is established. The callus consists of a high number of somatic embryos, which can proliferate very fast. Therefore within a short period of time it is possible to produce a large number of genetically identical plants.

Another advantage of somatic embryos is that they can be cryopreserved in liquid nitrogen. In conventional breeding programmes, with several forest species, by the time the superior genotypes have been identified in the field trials, they are too old to be successfully propagated vegetatively. Consequently, the identified elite genotypes are lost and they can only be used as parents for the next generation. However, if cryopreserved embryogenic calli from each genotype are available, the elite genotype identified during field trials, can be thawed and mass propagated for use in the plantation programmes

Genetic Engineering

Genetic engineering makes it possible to add new genes into selected elite genotypes without changing other properties. This gives the breeders the opportunity to improve economically important traits, which cannot be modified by conventional methods within a reasonable time frame. The full potential of genetic engineering will only be realized with the integration into conventional tree breeding programmes. Techniques are available for producing transgenic trees of many forest species. The scenario of traits to be improved using genetic engineering includes stress tolerance, growth rate, wood quality and resistance to insects, pathogens and herbicides. However more information about the genetics and the physiological and biochemical pathways involved in specific traits is still required, before commercial use can be made of this technology. Much research is currently underway to isolate genes of commercial interest, irrespective of organism or species.

Improved Silvicultural Techniques

Planting of improved and fast growing trees will definitely require higher input in terms of fertilizer etc. In a study conducted in Australia (Anon 1995) it was found that in a fast growing pine plantation, the uptake of nitrogen rises at an almost exponential rate from 7 kg per hectare in the first year to about 80 kg per hectare in the fifth year. Under these conditions demand for nitrogen is likely to be outstripped by supply after about 3 years growth indicating that fertilizer programmes which is not a norm in forestry will need to be seriously considered. In addition, other silvicultural operations like pruning, spacing etc need to be reviewed.

Changing Scenario of Timber Utilization

Traditionally, the largest group of timber obtained from the ASEAN countries – primarily Indonesia, Malaysia, Thailand and the Philippines belong to the Dipterocarp family such as meranti/luan. As a result of the depletion in supply of these traditional timbers, other species have been progressively introduced into the market. Due to the low concentration in any stand of natural forest of these newly introduced timber species, they are commonly marketed together as mixed species (or mixed hardwoods). Thus, there is a general change in the species of timber being marketed from the region. In addition to this changing scenario of supply, another compounding factor, which has greatly influenced utilization trends, is the 'anti tropical hardwood campaign' (ATHC) mounted by non-governmental organizations (NGO's), especially in the developed countries. Some local councils of developed countries have shown their support for ATHC by imposing a ban on the use of tropical hardwoods in house construction and other uses. Other related events like the call for 'eco-labelling' of tropical hardwoods and assurance of sustainable management of tropical forest followed. All these activities have affected the market for tropical timber and timber products. Following the call for sustainable forest management practices; there is now a drastic reduction in the logging intensity in the traditional tropical timber producing countries. It is projected that the local demand for round wood would not be met. It is projected that annual demand for round wood in the ASEAN countries would be about 57 million m^3 in the year 2000 (Hong & Razak 1996). The future supply of timber for the wood-based industries would be partially dependent on the success of forest plantations in addition to whatever is available from the natural forest. It is estimated that plantations will provide about 25% of the total demand. The demand for solid timber would continue to increase to satisfy the demand of the wood-based industry and for utility purposes. However, because of changing conditions of supply, environment and economy this demand for solid timber is being rationalized. This is evident in the increasing use of reconstituted panel products especially in the furniture and to some extend, the joinery and moulding industries. Therefore, given the situation that alternative timber species are required for substituting traditional timbers, there is the other alternative of using these timbers to produce reconstituted panel products. It is inevitable, judging by developments of the reconstituted panel product industry, products like particleboard, MDF, orientated strand boards and some others are becoming increasingly important.

Concluding Remarks

With the ever-increasing pressure to ensure sustainable management and biodiversity conservation of the natural forest, indiscriminate cutting of natural forest will become history. Today's forest managers are grappling with certification issues, carbon sequestration, minor forest products and benefits to forest dwellers. It therefore appears clear that the future of natural forest management would give less emphasis to timber production and more to conservation and recreational issues. Plantation forestry is poised to become the source of timber production for the future. There is a need to ensure high productivity per unit area from these plantations. To achieve this, tree improvement programmes employing the available new biotechnological tools have to be stepped up to ensure results in the shortest possible time. Traditional solid timber usage is now slowly giving way to reconstituted panel products as alternatives in line with the change to alternative fast growing timber species. More emphasis in the future will be placed in panel products and MDF.

Abstract

Consumption of paper products will increase along with worldwide population growth and economic development. This will inevitably lead to increased use of raw materials within the industry. In the foreseeable future wood fibre (primary or recycled) will remain the main raw material source for the expanding paper and board industry. Stora Enso is one of the largest forest products companies in the world. Stora Enso's target is to grow and expand its production particularly in the paper and board industry, and the sustainable supply of raw material is therefore a major concern for the company. Stora Enso conducts various research and development (R&D) activities at its research centres, mills, forest departments and plantation projects. Most of the R&D resources are assigned to the development of industrial processes and new products. The efficient use of raw materials and the reduction of environmental effects are also important subjects. The contents of actual forestry R&D programmes are assessed separately for each country of operation and are based, among other things, on the existing scientific knowledge, magnitude of the company's forestry operations, forest conditions, forest ownership, and social, economic and natural environment. In Europe and North America national forest research is highly advanced and therefore Stora Enso mainly seeks low-cost collaborative arrangements for its specific forestry R&D needs. Consequently only modest R&D resources are assigned for forestry issues, and most efforts are focused on improving harvesting, storage and transport logistics. Stora Enso is presently involved in forest plantation projects in Brazil, Indonesia, Portugal and Thailand. Practically oriented R&D programmes are substantial parts of these projects. The main justifications for high research inputs are prospects for great productivity and quality improvements through genetic tree improvement, genotype-site matching and appropriate silviculture. Securing sustainable site productivity and control of pests and diseases over successive rotations are also fundamental R&D topics. Social and environmental issues are important in each project and require appropriate R&D activities. Collaborative research between companies and institutions in these countries is often difficult to practise, and therefore efficient, individual R&D programmes are necessary.

Keywords: Stora Enso, Pulp raw material, Research, Fast-growing plantations.

Raw Material Supply for Stora Enso - Present Situation

Stora Enso is one of the largest forest products companies in the world, producing annually some 14 million tonnes of various papers and close to 5 million m^3 of sawn timber. Stora Enso's target is to grow and expand its production particularly in the paper and board industry (Stora Enso 1999b).

Wood is the most important raw material for Stora Enso. The Group's total annual wood consumption is about 40 million m^3. The company owns 2.7 million hectares of forest, of which 1.9 million hectares are located in Sweden, 0.6 million hectares in Finland and 0.14 million hectares in Brazil (smaller areas are owned in Canada, Portugal, Thailand and Estonia). In addition, the company has leased altogether about 0.8 million hectares of forests in Canada, Russia and Portugal. Own and leased forests provide only about 15-20% of Stora Enso's total raw material requirements and the remaining 80-85% are purchased from various sources (Stora Enso 1999a). The raw material supply, however, varies greatly between countries and between individual mills in each country. Stora Enso's current wood consumption and domestic raw material supply is presented in Table 1.
The annual wood import to the company's mills in Finland and Sweden is at the level of

some 8 million m^3. Most of the imported wood comes from Russia and Eastern Europe. Stora Enso has its roots in Finland and Sweden, but as a result of its rapid expansion over the past couple of decades, it has emerged as a truly international company. The growth and internationalisation have increased production in regions with abundant secondary fibre (recovered paper) supplies. Recovered paper is mainly available in areas with relatively high population density and paper consumption. The use of recycled material is therefore, common in Stora Enso's Central European mills. The Nordic mills continue to use predominantly primary fibre and export most of their products to densely populated market areas such as South and Central Europe. In 1998 the company utilised 1.9 million tonnes of recovered paper in its mills.

Stora Enso Celbi's eucalypt plantation programme in Portugal commenced in the 1960s to meet its fibre requirements. In addition, Stora Enso is now also involved in three plantation projects in the tropics in Asia and South America. These projects are being developed in co-operation with local partners, and their raw material supply strategies are tailored for local conditions. The development of economically, ecologically and socially sustainable raw material resources requires quite different research and development inputs in these hardwood plantation projects than in the Nordic, North American and Central European operations. Thus, even though the company is global, the practical research and development arrangements must always be local.

Research and Development Units Within Stora Enso

Most of Stora Enso's research and development (R&D) work is focused on the development of industrial processes and new products. This R&D work is conducted using joint resources at the four research centres of the corporation (one in Finland, one in Germany and two in Sweden) and within the business units. Some R&D services are also purchased from outside the Group. Stora Enso employs close to 400 researchers and engineers in the research centres and about the same number of R&D staff at the mills. Research work at mills is focused largely on day-to-day problem solving, whereas at the corporate level R&D is conducted in accordance with long-term corporate strategies. In addition, the role of R&D is being expanded in the planning of new investment projects; R&D experts are expected to provide the corporation and its divisions with reliable information for the assessment of each project.

Although most of the company's R&D activities are focused on product and process development, many of these research topics have links to the sustainability of raw material supply. For instance improvements in processes or development of new products may result in reduction of fibre need, decreased pollution, more efficient use of energy or enhancement of recycling. Replacing wood fibres with other raw materials would diversify raw material supply and could improve the sustainability of the fibre supply by reducing the need for primary fibres.

The R&D work carried out at Stora Enso's research centres and mills does not include forestry research. However, Stora Enso does have expertise in forestry R&D in the countries it operates in.

Contents of forestry R&D programmes (including tree breeding and silviculture) are assessed separately for each country of operation and are based, among other things, on the existing scientific knowledge, magnitude of the company's forestry operations, forest conditions, forest ownership, and social, economic and natural environment.

Table 1. Wood consumption of Stora Enso by countries (1999 estimate)

Country/Region	Consumption, mill. m3	Domestic supply, mill. m3
Finland	20.6	15.6
Sweden	14.8	12.3
Central and South Europe	4.6	4.6
Canada	1.4	1.4

Forestry Research within Stora Enso in Northern and Central Europe and in North America

In Europe and North America forest legislation ensures stable wood supply through the use of sustainable forest management practices. In addition, national forestry research is well established and exchange of scientific information occurs freely. Forestry is mainly based on management of natural forests or on planted indigenous trees with relatively slow growth rates, which means that prospects for remarkable growth increases are low even under intensive forest management practices. In these areas most of the wood for corporate mills is purchased from other forest owners. Stora Enso therefore mainly seeks low-cost collaborative arrangements for forestry R&D needs and consequently only modest R&D resources are assigned for forestry issues in these regions. However, the collaborative R&D is rather extensive. For instance, during the last year Stora Enso's forest department in Finland co-financed more than 20 wood harvesting technology projects and was involved in a dozen research consortia with various institutions.

On the other hand, the corporation has very extensive industrial operations in this region. A continuous flow of raw material has to be guaranteed to each mill daily, weekly, annually and year after year. Wood for each individual mill is procured from various sources the Group's own forests, private forests or from publicly owned forests in different parts of the country. Part of the raw material may also be imported from various sources in neighbouring countries, or it may be grown in plantations in another country or even on another continent. Forest departments of the corporation must be able to purchase, harvest and transport the needed wood without unnecessary storage and cross-transportation. Legal, political, social, environmental and economic constraints of wood procurement must be solved in a sustainable way.

The wood procurement operations are costly and therefore have a direct effect on company profitability. Thus one of the main interests in forestry R&D is the development of cost-efficient harvesting, measurement, transport and storage systems to ensure optimal distribution of wood between various mills. These issues are largely about logistics and it is therefore impossible to draw a clear line between R&D and daily management. Information systems are playing an increasingly important role in decision-making and problem solving. For instance, in Finland the planning of forestry activities in the company's own forests is assisted by geographical information systems, where all data concerning these forests are stored. Information about the other forest resources is obtained from a remote sensing based system developed in co-operation with the Finnish Forest Research Institute. Forwarders, harvesters and trucks working for Stora Enso are equipped with computers and Geographical Positioning Systems (GPS), and the transportation optimisation system designed in-house is used to give daily work instructions to each vehicle, including necessary maps.

Stora Enso's forest departments in Finland and in Sweden, as well as Stora Enso Forest Consulting have staff for the co-ordination and execution of various R&D projects. However, most of the work is carried out through collaborative work with external agencies. The development and testing of working methods and harvesting machinery are carried out mainly through the joint research organisations of the forest industry. Information systems are developed and updated as a joint effort between company specialists and external agencies. National research institutes carry out basic silvicultural and productivity research. Issues of special interest to Stora Enso are, however, studied through collaborative arrangements. Tree improvement in Finland and Sweden is carried out in close co-operation with all major forest owner groups and national research institutes. In recent years more research, both in-house projects and joint assignments with external agencies, has been focused on issues that are closely linked with the environmental and social responsibility policy of the company. This research includes biodiversity and conservation studies, and surveys on the acceptability of products and operations.

Forestry Research in Plantation Projects

Stora Enso is presently involved in forest plantation projects in Brazil, Indonesia, Portugal and Thailand. Forestry R&D inputs in these projects are relatively much higher than in operations in the European-North American conifer region. There are several reasons for this. First of all, these projects are based on exotic plantation species, and their domestication is still in process. These species have relatively short breeding cycles and rotation periods, and therefore prospects for greater productivity (growth and yield) and quality improvements through genetic tree improvement (conventional tree breeding and biotechnology), clonal forestry, species/genotype-site matching and improved silviculture are very good. These improvements and gains can be achieved in relatively short time frames. Secondly, the land available for forest plantations comprises degraded, marginal soils where tailored fertilisation regimes are required for satisfactory growth. Thus a competitive advantage can be achieved by developing in-house R&D programmes with well-focused objectives. Another factor driving in-house R&D in these countries is that collaborative research between companies and institutions is often difficult to practise and slow due to long distances, poor communication facilities and administrational obstacles. In addition, within large countries like Brazil and Indonesia environmental conditions vary greatly and therefore local species and clone testing and site improvement research are absolutely necessary.

Stora Enso Celbi, a pulp company in Portugal, has been developing *Eucalyptus globulus* plantations since the mid-1960s. The company's land base is partly owned and partly leased. Presently Stora Enso Celbi's own eucalypt plantations cover over 45,000 ha, plantations with other species 4,000 ha and 8,000 ha are designated for conservation and other uses. Intensive tree breeding and genetic selection (between 1987 and 1995) have increased the productivity (tonnes pulp/ha/a) of the latest *E. globulus* plantations by up to 60%. Improved silvicultural practices will further increase the productivity. Modern molecular genetic technology (molecular markers) has been applied in the selection of parent material. In addition to growth, wood properties have been successfully used as breeding criteria, and this has contributed to the significant reduction of wood consumption per tonne of pulp.

In Bahia, Brazil (16.5 degrees South), Stora Enso is engaged in a joint venture company Veracel. The aim is to establish eucalypt plantations large enough to supply a pulp mill. By the end of 1998, the land ownership comprised 138,000 ha, of which 43,000 ha hectares were already planted with eucalypts, 24,000 ha were designated for planting and 21,000 ha were considered non-productive and designated for reafforestation with indigenous tree species. The land was formerly used for low-intensity agriculture, such as cattle grazing. About 50,000 ha of the property are still covered with rainforest and will be preserved and restored as a nature conservation area.

Almost all Veracel's plantations are grown from clonal cuttings of *Eucalyptus grandis x E. urophylla* hybrids. Existing plantations are producing on average 40 m^3/ha/a. Intensive tree improvement and other R&D activities are expected to improve the current growth rate by about 40% in plantations established from year 2006 onwards. Basic wood density and pulp yield per kg of wood will also be increased. The productivity of these plantations (tonnes of pulp/ha/a) should therefore increase by

50%. In addition, the genetic diversity of plantations will be increased. Such improvements will greatly add to the profitability of the project. In tree improvement modern molecular techniques are applied, but no genetic engineering is practised.

In West Kalimantan, Indonesia (at the Equator), Stora Enso is a shareholder in a joint venture engaged in reforesting large areas of grassland and bushland. These vegetation types are results of shifting cultivation or forest fires, and are considered to have only minor ecological or social importance. So far, over 20,000 ha have been planted mainly with *Acacia mangium* - *A. crassicarpa, A. aulacocarpa* and *E. pellita* are planted on a small scale. R&D has mainly been focused on nutritional issues and tree improvement. Unimproved acacia plantations in the region yield an average of 20-25 m^3/ha/a. This productivity could double with intensive tree improvement, careful site selection and appropriate silvicultural practices (fertilisation and weeding). Local species are being tested as alternative plantation species. The project has also extensive community development and environmental components. As one part of that work, seedlings of local timber and multipurpose species are produced and supplied to rural people within the company's operating area.

In Thailand, Stora Enso owns a small trial plantation area for developing and testing improved eucalypts (mainly *E. camaldulensis, E. tereticornis* and their hybrids) and for silvicultural research and development. This operation is close to Advance Agro's pulp and paper mills where Stora Enso is a minority shareholder. Advance Agro wood requirements are met in part from own plantations. The rest is produced in plantations established by local farmers under a special out-growing scheme. The opportunities for remarkable growth and yield improvements of plantations through the application of R&D findings are good.

The R&D activities in these projects are managed through individual R&D departments in each project/company. Technical and scientific support for these departments is provided through Stora Enso Pulp and Stora Enso Forest Consulting. However, as Stora Enso's operations become more global and more complex, there will be an increasing need to coordinate, monitor and support the R&D activities at the corporate level. Cooperation between various projects would enable them to achieve quick progress through the implementation of best research practices. Such arrangements would ensure that the possible substantial returns from R&D are achieved in all fast-growing plantation projects of the corporation. In some cases, these returns may exceed 30% through reduced raw material costs.

Future Trends

It has been estimated that consumption of paper products will grow globally by 2.8% per year to 2010. Thus consumption will total 420 million tonnes in 2010, up from present 300 million tonnes (Jaakko Pöyry 1999). This development will inevitably lead to increased use of raw material within the industry. At the same time demand of logs for sawn timber or plywood will also grow, but at the slower rate of about 0.8% (Jaakko Pöyry 1994). As Stora Enso aims to be the leading paper products company in the world, the sustainable supply of pulpwood and other raw materials for paper making will be a major objective for the Group.

Primary Wood

Recycling, new raw materials and development of processes are expected to slow down the increase in pulpwood demand. However, pulpwood demand is forecast to grow by some 1.5% each year until 2015 (Jaakko Pöyry 1994). Forest resources are increasing in Europe and North America. On the other hand there is strong competition for this wood and prices are high. It is also likely that a considerable part of the increment may not be available at the wood markets as forest owners may not be willing to sell it or large forest areas may be reserved for conservation or recreation. At the corporate level this calls for increasing co-ordination of the limited R&D resources, and focusing them on issues where major savings or improvements in wood supply can be made. Russia has huge forest resources, about one fifth of the world's forests and 50% of the world's softwood, and these resources are considered underutilised (Saastamoinen 1999). Accurate forest inventory, functional legislation and improved logistics are key issues in enhancing the utilisation of this resource. R&D on economical and environmentally sound harvesting and transportation is needed, too.

Fast-growing plantations in the tropics are emerging major raw material sources for the pulp and paper industry, and global forestry corporations are getting increasingly involved in such plantations. Presently industrial fast-growing plantations cover some 17 million hectares worldwide. This is about 13% of all forest plantations and less than 1% of the closed forest area in the world. Growth rates of well-managed plantations are high, and the uniform wood is an excellent raw material for certain paper and paperboard products. The consumption of tropical wood for pulping is expected to double within the next 15 years to about 120-140 million m^3 per year (Brown *et al*. 1997, Jaakko Pöyry 1994). If sufficient plantations are not developed, pressure on indigenous tropical forests will increase and be severe.

Stora Enso does not use wood from natural forests in the tropics, but wood from plantations established on open, degraded sites is accepted. The afforestation efforts on degraded, often marginal sites require specialised knowledge in genetic improvement of trees (conventional and modern genetic technologies), clonal forestry, silvicultural practices and plantation management. Biodiversity and environmental aspects must always be carefully considered. The maintenance of soil productivity over successive rotations is a fundamental requirement for sustainable forestry operations. Harvesting and transport systems for the extreme climates and sensitive soils must be developed, too. Such plantation operations also require efficient management information systems, which are based on computerised mapping tools and database systems, which can be adapted to varying education levels of local staff. Local people must be involved in and benefit from the activities, and their rights and cultures must be respected. Thus, development of large-scale plantations will require major R&D inputs.

More Efficient Use of Wood Raw Material

Development of new products, use of alternative raw materials and more efficient and environmentally friendly pulp and paper making processes will reduce average wood fibre needs per unit of output in the future. More efficient use of wood raw material may still be possible by further integration of mills, better allocation of various wood components between mills, reducing losses during harvesting and processing, and by using wood presently wasted.

Recycling

More efficient recycling will be one essential source of raw material. Presently about 80% of paper worldwide is made from primary fibre, but according to some estimates by 2010 nearly half of the world's paper will be made from recycled fibres (Brown *et al*. 1997, Jaakko Pöyry 1999). For instance European Union countries aim to increase the recovery rates by up to 75% for paper by the year 2005. Such high levels of recovery will generate huge volumes, and for proper utilisation sorting procedures must be developed. Presently, impurities of collected paper and inadequate collection systems cause severe problems in repulping, and the resulting pulp does not allow mills to produce high quality paper grades at a reasonable cost (Brooks 1999). Exports of recovered paper from Europe and North America to Asian paper producers may increase substantially in the near future (PPI Asia News, 1999).

New Raw Materials

New raw materials   new tree species, use of waste wood, non-wood fibres and/or other potential raw materials   will be a major field of research and development. Theoretically the worldwide availability of non-wood fibres (e.g. straw, grasses, hemp, linen, bamboo, bagasse, components of oil palm, etc.) could be 3–4 times higher than that of wood fibres. Furthermore, the properties of non-wood pulps may allow replacement of wood pulp in many board and paper grades. Genetic breeding of several plant species to meet this demand for non-wood fibres is likely to yield quick results due to their short rotations. In addition, advances in biotechnology may also play a key role in the utilisation of new raw material sources. Commercial applications of new raw materials will depend on feasible solving of necessary logistics arrangements as competitive operations may require bigger mills than present ones. According to recent estimates, the share of non-wood fibres as paper raw materials will remain at about 5% (Jaakko Pöyry 1999). Replacing renewable plant fibres with inorganic materials must be critically considered and special attention must be paid on the environmental effects. Matching the properties of the raw material with the proposed end-use is essential, regardless of the raw material source. This calls for an open, fresh, collaborative research approach to explore all options for the diversification of raw material sources.

Conclusion

In the foreseeable future wood fibre primary or recycled will remain the main raw material for the expanding paper and board industry. This will require responsible management of the world's forests. Information generated through research will be of critical importance in achieving this goal. Research resources should be carefully focused to support the sustainable management of existing forests and the establishment of new forests on marginal lands. Long-term performance and sustainability of the wood processing industry is closely linked to the research advances and the application of the results in practical forest management.

Current Timber Supply and Demand in Taiwan Compared to that in Major Asian Countries

by
Shi-Chou Chen
Department of Forestry,
Council of A Agriculture,
Taipeh, Taiwan

Abstract

With the ever-increasing concern for environmental protection, it has become necessary for governments, resource managers, and forest industry to implement a reasonable forest establishment and utilization policy to ensure that environmental goals are met. This "Eco-management" has strongly influenced the supply of forest products in Asia, where people experienced a very fast economic growth from 1992 to 1996. The forest area in Asia in 1995 was about 565 million ha. There was a net loss of 16.6 million ha. between 1990 and 1995 due to the conversion of land to non-forest uses, representing an annual decrease of 3.3 million ha. Annual decrease was slightly less than one half of that rate from 1980 to 1990. While the area of the Asian forest has been steadily decreasing, the FAO data indicate that the consumption of roundwood in this region increased by 6.6% between 1992 and 1996. At the same time, the production of roundwood increased 6.1%. Exports of industrial roundwood from Asia decreased dramatically in 1993, resulting in an average annual decrease of 9.2% from 1992 to 1996, while world exports maintained an average increase of 1%. The unit value of the exports from Asia was one third higher than the world average, while those from Myanmar, Cambodia and Singapore were even three times the world average. Although world sawnwood exports increased 17.7% from 1992 to 1996, the amount from Asia decreased steadily from 9.6% to 5.9% of the world total. The unit value of the goods exported from Asia was nearly 70% higher than the world average ($US 223 thousands). Sawnwood products from Indonesia were valued almost three times the world mean value. Timber production has, for many decades, played an important role in support of economic development in Taiwan. Recent forest policy has emphasized conservation, sustainable management and multiple uses of forest resources. Imported sawnwood, on a log basis, totaled 5.02 million m^3 . Recycling of wastepaper provides 3.1 million tons of the fiber needs of the paper industry. The promotion of wastepaper recycling has increased domestic recovery from 2.30 to 2.79 million tons from 1992 to 1997. The total use of wastepaper in 1997 was 4.1 million tons. Four major factors--- more efficient processing, diversifying raw material sources, increased recycling and expanding the use of residues have enabled the forest industry in Taiwan to reach her goals for value-added processed products.

Keywords: Timber supply, Demand in Taiwan

Current Forest Status in Asia and Taiwan

Approximately 565 million hectares of forest, or about 16 percent of the world's total is located in Asia where one half of the world population resides. Due to the extremely rapid social and economic changes in recent years, expanding population has resulted in the highest annual deforestation rate (1.1 percent) in the tropical countries of Asia.

The fast depletion of traditional timber species from the tropical forests has resulted in more plantation species to be marketed. Recognizing that plantation wood will become an increasingly important lignocellulosic resource in the future with the anticipated reduced production of logs from the remaining natural forests, more than 22 million hectares of tropical plantation, about three-quarters of the world's total, have been established. While greater efforts have been made to bring timber harvest within sustainable levels, forest conservation and biodiversity have also increased at the same time.

Asia and North America dominate the world forest products economy. Asia has been gradually recovering from the monetary crisis of 1997. With its history of fast growing, this most populated area certainly will expect a dramatic growth in the coming years. Wood consumption is no exception. To satisfy this growing demand, we must create and use regional forest resources with increased effort and efficiency.

With a total area of 35,570Km^2, Taiwan lies between latitudes of 21°42'25" – 25°56'21" North and longitudes of 119°18'03" – 124°34'09" East. Nearly 2.1 million hectares, or 58.5 % of the land, is covered by forest (Tsou 1997). This is 6.5% more than 20 years ago when the 2nd forest resource inventory was conducted. Mountainous topography forms a wide range of environments and supports a diverse flora and a rich fauna. The number of plant species is about the same as in Australia, which is 200 times greater in area. About 25 % of the 4021 documented vascular plant species (Lin 1999) are endemic. Taiwan is also known for its rugged terrain, with 75 percent of hilly land and half of the land above 1,000 meters. Overall, 200 peaks are above 3,000 meters. Six types of forest can thus be recognized on this small territory.

The steep topography in most areas of the island has contributed to the limitation of large scale exploitation of forest resources since the late eighties. Table 1 shows the decreasing annual cut of timber, while Table 2 indicates that 34.3 percent of the area of forest reserves in Taiwan is on land steeper than 35 degree. These areas contain nearly 40 percent of the 360 million m^3 total timber volume. With a net growth rate of 2.3 percent, the forest produces 8.5 million cubic meters of wood annually. According to the 3rd survey of forest resources and land utilization 72.2% of the total forest is natural forest, the other 422,600 hectares is 51% coniferous plantation and the rest is hardwoods and mixture of both. The total volume in plantations is about 47 million m^3 which implies a usable volume of 1.1 to 1.5 million m^3. Changes of forest growing stock in the past three decades are shown in Fig 1.

Timber Demand and Supply in Major Asian Countries

Asia, Europe and North America dominate world forest products production. They account for 80 percent of roundwood and sawnwood production and more than 90 percent of wood based panels and pulp and paper products. Asia's consumption of forest products is rapidly approaching that of North America and exceeds that of Europe in total demand. The growth in demand is projected to outstrip supply for almost all products, leading to rapid increases in imports.

To compensate for the expanding gap between demand and supply from natural forests, serious consideration has long been given to the adequate management of the plantation resources in Asia. Forest plantation establishment in Asia was about 67 million hectares in 1995, up from 33 million hectares in 1980 (FAO 1997). Most of these plantations were intended for the production of industrial roundwood and/or fuelwood, though many were established for environmental protection or carbon sequestration. Annual increase in plantation establishment reached 70 million hectares in 1998 (Lai 1998), almost equaled the total of the developing counties.

Figures from FAO indicated that the consumption of roundwood in Asia increased by 6.6 percent between 1992 and 1996. At the same time, the production of roundwood increased 6.1 percent (Ho 1997). Strong social and economic ties existing among the Asian countries create intensive trade of forest products. When one government decides to reduce forest harvesting, the decision impacts neighboring countries in the form of increased harvesting and export.

Table1. Annual timber harvest and consumption in Taiwan (Ho, 1997; Jan 1999).

Year	Area(ha)	Volume cut (m^3)	Volume(%)	Wood consumption(m^3)
1987	5,546	670,410	100.0	7,866,551
1988	5,208	426,483	63.6	7,816,847
1989	2,493	264,492	39.5	7,308,823
1990	1,917	203,213	30.3	6,917,574
1991	1,046	126,059	18.8	7,973,353
1992	1,036	118,323	17.6	8,367,903
1993	575	71,735	10.7	7,191,878
1994	439	56,128	8.4	6,625,296
1995	625	63,176	9.4	6,527,707
1996	500	56,374	8.4	5,691,196
1997	--	--	--	6,020,926
1998	--	--	--	4,963,074

Table 2. Forest reserves distribution by slope class (Taiwan Forest Bureau, 1995).

Slope class	Area %	Growing stock %	Growing stock m^3/ha
<5°	2.19	0.98	76
5-15°	8.68	5.45	107
15-25°	20.72	19.15	158

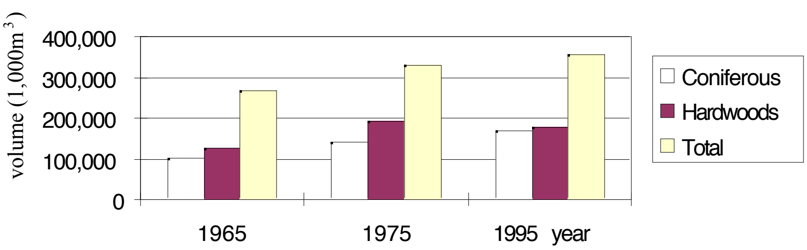
>45°	7.77	7.05	155
Total	100	100	171

Fig. 1 Changes of forest resources in Taiwan (Taiwan Forest Bureaus, 1995)



Among the ten countries contributing to 90 percent of roundwood production, Mainland China, India, Indonesia and Malaysia were the top four which produced three quarters out of the approximately 1,185 million m^3. Japan and Taiwan were the only two countries where roundwood consumption exceeded production. Japan, Korea and Mainland China were the top three importing countries and accounted for 90.4 percent of the total 72 million m^3 imported roundwood. Exports of industrial roundwood in Asia decreased dramatically in 1993, with an average annual decrease of 9.2 percent while world exports decreased an average of one percent from 1992 to 1996. Among the top ten exporting countries, exports from Malaysia in 1996 were only 40 percent those of 1992, as was also the case for Myanmar. Exports from China, decreased an average of one percent from 1992 to 1996. Among the top ten exporting countries, exports from Malaysia in 1996 were only 40 percent those of 1992, as was also the case for Myanmar. Exports from China, Indonesia, Viet Nam, North Korea and Laos have increased greatly on a percentage basis, however, the total amount of their exports accounted for only one third of the reduction from Malaysia.

As world sawnwood exports increased 17.7 percent from 1992 to 1996, the amount from Asia decreased steadily from 9.6 to 5.9 percent of the world total. Tropical hardwood production of veneer, plywood, particleboard, cement-bonded panels and medium density fiberboard, as well as furniture have registered very healthy growth in this region except in the recent monetary crisis beginning in 1997.

Forest Products Industry in Taiwan

The forest products industry in Taiwan encompasses sawnwood, furniture, plywood, composites as well as pulp and paper. The total market value of the industry in 1996 was 5,210 million US dollars which was 1.9 percent the figure of national GDP in that year and was 0.4 percent less than that of 1995 (Table 3).

Taiwan exported 3,345 million US dollars worth of forest products, contributing 2.9 percent to the grand total export, in the year 1996. This was significantly lower than the 3.5 percent in 1994 (Table 4). The reduction could be attributed to 1) the rocketing rise in price of imported logs, 2) the leaping increase in labor costs, and 3) the vigorous competition from the neighboring countries.

According to the employment statistics (Table 5), nearly 120 thousand workers were employed in the forest products industry in 1996, contributing 5 percent to the national manufacturing labor force. The percentage decreased from 5.2 and 5.1 percent in 1995 and 1994 respectively, indicating that the labor population in the industry was declining.

The sawnwood industry has been declining since the historical peak of economic development in 1976, due to the log export ban and the implementation of a policy favoring domestic wood processing exerted in the neighboring forest-rich countries. The import of sawnwood, in the meantime, significantly increased. The record in 1988 was 1,060,847m^3, with a value of about 320 million US dollars. The figures in 1997 increased to 1,512,075m_3 and 473 millions dollars. Fig.2 shows the total values of imported and exported forest products form 1984 to 1998 (Li *et al*. 1979).

Wood consumption in Taiwan reached its first peak in 1979 at 7.92 million m^3 then fluctuated between 6 and 8 million cubic meters (Fig 3). The second utilization summit occurred in 1992, when 8.36 million cubic meters were consumed, though the percentage used for lumber decreased from 88.2 to 78.4. The substantial reduction in consumption resulted from a dramatic decrease in plywood export. Only one sixth of the previous quantity was shipped out, which resulted in a great drop in log consumption. Wood imports have shifted from log to lumber and wood products in Taiwan. This trend has become more clear with the decreasing export of plywood. The recent surge of importing composite boards could mainly be attributed to the increasing demand of MDF in the furniture industry.

The continuous out-moving of the factories can be attributed to two major elements: lack of raw materials and higher labor cost. Forest products industry has experienced a serious decline since 1993. In contrast to the gradual recession of the plywood industry, the furniture industry had its first big boom during the past two decades in 1987□Fig 4□. Many plywood processors shifted their investment to furniture manufacturing. The recession of the latter industry has been much slower due to its higher requirement in manufacturing techniques. The historical success of Taiwan furniture industry could be attributed to the factors listed in Table 6. A competence survey of the furniture industry in Taiwan completed in 1995 showed that Taiwan was inferior to Malaysia, Indonesia, Mainland China and even Mexico only in labor costs and raw material supply while the world renowned furniture countries--Italy and Germany-- surpassed Taiwan in seven out of eight factors studied (Table 7).

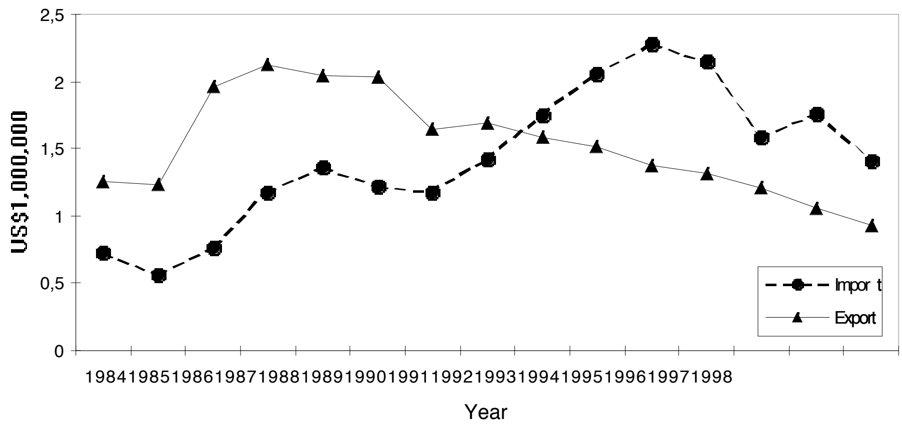
Table 3. Production value of Taiwan forest products (Million US $; Source: Lai, 1998).

Industry	**1994**	**1995**	**1996**
Lumber	198.5	150.4	159.4
Plywood	449.6	430.1	399.6
Furniture	912.1	753.6	710.4
Pulp and paper	3,806.4	4,505.4	3,931.6
Sub-total	5,366.6	5,839.6	5,200.9
GDP	241,077.5	251,808.5	271,464.8
Percent on GDP	2.2	2.3	1.9

Table 4. Export value of the forest products in Taiwan (Million US $; Source: Monthly report on salary and productivity statistics; Lai, 1998)

Industy	**1994**	**1995**	**1996**
Cork and Wood manufacture (excluding furniture)	728.5	696.5	664.8
Furniture parts	1,782.2	1,690.5	1,713.0
Pulp and paper	772.4	930.6	966.4
Sub-total	3,283.1	3,317.6	3,344.2
Total export	92,854.8	107,766.8	115,324.9
Percent on total export	3.5	3.1	2.9

Fig 2. Total value of imported and exported forest products in Taiwan (Source: Jen, 1999).



The pulp and paper industry in Taiwan accounted for 78 percent of the turnover value of the forest products industry in 1996. There has been downsizing within the sector due to increasingly stringent environmental regulations and difficulty in procuring skilled labor. Nearly thirty-five factories were closed or moved out of the State in the past ten years. There are currently 129 paper mills in the country, two of which are integrated pulp and paper mills. The products range from printing and writing, packaging, newsprint, household and joss paper to specialty products such as insoles and handmade Chinese calligraphy paper.

Table 5. Employment statistics in the forest products industries (Source: Monthly report on salary and productivity statistics; Lai, 1998.

Industries	1994	1995	1996
Wood and Bamboo products	33,900	31,102	29,165
Furniture	28,192	25,118	25,671

Table 6. Analysis on the factors contributing to the previous success of Taiwan furniture industry (Source : Investigation made by Information Division, Chemical Engineering Dept, Industrial Technology Research Institute; Tsou, 1997). The larger the figures the higher significance the factor exerted.

Factors	Furniture industry	Wooden furniture
Mill owner's diligence and creativity	1.63	1.65
Skillful technician	1.43	1.55
Raw material supply	1.39	1.57
Labor cost	1.32	1.33
Design and development capability	1.32	1.37
Potentiality in new techniques	1.30	1.28
Market accessing	1.23	1.23
Cooperation within the industries	0.69	0.72
Policy assistance	0.68	0.47
Technical assistance from abroad	0.25	0.35

Table 7. Competence analysis on the furniture industries of Taiwan with several other States (Source: Investigation made by Information Division, Chemical Engineering Dept, Industry Technology Research Institute; Tsou, 1997)

Country / Factor of Competition	Italy	Germany	Mexico	China	Indonesia	Malaysia
Labor cost	0.55	0.57	-0.90	-1.58	-1.62	-1.28
Effectiveness of the facility	-1.00	-1.07	0.37	0.76	0.79	0.61
Skillfulness of workers	-0.50	-0.33	0.60	1.16	1.29	0.92
Mill scale	-0.79	-0.67	0.16	0.57	0.48	0.27
Capability in designing and development	-1.19	-0.39	0.39	1.23	1.15	1.05
Supply of raw materials	-1.05	-1.11	-1.00	-0.50	-1.29	-1.18
Products quality	-1.15	-1.05	0.70	1.08	0.96	0.70
Marketing	-1.10	-1.00	-0.85	0.00	0.00	-0.12

Note 1. Negative figures indicate the inferiority in Taiwan's competence, zero implies equal capability.
Note 2. The smaller the figure the greater the discrepancy between Taiwan and the denoted country.

Most of the mills are of small to medium size compared to those in North America, Scandinavia and Japan. The production of the 13 largest companies (with annual business volume exceeding US $ 50 millions) accounts for 60% of the total production which is 4.50 million tons, ranking the 13th in the world. Increase in production fluctuated from -1.8 to 7.5 percents during the past five years, with an average increase of 2.6 percent per year. Fig.7 shows production and per capita GNP and paper consumption in the past decade.

The raw materials used for pulp production are wood chips and wastepaper exclusively. Bagasse and bamboo have been abandoned because of environment and economic considerations. Wastepaper contributes about 74 percent of total raw materials required (Taiwan Paper Industry Association, 1998). More than 4.1 million tons of wastepaper was consumed in 1997 with 2.8 million tons domestically collected and 1.3 million tons imported .The rest 26 percent materials came mostly from exotic pulps.

Timber Supply Strategy in Taiwan

The Taiwan forest industry has been heavily relying upon imported timber (Table 8). This dependence has been strained by exporting countries trying to promote their own manufacturing development. In order to support a prosperous forest industry, Taiwan needs not only to diversify its timber purchasing but also to maintain its own sustainable supply.

It is obvious that local timber production in Taiwan has never met consumption needs and large-scale import of wood has been increasing to meet domestic requirements. It is estimated that the annual timber consumption per person in Taiwan will reach 0.265m^3 in the year 2020 (Lin, 1999). The total timber required for Taiwan will be 6.6 million m^3 assuming population growth to 24,928 thousand in 2020.

Timber harvest has been the major source of government revenue since the late forties. Prominent forestry experts were consulted in 1957 and the main objective of Taiwan forest to perpetually produce renewable resource on a sustainable basis was established. In recognizing the importance of sound living environment and preserving natural resources, people in Taiwan have strongly requested a new guideline for forest management. " Program for Reform of Forest Management in Taiwan” was promulgated in 1976. The prospects for timber production have been changing as a result of strong calls for more balanced environment after long term exploitation. However, the meaning of "sustainability" has changed through time. To enhance conservation of forest resources in Taiwan, the annual allowable cut from natural forest has been lowered from 1.5 million m^3 to 500 thousands m^3 since 1987. At the same time, multiple use of Taiwan forests has been practiced through establishing conservation and recreation areas and enhancing watershed and wildlife management. Since 1987, 640 thousand hectares of plantations in the national forests have been established.

Fig 5. Paper and board consumption, per capita GNP in the past decade.

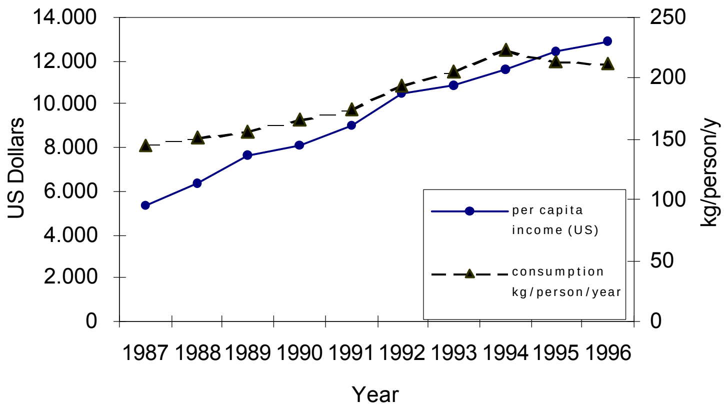

Table 8. Local timber supply and consumption in the past 20 years

Year	Local supply 1,000m^3	Total consumption 1000m^3	Percent of local supply
1975	1,027	5,323	19.3
1980	680	6,734	10.1
1985	574	6,105	9.4
1990	145	6,918	2.1
1995	40	6,528	0.6

We have relied not only on plantations to adequately increase the domestic supply of timber. Silvicultural systems developed abroad were also implemented in the late seventies. Through collaboration with a pulp and paper corporation owned by overseas Chinese in Parawan, Indonesia, Chung Hwa Pulp Cooperation and YFY paper company have successfully planted 110 thousand hectares of pulpwood. In Viet Nam, 40 thousand hectares of *Eucalyptus* for pulpwood were planted in 1993 with an investment of Taiwan capital. Another 500 thousand hectares is projected to be planted in the northern or central part of Viet Nam.

With the recognition of a resource crisis, sustained yield management has become one of the three significant guiding principles of Taiwan forestry. The long established “Timber Production Center in Taiwan" project was seriously promoted by the Council of Agriculture in 1995. Three guidelines were postulated in the plan (Lin, 1996):

1) At least two plantation centers, each of 10 thousands hectares, must be selected from the eight forest management districts on the island, with a goal of 20 centers in total.
2) The least average annual growth per hectare in each center is set to be 5 cubic meters.
3) After the establishment, 200-300 hectares could be harvested annually in each center. A total of 6,000 thousand hectares forest land could be felled and reforested, resulting in an annual timber production of 2 million m^3 and a total of 400 thousand hectares plantation forest within 20 years.

Many forestry programs have been lagging sharply since 1987 as a result of a significant financial crisis in the Taiwan Forest Bureau, which played a key role in forest management in the past. The deficit came partially from the sixfold increase of average wage costs and partially from lack of adaption to the quick change of forest management direction. As of 1996, nearly 80 thousand hectares have been planted in the 25 established plantation centers, 75 thousand hectares were found to be too rugged and inaccessible to be reforested. Some 82 thousands programmed hectares were suspended by the ban of natural forest cutting.

Conclusions

The area of the Asian forest has been steadily decreasing, while consumption of roundwood has increased by 6.6 percent between 1992 and 1996. Exports of industrial roundwood from Asia decreased at an average annual rate of 9.2 percent from 1992 to 1996 while world exports increased an average of one percent. Management of plantation forests has long gained attention throughout Asian countries due to the large-scale depletion of forest resources. Taiwan has been under tremendous pressure from environmental groups to reduce the extraction of timber from natural forests. Actions to maximize the utilization of plantation forests in Taiwan have been emphasized. The most important change in Taiwan forestry is that timber production is becoming less important. Forests have become a source of recreation, soil and water and biodiversity conservation and wildlife habitat.

With the ever growing enjoyment and appreciation of wood products, including paper and board, coupled with the restriction of log and lumber exports, the assurance of timber supply in Taiwan in the future is a very significant challenge that government and industry people will be facing. It is suggested that the non-cutting policy in natural forests should be reviewed as soon as possible and revised every five years by government and wood industries from the standpoints of international wood supply and the global village concept.

Abstract

The timber market of the Republic of Korea can be characterized as being 1) import-oriented supply and 2) domestic-oriented demand. Recently, import patterns have also been changing as follows: 3) from hardwood to softwood, 4) from high to low quality, and 5) from roundwood to wood products. These 5 characteristics indicate that the Republic of Korea is a typical country importing wood-based raw materials, and today faces difficulties in securing a sustainable supply of roundwood through both domestic production and imports. As a method meeting the needs of environmental protection while securing a stable supply of wood based materials, the establishment of overseas plantations of fast-growing tree species has been decided upon by Korean companies and government. It is primarily aimed at ensuring a sustainable supply of wood materials. The Korean Government also aims to avoid disadvantages as a log consumer country and to gain a good reputation as a country that contributes to preserve the global environment. In establishing plantations, there are basic principles proposed by the Government. Fast-growing tree species would be favoured and countries which are geographically close would be preferred to other countries farther afield. In any case, the political and economic safety of investments should be secured. To ensure the security of investment, a series of security pacts with partner countries have been concluded. For investment safety from the economic viewpoint, reports detailing the investment environments of various countries such as Malaysia, Vietnam, Myanmar, New Zealand, Australia, Solomon, PNG, Chile and China have been issued. The Government also finances corporations or personal investors who plan to establish plantations overseas. 90-100% of the cost of establishing plantations is financed with a low interest rate of 3%. The financing period is 10-20 years for fast-growing tree species and 28 years for tree species of long rotation.

Keywords: Timber market of Republic of Korea, Environment protection, Export restriction, Sustainable supply of roundwood, Establishment of fast-growing plantations, Support policies.

Introduction

The Republic of Korea has relatively poor forest resources compared with other Asian countries. As of 1997, in the Republic of Korea about 65 % of the total land area is covered with forest land, of which about 80% was newly afforested during the last 30 years and today represents a relatively young stage of forest. The average timber growing stock per ha is consequently very low at about 56 cubic meter as of 1998. This young forest is not expected to supply sufficient timber products to meet the national demand.

The Republic of Korea is inevitably a consumer of wood-based materials. At present about 90% of all roundwood used in the Republic of Korea is being imported. In recent years, the Republic of Korea has, however, experienced increasing difficulties in importing the roundwood, due to increases in log export restrictions in producer countries and world-wide concerns about environmental protection.

The objective of this paper is to review the import trends of roundwood and to examine various strategies for ensuring a long-term sustainable supply to the Republic of Korea.

Demand and Supply of Roundwood in Republic of Korea

Roundwood Demand

The total roundwood demand in the Republic of Korea increased dramatically in the early 1970s, peaked in 1978 and decreased rapidly towards 1982. Since then the total demand for roundwood has tended to increase slightly, showing fairly similar trends to the domestic demand, as can be seen in Fig 1a.

The roundwood demand for export had increased until 1977, exceeding the demand for domestic use. In the mid 1970s, about 60-70% of the total roundwood consumption occurred in wood-based industries producing wood products, especially plywood for export. After reaching the maximum in 1977, the demand for roundwood in the export sector began to decrease and dropped to 300 thousand cubic meters in 1990. Since then the demand of roundwood for export has remained fairly constant at low levels.

In contrast, the demand for roundwood for domestic use has been steadily increasing. It had drastically increased during 1976-1979, reaching the maximum in 1979, and dropped again towards 1981 during the oil shock period in 1979-1981. Since 1981, the domestic demand of roundwood has tended on the whole to increase slightly, determining the trend of total demand of roundwood, though there were slight fluctuations in this trend. The demand for roundwood for domestic use in 1997 has increased about 104% of its value in 1977, while the demand for export in 1997 has decreased about 94% over the same period.

The economic crisis which began in 1997 caused a dramatic decline in domestic and total demand of roundwood in 1998, while the demand of roundwood in export-oriented industries increased a little, perhaps due to the devaluation of the Korean currency and the resulting price competitiveness of wood products made in Korea.

Demand for Domestic Use

The demand of roundwood for domestic use shows a generally increasing trend, being very sensitive to the demand for sawnwood, which is mainly used by the domestic construction industry (Fig 1b). The yearly fluctuation of the domestic demand is very similar to the demand for sawnwood. The roundwood demand for producing pit props, plywood and pulp has stayed almost constant, not influencing the trend of the domestic demand. Here we can see that the roundwood market in the Republic of Korea is heavily dependent on the domestic construction industry. It appears that the construction industry would determine the demand for sawnwood which would again determine the domestic and total demand of roundwood.

Demand for Export Use

The tendency of the demand of roundwood for export use had followed a pattern similar to the demand for producing plywood to be re-exported to the middle of 1980s and since then has shown a rather similar pattern to the demand for producing sawnwood which has remained almost unchanged, though perhaps decreasing slightly (Fig 1c). Up to the mid 1980s, most of the roundwood in the export sector had been used for producing plywood. During the 1970s, the wood based market in the Republic of Korea was very dependent on the plywood processing industry, in which roundwood imported from southeast Asia was processed to plywood to be re-exported (FRI 1997b).

The demand for roundwood in the export-oriented plywood industry declined markedly after 1977, causing the decreasing tendency of roundwood demand in the export sector. It had been combined with the non-export policy of roundwood in producer countries since the late 1970s. Various policies prohibiting log exports in producer countries caused an increase in the price of roundwood on the international log market and accompanied difficulties in the availability of overseas roundwood to the Republic of Korea. In the long run, the competitive power of plywood made by Republic of Korea had been weakened in the international plywood market, the plywood industry in Korea had been on the decline, and the demand for roundwood for plywood also declined.

(c)

Supply of Roundwood

Fig. 2a represents the trend of roundwood supply in the Republic of Korea since the 1970s. As a whole, import of roundwood shows an increasing trend, fluctuating between 6,000 and 8,000 thousand cubic meters. In contrast, the domestic supply of roundwood remains almost constant at round 1,000 thousand cubic meters. The increasing rate of roundwood imported from 1980 to 1997 amounts to around 35%, while roundwood supplied domestically increased only 5% over the same period. Most of the roundwood demand in the Republic of Korea has been met by imported roundwood and only about 12-15% has been supplied domestically.

Domestic Supply of Roundwood

The domestic supply of roundwood shows a similar trend to the pit prop use until 1990 (Fig 2b), indicating that most of roundwood supplied domestically had been used for pit props over the period. Production of roundwood showed a minor increase due to increasing demand of pit props until 1987. Since then consumption of domestic roundwood for pit props had drastically decreased and today marks only about 100 thousand cubic meters. In contrast, use of domestic roundwood for sawnwood has increased since 1989, offsetting the decreasing use for pit props. Consumption of domestic roundwood for pulp had increased slightly from about 200 to 400 thousand cubic meters from 1974 to 1998. The domestic supply of roundwood as a whole shows little decrease

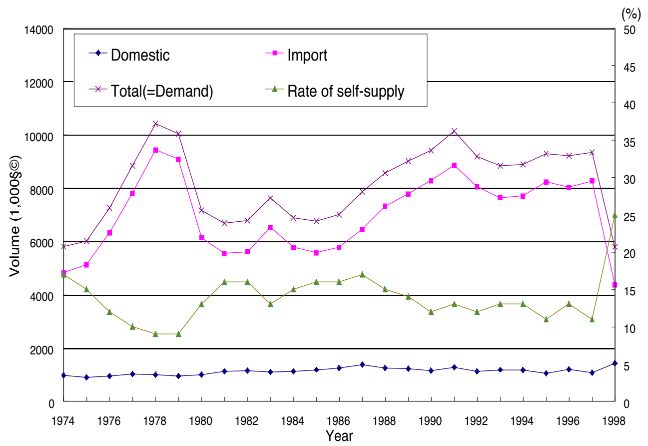
Roundwood Supply by Import

Fig. 2c shows the roundwood supply from overseas and it's uses. The import of roundwood had followed a similar trend to the export use in 1970s and the domestic use during 1980-1990s. Up to 1978, most imported roundwood had been used for producing plywood to be re-exported. But the use of imported roundwood in the export sector had decreased markedly from about 5,000 to 500 thousand cubic meters from 1978 to 1985, and remained at 500-600 thousand cubic meters until 1989 and since then at 300 thousand cubic meters. In contrast, the domestic use of imported roundwood has increased steadily since 1981. The volume of domestically imported roundwood use in 1997 increased about 175% of its value in 1981, while the volume for export use decreased about 87 % over the same period. Today, most imported roundwood is used for domestic wood based industry, especially for producing sawnwood - mainly used for construction purposes.

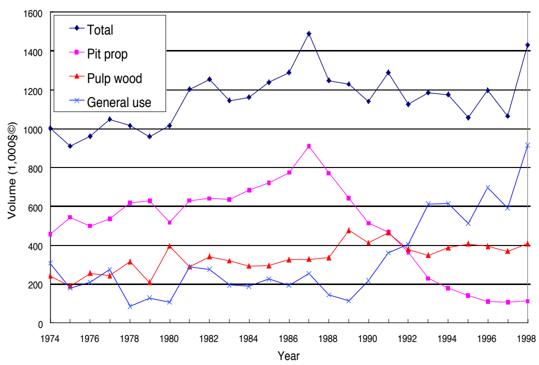
Roundwood Import by Region

Importing hardwood from South East Asian countries such as the Philippines, Malaysia, and Indonesia has decreased steadily, while importing softwood from other nations such as New Zealand, Chile, U.S.A., and Russia has increased. Since 1989 the imported log volume from temperate or boreal regions has exceeded that from South East Asian (Fig 3a).

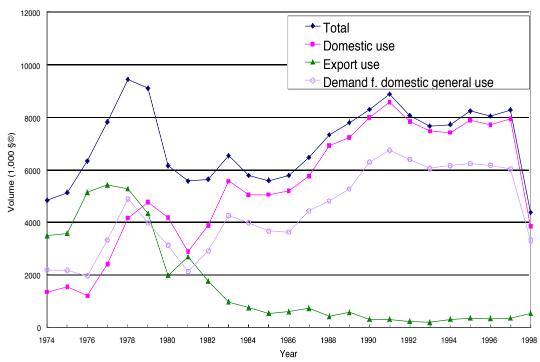
Fig 2. Total supply of roundwood (a), domestic supply (b) and import supply (c) (Source: Forest Administration 1999)



(a)



(b)



(c)

Tropical hardwood had been imported mainly from Indonesia, Malaysia and the Philippines up to the mid 1980s (Fig 3b). However, imports of roundwood from Indonesia had drastically decreased from 1978 to 1982 and there have been no roundwood imports from Indonesia since 1985. A small quantity of roundwood were imported from the Philippines up to 1986, since then there has also been no more roundwood trade with the Philippines. Yearly around 2,000 - 3,000 thousand cubic meters of roundwood had been imported from Malaysia from 1977 to 1992, representing the highest ranking in volume of roundwood imported from tropical lands. But it dropped to about 1,000 thousand cubic meters in 1993 and has continued to decrease so that today only 300 thousand cubic meters of roundwood are imported from Malaysia. Over the past 20 years, import of roundwood from PNG including the Solomons has increased to a small extent and was composed of about 60% of roundwood imported from tropical forest in 1997.

The partner countries for importing softwood have changed from USA to New Zealand, Chile and Russia (Fig 3c). Up until the early 1990s, most softwood logs had been imported from the USA. Import of softwood logs from the USA had increased to 1989 and then began to decrease, drastically while import from New Zealand, Chile and Russia went up since the early 1990s. Today most softwood logs are imported mainly from New Zealand (46%) and Chile (24%). From USA and Russia, about 11% of softwood logs are imported respectively, showing a decreasing trend from the USA and an increasing trend from Russia.

Roundwood Import by Tree Species

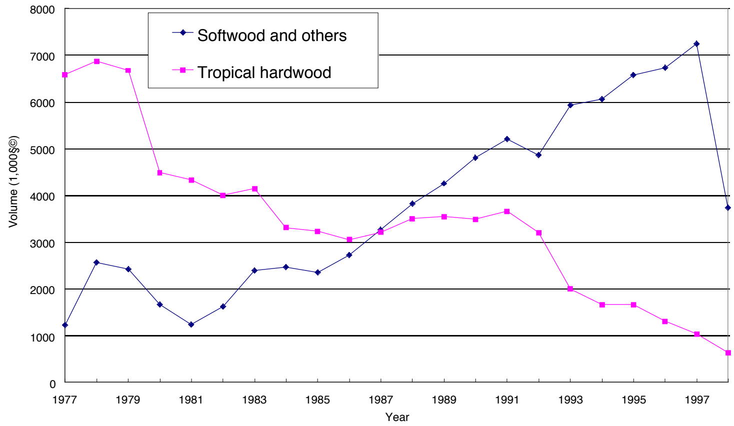
The main tree species of imported roundwood changed from tropical hardwood to temperate and boreal softwood. The ratio of tropical hardwood in imported logs has declined sharply, whereas the volume of softwood has increased. Of the roundwood volume imported in 1980, 73% was tropical hardwood and 27% temperate softwood. But it changed in 1997, so that tropical hardwood amounted to only 16% and temperate and boreal softwood occupied about 84% of imported roundwood (Fig 3a). Correspondingly, there have also been changes in tree species and quality, changing from high to low quality. In the case of hardwoods, Lauan of high quality has been substituted with Keruing and finally MLH (Mixed Light Hardwoods) of relatively low quality. In softwoods, Douglas fir of high quality, mainly imported from the USA, has been substituted with low quality radiata pine from New Zealand and spruce from Russia (Table 1).

Flow of Roundwood in Republic of Korea in 1997

Fig. 4 represents the marketing flow of roundwood in the Republic of Korea in 1997. Roundwoods supplied domestically were all consumed domestically. For the year 1997, roundwoods produced domestically totalled 1,062 thousand cubic meters of which 55% were used for sawnwood and other wood products, 35% for pulpwood, and 10% for pit props.

Of the imported roundwoods, amounting to 9,328 thousand cubic meters, about 96% were consumed domestically and only 4% were used for sawn- and plywood to be re-exported. All roundwoods demanded for export were imported. About 68% of the domestic consumption of imported roundwoods occurred for sawnwood and other wood products, 20% for plywood, and 12% for pulp respectively. All the roundwood required for pit props was domestically supplied, while all roundwood required for plywood was imported. Of the roundwood for producing pulp used domestically, 71% was imported and 29% was supplied domestically. About 90% of the roundwood used for producing sawnwood and other wood products consumed domestically was imported and only 10% was supplied domestically. As a whole it can be seen that producing sawnwood and other wood products for domestic use led the roundwoods market in Republic of Korea.

Fig 3. Roundwood import of soft- and hardwood(a), roundwood import of hardwood (b), roundwood import of softwood (c) (Source: Forest Administration 1999)



(a)

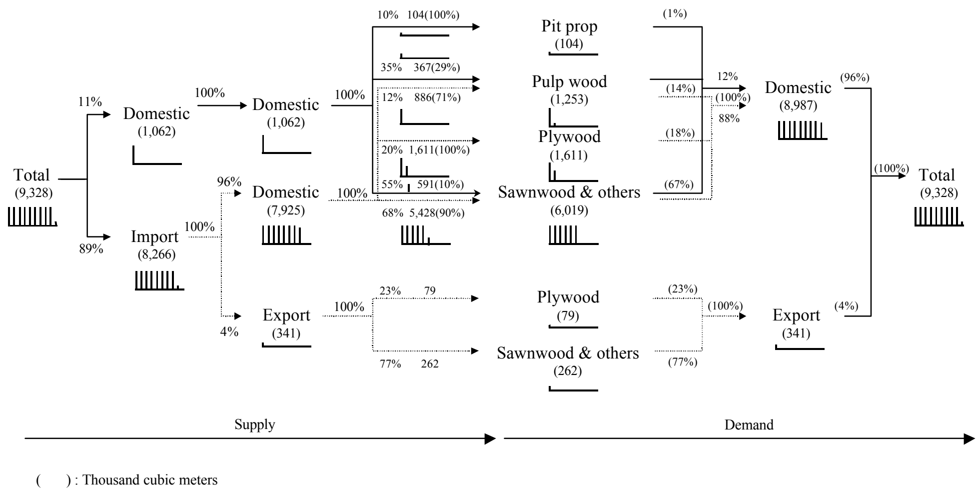
Of the imported roundwoods, amounting to 9,328 thousand cubic meters, about 96% were consumed domestically and only 4% were used for sawn- and plywood to be re-exported. All roundwoods demanded for export were imported. About 68% of the domestic consumption of imported roundwoods occurred for sawnwood and other wood products, 20% for plywood, and 12% for pulp respectively. All the roundwood required for pit props was domestically supplied, while all roundwood required for plywood was imported. Of the roundwood for producing pulp used domestically, 71% was imported and 29% was supplied domestically. About 90% of the roundwood used for producing sawnwood and other wood products consumed domestically was imported and only 10% was supplied domestically. As a whole it can be seen that producing sawnwood and other wood products for domestic use led the roundwoods market in Republic of Korea.

Fig. 4: Market flow of roundwood in Republic of Korea in 1997(unit: 1,000 cubic meter)



Import of Wood Products

In Fig. 5, an obvious shift in imports from roundwoods towards high-priced wood products can be clearly seen. Starting from 1991, the increasing trend of roundwood import turned to a slightly decreasing trend. In contrast, the import of wood products such as ply- and sawnwood tended to increase steadily since the mid 1980s and its volume exceeded the volume of roundwood imported since 1988. While imported log volumes by 1997 were almost the same as those of 1990, the imported wood products increased by about 39% over 1990-1997. These increasing imports of wood products were accompanied by log export prohibition in producer countries (FRI 1997b).

Characteristics of the roundwood market in Korea

The timber market of the Republic of Korea can be characterized by 1) import-oriented supply and 2) domestic-oriented demand. Recently, the import pattern has changed as follows: 3) from hardwood to softwood, 4) from high to low quality, and 5) from roundwood to wood products. These 5 characteristics indicate that the Republic of Korea is a country importing wood based raw materials and today faces difficulties in sustaining a supply of roundwood through both domestic production and import. As one of the consumer countries of wood materials, the Republic of Korea would not like to have a reputation as being a country causing the deforestation of tropical forests with associated harmful effects on the global environment. It would thus be very important for the Republic of Korea to stabilize the supply of wood based materials, especially roundwood, without any destruction of both domestic and foreign forests

Strategies for Sustainable Timber Supply in Industry

The view that exports of roundwood are being curbed by producer countries motivates wood-based companies in Republic of Korea to invest directly in tropical and sub-tropical countries. Plantations of fast-growing hardwood species are being established by several wood-based companies to meet the anticipated increases in the demand for wood-based materials, as a long-term means of coping with a shortage of raw material (KFS 1999). Up to date, about 270 thousand forest concessions from 7 countries were acquired and a total plantation area of about 32 thousand ha has been established with such fast-growing species as *Acacia mangium* (Vietnam), *Eucalyptus* (Australia, Solomon), and radiata pine (New Zealand) by several companies (Table 2).

Table 2: Establishment of plantation in tropical and sub tropical countries by several companies (KFS 1999). Unit: ha

Year	Australia	New Zealand	Solomon	Vietnam	Indonesia	China	Sum
1993	508	-	-	-	-	-	508
1994	1,000	-	-	498	-	-	1,498
1995	854	-	413	1,124	-	-	2,391
1996	2,248	504	1,796	956	1,150	-	6,654
1997	2,035	1,515	2,016	1,000	510	-	7,076
1998	1,400	1,300	2,010	1,786	1,100	150	7,746
1999	2,013	1,000	1,513	-	577	1,250	6,353
Sum	10,058	4,319	7,748	5,364	3,337	1,400	32,226

In the economic view, roundwood production from plantations in tropical and subtropical countries is considered more profitable in relation to cost, price and yield. For example, the planting cost of radiata pine in a plantation would be only one third of the planting cost for *Pinus koraiensis* in the Republic of Korea while 5 times the volume could be yielded with the same rotation period of 30 years (KFS 1999). The price of roundwood from plantations established by Korean companies in tropical and subtropical countries would be 40-60% of the price of roundwood imported (KFS 1999).

Various projects to promote the establishment of plantations have been carried out by the Korean government. According to the Korea Forest Service (KFS, 1999), about 1 million ha of plantation is planned to be established by 2050, and about 50% of the roundwood demand in the Republic of Korea will be met by wood materials produced in the plantations (Table 3).

Support system

In establishing plantations, there are basic principles proposed by the government. Fast-growing tree species would be favoured and countries located geographically nearby would be preferred to more distant countries. In any case, political safety of investments should be secured, therefore the political stability of the partner countries plays an important role in the decision-making process prior to investment. To ensure the security of investments, a series of security pacts with partner countries have been concluded. Forestry pacts with Indonesia, Russia, New Zealand, Australia, China, Vietnam and Myanmar have already been concluded, and forestry pacts with other countries will be set in process (KFS, 1999).

Investment security in the economic view is also a very important principle in decision-making. It is important for successful investments in foreign countries to have accurate information on partner countries. False information or lack of good information would hinder the success of investments. Thus political, economic, social and cultural information on partner countries has been compiled by the Forestry Research Institute and distributed to investor companies. In recent years, reports on the investment environment of several countries such as Malaysia, Vietnam, Myanmar, New Zealand, Australia, Solomon, PNG, Chile and China have been issued (Forest Administration, 1996; FRI, 1994,1996,1997a,1998a,1998b). In these reports, the political and economic situations, information on forest resources and forestry, infrastructure, laws and institutions related to forest, and incentives for investment were detailed.

Various projects to promote the establishment of plantations have been carried out by the Korean government. According to the Korea Forest Service (KFS, 1999), about 1 million ha of plantation is planned to be established by 2050, and about 50% of the roundwood demand in the Republic of Korea will be met by wood materials produced in the plantations (Table 3).

To ensure the security of investments, a series of security pacts with partner countries have been concluded. Forestry pacts with Indonesia, Russia, New Zealand, Australia, China, Vietnam and Myanmar have already been concluded, and forestry pacts with other countries will be set in process (KFS, 1999).

Investment security in the economic view is also a very important principle in decision-making. It is important for successful investments in foreign countries to have accurate information on partner countries. False information or lack of good information would hinder the success of investments. Thus political, economic, social and cultural information on partner countries has been compiled by the Forestry Research Institute and distributed to investor companies. In recent years, reports on the investment environment of several countries such as Malaysia, Vietnam, Myanmar, New Zealand, Australia, Solomon, PNG, Chile and China have been issued (Forest Administration, 1996; FRI, 1994,1996,1997a,1998a,1998b). In these reports, the political and economic situations, information on forest resources and forestry, infrastructure, laws and institutions related to forest, and incentives for investment were detailed.

The Government also finances companies or personal investors who plan to establish plantations overseas. 90-100% of the cost of establishing plantations is financed with a low interest rate of 3%. The financing period is 10-20 years for fast-growing tree species and 28 years for tree species with a long rotation.

Conclusion

It is not anticipated that the domestic supply of roundwood in the Republic of Korea will improve sufficiently to meet the roundwood needs in the near future. The current demand for roundwood will inevitably rely upon imports for some time. In view of environmental concerns, importing wood materials in the form of roundwood will be more difficult in any case. Accordingly, in the long run, the Korean government needs to make efforts to improve its own forest resources and to diversify its log imports from overseas. As a method meeting the needs of environmental protection while stabilising a supply of wood-based materials, the establishment of plantations of fast-growing tree species overseas has been decided upon by Korean companies and government.

Criteria and Indicators For Sustainable Forest Management at The U.S.A. National and Regional Level

by
Richard W. Haynes, James A. Stevens and R. James Barbour
Research Forestres, Pacific Northwest Research Station,
Portland, Oregon, USA

Abstract

At a variety of scales, and in a number of arenas, efforts are underway to define "sustainable forest management" and to measure it (or progress toward it) using criteria and indicators. The purpose of this paper is to use readily available information to describe several broad scale measures that can be used both to describe the state of ecological and social conditions and in a discussion of joint consequences of various management actions. Here we develop an index of timberland integrity that is a combination of six measures of various indicators of forest condition and status. We used growing stock value as a measure of the various economic and social criteria, i.e., a broad proxy for timberland wealth. These broad-scale composite measures helped us to look at the notion of tradeoffs, compatible production, and the integrative nature of ecosystems. Our experience suggests that scientists can contribute to both developing individual broad scale measures and composite indexes and the process for aggregation to higher spatial scales and thus make the discussion about sustainable forest management more productive.

Keywords: Sustainable forest management, Criteria and indicators

Introduction

At a variety of scales, and in a number of arenas, efforts are underway to define "sustainable forest management" and to measure it (or progress toward it) using criteria and indicators. Efforts like the Montreal Process share: a desire to provide a factual basis for increasingly contentious policy debates; recognition that some information is more important in the sense of being policy relevant; and knowledge of the fact that success in condensing a large quantity of complex information will "add-value" and help focus policy debates on critical issues. In the United States (which is attempting to use the Montreal Process) we are just seeing "first approximation"[1] types of reports that focus on developing measures of the criteria and indicators.

Measurement of criteria and indicators for sustainable forest management poses two challenges for the science community. First there is the empirical challenge that focuses on the process of developing broad scale measures of ecosystem condition from highly disparate data often at different spatial scales. The second challenge is to develop judgments relative to sustainable forest management based on broad scale measures developed from various combinations of indicator variables. The purpose of this paper is to use readily available information to describe several broad scale measures that can be used both to describe the state of ecological and social conditions and in a discussion of joint consequences of various management actions.

This exercise is entered into acknowledging that the Santiago Declaration stated that "(t)he C & I should be used as a complete set and when applied as such, provides an implicit definition of the sustainable management of forest ecosystems. No single Indicator implies sustainability when isolated and should be considered within the context of the other C & I." At the same time the Declaration recognized that "(t)he C & I contain some Indicators that may not be quantifiable at this time for any or all of the signatory countries." In fact 79% of the indicators in Criteria 1-6 are described as data availability being a problem. We feel that to meet our objective of focusing the discussion on broad scale measures, it is not feasible or necessary to wait for agreed upon measures of all criteria.

Background

[1]See the report for the state of Oregon (Oregon's Forests at the Millennium. First Approximation Report 1999 http://www.odf.state.or.us/FAR/FARdefault.html).

In this paper, we focus on developing two broad scale measures that allow us to link together the concepts of sustainable interactions between humans and ecosystems to maintain ecosystem integrity. We have been influenced by work done for large-scale ecoregion assessments that attempted to develop explicit measures for broad scale goals of ecological integrity and some socioeconomic counterparts such as resiliency (Quigley *et al*. 1996, Haynes *et al*. 1996). In this context, ecological integrity refers to the presence and functioning of ecological components and processes. The social and economic counterpart to ecological integrity is resiliency, which in the context of ecosystem sustainability reflects the abilities of people to maintain well-being through personal and community transitions. In practice, both of these are composite measures of ecosystem condition and function that are derived from more specific ratings for individual processes or functions. Often these individual ratings for individual indicators are based on proxies that represent relative conditions. We acknowledge that much of this effort will involve value judgments.

Development of Two Broad Scale Measures

Our two broad scale measures are timberland integrity and timberland wealth. Both of these are narrower measures than those defined above but our purpose is to assess the prospects for forest management rather than the broader concerns about complete ecosystems. We will develop these measures for both the United States and for four major regions within the United States. Our discussion includes the basis for and the construction of the two measures, hierarchical concerns, and policy inferences. Much of the data comes from the periodic Timber Assessments required in the United States as part of the Resources Planning Act (Haynes *et al*. 1995). On the biophysical side we develop what we call an index of timberland integrity (mostly based on indicators found in the first two criteria from the Montreal Process, see Appendix). For the socioeconomic criterion we use a very broad proxy — gross value of U.S. growing stock inventory or timberland wealth.

The timberland integrity index was developed in an exploratory fashion to illustrate the usefulness of a broad scale composite measure for U.S. timberlands. Some of the current broad scale assessments of either ecological conditions (Committee of Scientists, 1999) or those concerned about the conservation of biological diversity of forests assume the premise that ecological conditions of U.S. forests are in decline. These inferences are generally based on a collection of various anecdotes rather than a more systematic consideration of data.

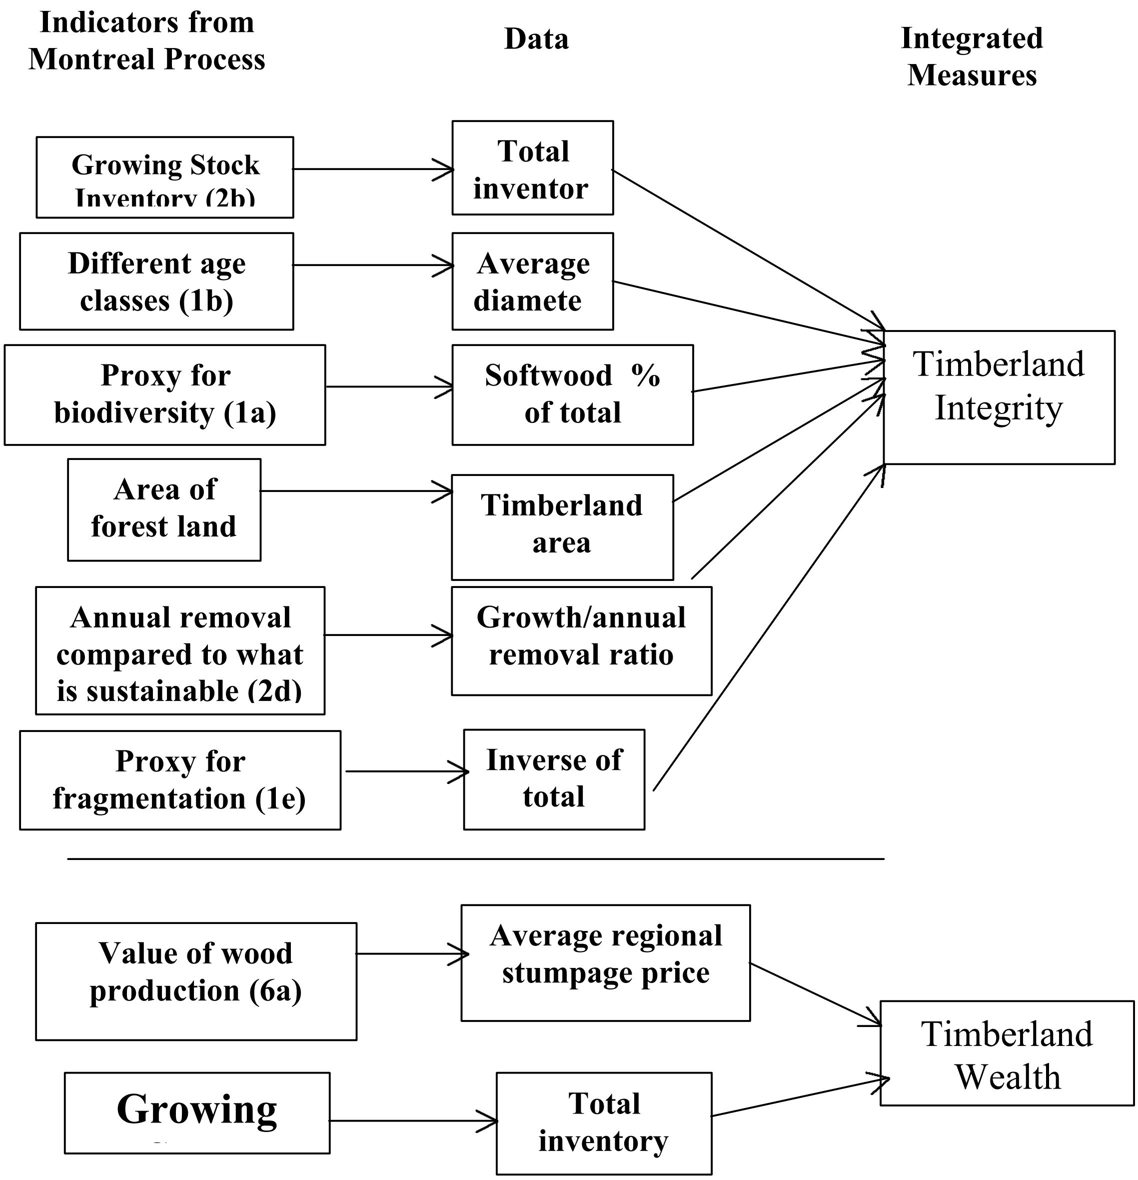
Here we develop an index of timberland integrity that is a linear combination of six measures of various indicators of forest condition and status. These indicators are growing stock inventory[2], area of timberland, annual growth to removal ratio, and proxies for fragmentation (inverse of total harvest), age class structure (average diameter), and biodiversity (softwood percentage of total inventory). Figure 1 shows the general representation and the cross walk of the selected variables with those from the Montreal Process. The data is shown in table 1 and is taken from the 1993 RPA Timber Assessment Update. The data is for the national level but later we will discuss the implications for different regional representations. The actual index was constructed by converting each data series into indices where 1952 equals 100, than summing the indices where each indicator has equal weight (different weights will be discussed), and finally dividing by the number of variables in the index.

The results (equal weight line shown in figure 2) illustrate that there has been a general decline in timberland integrity since 1952 but the decline has slowed in the 1990s and is expected to stabilize in the future. Several interesting trends are hidden in the index. First, increases in overall growing stock inventory offset increased fragmentation and slow the shift from softwood to hardwoods. Second, these changes take place against a 250 percent increase in harvest during the nearly

[2]All inventory definitions follow U.S. Forest Inventory and Monitoring definitions. See Powell and others (1992) for specific definitions.

90-year period (1952 to 2040). In terms of magnitude of change the greatest change took place between 1976 and 1986. Changes both before and since involve smaller magnitudes.

Figure 1–Schematic for integration at the broad scale[1]



The proxies for the Indicators from the Montreal Process shown in Table 1 and plotted in Figure 2 provide a starting point for discussions about how to quantify the concept of sustainability at the broad scale. Using this process it is possible to discuss, and hopefully reach some consensus about, the relative importance or weights of the different Criteria and Indicators for evaluating sustainability. For example, some might argue that Average Diameter is relatively more important than some of the other indicators because it measures the ability of forested landscapes to provide multiple values such as habitat for cavity nesting species, hibernacula for large over-wintering animals, coarse woody debris, and high value clear timber. Others might counter that Total Inventory is relatively more

[1] See Appendix for Montreal Process Criteria and Indicators

important than the other indicators because it measures the suitability of forested areas to provide a different range of values. The methods described here may facilitate such debates by providing a way to quantify and illustrate differences that are not possible through discussion alone. This process is illustrated in Figure 2 where the base case, all indicators given equal weight, is contrasted with the two scenarios proposed here. In the first, Average Diameter is given a 5X weight (Dia 5X) and all other indicators given equal weight. If this indicator is considered relatively more important than the others, under this projection timberland integrity decreases at a faster rate. In the other, Total Inventory is given a 5X weight (Inv 5X) and all other indicators are given equal weight. In this scenario, the weighting of timber inventory increases timberland integrity above historical levels. We can see that depending on what consensus is reached about the relative importance of the various indicators, the magnitude if not the shape of the curve could change markedly and with it our perception of the broad scale sustainability of a region.

Broad scale measures covering socioeconomic indicators, societal benefits, and institutional criterion that make up 58 percent (39) of the indicators in the Montreal Process, have been especially elusive. In recent Forest Service ecoregion planning efforts broad scale socioeconomic measures were developed using the concepts of social and economic resiliency (Horne and Haynes 1999). In this sense resiliency is a measure of the extent that human systems are adaptable to change, that "sense of place" is recognized in management actions, and that the mix of goods, functions, and services that society wants from ecosystems is maintained. This approach is difficult to apply at the national level where recent related discussions have been more in the context of expanding the National Income and Product Accounts to include the environment. The first attempt to add forests used gross forest value[1].

We used the gross variable of the growing stock value (Figure 3) as a relatively parsimonious measure of the various economic and social criteria, i.e., a broad proxy for ecosystem wealth. The essential data is summarized in Tables 2 and 3 where the data sources are again the 1993 RPA Timber Assessment. The construction of the index is much the same as for timberland integrity except the national index is a weighted index where the weights are the regional proportions of total inventory (this follows the convention in the U.S. of using volume weighted average prices for regional proxies).

Our intention is to contribute to the emerging discussion of Sustainable Forest Management as well as the general interest in understanding how broad conditions have changed. In the next section we will look at one policy context where we use this index and a measure for timber wealth to discuss the extent that changes in timberland integrity have resulted in reductions in timberland wealth. Or as some in the environmental movement would like to believe that the forest landscape is unraveling because landowners do not act in the forest's best interest to preserve biodiversity and ecosystem wealth.

Discussion

The choice of measures and proxies used in this analysis was in part dictated by the ability to project changes in these measures based on accepted forecasts. There are other broad-based measures suggested in the Montreal Process that would lend themselves to historical analysis, especially under Criteria 6, including forest products percentage of GDP, employment in the forest sector, and others. The addition of these measures would add richness to the discussion of where we have been but the lack of useful projections of these indicators does not allow analysis of where we are headed.

[1]Nordhaus and Kokkelenberg (1999) review this effort and offer a number of suggestions for an improved measured of the economic contribution of forests.

Table 1. Indexes of timberland integrity

Year	Inventory	Diameter	Softwood Inventory	Area	Growth/ Harvest	Harvest	Total
1952	100		100	100	100	100	100
1962	108		96	101	126	105	107
1970	114		94	99	128	90	105
1976	119	100	87	97	134	85	104
1986	124	76	84	95	98	62	90
1991	128	75	82	96	96	61	90
2000	131	68	80	94	90	56	86
2010	138	68	81	93	89	52	87
2020	145	67	84	92	83	48	87
2030	150	67	86	91	80	46	87
2040	154	66	87	91	75	43	86

Table 2. Softwood inventory price, billion 1982 dollars

Year	Total	North	South	Rocky Mtns.	Pacific Coast
1952	137	12	39	12	74
1962	118	10	41	9	58
1970	173	10	53	17	92
1976	256	11	71	32	142
1986	167	6	54	15	91
1991	269	12	62	28	166
2000	423	22	116	73	212
2010	462	38	141	79	205
2020	608	47	164	108	288
2030	637	58	162	118	300

Table 3. Hardwood inventory price, billion 1982 dollars

Year	Total	North	South	West
1962	51	34	15	1
1970	67	41	25	2
1976	83	46	35	2
1986	97	65	29	3
1991	106	73	30	3
2000	153	102	49	2
2010	170	109	58	2
2020	194	123	68	3
2030	220	142	75	3

National indices can mask differences that only become apparent in less aggregate analysis. Figure 4 shows the timberland integrity measure for the four U.S. regions. The national historical trend shown in Figure 2 was clearly being driven by the eastern region (North and South). Projections 2000 and beyond are based on the 1993 RPA estimates and may change with the next revision due later this year.

Similarly the regional timberland wealth index (Figure 5) shows that the projections for the western region have a much different trajectory than the rest of the country. An even more disaggregated analysis could further refine regional influences.

These estimates are based on broad proxies for various processes. Some of the proxies for ecological measures, for example, reflect structure rather than the underlying process. We did not presume to have measured nor revealed the absolute levels of ecosystem integrity or resiliency. Rather, these ratings represent a first attempt at estimating integrity and resiliency at this spatial level. Given more time and information, integrity indices might include direct consideration for elements such as recovery cycles, synergistic interactions between environmental components and biophysical linkages, and feedback mechanisms operating on different spatial and temporal scales within the area.

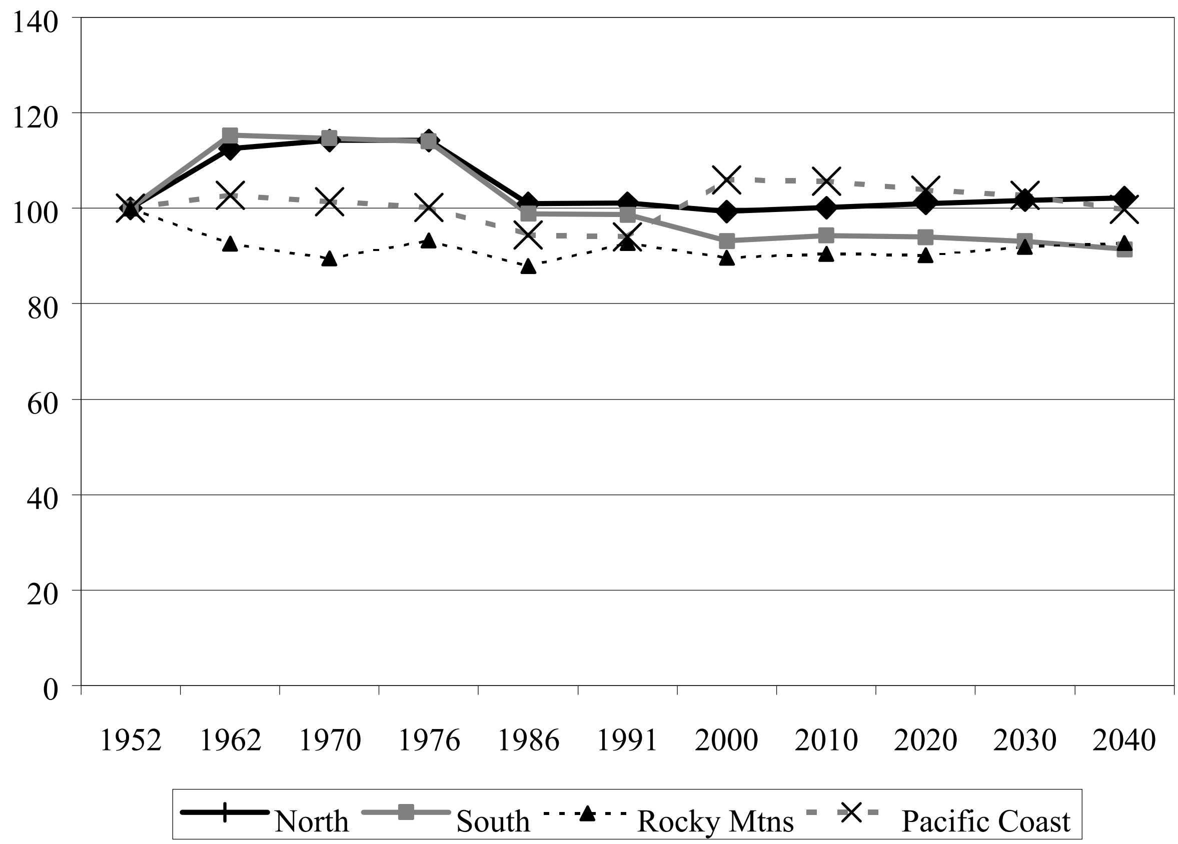

Figure 5. Regional Timberland Wealth

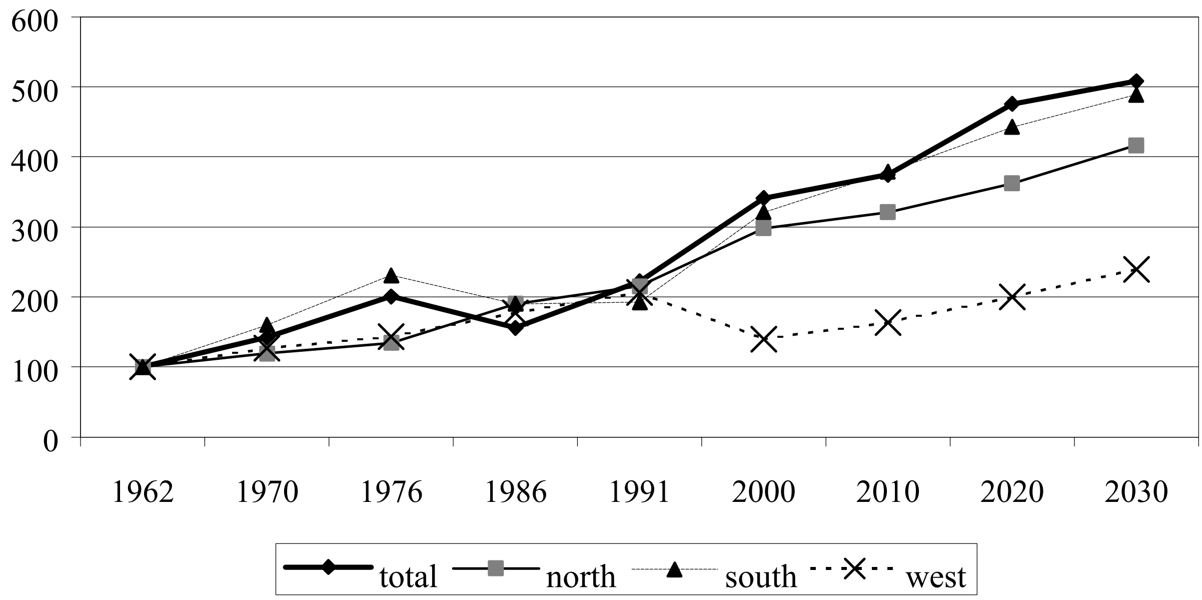

Summary

The challenge of measurable goals moved us beyond describing goals using platitudes. No longer can we conduct an assessment around vague and often misunderstood goals such as sustainability, healthy forests or community stability. At the same time there is a great interest on the part of scientists to avoid the "owl vs. jobs" nature of the spotted owl debate in the U.S. Pacific Northwest. In that debate all concerns for ecological conditions were reduced to habitat conditions for the northern spotted owl while all concerns about social well-being centered on employment in the lumber and wood products industries. These broad scale composite measures (like criteria based on selected indicators) do help us to look more broadly at the notion of tradeoffs, compatible production, and the integrative nature of ecosystems.

One measure of success for protocols like the Montreal Process will be the extent to which they shift the debate about Sustainable Forest Management away from two-dimensional arguments about tradeoffs to one that addresses strategic questions about the compatibility of wood production with ecological and socioeconomic goals. Scientists can contribute to both; developing individual broad scale measures as well as composite indexes and the process for aggregation to higher spatial scales.

Appendix

Montreal Process Criteria and Indicators (adapted from US Forest Service Report to Facilitate Discussion of Indicators of Sustainable Forest Management, http://www.fs.fed.us/land/sustain_dev/sd/welcome.htm)
Those in italics are included in this analysis with the specific measure in parentheses

Criterion 1: Conservation of biological diversity
Biological diversity includes the elements of the diversity of ecosystems, the diversity between species, and genetic diversity in species.

Indicators:

Ecosystem Diversity

a) Extent of area by forest type relative to total forest area; (a)[1] (softwood)
b) Extent of area by forest type and by age class or successional stage;(b) (average dbh)
c) Extent of area by forest type in protected area categories;(a)
d) Extent of areas by forest type in protected areas defined by age class or successional stage;(b)
e) Fragmentation of forest types;(b) (total harvest)

Species Diversity

f) The number of forest dependent species;(b)
g) The status (rare, threatened, endangered, or extinct) of forest dependent species at risk of not maintaining viable breeding populations, as determined by legislation or scientific assessment;(a)

[1] Indicators followed by an "a" are those for which most data are available. Indicators followed by a "b" are those which may require the gathering of new or additional data and/or a new program of systematic sampling or basic research. No priority is implied in the "a" and "b" designations.

Genetic Diversity

h) Number of forest dependent species that occupy a small portion of their former range;(b)
i) Population levels of representative species from diverse habitats monitored across their range.(b)

Criterion 2: Maintenance of productive capacity of forest ecosystems:

a) Area of forest land and net area of forest land available for timber production;(a) (timberland area)
b) Total growing stock of both merchantable and nonmerchantable tree species on forest land available for timber production;(a) (growing stock)
c) The area and growing stock of plantations of native and exotic species;(a)
d) Annual removal of wood products compared to the volume determined to be sustainable;(b) (Growth/drain ratio)
e) Annual removal of non-timber forest products (e.g. fur bearers, berries, mushrooms, game), compared to the level determined to be sustainable;(b)

Criterion 3: Maintenance of forest ecosystem health and vitality:
Indicators:

a) Area and percent of forest affected by processes or agents beyond the range of historic variation, e.g. by insects, disease, competition from exotic species, fire, storm, land clearance, permanent flooding, salinisation, and domestic animals;(b)
b) Area and percent of forest land subjected to levels of specific air pollutants (e.g. sulfates, nitrate, ozone) or ultra violet B that may cause negative impacts on the forest ecosystem;(b)
c) Area and percent of forest land with diminished biological components indicative of changes in fundamental ecological processes (e.g. soil, nutrient cycling, seed dispersion, pollination) and/or ecological continuity (monitoring of functionally important species such as

nematodes, arboreal epiphytes, beetles, fungi, wasps, etc.);(b)

Criterion 4: Conservation and maintenance of soil and water

This criterion encompasses the conservation of soil and water resources and the protective and productive functions of forests.

Indicators:

a) Area and percent of forest land with significant soil erosion;(b)

b) Area and percent of forest land managed primarily for protective functions. e.g. watersheds, flood protection, avalanche protection, riparian zones;(a)

c) Percent of stream kilometers in forested catchments in which stream flow and timing has significantly deviated from the historic range of variation;(b)

d) Area and percent of forest land with significantly diminished soil organic matter and/or changes in other soil chemical properties;(b)

e) Area and percent of forest land with significant compaction or change in soil physical properties resulting from human activities;(b)

f) Percent of water bodies in forest areas (e.g. stream kilometers, lake hectares) with significant variance of biological diversity from the historic range of variability;(b)

g) Percent of water bodies in forest areas (e.g. stream kilometers, lake hectares) with significant variation from the historic range of variability in pH, dissolved oxygen, levels of chemicals (electrical conductivity), sedimentation or temperature change; (b)

h) Area and percent of forest land experiencing an accumulation of persistent toxic substances.(b)

Criterion 5: Maintenance of forest contribution to global carbon cycles
Indicators:

a) Total forest ecosystem biomass and carbon pool, and if appropriate, by forest type, age class, and successional stages;(b)

b) Contribution of forest ecosystems to the total global carbon budget, including absorption and release of carbon (standing biomass, coarse woody debris, peat and soil carbon);(a or b)

c) Contribution of forest products to the global carbon budget;(b)

Criterion 6: Maintenance and enhancement of long-term multiple socioeconomic benefits to meet the needs of societies

Indicators:
Production and consumption

a) Value and volume of wood and wood products production, including value added through downstream processing;(a) (wood value)

b) Value and quantities of production of non-wood forest products;(b)

c) Supply and consumption of wood and wood products, including consumption per capita;(a)

d) Value of wood and non-wood products production as percentage of GDP;(a or b)

e) Degree of recycling of forest products;(a or b)

f) Supply and consumption/use of non-wood products;(a or b)

Recreation and tourism

g) Area and percent of forest land managed for general recreation and tourism, in relation to the total area of forestland (a or b)

h) Number and type of facilities available for general recreation and tourism, in relation to population and forest area;(a or b)

i) Number of visitor days attributed to recreation and tourism, in relation to population and forest area; (b)

Investment in the forest sector

j) Value of investment, including investment in forest growing, forest health and management, planted forests, wood processing, recreation and tourism;(a)

k) Level of expenditure on research and development, and education;(b)

l) Extension and use of new and improved technology;(b)

m) Rates of return on investment;(b)

Cultural, social and spiritual needs and values

n) Area and percent of forest land managed in relation to the total area of forest land to protect the range of cultural, social and spiritual needs and values;(a or b)

o) Non-consumptive use forest values;(b)

Employment and community needs

p) Direct and indirect employment in the forest sector and the forest sector employment as a proportion of total employment;(a or b)

q) Average wage rates and injury rates in major employment categories within the forest sector; (a or b)

r) Viability and adaptability to changing economic conditions, of forest dependent communities, including indigenous communities;(b)

s) Area and percent of forest land used for subsistence purposes;(b)

Criterion 7: Legal, institutional and economic framework for forest conservation and sustainable management[2]

Indicators:

Extent to which the legal framework (laws, regulations, guidelines) supports the conservation and sustainable management of forests, including the extent to which it:

a) Clarifies property rights, provides for appropriate land tenure arrangements, recognizes customary and traditional rights of indigenous people, and provides means of resolving property disputes by due process;

b) Provides for periodic forest related planning, assessment, and policy review that recognizes the range of forest values, including coordination with relevant sectors;

c) Provides opportunities for public participation in public policy and decision making related to forests and public access to information;

d) Encourages best practice codes for forest management;

e) Provides for the management of forests to conserve special environmental, cultural, social and/or scientific values.

Extent to which the institutional framework supports the conservation and sustainable management of forests, including the capacity to:

f) Provide for public involvement activities and public education, awareness and extension programs, and make available forest related information;

g) Undertake and implement periodic forest related planning, assessment, and policy review including cross-sectoral planning and coordination;

h) Develop and maintain human resource skills across relevant disciplines;

i) Develop and maintain efficient physical infrastructure to facilitate the supply of forest products and services and support forest management;

j) Enforce laws, regulations and guidelines;

Extent to which the economic framework (economic policies and measures) supports the conservation and sustainable management of forests through:

k) Investment and taxation policies and a regulatory environment which recognize the long-term nature of investments and permit the flow of capital in and out of the forest sector in response to market signals, non-

[2] Criterion 7 and associated indicators relate to the overall policy framework of a country that can facilitate the conservation and sustainable management of forests. Included are the broader societal conditions and processes often external to the forest itself but which may support efforts to conserve, maintain or enhance one or more of the conditions, attributes, functions and benefits captured in criteria 1-6. No priority or order is implied in the listing of the indicators.

market economic valuations, and public policy decisions in order to meet long-term demands for forest products and services;

l) Nondiscriminatory trade policies for forest products;

Capacity to measure and monitor changes in the conservation and sustainable management of forests, including:

m) Availability and extent of up-to-date data, statistics and other information important to measuring or describing indicators associated with criteria 1-7;
n) Scope, frequency and statistical reliability of forest inventories, assessments, monitoring and other relevant information:
o) Compatibility with other countries in measuring, monitoring and reporting on indicators.

Capacity to conduct and apply research and development aimed at improving forest management and delivery of forest goods and services, including:

p) Development of scientific understanding of forest ecosystem characteristics and functions;

q) Development of methodologies to measure and integrate environmental and social costs and benefits into markets and public policies, and to reflect forest related resource depletion or replenishment in national accounting systems;

r) New technologies and the capacity to assess the socioeconomic consequences associated with the introduction of new technologies;

s) Enhancement of ability to predict impacts of human intervention on forests;

t) Ability to predict impacts on forests of possible climate change.

Assessing State and Change in Global Forest Cover: 2000 and Beyond

Abstract

The United National Food and Agriculture Organisation (FAO), at the request of the member nations and the world community, regularly reports on status and trends in the world's forest resources. This paper briefly describes the methods used in past surveys, describes the data and methods to be used to complete the 2000 Forest Resource Assessments, and proposes a follow-on continuous world forest survey system to enable FAO to provide the necessary information on a permanent basis. This paper is based on a background document and on the results of an Expert Advisory Meeting on FRA 2000 held in Rome, Italy on March 6-10, 2000.

Keywords: Inventory, Assessment, Monitoring, Global, Satellite, Tropical

Introduction

The United National Food and Agriculture Organisation (FAO), at the request of the member nations and the world community, regularly reports on the world's forest resources through its Forest Resources Assessment Programme (FRA). FRA is now executing the Global Forest Resources Assessment 2000 (FRA 2000). Reliable information on forest change (both negative and positive changes) and its trends has been widely recognised as indispensable for ensuring the sustainable management of the world's forests.

The purpose of this paper is to (a) describe the data and methods used to complete past and current Forest Resource Assessments, and (b) to propose a follow-on continuous world forest survey system to provide FRA products in future years. This paper is based on a background document (Paivinen and Gillespie 2000) and on the results of an Expert Advisory Meeting on FRA 2000 held in Rome, Italy on March 6-10, 2000.

FAO Forest Resource Assessment in 1980-90

The 1980 FRA was essentially an expert assessment based on existing inventory information for each of 76 tropical countries. A small team of experts in FAO headquarters gathered and synthesised whatever information they could find regarding the status of forests in each of 76 tropical countries. The diversity of the information was seen in three different angles: subject, scale and reliability. The FRA 1980 study 'consisted mainly in the selection, organisation, compilation and interpretation of this abundant and diverse mass of information using a single framework of classifications and concepts for the 76 tropical countries' (Lanly 1982). Although it was clearly the best available global synthesis of its time, the 1980 FRA was criticised for over reliance on country-reported data, which was feared to be biased in favour of underreporting rates of forest loss. Another criticism was that the methods used to synthesise and update data were not fully documented and made available to potential users of the data.

Partly due to this, as well as to the increased staff capacity and access to technology, the 1990 FRA incorporated a statistical sample of satellite imagery to produce regional levels of forest cover change, as a validation of the aggregated country level results produced by country data and models. This survey covered, with 10 percent intensity, all tropical forests in wet, moist and dry conditions. The survey was based on a statistical sample composed by multi-temporal satellite images over 117 sampling units. For each unit the study included the analysis of one entire Landsat image close to year 1990 and one (or more) close to year 1980.

The 1990 FRA also used a set of models to predict forest change as a function of population, based on the assumption that "the growth of human population, independently in the absence of economic development, and jointly with poorly planned and uncontrolled economic development, are the driving forces behind human activities that initiate deforestation" (Scotti 1990, Palo 1986). It was assumed that forest area reduction increases slowly at initial stages, faster in intermediate stages and slows down at final stages, following principles of biological growth processes, often described with well-known Chapman-Richards function. The mathematical connection between population density and non-forest area was created using forest cover data in a number of sub-country regions in Tropical countries. Finally, the deforestation rate was estimated assuming that the increase in the population will determine the decrease in the change of forest cover.

Forest Resource Assessment 2000 Data Available

The FRA 2000 continues the use of satellite image assessment for estimating rates of forest cover and change at the regional level. However, resources do not provide for extension of this approach to the country level, nor has FAO been given the mandate to conduct this level of work. Since estimates at the country level are still needed, such estimates will have to be based on other types of data. Sources of information available for completing FRA 2000 include the following:

1. Update of the 2000 Remote Sensing survey of tropical countries. The strategy for the Tropical 2000 Update approach is to revisit the topical FRA 1990 sampling units, and update them with a third date of TM imagery for the reference year 2000. Such a survey will provide up-to-date information on change processes, as well as new and unprecedented insights on deforestation trends over the periods 1980-1990 and 1990-2000.

   The key strength of the TM change assessment approach is that it utilises advanced satellite technology in a way that provides consistent, reliable results. This approach also helps reduce program costs by allowing use of the photographic image archive already maintained by FAO. Although the method of manual interpretation does not take full advantage of current image processing technology, the method is simple to replicate, relatively inexpensive, and is readily familiar to foresters all over the world. The primary weakness of the TM change assessment as implemented by FRA is that, due to financial and time constraints, the sample intensity is designed for regional results only; few countries will have sufficient samples to support estimates at the country level. Thus, some subtle forms of forest degradation or deforestation may be missed in the stratification process, which may lead to false estimates of rates of forest loss.

2. AVHRR (Advanced Very High Resolution Radiometer) forest map. FRA 2000 will feature a global forest cover map produced at 1-km spatial resolution, produced at the U.S. Geological Survey (USGS) EROS Data Centre (EDC) in cooperation with FAO. This map is a complete global coverage produced with a consistent methodology and a flexible database philosophy, using AVHRR Normalized Difference Vegetation Index (NDVI) as the primary input data. Two levels of land cover are available from the database: the full classification based on seasonal definitions and the aggregated 17-category International Geosphere and Biosphere Programme (IGBP) classification. The FAO forest cover mapping effort builds on the full USGS

seasonal database, refining forest classes to reflect forest density classification.

The primary advantage of AVHRR imagery is that the imagery is acquired for all lands (wall to wall) on a daily basis. This presents a low cost alternative to TM imagery, and the frequent availability makes it more likely that cloud free imagery will be available for any given target area close to any given target date. The primary weakness of AVHRR imagery is the lower resolution (1 km pixel size vs. 30m for TM), which leads to much coarser interpretability and less precision than interpretation TM imagery. The wider angle and interference of atmospheric effects cause problems with interpretation near to the edge of images. Thus, while AVHR may be very suited for change assessment in large (e.g. regional) areas, it may not be so useful for assessment at the national level, particularly for small or medium sized land areas

3. <u>Existing country level inventory data.</u> Many countries have in place systems for monitoring their forests on a periodic or occasional basis. Other countries have conducted studies of subsets of their forests, or complete or partial forest inventories sponsored by a variety of donor organisations. The result is a huge set of information regarding status and trends in forest statistics at the national and sub national level. FRA 2000 professional staff have been working for years to make and keep current a metadata base describing what data exist, by country, throughout the tropical world, as well as archiving the actual data in the FORIS (Forest Resources Information System) database. Regional specialists travel to the countries in their region, gleaning available information and assembling it for potential incorporation into the FRA 2000 and future studies. FRA will make these data available, along with appropriate metadata, via the World Wide Web.

   The strength of using data reported by countries is that results tend to be of higher precision than results from studies conducted at the regional scale. National forest statistics would be harmonised with other reports and analyses produced by and used in the target country, increasing consistency between FAO and National reports. Presumably, forest statistics gathered at the National level would be overseen by experts with more familiarity with the target country and with more time to spend on a single country, which should lead to improved data quality. The primary weakness with the aggregation of country level is that there is tremendous inconsistency and incompleteness in country inventory data, both within countries over time as well as between countries. Assessments are conducted with different objectives and populations of interest, using different definitions, standards, sample designs, and field methods from those used by FAO or by neighbouring countries. The results can be difficult to interpret and harmonise for comparison across countries, as FRA must do. Additionally, many countries particularly in Africa simply lack the resources to conduct forest assessments, so that data are lacking.

4. <u>Models to derive forest change as a function of other attributes.</u> The strength of the modelling approach used already in FRA1990 is that it provides a platform for generating estimates for all countries regardless of availability of country level data. Data gaps would simply be modelled by more generalised functions. Generation of models is a useful exercise in that it forces study of cause and effect relationships and can lead to insights regarding true mechanisms or drivers of forest cover change, which in turn could lead to better investment decisions by national governments seeking to manage their forests. The results of existing models are probably reasonable at the global level. However, the greatest weakness of the modelling approach continues to be inadequacy of existing models when applied to specific countries. The process of deforestation is such a complex process, involving physical, climatalogical, political, and socio-economic forces which are themselves very complex, that simple generalised models of forest change have so far not been developed. Current models are

oversimplified and yield similar predictions of forest cover change rates for countries which are known to be very different. More complex models are yet to be developed and tested.

New Methods

Remote Sensing

The most straightforward way to intensify Remote Sensing based approach is to maximise the coverage of TM figures to cover up to 100% of the tropical belt. This, however, would require plenty of resources for purchasing the data and staff for working on it using present visual interpretation approach.

There are other potential useful sources of remote sensing imagery which may be incorporated into the final analysis. In 1999 FRA commissioned a global forest cover map to be produced by the Eros Data Center (EDC) of the US Geologic Survey (USGS). This map, based on AVHRR coverage, provides a global snapshot of forest cover at a relatively coarse scale. There are also other AVHRR – based forest cover mapping projects ongoing (see for instance http://fellini.gvm.sai.jrc.it/trees/ or http://www.geog.umd.edu/tropical/main.html.

The primary advantage of increased use of satellite imagery is that it provides a tool for objectively filling in existing data gaps by use of an information source which is universally available. Linking TM and AVHRR data - using multi-stage or multi-phase sampling or ratio estimates - would be objective and simple to implement once the data and methods were available. The primary weakness of this approach is the lack of existing strong relationships between TM and AVHRR. Significant amounts of research have sought such correlations, with mixed results. Correlations may not be universally strong enough to act as a reliable source for filling in data gaps.

Formalizing Expert Opinions

Given the lack of globally consistent forest inventory data, some kind of synthesis based on partial data plus expert opinion is not an unreasonable way to arrive at answers. Certainly expert opinion can be subject to bias and imprecision; yet it will generally be better than no information at all. Two of these methods are the Delphi Technique and Convergence of Evidence.

Delphi Technique

The Delphi Technique applies elementary statistics to a sample of expert opinions in an iterative fashion, with the intention of eliminating outliers, providing feedback, and converging to a level of consensus. The technique was originally developed for making forecasts of socio-economic trends and has since been generalized for use in a variety of estimation or problem solving situations (Sackman 1975).

The original Delphi Technique had several distinguishing characteristics. A pool of experts was chosen to make predictions on some topic. However, rather than assembling the group together, each group member was asked to submit their estimates anonymously, to avoid the chance that more prestigious or dominant group members would unduly influence the estimates made by other group members. The set of estimates was then averaged, and individual estimates which were outside some range of standard error were returned to the expert who had submitted it along with a request for justification or for a new estimate. The process would iterate several times until all there were no further changes in individual estimates, at which time a consensus estimated would be adopted. Advantages of the Delphi Technique are that it will always provide an answer in the time available, and that it takes advantage of expertise and experience which may be relevant but non quantitative. Disadvantages are that the method may lack repeatability, and that the quality of the answers depends heavily on the quality of the experts. In our case, it may be difficult to find a qualified pool of experts for each of the many countries for which we wish to derive estimates.

Convergence of Evidence

A second qualitative technique called Convergence of Evidence is currently used by the Foreign Agriculture Service of the US to produce annual assessments of agriculture crops in major producing or consuming countries of the world. Whereas the Delphi Technique relies on a group of experts arriving at consensus based on their (somewhat different) experience, Convergence of Evidence instead relies on a single expert who has at their disposal a variety of independent or quasi-independent information sources regarding the parameter of interest (Roke 1999, www.fas.usda.gov/pecad/who_what.htm).

For example, for estimating future wheat harvest in country X, an analyst has at their disposal historical records of past crop yields, recent weather data affecting the current year's crop, short term future weather forecasts, historical land ownership and farming data, agricultural statistics and forecasts produced by country X, and satellite data at different points over the current growing season showing potential areas and biomass accumulation of the target crop. The analyst synthesizes this information internally, using their experience and knowledge for assigning more weight to information that they feel is more reliable and arriving at a final answer. Ideally, over time, the expert has a chance to validate their estimate against a future measurement, allowing for learning over time.

This technique most closely resembles the methods used in the 1980 Assessment, where a small group of individuals immersed themselves in various available data sources. This trend continues to some extent in the current FRA 2000 where a small group of regional analysts are compiling, interpreting, and preparing to analyse regional and country level data. Clearly, the quality of the estimates for each country relies heavily upon the expertise and experience of the analyst. One advantage of this method is flexibility in that estimates can be derived when the data sources vary in availability and quality from country to country. Like the Delphi Technique, an estimate can be generated for every country and can be completed within a finite time window, recognizing that lack of time can limit the depth of the analysis. Disadvantages of this approach are dependence upon the skill of a single expert which can readily lead to bias, imprecision, and lack of repeatability.

Recommended Methodology for FRA 2000

An international panel of experts in forest assessment met in March 2000 to review progress and plans for completing FRA 2000, and to make recommendations for how the final results could be completed by the deadline of December 31 2000. The group reviewed the available sources of data and the proposed methods for combining the data, proposed additional data sources and analysis methods, and evaluated several alternatives for both scientific rigor and for practicality within the time and resource constraints. Criteria used to evaluate the alternatives included (1) statistical accuracy and precision of estimates, (2) ability to be used within available time, resource, and data availability constraints, (3) degree of general scientific acceptance of methods, (4) degree of transparency in methods, (5) ability to yield estimates for all countries of interest regardless of data constraints, and (6) simplicity.

After significant debate, the Panel recommended a combination of the Delphi Technique (an interative process using blind expert opinion to refine estimates) and a Convergence of Evidence (a method for weighing and combining different sources of information to arrive at a single country level estimate). The recommended approach uses a small group of experts to weigh the different available data sources for each country and attempt to arrive at final estimates. The experts are led in each region by the FRA Regional Coordinator. The Coordinator summarizes all available information (from TM image analysis, country reports, relevant models, other satellite imagery, etc.) and derives an initial estimate or range of estimates for each country, explaining their decision process and documenting the weight that they assigned to the various available sources of information. They then share the results with the small set of regional or country level experts to validate the results, asking the other experts to critique the reasoning or assignation of weights in the production of country level estimates and attempting to seek some consensus on final estimates. The process is illustrated schematically in Figure 1.

All available data will be used in the process. However, there were some observations and recommendations regarding the reliability of data sources. The use of AVHRR data was to be carefully considered, since the observed low correlation between FRA TM data and AVHRR map, especially on dry and semi-dry lands in the Tropics. Therefore, the panel recommended FRA 2000 to consider an additional sample of TM images to complete FRA 2000 change assessmentin Africa where other sources of data are very limited. The change model based on population, due to its limitations mentioned earlier, was recommended to use only as ancillary data in cased of very poor quality data from other sources.

The primary strength of this combined approach is that it allows the flexibility to include a variety of information sources assessed by people familiar with the situations in the countries, while mitigating some of the disadvantages inherent in relying on a single expert to integrate the data sources. This approach makes maximal use of available information, which varies from country to country. It allows incorporation of experience and qualitative information which is relevant but is normally not considered by more objective, purely quantitative analyses. The validation procedure adds a second set of information useful for comparative purposes or for calibration.

The primary weakness of this approach is the reliance on sufficiently diverse group of experts to add value in each country, and the unavoidable reliance on the availability of expertise and data. Time and resource constraints may limit the ability of FRA staff to seek sufficient input for each country. This difficulty could be partly mitigated by conducting a triage, whereby certain countries with known strong data were given less discussion, and countries with weaker data had more attention. Triage might also include stratifying countries by amount of forest cover to ensure that countries with the most forest are examined more closely, in order to minimise the chances of making relatively larger estimation errors.

FRA Beyond 2000: Towards a World Forest Survey

Since 1996, FAO has worked toward the development of a continuous monitoring programme of forests at the global level, or **World Forest Survey (WFS).** This programme is intended to extend a statistical sample over the entire world following new stratification criteria to improve its efficiency. At present, due to several technical and financial considerations, a phase-in of the new long-term Global Continuous Monitoring Programme is being envisioned along with the implementation of the 2000 Update for the year 2000 assessment. Ultimately, the WFS will provide continuously updated country level data, with global reports and analyses published at 5 year intervals. In this document, we concentrate on the tropical FRA2000, but keeping the development of a global monitoring programme in mind for after the year 2000.

The participants in the Expert Advisory meeting reviewed the current state of FAO thinking on the WFS concept and agreed that the FRA program of the FAO should take the lead in developing a proposal for a World Forest Survey. The proposal should identify the potential customers, costs and benefits of such a system. A logical first step in such a process should be to further identify potential WFS customers and their needs. It was further agreed that the FRA team should prepare a technical document on the WFS concept, to be shared with the global forest monitoring community and that a future Expert Advisory meeting should be called to help move the concept towards implementation.

Figure 1. Schematic diagram showing the steps used to take available data and arrive at a final country level estimate.

Abstract

Being a key link in the chain of sustainable forest management practices, silviculture occupies an important place in British Columbia's forest policy considerations. This poster aims at providing an economic and policy analysis of the silvicultural investment in BC's public forestlands. First, a brief historical overview of the Province's silviculture programs is presented to outline the institutional context in which the silviculture sector has evolved. Next, silvicultural activities and expenditures are reviewed statistically. Then, a regression analysis is undertaken in an attempt to reveal the effects of several explanatory variables such as harvest areas, timber prices, non-timber values and government stumpage revenues on the levels of silvicultural investment. Finally, the policy implications of the research findings are discussed from the perspective of sustainable forestry. The paper ends with a comment on the emerging trends of BC's forest policy regarding silvicultural operations in the Province.

Détermination de la Productivité des Jachères dans Cinq Régions du Mali

by
Nouvellet, Yves, Mallick sylla, Amadou kassambara
CIRAD-Forêt
E-mail: Mali nouvellet@cirad.fr

Abstract

La filière bois-énergie au Mali permet de couvrir 91 % des besoins énergétiques natinaux. Le bois est issu des formations naturelles et des formations "hors forêt" ou diffuses des espaces agro-sylvo-pastoraux. Pour mettre en place une gestion durable et raisonnée de la ressource ligneuse, le Mali s'est doté d'une politique énergétique : la Stratégie Energie Domestique. La production de la biomasse ligneuse des formations forestières est connue, alors que celles des jachères (formations forestières diffuses) sont tout à fait empiriques.

Pour mieux appréhender sa production, la Cellule Combustibles Ligneux (volet offre de la Stratégie Energie Domestique) en liaison avec l'Institut Polytechnique Rural de Katibougou, a installé des sites d'étude dans cinq régions du Mali d'Ouest en Est : Négala, Ouéllésebougou, Fana, Cinzana et Koutiala. Les sites choisis doivent permettre une meilleure connaissance des formations "hors forêt" du pays.

'inventaire des arbres (de jachères et de parc), de la régénération, le cubage par classes (0- 5 ans, 6-10 ans, 11-15 ans, 16-20 ans et plus de vingt ans) ont été réalisés dans ces sites. La répartition par classes d'âge a été obtenue par enquêtes auprès des paysans exploitants de ces jachères.

La productivité annuelle de ces formations est fortement liée à l'anthropisation, elle varie de 0,06 m3/ha/an à Koutiala (fortes occupations des terres pour la production du coton) à plus de 0,25 m3/ha/an dans les régions de Fana et Négala. Ces résultats n'incluent pas les arbres dits de "parc" tel que Vitellaria paradoxa, Parkia biglosa, et Lannea spp..

Les essences caractéristiques de ces formations "hors forêt" sont pour l'étage dominant les arbres de parcs cités au pargraphe précédent, pour l'étage dominé : Combretum nigricans, Acacia macrostachya, Combretum glutinosum ; la régénération est caractérisée par des espèces pionnières : Piliostigma reticulatum, Acacia macrostachya, Guiera senegalensis.

Ces données partielles seront utilisées pour la réactualisation des Schémas Directeurs d'Approvisionnement des principales villes du Mali (Bamako, Ségou, Mopti et Koutiala).

Abstract

Natural spruce forests of the boreal taiga are usually presented by multiple-aged forest stands. Spruce reforestation under the canopy of such crops is a natural process, corresponding to the natural peculiarities of the zonal (area) forests. However, in the considerable area of the exploitable crops of the European part of Russian boreal forests it is quite difficult to run a forestry, orientated to the conservation and further utilization of the young growth during the cutting of the mature forest stand. During the last 35 years in the north-western and central parts of Russia there were probated new methods of planting and conditions of artificial growing of spruce and other shade-requiring species under the canopy. Depending on their purpose these cultures are subdivided into preliminary and under-canopy.

Common to both types is the fact they are planted under already existing (growing) canopy; while the difference is that preliminary cultures are planted under the canopy of maturing and mature crops (approximately 10-12 years before cutting), but under-canopy cultures- under the canopy of open undergrowth(I-II age class). The technological system of preliminary cultures provides for preventing unfavorable succession of spruce species and gradual(progressive) replacement of old generations by young, ecologically stable forests. Planting and growing of preliminary cultures, unlike the clear cutting forestry management and further reforestation, has a number of technological, ecologically-silvicultural and economic advantages.

The purpose of under-canopy cultures is slightly different and consists in planting structurally and compositionally complex forest crops on the basis of open unsuccessful or damaged forest stands. Young spruce growth in the open cutting usually suffers greatly because of the late frosts and sun burns. Besides, its growth is greatly restrained by grassy vegetation and broad-leaved sprouting. Microclimatic conditions are much softer and more favorable for survival and growth of young plants under the parent canopy. In particular, there is no competitive pressure on the crops from grassy vegetation and broad-leaved sprouting, the fact that greatly decreases care costs.

Moreover, under the canopy of forest crops the processes of bogging are weakened as here, in contrast to clear cuttings, water regime(condition) is regulated by growing forest crops. We can't help mentioning a most important ecological effect of the under-canopy reforestation system, that is reduction of the amount of open forests peculiar to clear cutting forestry. Nowadays, when forests suffer immensely from air emissions and other technogenic(industrial) pollutions, under-canopy "covered" system of forest growing considerably reduces the probability and degree of salvage. The under-canopy system of forest growing essentially reduces and prevents CO_2 release into atmosphere owing to unproductive temporal interval (10-15 years), until the territory of cutting is planted by new crops. The long-tem researches of the stationary plots showed that during the processes of planting and growing of preliminary cultures. The latter accelerate their growth abruptly when the upper canopy is cut or thinned. Their biometric parameters and productivity become similar to those of the cultures planted earlier in the open areas. In all its technological and forestry components the under-canopy system of reforestation and forest growing will favor ecologolization of the forestry management system in the boreal forests.

Abstract

Yield regulation has been identified as a key constraint to sustainable management of natural tropical forests. Growth and yield simulation models are being developed as tools for growth prediction and yield regulation using data from permanent sample plots and forest inventory. This paper illustrates the application of an individual-based (single-tree spatial) model for simulation of the growth and yield of moist tropical forest systems. SYMFOR is a modelling framework that has been principally designed to study and predict the effects of different silvicultural treatments for sustainable yield management of natural Dipterocarp forests in Indonesia.

The current version of SYMFOR has been applied to illustrate the utility of both empirical and process-based growth and yield models for three applications: (1) growth and yield prediction, (2) evaluation of alternative silvicultural systems and (3) evaluation of indicators of sustainable forest management. Predictions of growth and yield are presented for an area of lowland dipterocarp forest in East Kalimantan (Indonesian Borneo). These predictions are used to describe and predict the recovery of the forest following logging compared to its pre-logging condition. This analysis is then extended for the same dataset to determine the effect of altering the silvicultural system applied to the forest through alterations in either diameter cutting limits or length of cutting cycle. These results are then further analysed to illustrate simple indicators of sustainable forest management. The analysis of these simulation runs demonstrated the importance of appropriate statistical analysis of model simulations.

The paper concludes that growth and yield models will become an increasingly important tool for the management for sustained yield of tropical forests and can be further applied to develop and implement effective criteria and indicators for sustainable forest management. These applications will require the development of appropriate analytical procedures to utilise output from simulation models and to make their results readily available for application by forest managers.

Tropical Forests Management Based on Tree Populations Dynamics:The Example of Moabi in The Dja Forest (Cameroon)

by
L. Debroux, Philip Le Jeune
World Bank
Cameroon
ldebroux@worldbank.org

Abstract

Though Central African rain forests contain a wide diversity of tree species, present logging practices are extensive and mining, and focus on a relatively restricted range of valuable timber species Considering the complexity of management practices aimed at controlling global stand dynamics, we propose an approach based on ecological characteristics and demography of particular timber species and we assume that forest management mainly consists in the management of timber tree populations living in their natural environment. This approach is illustrated with the example of moabi (*Baillonella toxisperma* Pierre, *Sapotaceae*), a timber species from Cameroon.

For two and a half years (1994-1997), we measured survival, growth, fecundity and spatial distribution of every class of seedlings and trees of this species in permanent plots covering 347 ha, located in the Réserve de Faune du Dja and in the adjoining logging concession (South-East Cameroon).

After a description of the Dja's floristic diversity (chapter 1), we present the phenology and germination of moabi (chapter 2), seed dispersal and predation by mammals as well as impact of hunting on its natural regeneration (chapter 3), and then seedling growth in the understorey related to light availability (chapter 4) and finally the demographic parameters of its adult population: diametrical structure, growth, mortality and spatial distribution (chapter 5). Moabi start fruiting from 70 cm DBH, some individuals reach 280 cm DBH as maximum size and trees are cut over the legal limit diameter which is 100 cm. The density of adult trees is 0.1 stem/hectare. The specific growth curve is calculated by mean of three different methods: measurement of 273 living individuals for a period of 2,5 years analysed with both Gompertz's model and a polynomial model; annual growth rings counting for 10 trees; and carbon dating for 4 trees.
On the basis of these observed values of fecundity, survival and growth, we build a matrix model (Lefkovitch 1965, Usher 1966, Favrichon 1995) which reproduces the evolution of class sizes of moabi over a period of time (chapter 6). This demographic model is a management tool which can be used for predictive simulations. On the one hand (chapter 7), we quantify the impact of the present logging practices on moabi population dynamics. Thirty years after first logging, moabi population will recover 27% of the initial number of adult stems and this reconstitution level will be 83% after 300 years.

On the other hand (chapter 8), the matrix model enables to assess the impact of forest management scenarios designed by changing management parameters. We successively simulate (1) the elevation of limit diameter from 100 to 130 and 160 cm, (2) the lenghtening of rotation period from 30 to 60 years; (3) the reduction of impact of logging from 10 to 5% of the ground area and (4) the increase of growth speed due to the implementation of selective thinning. These simulations enables to compare the cumulative timber production yielded over a period of 480 years by the present logging practice *vs* an extremely conservative management scenario (limit diameter = 160 cm; rotation time = 60 years; reduced impact logging; selective thinning). This approach based on tree population dynamics with regard to their natural regeneration logically fits into the classical scheme of natural forest management plans in Central Africa baesd on selection system. It enables quantitative recommandations for long term timber production from these forests to be formulated and, consequently, contributes to their sustainability.

Using Forest Inventory, Remote Sensing, GIS and Growth Models to Monitor Some Sustainability Indicators at Management Level

by
Margarida Tomé[1], Paula Soares[1], José Carlos Paúl[2] and João Moreira[2]
[1]Centro de Estudos Florestais, Department of Forestry, Instituto Superior de Agronomia, Tapada da Ajuda, 1349-017 Lisboa, Portugal
[2]Direcção Geral das Florestas, Av. João Crisóstomo, nº 26-28, 1069-040 Lisboa, Portugal

Abstract

Criteria and indicators for the sustainable management of forests have emerged as a central element of international and domestic forest policy discussions. The Third Ministerial Conference on the Protection of Forests in Europe, that took place in Lisbon, Portugal, in June 1998, adopted the six Pan-European criteria for sustainable forest management. The European countries involved in this conference committed themselves to promote the development and implementation of national criteria and indicators, taking into account specific country conditions, as well as to improve the quality and promote the necessary adaptations of national data collection systems, to fulfill the needs of information to assess sustainable forest management. In Portugal, the definition and implementation of adequate indicators to be used at a practical level in the assessment and monitoring of forest management sustainability at management area level have attracted particular interest since then. The implementation, in practice, of the proposed indicators strongly rely on the availability of forest inventory and mapping of forest resources over time, seldom available in Portugal at the management area level. In this context, a management area is a forest area, subdivided into management units (stands) that is subject to the same management plan. The objective of this poster is to analyse alternative methodologies of up dating forest resources information, including spatially specified information. Data from the continuous forest inventory of the National Forest of Leiria are the basis for this study. The National Forest of Leiria is a state property with an area of 11,000 ha located in the coastal dunes of Marinha Grande in central Portugal. Most of the area (8,700 ha) is made up of pure maritime pine stands managed for high quality timber production. A relative small percentage along the coast is protection forest with the maritime pine as dominant species (2,000 ha) and a little more than 300 ha are devoted to other land uses. The forest is subdivided into 342 management units approximately rectangular that are sometimes subdivided into 2 or more stands. For management purposes, a continuous forest inventory systematically covers the forest since 1979 with an intensity of one 500-1,000 m^2 plot per ha (two plots per ha till 1988) and a periodicity of 5 years. Alternative methodologies of up-dating forest information were simulated on the basis of these data, including the use of traditional forest inventories of different intensity, combined or not with the use of growth models, as well as the use of remotely sensed information and other ancillary data available in a GIS system that is available for the area.

Abstract

In Central Europe there is an increasing trend to convert even-aged to uneven-aged forests, aiming at a *Dauerwald* (permanent forest) forest management system. Under this situation the former age class methods, derived from the "normal forest model", or from the dbh-class models based on de Liocourt's negative exponential dbh-class distribution, are appropriate to both, determine and control sustainable annual cut with respect to age classes or dbh-classes and the way how to best approach the *Dauerwald*-structure of the forests.

Two developments in European forest science help this situation: (i) individual tree growth models have been developed, aiming at the substitution of classical yield tables, and (ii) forest inventory designs have shifted to permanent sampling methods in order to more accurately identify changes in forest structures and damage.

This presentation will demonstrate that combining both, permanent inventories based on angle count sampling and the distance independent individual tree growth model PROGNAUS, will enable foresters to choose harvesting strategies, appropriate to achieve both high value sustainable yield and uneven-aged forest structures.

The example presented is a forest management area of 1270 ha, where more than 40 years ago the clear cut system was abandoned and replaced by target diameter harvest. In 1988 permanent plots were established. Sample trees were selected using Bitterlich's angle count method with a basal area factor of 4 m²/ha. The first remeasurement in 1998 served to calibrate the growth model PROGNAUS. With the calibrated model, different harvesting scenarios are calculated for a 40 year period. Stocking volume, dbh- and stem quality distributions are compared .

Abstract

Guidance on the nutrient management requirements to support enhanced productivity goals for new plantations of loblolly pine (*Pinus taeda*) in the southeastern United States or of Douglas-fir (*Pseudotsuga menziesii*) in the northwestern United States is developed. Sustainable forest management with enhanced productivity is needed on commercial forestland as opportunities for timber harvests from public forests declines in the United States. A suite of Excel spreadsheet “models”, derived by simplification of simulation models, is provided at two Internet websites for use by the Forest Industry in their stand management planning. A three-step procedure is designed for use with personal computer systems.

First, the productivity goal for a new plantation is estimated for the specific soil and climate conditions of a field site to be planted with selected planting stock and managed with practices that enhance productivity (e.g., planting density, vegetation control, fertilization, thinning). The target biomass projection for each year of the new plantation is determined from growth and yield models available to the forest company or from the 3PG spreadsheet model calibrated for plantation growth. The 3PG model was developed by Landsberg and Waring (1997, Forest Ecol. and Manage. 95:209-228).

The nutrients required to support the target growth are next estimated with the REMSS spreadsheet model. This code determines nutrient requirements from empirical relationships established from the nutrient content of stems, branches, foliage and roots of the two tree species. These calculations determine the time course of nutrient requirements for the target plantation growth.

In the third step, the soil supply of nutrients for the specific soil and climate characteristics of a selected site is determined with the NuCSS spreadsheet model. Soil data from forest company measurements or from estimates provided from soil databases are used to determine the annual nutrient supply from the soil to the vegetation. The difference between the REMSS vegetation nutrient demand and the NuCSS soil nutrient supply provides guidance on the fertilizer requirements to meet the target productivity. Repeated simulations with the spreadsheet models provide insight on the nutrient management requirements for sustaining enhanced forest productivity through several rotations. The procedures also estimate changes in soil carbon sequestration due to nutrient management. Supplemental features are included at the Internet websites. The nutrient status at a field site may be evaluated prior to planting by foliar vector analysis with the DIAGNOSIS spreadsheet model. This analysis can be made if foliar mass and nutrient data are available from the previous forest stand. Further, the Crystal Ball software may be used with all Excel spreadsheet models for conducting sensitivity and uncertainty analyses. Sensitivity analysis shows the important variables that contribute significantly to the outputs at each step. Sensitive variables need to be accurately determined. However, variability (uncertainty) of soil, climate and vegetation attributes is often large at field sites. If this variability is known, uncertainty analysis may be undertaken with Crystal Ball to estimate plantation nutrient requirements with statistical confidence intervals.

Abstract

There are an expectation of new plantation and regeneration on abandoned agricultural land in Europe. These new plantations should be ecologically stable and sound. The models for regeneration and young stand development are sought as one of the tool to reach the above given goals.

The presented model is based on the IUFRO international stem number experiment for Norway spruce where radical reduction of the number of trees per hectare in the juvenile stage has been done. The experiment was established in 1971 in eight years old spruce thicket originated from planting in regular spacing with density 2 500 trees per hectare. The series consists of five obligatory treatments with two replications. The stand is situated on previously cultivated agricultural land in 5th (spruce-beech) vegetation degree on elevation of 600 m above sea level. The pattern of experiment includes control plot 1 without thinning. All other programmes are based on first heavy thinning (top height 10 m). Thinning regime 2 represents heavy treatment in young age (top height 12.5 and 15 m). The regimes 3 and 4 (fully mechanised selection) are similar treatments planned later when the stands achieve top height 20 and 22.5 m.. Thinning along with treatment 5 (commercial thinning) is to be done only when 80 m^3 of stem wood can be removed on trees with DBH over 12 cm excluded 400 crop trees.

The data set gives detailed information on every tree growth including the stem and crown shape and the position of the tree within the stand. The data are recorded since 1971 and represent high quality long time period for juvenile growth stand. The higher volume of stem wood (474.7 m^3 per hectare) is accumulated (last survey in 1998) in the control stands 1, but total production (together with volume removed by thinning) is the highest on plot 2 (541,1 m^3) as well as the volume of selected trees - 217.5 m^3. Various thinning programmes affected stability of experimental stands in favour of tended stands.

The model could help with the formulation of the growth process of young Spruce stands under very new silviculture regimes which should create the stable stems with low value of stem sliminess coefficient and long and vital crowns. It is expected that these silvicultural regimes could increase the vitality of the stands suffering in Central Europe by the air pollution and other climate stress.

Abstract

Forest management in Malaysia, including in the State of Sabah, has always been carried out by the public sector, viz. the Forestry Department, even though forest harvesting and the processing of forest products is usually managed by the private sector. Semi-governmental organizations also exist which are responsible for managing some areas of forest lands. Concessions are usually given for harvesting as logging concessions after which the responsibility of "management" reverts back to the Forestry Department. In 1997, the Sabah State Government made a major and bold decision to "privatise" forest management in the state by establishing ten Forest Management Units (FMUs), whereby, the private sector is given considerable areas of logged over or currently being logged forests, to be managed over a concession period of 100 years. The FMUs cover an area of about one million hectares or about a third of the land area of Sabah, with each FMU ranging between 60,000 to 160,000 hectares. The FMU Agreement requires the agreement holder to prepare a Forest Management Plan (FMP) within two years after signing the FMU Agreement. The Forestry Department of Sabah sets certain criteria for development of the FMUs, and they must approve the FMP before any developmental activities can be carried out. For the preparation of the FMP, a forest inventory must be carried out to assess the quantity and quality of the standing timber stands while a social survey must also be carried out to assess the status of the communities living within and around the FMUs.

As most of the areas have been logged, some more than once, the FMU owner has no other option but to invest into reforestation and afforestation activities, in order to increase and improve the forest stands. However, as forestry is a long term investment with returns taking considerable periods of time, the FMU owners are faced with raising capital for these purposes. One option considered is to seek approval for developing a small portion of the FMU for agro-forestry and forest plantations, but no decision has yet been made by the authorities. International funding is also an option being examined.

It is too early to make a conclusion on the wisdom of the State in forming the FMUs, but this has offered an excellent opportunity for the private sector to be involved in forest management on a long term basis. It is also the hoped that these FMUs will ultimately be managed on a sustainable basis.

Abstract

Sustainable forest management (SFM) integrates social, economic and environmental factors, and must reflect the goals and outcomes negotiated among those with legitimate interests in forests. The relative weightings given to these factors will vary substantially depending on local circumstances. Thus a working definition of SFM must capture 'local' issues and values and on-going dialogue is needed to refine management objectives and targets over time. Stakeholders must be prepared to state their objectives and preferred outcomes in a transparent manner. Increasingly, communities are demanding a capacity for adaptive forest management based on assessment of the outcomes of forest management activities. The application of Criteria and Indicators (C&I) at appropriate (management unit) scales can assist with measuring such outcomes. Criteria describe the components of sustainability and indicators are being developed to measure aspects of each criterion. Consideration of scale issues is critical to the application of C&I, and this issue was addressed at an international conference in Australia in 1998 organised by IUFRO, CIFOR and FAO. To provide a useful basis for adaptive management, they will generally need to be applied to a sample of representative forest management units (coupes, compartments). Information collected at finer scales often needs to be synthesized or aggregated for interpretation at larger (Regional, State or National) scales. The relevant scale for data collection and interpretation will vary for different forest values (Criteria) and management goals (e.g. soil and water values at the site scale; social values at larger scales). Practical application of C&I requires that the steps of indicator selection, monitoring, and evaluation of trends be addressed as linked processes. Insufficient attention has been paid to monitoring and evaluation, which are critical steps in adaptive forest management.

Establishing clear and shared forest management goals is essential to guiding application of C&I. The goals should be expressed in measurable terms enabling agreed indicators and associated performance measures or targets to be established. Thus forest management plans will reflect expectations, how they will be measured, and how evaluation, review and communication of findings will be conducted. The scientific underpinning for indicator selection, monitoring and evaluation should provide guidance to these decisions.

Monitoring must address spatial and temporal scale issues. A stratification of the forest environment is needed to guide sampling and scaling-up from point measurements where this is required. Risk assessment can be used to guide monitoring of those areas where there is a perceived threat to SFM. The frequency of temporal monitoring should be varied according to the likelihood of important temporal change in the indicator being used. The key point is that monitoring should be thoughtful and strategic if it is to be cost-effective. The science and application of sustainability indicators in forestry is still in its infancy. C&I have the potential to help track temporal change in forest values and to facilitate adaptive management, but expectations need to be kept realistic. Much could be learned from initial efforts to apply a modest 'core-set' of indicators at the forest management unit level. Close linking of research, monitoring and forest management will facilitate progress.

Criteria and Indicators for The Assessment of Sustainability at The Forest Management Unit Level – A Neotropical Perspective

Abstract

The contribution of forestry to GDPs in the neotropics is small, but market trends and extensive natural forests indicate significant potential for sustainable forest management (SFM). The growth of forest certification and a number of C & I development processes demonstrate willingness and capacity to adopt SFM in the region, and a IUFRO Sustainability Task Force Conference/Workshop in Costa Rica reviewed C & I development for SFM in the neotropics in 1999. Public sectors may see the adoption of C & I as an advance, but for the private sector and communities, current concepts of sustainability may lean too far towards environmental rather than financial and economic aspects; all sectors are concerned about the lack of financial incentives for SFM rather than logging or land use change. Arguments for more people-centred approaches to SFM emphasize the lack of participation of certain stakeholders in C & I development and the likely benefits of assessing the sustainability of livelihoods. The technical and scientific basis for C & I for production in natural neotropical forests is well established, but assessment of ecosystem health and integrity in general, and soil, water and biodiversity in particular, continues to require precautionary approaches; indicators for contributions to climate change mitigation, and SFM for plantations, largely remain to be developed. Much more effective information transfer by scientists, research on both socioeconomic and biophysical aspects, the inclusion of sustainability assessment in higher education curricula, progress towards a concept of SFM which is less restrictive to the forest manager – probably based on an explicitly adaptive concept of management – and a more inclusive focus on scale are priorities for C & I development and adoption in the neotropics.

Introduction

The neotropics are one of the environments in which the quest for sustainable forest management (SFM) offers the greatest challenges, and the development and implementation of Criteria and Indicators (C & I) as a tool for "conceptualizing, implementing and evaluating" (Stork *et al*. 1997) SFM may potentially offer the greatest rewards. Challenges arise on all fronts, from the ecological (the complexity of the natural forest coupled with the requirement that forest management conserve biodiversity, for example, or the poverty and swift degradation under inappropriate use of many soils) to the sociocultural and political (continuing demand for forest land for settlement and agricultural use, environmentalist pressure for forest preservation rather than conservation through sustainable management) and economic (the current lack of financial incentives to switch from traditional logging to SFM). Rewards may come, on the other hand, if the development of C & I contributes, as it could, to the fulfillment of the potential for sustainable forest management which the neotropical region possesses. Regarding this potential, de Camino (1999a) points out that while the contribution of forestry activity to gross domestic product (GDP) in the region is currently small, the neotropics retains a large proportion of its natural forest cover, in comparison with tropical Asian and African countries where the capacity of natural forests to supply timber is declining. He adds that the neotropics have large land areas suitable for plantation forestry and proven capacity in the execution of this activity, while the large areas of secondary forest (including that developing on abandoned agricultural land) may be highly productive. Trends in market demand for forest products and awareness of the value of the ecological services provided by the region's forests represent clear opportunities for progress towards SFM (de Camino 1999a).

Progress towards sustainability is stepwise, of course. One of the first operational steps towards the sustainable management of natural tropical forests for timber production is that from traditional logging methods to reduced-impact logging (RIL). Although RIL may often result in lower costs for timber harvesting, destructive logging is still common in the tropics as a whole (Putz *et al.* in press). That the first step towards SFM so often remains to be taken is one indicator of the amount of work which remains to be done, but should nevertheless be set against what de Camino (1999a) calls the "explosion" of forest certification in the neotropics, with 48 FMUs now certified in Latin America, most of them during 1998 and 1999, and representing 10% of the total forest area certified globally. The neotropics has a clear lead over tropical Africa and Asia in the advance of certification. Although the area certified is minimal in relation to total forest area, this advance is not mere confirmation that forests are being well-managed, as it might be in North America or Scandinavia, but clear evidence of willingness and capacity to progress from non-sustainable forest exploitation towards SFM in the region (de Camino 1999a). Certifiers are only one potential user of C & I, of course, and other evidence of progress in the neotropics is provided by the international, regional and national C & I development processes reviewed in the present paper. From their inception, all these processes have focused on both national and FMU levels. The emphasis on the FMU distinguishes the neotropical processes from, for example, Montreal and Helsinki – possibly in recognition of a more urgent need to "conceptualize, implement and evaluate" SFM at this level in the region.

It was against this background that the IUFRO Task Force for Sustainable Forest Management carried out its second Conference/Workshop on Criteria and Indicators at CATIE, Turrialba, Costa Rica in November 1999[1]. This series of activities was conceived as a response to the growing attention being directed, globally, to all aspects of sustainable forest management, and had the overall objective of involving the scientific community with stakeholders in the development of C & I for SFM. The general objective of the Turrialba event was to contribute to the development of scientifically-based Criteria and Indicators for the sustainable management of primary, secondary and plantation forests in the neotropics, at the FMU level. The present paper summarizes and reviews the proceedings at Turrialba, following the specific objectives of the event: to review the development and implementation of Criteria and Indicators in the Neotropics, to review the state-of-the-art of scientific knowledge of the sociocultural, financial, economic, policy and institutional, technological and biophysical factors which determine the sustainability of the management of neotropical forests; to evaluate the suitability of this scientific knowledge, and the ways in which it is presented and communicated, for the satisfaction of the expectations of stakeholders in the management of forests, to identify priorities for future research and development work on C & I for neotropical forests, and develop proposals for action to be implemented in the short term. Conference proceedings are in preparation and will be available from the authors of the present paper.

The Turrialba Meeting – a Neotropical Perspective on C & I Development

Status of Current Proposals and Processes for C & I Development in the Neotropics

Presentations on current proposals and processes in the neotropics were preceded by an overview of C & I development since UNCED 1992 by Castañeda (1999). Castañeda

[1] IUFRO, CATIE, CIFOR and FAO: International Conference and Workshop on Indicators for Sustainable Forest Management in the Neotropics: formulating multisectorial action in the development and implementation of scientifically-based indicators. Tropical Agricultural Centre for Research and Higher Education (CATIE), Turrialba, Costa Rica, 9-12 November 1999. Sponsored by IUFRO, CATIE, the Centre for International Forestry Research (CIFOR), the Food and Agroculture Organization of the United Nations (FAO), the World Wide Fund for Nature (WWF), GTZ (Germany) and the Directorate for Development Cooperation and Humanitarian Aid (COSUDE), Switzerland.

reminded the audience that the International Tropical Timber Organization (ITTO) began to work on C & I before UNCED. Leigh (1999) presented the ITTO process at Turrialba. The initial ITTO C & I set was endorsed by member countries in 1992, so this process is by far the most advanced of those relevant to the neotropics. ITTO's seven Criteria are valid at both national and FMU levels though the indicators naturally differ between these levels. In common with all the other processes reviewed at the Turrialba conference, except that of Costa Rica (see below), ITTO has not yet developed C & I for plantations, as natural forests were considered to be the main focus of the international debate on forests. The initiation of C & I development by ITTO was a response to pre-UNCED warnings of the lack of progress towards SFM in the tropics, the role of Criteria as an instrument for defining and communicating the characteristics of SFM, emphasized at Turrialba by Prabhu *et al.* (1999), being endorsed by Leigh (1999). The ITTO C & I became a basic tool for the evaluation of progress towards the organization´s "Year 2000 objective" - that significant advances be made towards trade between member countries in timber from sustainably managed forests. The original C & I were nevertheless considered deficient in aspects such as biodiversity and the involvement of communities in forest management. A revision of the ITTO C & I was carried out in 1998 in order to correct these deficiencies, take into account a number of elements of UNCED and other international agreements, ITTO´s own experience, the latest International Tropical Timber Agreement reached in 1994, and results of research and development work on C & I carried out by organizations such as CIFOR and TROPENBOS. Training activities and pilot projects to improve data gathering and reporting have been carried out by ITTO, and operational manuals for the application of the C & I have been developed for both national and FMU levels.

Tarapoto (begun by the signatory countries of the Amazonian Cooperation Treaty in 1995) and the Central American Lepaterique Process (begun in 1997) are more recent initiatives than that of ITTO. Lepaterique drew strongly on Tarapoto in the development of its FMU.-level C & I, as is shown by the its adoption of Tarapoto's four Criteria – Legal, Institutional and Policy Framework, Sustainable Forest Production, Conservation of Forest Ecosystems and Local Socioeconomic Benefits – with only slight differences of wording. Tarapoto is currently concluding a series of national workshops in which the original C & I set is reviewed with respect to its relevance to national circumstances and the abilities of countries to implement the proposal; the ACT countries are also focusing on the development of mechanisms for the systematic gathering and analysis of information for decision-makers (Palma and Toledo 1999). The final national revision of the proposal is that of Brasil, projected to be finished by March 2000. A second regional workshop (Tarapoto II) will then lead into operational testing of the C & I, at which point the Tarapoto Proposal will become the Tarapoto Process (Palma and Toledo 1999). To date, Lepaterique has consisted of one initial regional workshop at which the regional and national C & I were identified, two subregional workshops (one in Honduras and one in Costa Rica) where FMU level C & I were established, and seven national seminars. Currently, the continuation of the Lepaterique Process is assured by the involvement of the Central American Council for Forests and Protected Areas (CCAB-AP) and funding for the activity is currently being generated (Zapata 1999). The lack of participation of Caribbean countries in C & I processes, identified by Castañeda (1999) as one of the relatively few geographical gaps remaining in progress towards sustainability assessment, is beginning to be filled by the linkage of Cuba to Lepaterique, and a strong Cuban delegation was present at Turrialba.

Costa Rica started developing its national standard in 1994, led by the private sector, followed by the academic, public and NGO sectors (the Bolivian case is referred to in the section on stakeholder viewpoints). A first achievement of this process was the laying down by the 1996 Forest Law that all management of natural forests should follow a standard for SFM (Campos and Muller 1999). The same Law also created the National System of Forest Certification and the National Commission of Forest Certification, these being directed at the domestic market in order to complement international certification schemes. C & I based on the FSC Principles and Criteria, and covering primary and secondary forests as well as plantations, became law between 1998 and 1999 after a consultative process involving more than 200 people. The C&I take into account specific characteristics of Costa Rican forestry such as small FMU.s, a highly fragmented landscape and a market for a large proportion of native tree species. The standard established is currently being applied and validated over a three year period. Future work will focus on the international endorsement of the standard, the development of national policies linking certification with the ongoing Environmental Services Payment programme and the creation of domestic markets for certified forest products.

Stakeholder Viewpoints

Stakeholders raised a number of crucial questions regarding the development and adoption of C & I in the neotropics. The President of Costa Rica's Chamber of Forestry reiterated the leadership of that country's private sector in the development of the national standard for SFM, and emphasized that some of the country's certified forest management operations are internationally known (Alfaro 1999). Understanding of the need for sustainability assessment is nevertheless still limited to a small group among the private sector, while the forestry profession has arguably not contributed as it should to the process. Alfaro argued that from the point of view of the private sector, the balance between economic, social and environmental sustainability could easily become inclined unfavourably far towards the latter two aspects, with the last decade seeing the imposition of numerous responsibilities on the forest owner while rights and freedom in the use of the resource have been progressively eroded. Similarly, pressure groups must recognize that progress towards SFM must be gradual. She concluded that these and several other challenges remain to be faced up to if a type of SFM which satisfies the needs and aspirations of private forest owners is to be achieved (Alfaro 1999).

Points of view from rural communities were presented at the Turrialba meeting by representatives of communities involved in the management of natural forests in Guatemala and Honduras. Cortave (1999) and Castro Pérez (1999) spoke on the basis of experience in the management of community forest concessions in Guatemala's Petén Department, which contains a significant proportion of Mesoamerica's remaining forest. These communities are well organized with respect to forest management – ACOFOP unites 30 communities involved in forest management in the Maya Biosphere Reserve in the northern Petén (Cortave 1999) while an association of community members involved in forestry has formed around each concession, such as that of La Pasadita (Castro Pérez 1999). The two community representatives expressed similar concepts of sustainability in forest management, referring to the satisfaction of the needs of present and future generations, through the generation of satisfactory levels of income by activities with which a majority of the community are in agreement. As indicators that the forest is being well-managed the communities take the maintenance of forest cover and productivity, the harvesting of both timber and traditional non-timber products with low impact and minimum wastage, and the continuing disposition of community members to participate in the work (Cortave 1999, Castro Pérez 1999). Five community concessions are currently certified, including La Pasadita. The two speakers reported that the communities recognize and appreciate the prestige, raised public image and access to new markets brought by certification, while regretting the costs entailed in meeting the certifier's standards – which may mean that timber is sold on the national market at a loss (Castro Pérez 1999) - and questioning aspects such as the requirement that communities with high illiteracy rates carry out monitoring. Illegal timber harvesting outside the concessions is one of a number of factors which affect the sustainability of the concessions, but which are beyond the control of their managers.

Perhaps predictably, the public sector point of view, as presented by Guzmán *et al*. (1999) on the basis of the Bolivian experience, was in general more at ease with sustainability assessment, as currently practised, than in the cases of the private sector and the rural communities. Guzmán *et al*. set their presentation in the framework of Bolivia's new forestry law, promulgated in 1996, which saw the country move from a typical neotropical scenario of "timber mining" with little state control, to an environment in which SFM is firmly on the agenda and in which new actors – private individual forest owners, and communities, for example – have begun to play important roles. The Bolivian government´s forest management norms (equivalent to indicators) set a high standard which has permitted the achievement of voluntary certification by private forest owners, concession operators and rural communities. Guzmán *et al.* (1999) warned, however, that prices and markets for forest products are still not favourable for SFM in Bolivia (see below). Finally, they provided a clear pointer regarding research needs for for further C & I development during the coming years, observing that "due to the scarcity of information on the long-term impacts of harvesting on the structure, composition and biodiversity of the forest, the principles of graduality and precaution established in the forestry law are basic to the assumptions on which forest management is currently founded … many of these assumptions await testing using the information which will be generated by studies in permanent sample plots …".

The forest worker, of course, is a major stakeholder in SFM and has a major contribution to make to the achivement of the goal of SFM. A statement from neotropical forest workers could not be obtained for the Turrialba meeting, though Alfter's (1999) report on work carried out on C & I for working conditions of forest workers in Zimbabwe contained many messages relevant to the neotropics. Alfter pointed out that detailed information on working conditions in forestry is often lacking for developing countries, so that social and specifically worker-related C & I are often poorly developed in international processes. Alfter and colleagues questioned company and worker representatives, and workers themselves, in eight Zimbabwean forestry companies, the questions concerning the core areas, derived from International Labour Organization (ILO) standards, of wages, health and safety, freedom of association, discrimination, child labour and training. Working conditions in eight Zimbabwean forestry companies were found to be heterogeneous, and while national labour laws were generally respected, salaries were found to be low and the safely of the majority of workers was not ensured. Bowling and Fitzpatrick (1998) concluded at a more general level that forest workers are in poorly paid, unstable and unsafe jobs, a situation which is not compatible with SFM. The areas of concern identified by Alfter (1999) and Bowling and Fitzpatrick (1998) urgently require attention if progress towards SFM is to be ensured.

The State-of-the-art of Scientific Knowledge as a Basis for C & I Development for Neotropical Forests

Revisiting the Need for C & I

Prabhu *et al*. (1999) suggested that Turrialba was an appropriate moment to revisit the reasons why C & I are generating so much activity, the ways in which they are being used and how they might contribute to improvements in real-world forest management. They asserted that one of the greatest challenges of C & I development is to reconcile the desirability of simple, practical indicator sets with the fact that forests and their interacting social and economic systems are complex systems, and that to expect simplicity may often be simplistic. C & I, they argued, must seek to address gaps and inadequacies in information and communication systems which arise, among other reasons, due to failure to recognize complexity, and which lead to inadequate management. Adaptive management strategies are required for SFM, based on monitoring and emphasizing the institutionalization of conscious learning; in such a context, sustainability would become a measure of the relationship between forest managers as learners and the complex environments in which they manage, and not an externally defined goal. The application of this approach in the neotropics is a medium-term goal.

Sociocultural, Financial, Economic, Policy and Institutional Aspects

The social and cultural aspects that should be taken into consideration in the formulation of C&I became a central question at the Turrialba conference. Brenes (1999) suggested that the success of forest management is a function of the interpersonal relationships between forest managers (the social system) and between them and the forest ecosystem, as well as the social environment in which SFM takes place. It is particularly important to note that SFM is receiving increasing demands at several scales: global, national and local; different decisions are necessary at each scale if SFM is to succeed. Realising the opportunities and meeting the needs of the rural environment is particularly important if society intends to alleviate poverty as well as maintaining or increasing the benefits of SFM. In this context, the basic social aspects that should be taken into consideration in the formulation of C&I are clear: property/use rights and living conditions of the local people, conditions for forest workers at all levels, participation and control of local people in the formulation of C&I, and crucially, the sharing of costs and benefits among stakeholders. Both Brenes (1999) and Davies (1999, see below) asserted that the priority given to people in C&I development for the neotropics is still insufficient and that much work on this subject remains to be done, a certain conceptual tension being evident between the views of social scientists on the one hand, and foresters and biophysical scientists on the other. This need for further work and perceived lack of balance between disciplines is reflected in other recent papers on social (and economic) C & I, and not only in the tropics; Colfer *et al.* (in press) report, for example, that gaining access to certain sectors of rural or indigenous communities is often difficult in the tropics, while Duinker (2000) comments that the dominance of Canada's national Criteria by ecological concerns seems to represent prevailing moods and the personal and profeesional attitudes of most participants in the C & I – SFM design process.

One of the main issues regarding financial sustainability of SFM in the neotropics is that the activity has been profitable only in a few cases and generally, the financial incentives for conventional logging and land clearance for agriculture continue to be greater than those for SFM (Davies 1999). The driving forces behind this situation are a number of market, policy and institutional "failures" related to the forestry sector – for example, the undervaluation of forest products and services and the lack of policy measures to change this situation. Moreover, the opportunity costs of SFM are also high because of the impact of discounting its net benefits over a long period, in contrast to the short-term profits generated by conventional logging and land clearance for agriculture. This situation has the effect of driving a wedge between the private and the social costs and benefits of good forest management; it is therefore necessary to develop mechanisms that allow for the forest owner, concessionaire or forest user to capture the benefits of SFM. Davies discussed several incentive mechanisms at the national and international level that could help to correct market, policy and institutional failures, including transfer payments (via taxes, trust funds, etc.), market approaches based on public good benefits (environmental services payments[2], certification, etc.), and property rights approaches. The opportunity costs of SFM need to be lowered through the promotion of agricultural intensification and the reduction of rural poverty. Davies pointed out that, in addition, the limited information on financial and economic aspects of SFM in the neotropics has focused on industrial forestry, and that stakeholders whose livelihoods depend on the forest via other types of interaction must be taken into account for progress towards sustainability. In the same vein, he perceived C & I development in the region as a "top-down", technocratic process, with an alarming gap between international/national agendas and local perspectives, stating that there has been little progress in developing C & I that are participatory, inclusive and reflect local realities, and allow for negotiation of trade-offs between rural livelihoods and environmental goals. He asked for greater emphasis on C & I that measure progress towards Sustainable Livelihoods (SL) in general, and poverty alleviation in particular, for stakeholders in forests. Echoing Brenes (1999), he stated that an SL approach would put people, their assets and activities, rather than the forest, at the

[2] The Costa Rican Forest Law (1996), for example, establishes an innovative mechanism where forest owners should be compensated by society for the environmental services these ecosystems provide. These payments are financed by a tax on fossil fuels, hydroelectric companies and carbon offsets sales.

centre of sustainability evaluation; livelihood indicators would have to be negotiated with the people concerned.

The economic aspects of SFM raised by Davies along with his discussion of financial aspects were carried further at the conference by Ammour (1999). The term "sustainable" requires that forest management and C & I take into account principles dealing with efficiency in the use of the forest resource, equity in the distribution of costs and benefits, and ecosystem integrity. Society is demanding that forest management should maintain the flow of several environmental services whose benefits are perceived at global, national or subnational levels, while most of the costs associated with the maintenance of services stay with the forest manager/user. In this respect, several speakers agreed that "internalising the externalities" of SFM should be a priority at the national and international level in order to make it financially profitable (Davies 1999, Ammour 1999, de Camino 1999b). The current lack of mechanisms that allow forest owners and countries to capture the benefits of SFM may mean that the maintenance of extensive forest cover might not be the best strategy, from the social and economic points of view, for neotropical countries.

Although decisions concerning the political, legal and institutional conditions that affect forest management are taken outside the FMU, those decisions play a crucial role in determining the success or failure of SFM. The current world economic model is resulting, in general, in a less favourable environment for SFM (de Camino 1999b), though the effects of policy differ between forest types and countries. As a result of the poor performance of the forestry sector in the past, governments tend to impose restrictive policies that in fact encourage illegal logging, making SFM less competitive. Effective control is therefore a basic condition for SFM, and continues to be absent in many neotropical countries (de Camino 1999b). Other conditions include clear property rights, including forest concessions, a proper structure of tariffs and taxes, and a the definition and implementation of national land use plans that identify forest lands for protection and forest lands for SFM. Forestry law in many neotropical countries continues to show easily identifiable weaknesses such as the reduction of freedom for the forester to implement SFM (restrictive, recipe type regulations), but also some positive trends such as the reduction of burdens for obtaining harvesting permits. De Camino argued that there is a general trend for more policy decisions that affect SFM in the neotropics to be taken outside the forestry sector and even the country or region itself. It was stressed that among favourable conditions for SFM are not only an increase of the control of forest managers over the forests they manage, but also their participation in the policy dialogue; in this respect the importance of efficient organisations of forest managers is evident.

Ecosystem Health and Integrity, Forest Productive Capacity and the Fixation and Storage of Carbon.

The maintenance of the health, condition, integrity and vitality of forest ecosystems frequently appears among Principles and C & I for SFM – for example, Montreal (Criterion 3, Maintenance of Forest Ecosystem Health and Vitality), FSC (Principle 6, "Forest management shall conserve … the integrity of the forest"), ITTO (Criterion 3, Forest Ecosystem Health and Condition) and CIFOR (Principle 2, Maintenance of Ecosystem Integrity). The definition of these concepts is still a matter of debate, however, as Schlichter et al. (1999) emphasized at the Turrialba meeting. This is a value-laden and regionally specific field – for example, any concept relating atmospheric pollution to ecosystem health seems unlikely to be relevant to either the tropical or the southern temperate forests of the Americas (Schlichter *et al*. 1999). Ecosystem integrity, they felt, seems to be a more easily definable and communicable concept then ecosystem health, integrity referring to the maintenance of the wholeness of ecosystems, the interconnections among their components and their self-organizing and complex character. Nevertheless, the establishment of indicators for the assessment of ecosystem integrity requires a certain degree of understanding of the system and the identification of key components and processes. Lack of knowledge of tropical forests therefore requires, provisionally, a precautionary approach to the definition of forest management standards and the assessment of sustainability. Precaution, Schlichter *et al*. warned, may bring opposition from those stakeholders who dislike having their freedom of action limited due to ignorance, while lack of funding for research may mean that provisional measures become permanent. They also warned that ecosystem integrity may depend on factors and processes at scales beyond that of the FMU – while indicators at the level of the FMU may be useful for the purposes of certifiers, then, they may not be giving sufficient information for an accurate assessment of the true sustainability of the management process, which partially depends in the landscape in which the FMU is located. (Schlichter *et al.* 1999).

Aspects of the sustainability of forest production were dealt with at the meeting by Wadsworth (1999), who observed that the Turrialba meeting was an opportune moment to review technical knowledge regarding production in neotropical forests in the light of new demands regarding sustainability. He began by suggesting that the definition of best practice for forest management is a more realistic basis for forest production and conservation than the elusive concept of sustainability. He felt it premature to conclude that no technical problems remain in the management of natural neotropical forests, but set out a number of elements of best practice for their silviculture which have been proven by decades of experience, and which may be used with confidence in the definition of standards and as input and process indicators for sustainability assessment. Selective harvesting of timber does not cause the collapse of lowland tropical moist forest ecosystems, especially but not only when RIL is adopted, due possibly to a large degree of ecological redundancy among the tree species of these forests. Timber productivity is greatest when stand basal areas are maintained between 15 and 25 m^2 ha^{-1} by silvicultural treatment, and may be raised to at least 5 m^3 ha^{-1} yr^{-1}, growth responses to liberation treatment by future crop trees being immediate. Poles (individuals $\geq$ 10 cm dbh) are more important than smaller individuals with respect to the evaluation of future crops, are normally present in sufficient abundance to ensure those crops, and show very low mortality after liberation. Timber harvesting should be integrated with the liberation of the trees which will form the next crop. Wadsworth (1999) finished by echoing previous speakers regarding the need for stakeholders in FMUs to receive the benefits of environmental services, and recommending that monitoring of the ecological response of the forest to management operations is carried out in a context of adaptive management.

Among the environmental services provided by neotropical forests, of course, is their contribution to the mitigation of global climate change through the fixation and storage of carbon. Kanninen and Masera (1999) discussed carbon and forest management at the Turrialba meeting, pointing out that sustainable development is the principal objective of the UN Conference on Climate Change and the Kyoto Protocol. The achievement of SFM is the major contribution which the forestry sector can make to this objective, though conflict between policy measures for climate change mitigation and those for sustainable production should be avoided. The inclusion of indicators related to carbon cycles in C & I sets for sustainability assessment automatically creates new information needs which will have to satisfied by additional research and monitoring (Kanninen and Masera 1999). The basic options for fixation and storage of C through forestry activities are the conservation and increase of forest area and the increase of biomass per unit area, though optimal strategies for a contribution of forestry to climate change mitigation will vary between countries in relation to areas of natural forest, levels of reforestation or afforestation activity and the principle uses to which forests are put. These authors considered the setting of objectives related to climate change mitigation in the management of neotropical forests to be unlikely in the near future, although basic elements of SFM such as RIL, fire control and the reduction of waste during transformation, as well as increased emphasis on long-lived forest products, all make a contribution to such objectives.

Soil and Water Conservation, Biodiversity and Plant-animal Interactions

SFM requires the assessment of soil and water as values in themselves rather than simply as factors which underpin sustainable yield. Lima *et al*. (1999) pointed out that most potential soil and water indicators of sustainability are relatively costly to measure as well as being highly site-specific and spatially and temporally variable, so that investment in research as a basis for the development of appropriate indicators is necessary. A precautionary approach to management must be implemented, they maintained, until valid soil and water indicators are in place. They also emphasized the need to involve stakeholders in discussions related to soil and water because of the importance of these resources to local people and "ongoing complaints" about possible effects of forestry activities on water quality and yield. Lima *et al*. (1999) recommended the adoption of *integrated catchment management* as the organizing concept for the management not only of soil and water resources in FMUs, but also for the maintenance of the capacity of the land and vegetation resources in general to produce goods and services - overall goals related to the sustainability of the catchment and its ecological and hydrological functions include the maintenance of productivity, the maintenance of biological diversity and the maintenance of hydrological processes. They also pointed out the importance of an integrated approach to soil and water management across several spatial scales, at each of which different environmental impacts of human activity on soil and water resources may be identified, each with its corresponding set of causes and possible indicators. The protection of riparian zones is an essential component of sustainability at the "micro" (FMU) scale, for example, and the existence and implementation of measures to achieve this are obvious indicators or verifiers for sustainability. Techniques for the identification of riparian zones must be refined, however, as these may not correspond with the areas which current forestry legislation requires to be protected, which may be defined simply on the basis of distance from water resources, as in the cases of Brazil and Costa Rica, for example. Lima *et al*. (1999) recommend that in general, monitoring of catchment parameters be carried out to provide feedback to management plans and codes of practice in an adaptive management context.

Besides the references to biodiversity conservation in the papers by Schlichter *et al*., Wadsworth and Lima *et al.,* two papers at the Turrialba meeting analysed this subject directly - those by Finegan (1999) and Guariguata (1999). Finegan reminded the meeting that although there is certainly no unanimity on the subject, a broad consensus exists that well-managed tropical forests can contribute significantly to the conservation of biodiversity, while the conservation of biodiversity is considered to be one of the factors which underpins the sustainability of forest management. Finegan's review of C & I sets relevant to the neotropics (he took in ITTO, Tarapoto, Lepaterique, Costa Rica and Bolivia, as well as FSC) emphasized the universal adoption of a precautionary approach, centred around input and process indicators. Indicators under this precautionary approach include the maintenance of strictly protected reserves within the FMU, required by FSC to cover each forest type found in the FMU – an extension of the so-called "coarse filter" approach to conservation which could usefully underlie all planning for conservation in FMUs. All the sets reviewed propose variations on the theme of identification and protection of "rare, threatened and endangered species". Finegan observed that this type of criterion and associated indicators might be better framed in terms of the current IUCN threat categories (among which the highly ambiguous term "rare" no longer appears); lists of fauna in different threat categories exist for many neotropical countries, though forest managers are still faced with the task of determining which species are likely to be present in a given FMU, and measures for their protection are unlikely to exist beyond control of hunting and habitat conservation. Finally, Finegan commented that the incompleteness of knowledge of tropical forest biodiversity is matched by a lack of techniques for its monitoring in managed forests in an adaptive management context. Some relatively easy-to-assess outcome indicators are relevant to biodiversity conservation in any forest type, however (many forest structural characteristics, for example) while others may give clear signals regarding changes in tropical forest biodiversity at different spatial and temporal scales (the composition and abundance of diurnal Lepidoptera communities, the guild composition of tree stands); preliminary approaches to monitoring should be developed and tested.

Within the general context of biodiversity conservation and the sustainability of forest management, Guariguata (1999) provided an invaluable perspective regarding the importance of plant-animal interactions in natural neotropical forests. The high levels of outbreeding shown by tropical tree species and the low densities of the populations of most of them, for example, render the presence of pollinators capable of covering hundreds of metres between conspecific trees vital to population viability. If forest area or the abundance of pollinators are significantly reduced, the size of seed crops per tree, or seed percent viability, may decline (Guariguata 1999). Besides being pollinated by animal vectors, the seeds of a majority of the tree species of neotropical moist forests are dispersed by animals and birds, and strong evidence indicates that the probability of seedling survival often increases disproportionately with distance from conspecific trees. Guariguata pointed out that reductions in population sizes - due to hunting or fragmentation, or both - of the medium-sized rodents which are key players in the dispersal of relatively large seeds can severely impact the seed dispersal process, with particularly important consequences for sustainability in forests such as those of the Guianas in which up to 50% of the tree species may be large-seeded and dispersed by such rodents. Finally, Guariguata cited evidence that grazing of seedlings and saplings by vertebrate herbivores, by reducing the likelihood that certain tree species come to dominate the forest, also plays an important role in the determination of forest composition - again, the absence of these animals may bring about changes in forest characteristics. Among indicators which would be appropriate for the assessment of animal populations and the tree demographic processes they contribute to are measures for the control of hunting in the FMU, changes in the abundance of key elements of the fauna as determined by simple monitoring techniques, seed removal rates, changes in the abundance and spatial distribution of reproductively mature trees and regeneration, and the existence and implementation of measures to restrict harvesting impacts on vertebrate-dependent tree populations in small FMUs; some but not all of these indicators are covered by CIFOR (1999), but they are generally absent from other neotropial C & I sets.

Discussion, Conclusions and Recommendations

The following discussion, conclusions and recommendations are based on largely on the resolutions of the conference/workshop, which synthesize the discussions held during the event and will be published in the proceedings. The conference delegates recognized that C & I are valid and useful tools for sustainability assessment and that significant progress has been made in their development for the management of natural tropical forests. Considerable work remains to be done, however. National testing and validation of existing generic C & I sets is one major priority, while the C & I sets often show internal inconsistencies and contradictions (de Camino 1999a) and FMU-level C & I for neotropical forest plantations have only been explicitly addressed by Costa Rica. It was also recognized that while the scientific basis of C & I is well-established in areas such as harvesting and silviculture for timber production, research is required on aspects such as soil, water and biodiversity, though the state-of-the-art papers on these subjects indicated scope for strengthening C & I using existing knowledge. The delegates also considered that C & I for sociocultural aspects require reassessment, as many stakeholders do not appear to have participated in the development of those which exist, and sustainability assessments can not therefore be expected to cover the interests of those stakeholders. The delegates felt very strongly that the effectiveness of the neotropical C & I process is severely limited by a lack of effective communication, on the part of researchers, of the existing scientific information which forms, or should form, the basis for C & I development. This viewpoint was expressed with respect to all the scientific disciplines represented in the conference programme, and a concerted effort for effective information-sharing, with the use of existing networks, or the creation of new ones, was recommended as one means of overcoming this major problem. Practical guides for the application of existing C & I were identified as a particular necessity. Regional and national institutions were called upon to assume leadership in work directed towards the resolution of these and other problems. Horizontal cooperation between C & I development processes may also be useful, and institutions offering intermediate or higher education in forest management and related fields were recommended to put sustainability assessment and its scientific basis firmly on their curricula. The delegates felt, in addition, that state forest services should play more active roles in the promotion and implementation of C & I as one of the legal requirements for forest management, while the absence from the Turrialba event of representatives of certifiers, although representatives of managers of certified FMUs *were* present, was regretted. Besides debate on the need for a more people-centred approach to sustainability assessment, the implications of the precautionary approach to biophysical aspects was also discussed. On the one hand, support was voiced for the implementation of C & I within a precautionary framework for crucial but still poorly known aspects such as soil, water and biodiversity, while on the other, there were strong calls for progress towards less restrictive and inflexible concepts of ecological sustainability which will give the forest manager greater freedom of action and pose less of a perceived threat to financial and economic sustainability (e.g. Alfaro 1999, de Camino 1999a,b). The use of existing monitoring techniques, and the development of new ones where necessary (Wadsworth 1999, Lima *et al*. 1999, Finegan 1999), permitting movement towards C & I-based adaptive management systems which "promote active and conscious institutional learning" (Prabhu *et al.* 1999) would contribute to the resolution of this tension and could be set as a medium-term objective. Appropriate institutional arrangements for the execution of monitoring are badly needed, however – this responsibility should not simply be assigned to the operators of each individual FMU. Finally, both invited speakers (de Camino 1999a,b, Prabhu *et al*. 1999, Lima *et al.* 1999, Finegan 1999) and conference delegates referred to the artificial and undesirable gaps currently existing in the concept and the focus of C & I development. The division between national and FMU levels, for example, leaves open intermediate spatial scales at which land use planning could contribute to sustainability at the FMU level, but at which managers of FMUs are unable to exert any direct influence.

Abstract

In this paper, we report on the main conclusions elaborated through presentations and discussions at the Nancy meeting, March 22nd – March 25th. We recall that Criteria and Indicators are at this fringe between so called hard science and social science. C & I are as well a tool for reaching a consensus as a set of guideline for making decisions, i.e. C&I reflect as well the state of consensus/conflict with a society. We then recall some issues which have emerged as crucial, such as scaling and harmonization. Some hints have been proposed on how to rely C&I and biodiversity, as biodiversity may be taken as a surrogate for sustainability. Some emphasis is put on the necessity to develop the usefulness of C&I as decision making tools. Finally, an hierarchical framework derived by Tropenbos is presented in the setting of harmonization.

Keywords : Criteria and indicators – Sustainable forest management – Tropenbos hierarchical framework

Introduction

Forest management is a very old and universal human activity as most of societies have set up rules for managing the forested areas belonging either to individuals or to communities, including the state. Despite this long tradition, forest managers have experienced in the past decades, and are still driven by a main shift in paradigm. This shift refers to the notion that sustainable yield is not the same as sustainable forest management.

Some European historical texts from the Middle Ages convey to us the rules according to which forest management was driven at those times. The long term sustainability of the forests was the first, among other, of the goals, leading to the rule that benefit from forest must rely on harvesting the interest, and not the capital, of the forest stock. Such a concern was explicit in many societies, all over the continents and the times, as regulating the access to resources is a corner stone of social organisation. Management practises were put on a scientific basis and within a compelling legal framework in several European countries by the beginning of the 19th century. The necessity of putting long term sustainability of forests cover as a compelling rule was at the basis of this system. Whether the management has been successful or not is another story, but this goal was firmly maintained. This period has lasted in Europe until the late sixties. The widely accepted assumption was that sustained yield is a surrogate for sustainability of all functions fulfilled by the forests. In the seventies, due mainly to the development of plantation forests, some question rose on the scientific relevance of such an assertion : there may be some conflict between sustainability of biological diversity, or recreation values, and sustained yield.

Simultaneously a tremendous extension of the functions is recognised to forest cover since the early seventies, which means an equally tremendous increase of requirements to be accommodated by forest managers . This diversification has lead to many conceptual developments, such as multipurpose forest management, where the diversity and equally relevance of needs as expressed by different stakeholders was explicitly recognised and taken into account in management tools. However, such an increase and diversification of requirements goes often with an increase of conflicts regarding the management of the forested areas.

In any country, whether in Boreal, Temperate or Tropical zone, whether developed or developing, such a change is obvious. Any reader can compare the state of forest affairs in his/her own country in the early seventies with current state. Functions recognised to forest areas are more diverse, stakeholders represent more diverse parts of the society, sometimes close to or sometimes far from the area where the forest is located, and conflicts for forest use are more widespread.

The need for regulating the exchanges between stakeholders, and the access to forest resources, has never been as acute as nowadays. There is a widespread consensus on the necessity for forest management to preserve the sustainability of all functions and values as recognised by stakeholders, but the consensus is not as widespread on how to implement in management practises this request for sustainability. Moreover, some requirements may be conflicting. One tool is currently developed for this purpose : to derive Criteria and Indicators for Sustainable Forest Management from current scientific knowledge.

Main Issues for C & I for SFM at FMU Level

What are C & I about

Most of the forest values have been allocated classically into a three fold framework which is

Productive values : wood quantity and quality, forested areas, etc. …

Biological values : conservation of local flora and fauna, …

Social benefit : recreation, suburban forests, etc …

Most of these functions were recognised at the forest management unit level.

Recently, some new values have emerged as equally important versus the former :

Extension of productive values to non wood products

Preservation of ecological functions at a landscape level, such as hydrological cycles, biochemical cycles, etc. …

Preservation of ecological functions at a global level, such as carbon sequestration

Preservation of biological diversity

Preservation of cultural and spiritual values

As mentioned above, it was felt some decades ago that the sustainability of the sole forest cover would guarantee the sustainability of all other functions. As these functions have widely evolved and are far more diversified, the questions arises to know whether this assumption is still valid. The current consensus is a sort of precautionary principle : it is not the case. However, the scientific basis for such an assumption is still a matter of debate.

Then, forest managers are faced with the obligation of proving that their management practises will not damage any of the functions or values of the forest. One objective of deriving Criteria and Indicators for Sustainable Forest Management at the Forest Management Unit Level on a sound scientific basis is to provide forest managers with reliable tools to evaluate and monitor sustainability of forest values as an outcome of forest management and protection practises. As such, C & I should be distinguished from certification issue, which deals with comparing forest management activities/progress for different forests at the same time, with accepted upon standards. There exist links between both, as certification can use C & I for deriving standards.

Scaling

One obvious difficulty is that the values are assessed at different scales : the forest management unit, the landscape, the ecoregion, and even the global scale. Assessing C&I at the FMU level can be an example of the motto ‘think globally, act locally’. It should be kept in mind that such a scaling is far from being either obvious or even relying on a firm and steady scientific basis. This is an immense, complex area where suitable research is highly needed. It is one objective of the Iufro task Force to share experience between stakeholder and scientists to evaluate the feasibility of such a programme.

Indeed, the necessity to deal with different scales is widely accepted even if recognised as difficult. Two levels are identified, National and FMU, and the scale of FMU is variable within and between countries. A new framework of multiscale approach, with common vocabulary, is suitable. An example for progress into this direction is presented in part two of this paper. There is a consensus on the existence of mutual interactions between levels, both as adaptation or influences. Relevant scale may be dissimilar between criteria, which makes the integration more difficult. Moreover, some criteria are better understood within the framework of nested scales.

Harmonization

There is however not yet a commonly agreed or shared definition of what a Criteria and Indicator for Sustainable Forest Management is, or should be, and we do not suggest any. Although some progress has been made and some clarification has emerged, such as the one presented in part two of this paper, discussions are still open as, sometimes, several viewpoints are presented in different arenas or publications, and it is too early to agree for an harmonisation of definitions which is a matter of long term research, and negotiation. Indeed, definitions are available, common definitions are requested but not yet operational.

The issue of sharing a common vocabulary is crucial. It is natural to expect a consensus on vocabulary for easing discussions and reaching a consensus. However, the case might be more complex, and it can be said that the reality of a common vocabulary is an outcome of a consensus on the ideas and concepts. In other words, it is impossible to separate the negotiations and discussions for harmonisation upon ideas and concepts from the one for harmonisation of vocabulary.

The level of reachable harmonisation is variable. Within the hierarchical framework of Principles, Criteria and Indicators presented in part two, it is commonly accepted that harmonisation decreases from principles to indicators. Principles are accepted as intangible whereas indicators are most commonly adapted locally. The situation of criteria is more unbalanced. Criteria are getting harmonised at national level, and such an harmonisation is still questionable for criteria at local level.

C & I Between Social and Biological Disciplines

Among the different, and overlapping viewpoints, we can mention that C&I for SFM are linked with the tradeoffs between current and future generation needs and protection and utilisation of forested lands. This is an example of the diversity of approaches related to C&I for SFM, which may be discouraging. However, two main streamlines can be recognised on a scientifically basis :

- One favouring ecosystemic approach, originating from ecological and biophysical sciences, where the main question is : how does the (biological) system work ?
- One favouring an approach with social science: how do human affairs interact with the functioning of the forest ecosystem ?

C & I and Biodiversity

Recently, a new streamline has developed on the link between sustainability issues and biological diversity issues. As there is a wide consensus that sustainable yield cannot be a surrogate for sustainability of the system as a whole, such an issue for diversity has not been settled. There is a widely spread temptation to use biological diversity as a surrogate for sustainability, and a danger that this assumption is not scientifically evaluated. However, it becomes clearer and clearer that biodiversity is not a surrogate for sustainability. This paradigm is linked with precautionary principle in conservation biology, and there exist some cases where society needs are not automatically fulfilled with highly diverse forests.

Another point is that there should be a differentiation between biodiversity and naturalness. For example, biodiversity can be conserved by management practices whereas naturalness cannot unless by protection measures.

Transfer into Decision Making

There is an opportunity for developing planning and management tools from C & I. They can be quantitative or qualitative, and the negotiation between stakeholders for agreeing on C & I and their scoring is part of the process.

Even if some progress is still needed, a suitable and reachable objective is to have sets of criteria and indicators to evaluate how the management practises reach social, ecological and biophysical goals for sustainability. As such, criteria and indicators are one of the means to monitor and evaluate forest management, and should be associated with benchmarks for rating and scoring. Such a process should rely on sound scientific basis but, more than a lack of knowledge, there is a lack of communication between scientific knowledge and tools for decision-making. For example, there is a need to convert scientific knowledge into valid operational techniques, without loosing genuine scientific information.

There exist several ways to implement this process:

- to develop a network of model forests, on which international co-operation should be enhanced, and for which stakeholders should be associated ;
- modelling and data analysis, keeping in mind that deriving C & I is not an optimisation process, and that black box models should be avoided.

Whatever the choice, there is an opportunity to develop international co-operation on data, measurements and validation on case studies and model forests.

C & I as a Bridge Between Science and Policy

The process of proposing C & I for SFM has started, in its actual form, in the beginning of the 90's at a intergovernmental level. Several processes are going on, and one major issue in SFM debate is to evaluate the state of the art for C & I at the FMU level, particularly in relation with the C & I as agreed at the national level by ongoing processes (ITTO, Helsinki, Montreal, Tarapoto, etc).

The debate on C & I for SFM has a very specific niche as far as relationships between science and policy is concerned. The demand for developing, adopting and assessing C & I on a firm scientific basis is high. Is it however sensible to expect such an achievement in the coming years ? There exist some disciplinary approaches, such as growth modelling, site evaluation, tree breeding, etc., which rely on a firm, well established and accepted scientific basis. This is not the case for C & I for SFM. For example, there is even a difficulty in assessing a commonly accepted definition. One reason may be that C & I are part of the debate within and between societies on the regulation of the access to forest benefit and resources. Those regulations vary widely between countries and societies, and every society may select the C&I adapted to its own regulation process. If true, this means there will be accepted, scientifically based C & I only when access to forest resources will be smoothly regulated by negotiation. Indeed, agreement on C & I for SFM means an agreement between stakeholders on how and why to manage or protect a forest, and failure of an agreement means there still exist a given level of conflict. Technical C & I will not solve the conflicts : this is a matter of negotiation. Technical C & I will be commonly accepted when the negotiation has ended successfully.

An Example : The Hierarchical Framework Derived by Tropenbos

In 1997, Tropenbos published the document 'Hierarchical Framework for the Formulation of Sustainable Forest Management Standards'. This publication is intended to serve as a manual for participants in any process aimed at developing a consistent standard for sustainable forest management SFM), at national and forest management unit (FMU) level. A standard is defined as a set of parameters on different hierarchical levels: principles, criteria and indicators (P, C, I).

Rationale

Existing sets of P, C, and I (C & I) for monitoring, reporting and assessment at the regional, national and Forest Management Unit (FMU) level contain a wide range of interpretations of terms. Confusion persists in the use of terms and the perception of the concept of C & I. Discussions and communication suffer from these deficiencies and comparisons between sets are difficult to make leaving room for not easily to recognise differences in requirements as to sustainable forest management. The call from IPF for developing a global consensus on concepts, terms and definitions related to SFM is still valid. The merit of achieving such consensus became apparent again in the discussion during the C & I conference in Nancy.

Communication and indeed understanding of sustainable forest management could benefit tremendously if we were more considerate in using universally accepted terms and if we would build in more consistency in the design of C & I sets. It would be helpful for effective communication if parties would use the same name for any particular thing, aspect or phenomenon. It is for instance very confusing if we discover that the word verifier used in the CIFOR template points to parameters that in fact are indicators by their nature and character. In this example confusion could have been avoided if the term verifier would have been used to refer to the more generally accepted meaning notably “source of information”.

Even more serious than mixing up terms is the fact that people participating in the development of sets of C & I have different perceptions and interpretations of the entire meaning of the concept of P, C & I.. We should ask our selves the question what do we try to establish, organise and control with a framework of P, C & I..

The purpose is to establish a **Transparent systematical relationship** between:

: Agreed (long-term) goals for the values (functions or services) of the forests.

: Implications of the realisation of these goals for the size and condition of the forests and for the interacting social system.

: Elements to direct management measures and/or to assess compliance with the required condition of the forests and the interacting social system or, in some cases directly with the formulated goals.

This systematical approach shows the translation from goals formulated in societal values to relevant forest management aspects in terms of forest cover, forest condition and condition of groups of the civil society. It is necessary to follow the systematical scheme closely in order to keep the discussion at the right level and to design a set of C & I that is effectively serving the purposes that it was meant to be designed for.

Basic Starting Points of the Hierarchical Framework

The proposed hierarchical framework has been developed on the basis of several starting points and considerations:

Types of parameters

In the framework a clear distinction is made between different types of parameters:

1. Input: an object, capacity, or intention, put in, or taken in, or operated on by any human driven process;
2. Process: the management process or a component thereof, or other human action, describing human activities but not the result of the activity;
3. Outcome: the actual or desired result of a management process which describes the state or capacity of the ecosystem, the state of a physical component or the state of the related social system or its components.

Vertical and horizontal consistency

The framework prescribes that a standard should be horizontally consistent, meaning that parameters at one hierarchical level (P, C or I) do not have any implicit or explicit overlap or duplication, while at the same time all aspects are covered. It should also be vertically consistent meaning that all the parameters are placed at the right hierarchical level, expressed in correct terms, and linked to the appropriate parameter on the higher hierarchical level.

Clear description of functions and characteristics of each hierarchical level

For each hierarchical level an extensive definition is formulated based on the proposed function and characteristics of the level. Besides, important points of attention for each level are given. Summarised:

* **Sustainable forest management (SFM):** The level of SFM represents the overall goal in the P, C & I hierarchy.
* **Principles:** 'A principle is a fundamental law or rule, serving as a basis for reasoning and action. Principles have the character of an objective or attitude concerning the function of the forest ecosystem or concerning a relevant aspect of the social system that interacts with the ecosystem'. The level of principles makes the meaning of SFM more explicit and comprehensive. It splits the goal into separate components which together fully cover the meaning of SFM. A principle should refer to a function of the forest (economic, ecological or social) or to an attitude to be held by society. Measures and prerequisites should not be formulated as principles.
* **Criteria:** 'A criterion is a state or aspect of the dynamic process of the forest ecosystem, which should be in place as a result of adherence to a principle. The way criteria are formulated should give rise to a verdict on the degree of compliance in an actual situation'. The function of the level of criteria is to show compliance with a principle in relation to the forest ecosystem, or related social system. Criteria should be formulated in terms of outcome. The combined set of criteria should cover the full scope of all the principles.

  * **Indicators:** 'An indicator is a quantitative or qualitative parameter which can be assessed in relation to a criterion., or occasionnally directly to a principle. It describes in an objectively verifiable and unambiguous way features of the ecosystem or the related social system, or it describes elements of the prevailing policy and management conditions and human driven processes indicative of the state of the eco- and social system'. Indicators attach assessable parameters to criteria. Therefore, they should be formulated in an objectively verifiable way. Quantitative indicators are preferred above qualitative indicators. Indicators can directly describe features of the ecosystem or social system which should be achieved (outcome indicators) but they can also indirectly describe human processes or input necessary to achieve SFM (process or input indicators). In practice, it appears that quite some process and input indicators are not necessarily indicative for just one criterion (e.g. 'there is a management plan'). In view of this reality a distinction is made between specific input and process indicators, and general input and process indicators. While maintaining the concept of vertical consistency specific indicators, including the outcome indicators are placed under the criterion they refer to. The general input and process indicators are put in a bag stretching along the full gammit of criteria.

  The actual assessment of management performance should be based on a comparison between the actual value of the indicator and its reference value (norm) [s]. By comparing the norm with the actual measured value, the result demonstrates by what degree management fulfils a criterion and complies with a principle.

* **Verifiers:**'A verifier is the source of information for the indicator or for the reference value for the indicator'. The quality of the verifier determines the credibility of the indicator value

Enabling Conditions

Following the logic and the consistency of the above described coherence between P, C & I it is felt that a certain group of parameters, referring to institutional and economic requirements, calls for a distinct position. This group of parameters is not deducted from the principles, but constitutes rather the enabling environment in which SFM may be achieved. This group of parameters will be elaborated at the level of indicators under the umbrella of enabling conditions. The common denominator, enabling conditions, will be placed at the level of criteria.

Conclusions

With the proposed hierarchical framework, Tropenbos aims to contribute to the development of globally comparable (not necessarily harmonised) and individually consistent standards. Some aspects however, need further attention and thinking. Examples are the linkage between standards for the national level and the FMU level and the distinction between criteria and outcome indicators. Tropenbos hopes that others may join to further develop the ideas for a hierarchical framework as described in this document.

Abstract

Malaysia, like many tropical countries worldwide, is faced with the serious problem of forest land degradation. Due primarily to agricultural development, including shifting cultivation, the forests of Malaysia have been seriously depleted and degraded. Assuming that a third of every hectare harvested would become degraded (including those areas currently under active logging, the previously mined land and those areas under shifting cultivation in Sarawak and Sabah), the extent of degraded forest land in the country will be over 1.5 million hectares. Hence, to sustain the economic, environmental, social and cultural benefits derived from the forests there is a need to repair the damage resulting from deforestation. Consequently, previous efforts towards this direction had involved restoration, rehabilitation and reclamation. Forest rehabilitation is expected to improve, if not to restore, the natural productivity as well as the environmental and aesthetic values of the degraded forested land. Traditional approach of forest rehabilitation usually involve planting a mixture of agronomic crops, particularly legumes and trees with erosion control capabilities, as the primary objective. Recent rehabilitation projects though have more demanding objectives, such as re-establishing a commercial forest. Most of the previous rehabilitation projects that were carried out in Malaysia primarily involved the planting of exotic species. However, the planting of indigenous tree species using different techniques has been recently emphasised. By using these different techniques of forest rehabilitation, it is expected that landscape rehabilitation technology can be applied to different land use and types of forests including urban areas, degraded coastal and hill forest and mangrove forest. Hence, to promote the role of forestry in landscape rehabilitation, forest rehabilitation issues must also be given appropriate recognition in policy and legislation by applying the principles through the recommended actions. This paper discusses the current status of reforestation in the country and the main techniques used in forest rehabilitation, such as line planting, gap planting, and enrichment planting. Moreover, in as much as policy matters significantly affect the success or failure of the rehabilitation/reforestation projects, the latter part of the paper includes issues related to government policy on forestry.

Keywords: Malaysia, Forest rehabilitation, Gap planting, Line planting, Forest policy

Introduction

Malaysia has a total land area of 32.9 million ha (approximately 330, 000 square kilometres) with 13.2 million ha in Peninsular Malaysia comprising 11 states and the Federal Territory of Kuala Lumpur, 7.4 million ha in Sabah and the Federal Territory of Labuan, and 12.3 million ha in Sarawak (Anonymous 1997). Its climate is equatorial with year round high temperature and high rainfall during the Northeast Monsoon from Oct/Nov to Feb/Mar. Humidity is always high and ranges from 70 to 98 percent.

As of 1998, its population was 22.23 million and the growth rate for the periods 1996-1998 was 2 percent. The 1998 estimates showed that Malaysia has almost 80 percent of its population staying in Peninsular Malaysia. Malaysia is categorised by the World Bank as an upper-middle income country. Its economy is one of the fastest growing in South East Asia. Foreign investment in the country is high and has made Malaysia the second most open market after Singapore. Among its trading partners are United States of America, Japan, Singapore and Taiwan (Anonymous 1996).

The Forests of Malaysia

Malaysia is fortunate to be endowed with extensive areas of valuable natural tropical rainforests. Malaysia has 20.1 million ha of the 1.7 billion ha of the world's rich tropical rainforests (Hammond 1996, Nik Muhamad & Mohd. Zaki 1996). Throughout the years, however, this resource has decreased mainly due to conversion of forest areas to other land use.

In 1998, 78 percent of the total forested land in Peninsular Malaysia is mainly in the states of Pahang, Perak, Kelantan and Terengganu (Tables 1 and 2). Tables 3 and 4 present the total forested area in the states of Sarawak and Sabah.

Status of Degraded Land in Malaysia

Over-exploitation of the forests through harvesting, degazettement of forest areas and human encroachment primarily caused forest land degradation in Malaysia (Nik Muhamad & Mohd Zaki 1996, Nik Muhamad 1995, Weidelt 1993).

One adverse impact of harvesting is land degradation, which is reflected by increased soil compaction and erosion, decrease in soil fertility and biological degradation of the soil. To counter this, the government has introduced replanting, rehabilitation and reclamation programmes.

Causes of Forest Land Degradation

The Malaysian forests are destroyed in two ways; natural and man-made. However, the effect of the former is considered insignificant as compared to that of the latter (Nik Muhamad & Mohd Zaki 1996, Nik Muhamad 1995). Among the human-related causes are the following:

Table 1. Forested Area by State in Peninsular Malaysia, 1998 (ha)

- Excessive harvesting/commercial logging - In Peninsular Malaysia, the total logged area ranged between 55 and 48 percent of the total forested area (excluding wildlife reserve) in the PRF and state land between 1994 - 1998, (Table 5 and 6). Moreover, in 1998 a total of 114, 998 ha is opened for logging (Table 7).
- Commercial agriculture - forests are removed due to expansion of tree crop plantations (rubber and oil palm) which appear to be the sustainable uses of converted forest land.
- Shifting cultivation - In Sarawak, the area affected by shifting cultivation has increased from 2.25 million ha in 1960 to

3.33 million ha in 1985 due to shifting cultivation.

- Development projects - Bakun hydroelectric dam has inundated 69, 640 ha of forests for the reservoir.
- Mining - Lim *et al* (1981) reported that tin mining operations have produced some 250, 000 ha of barren, desert-like environment, a figure which is nearly one percent of the total land area of Peninsular Malaysia.
- Degazettement - Between 1986 and 1994, some 144, 406 ha of Permanent Forest Estates (PFE) equivalent to the size of Malacca have been degazetted by various State governments despite the 800,000 ha outside the boundaries of the PFE available for development.

Concept of Rehabilitation

The current rate of tropical deforestation and its environmental threat is apparently echoing the urgent call for an improved management of the forest recovery process, particularly, reforestation (Wilson 1988).

In order to overcome further degradation and hasten the recovery process, Malaysia has taken all of the three approaches identified by Lamb (1994). The first approach is **restoration** that attempts to recreate the original forest ecosystem by putting back the original composition of plants and animals that were once occupying the site. Second is **rehabilitation** which uses some of the original species and, where necessary, exotic species to reforest the site. This approach does not attempt to recreate the original ecosystem but to return the forest to a stable and productive condition by using some of the original species. Third is **reclamation** that uses one or more exotic species to achieve stability and productivity. This approach does not attempt to restore any of the original biodiversity at the site.

In as much as rehabilitation is a human-facilitated recovery process, the right forms and amount of input such as appropriate species, canopy/gap opening and silvicultural treatments, are necessary to enhance the process. Moreover, these silvicultural treatments or prescriptions for forest rehabilitation must consider the following; conservation of biodiversity, conservation of wildlife resource and its food source, accessibility and terrain of rehabilitation sites, and economics of the operations (Chai & Lee 1992, Lim 1992, Johns 1997).

The objective of rehabilitation may be the restoration of the degraded forest to its original pristine state in terms of its structure and function or, rehabilitation to a state that is similar in terms of its productivity or, to a state where there is some vegetative cover - that is, the establishment of industrial wood plantations and/or establishment of forests with as much natural structure and functions as possible (Lim 1992). The approach to take and the cost of rehabilitation will differ between different objectives.

Certain factors are considered important in the success or failure of the reforestation project (Walters 1997, Lamb & Lawrence 1993, Baguinon 1992, Lim 1992, Gomez-Pompa & Burley 1991, Oldeman & van Dijk 1991). These include:

Economic factors - factors involving the cost of rehabilitation

a) Finances - Often times, fast-growing tree species are chosen so that the return on the outlay can be recovered rapidly.
b) Manpower and management considerations and scale of operations
c) Land availability

Ecological factors – factors involving the natural environment and the plant species related to the natural regeneration of the forests. These factors address the problem of species-site compatibility.

a) Systems considerations – refers to the conditions of the site (topography, soils, rainfall, climatic regimes and vegetative cover) as these factors affect the survival and growth performance of the plants used in the rehabilitation scheme. This also involves the ecological succession patterns of the area.
b) Species considerations – refer to the growth rates, life span, seed supply, ecophysiological requirements for germination and growth, and tolerances and adaptability of the species to be used. This requires a thorough knowledge of the

indigenous flora and their seed production and propagation systems.

The choice of species is directly affected by the objective of the rehabilitation program. A restorative program requires greater number of species than a rehabilitative one. A complex system requires a greater understanding of more species, their interactions as well as a longer time to achieve some form of stability, equilibrium and an ability to sustain itself (Lim 1992).

Social factors - refers to human ecology. It is equally important to include the human element in any rehabilitation project as they can significantly contribute to its success (or failure). Walters (1997) stressed that social and economic factors were more important than ecological factors in determining the relative success of restoration efforts between and within different sites. These include people's knowledge about trees and tree planting, their patterns of land use and ownership, and their social organisation. Success of restoration efforts often depends on the management of these human influences which are either sustaining desired habitats or restricting their recovery. If the aim is to convince people to plant trees then it is just appropriate to understand the factors that motivate or limit them from getting involved in reforestation activities. The local people may have positive contributions by sharing their ecological knowledge, by providing skills, labour and materials to projects, and by conveying knowledge about restoration to other people (Walters 1997).

Constraints to the Use of Indigenous Species

In Malaysia, rehabilitation using indigenous timber species on a larger scale has encountered the following obstacles; irregular supply and recalcitrancy of seeds, high variability in growth yet of unknown genetic potential as seedlings are raised from stumps or wildlings (Lim & George 1996). Thus, the need for selection/breeding of indigenous timber species in the country is also urgent. Abas (1993) also identified some problems, namely; occurrence of drought which has affected the planting schedule and mortality of seedlings at the nursery and in the field; unpredictable flowering and fruiting of Dipterocarps; high mortality rate of wildlings; inadequate knowledge

and understanding of indigenous species; and high financial and labour-intensive requirements of weed control after planting. To address these concerns, Abas (1993) recommended the following; research on alternative methods of producing planting stock for large-scale replanting projects; further studies on the technology of rehabilitation (that is, various requirements of indigenous species); and further training and exposure for the local researchers to be able to handle future research in rehabilitation.

Rehabilitation Efforts

Cognisant of the urgent need to meet the domestic wood requirements in Peninsular Malaysia and to sustain timber exports in Sabah, the government moved for the plantation establishment of fast-growing tree species of *Acacia mangium*, *Gmelina arborea*, *Paraserianthes falcataria*, *Eucalyptus deglupta* and *Pinus caribaea* (Leslie 1989). In 1910, plantations of *Palaquim gutta* and *Hevea brasiliensis* with enrichment planting of *Neobalanocarpus heimii* were established in Peninsular Malaysia (Wan Yusoff and Abdul Rahman 1997). However, this endeavour failed due to lack of subsequent tendings. Between 1960's and 1970's, Peninsular Malaysia introduced the Taungya system as a means of artificial regeneration to re-forest patches of Forest Reserves damaged due to illegal cultivation. Illegal farmers were given permits to use the land with the condition that they would in turn plant tree seedlings provided by the Forestry Department. The tree species used were both exotic and indigenous; *Pinus caribaea*, *Dryobalanops aromatica*, *Shorea leprosula*, *S. ovalis*, *S. curtisii* and *Swietenia macrophylla* combined with agricultural cash crops mainly banana and tapioca. Again, this system was discontinued because of the cultivators' low response due to insecurity of land tenure, the accelerated development of large-scale agricultural schemes and the high costs of supervision.

Rehabilitation with indigenous species in Malaysia was also done at the 47 ha of the

Bintulu campus of Malaysia Agriculture University (UPM) through a joint project between Yokohama National University (YNU) and UPM. The project aimed to restore and recover the natural or at least quasi-natural forest ecosystems with native trees after the area has been logged and burnt for over 50 years (Mohd. Azani 1998, Miyawaki 1993).The concept has also been applied in Peninsular Malaysia using the gap and line planting, yet at an experimental stage.
Artificial regeneration with indigenous species, however, looks feasible and promising as indicated by the experimental/initial results of *Shorea parvifolia, S. leprosula, Neobalanocarpus hemii, Alstonia angustiloba, Dyera costulata* and *Azadirachta excelsa* (Ahmad Zuhaidi & Mohd Noor 1996, Lim & George 1996, Takai *et al* 1996; Ueda *et al* 1996, and Leslie 1989). Nevertheless, more research and development efforts on seed storage, vegetative propagation of superior trees and production of planting materials at reasonable cost are necessary (Lim & George 1996). As of 1998, plantations of exotic and indigenous species totalled 73,735 ha (Table8).

Table 8. Area of Plantation Forest by State in 1998 (ha)

State	Compensatory forest plantations	Teak plantation	Pine plantation	Rubber plantation	Azadirachta plantation	Total

Rehabilitation Methods

Two general categories of planting methods were tried in Malaysia; namely, open planting (applied in grassland and previously mined areas) and shade planting (applied in secondary forests or those in big forest gaps/openings)(Mohamad Azani 1998).

The open planting techniques involved line planting at different spacing (1m x 1m, 2m x 2m, 3m x 3m) and dense planting at three seedlings per m^2 as in the Bintulu project. The shade planting technique involved also line planting and gap/patch/clump planting as in the case of Chikus Forest Reserve, Perak. Gap planting at different gap sizes has also been tried but still at its experimental stage.

When applied to indigenous species, these techniques proved to be promising (Mohd. Zaki *et al* 1995). The open planting was favourable for the growth of the light demanding dipterocarp species. Other dipterocarp seedlings however, survived better but had low growth increment under partial shade. Mohd. Zaki *et al*'s (1995) experience in Sarawak also showed that open planting worked better when seedlings, particularly dipterocarps, have undergone hardening before planting for 6-8 weeks at the nursery and one month at the planting site. As of 1998, rehabilitation efforts in Malaysia has reached a certain level as indicated in Tables 9 and 10.

Problems of Policy Implementation

Although forest policy is clearly defined in Malaysia, its implementation is faced with various obstacles due to the constitutional separation of functions between the Federal and State governments. Land is a state matter. States may enact separate laws to pursue separate policies. The Federal Government's National Land Council may formulate policies and recommend measures for implementation but does not have the legal and administrative means to ensure that the policies are implemented (e.g. degazettement of natural forest areas)

Table 9. Rehabilitation Activities in Peninsular Malaysia

Activities	Target 1998	1998	Achievement (%)

Several commonalties and differences in forest policies and utilisation can be observed between the three principal States of Malaysia. Each State takes a different view of its forest and has different issues to cope with. Sabah harbours some of the world's richest remaining rainforest while the shifting cultivators are still a major cause of deforestation. Peninsular Malaysia has poorer forests and conversion of forests to permanent agriculture is the major cause of deforestation. Sarawak possesses valuable peat swamps where the much prized *ramin* trees are exploited. Like in other countries, Malaysian forest policies cannot work apart from economic and infrastructural policies.

Another significant policy is the indiscriminate awarding of timber concessions. Through this policy a substantial number of people are awarded but lack the knowledge on sound forest management principles. Hence, the lack of commitment to long-term investment and care for the environment. Thus, the concept of privatisation that has been highly successful in other sectors (and other countries) need to be incorporated in the Malaysian forestry. The Forestry Department and other related agencies could be relieved of the financial and manpower constraints they are faced with if some activities, including forest rehabilitation, are privatised.

Another major constraint to forest rehabilitation/restoration is the dispersed location of scientific knowledge on the subject. A sufficient body of scientific knowledge which can provide the technical backing for successful rehabilitation, already exists within the country. However, this body seems to be uncoordinated in such a way that the expertise is dispersed in the various research and academic institutions. Thus, a more integrated and co-ordinated research approach is much needed.

Lastly, research efforts need to be intensified. Some areas still need investigations, namely; quantitative and qualitative evaluation of degraded forest land using space technology, site-species quality studies, growth and yield studies, reproductive phenology, seedling regeneration and propagation, economics of rehabilitation, policy and the socio-political aspects, and agroforestry as an approach to rehabilitation and restoration.

Conclusions

Tropical deforestation involves the political, socio-economic, cultural, and ecological/ geographical conditions of the tropical countries and other countries of the world. Likewise, any forest rehabilitation scheme must also consider these factors. As such, reasonable and satisfactory solutions to this complex problem of tropical deforestation/rehabilitation demand a spirit of cooperation, assistance and collaboration, not only among the citizens of the country, but of the world.

As a process, forest land degradation is likened to a spider's web that hangs in the balance and is exposed to the wind. While intact, the web can withstand the pressure; if one thread breaks down, the spider can repair it. However, if the pressure is gradually increased, time will come when the spider succumbs to the wind and the web becomes totally destroyed.

As foresters, we need to create valuable forests, to manage them wisely and to take good care of this heritage/legacy for our future generations. A rich stock of timber is not enough, we need a rich nature, too. The current generation must salvage the remaining indigenous tropical forests if they are to leave a forest legacy to the next generation. Lost forest resources are not easily replaced. For some species, once lost they are forever lost. They go extinct and are gone forever. For others, replacing them may require enormous amount of money, time and effort. Some people think that oftentimes, it is economically better to manage the resulting existing forest than to replace what was lost. Socially, this may be more imperative. However, environmentally, replacement is the cry of the hour.

The web is our remaining intact forests. The spider is our foresters who can repair/alleviate the damaged web. Sadly though, by themselves, the foresters cannot effectively repair the damage. Forest protection management can no longer be treated in a strictly sectoral fashion, that is in isolation from the rest of natural resources development. Hence, the need for innovation and political commitment, particularly at the state level, to address the problem facing our forests and to ensure that the forest goods and services are sustainably produced for the most number of people in the longest time possible.

Unfortunately, we humans cannot just leave to nature the "unease" of our "misconduct" towards the forests. We must pay the cost of forest degradation - so rehabilitation (or assisted natural regeneration) we must do. And to discourage further loss of biodiversity, efforts must be directed towards the use of indigenous species, whenever and wherever possible. Hopefully, only then can we do something towards the fulfilment of the objectives of rehabilitation, which are to; outpace the rate of deforestation, restore biological diversity, diversify the products & increase the productivity of deforested lands, provide socio-economic benefits to both the government and rural community, and to supply raw materials to the wood industry so that the pressure on the remaining primary forests can be reduced if not eliminated.

As in other countries, the utilisation of forests has brought substantial increases in gross domestic product, which benefit the Malaysians. However, in like manner with other countries, a time will come when further removal of the forest will reduce instead of enhance the people's living standards. Hence, a rational development of forest management technology becomes an obviously urgent need – a holistic view that requires a more unified approach to forests on the part of the various governments (State & Federal).

Recommendations

Malaysia and other countries with similar situation can learn from the experiences and findings of the experts and may need to carry out any or a combination of the following recommended courses of actions: (Walters 1997, Nik Muhamad and Mohd Zaki 1996, Lim and George 1996, Wadsworth 1995, Abas 1993, Baguinon 1992, Robinson 1988):

Continuing research on alternative methods of producing planting stock for large-scale replanting projects

Further studies on the technology of rehabilitation (e.g. various requirements of indigenous species)

Further training and exposure for the local researchers to be able to handle future research in rehabilitation

Data base for rehabilitation efforts - survey & compilation of published papers on all aspects of natural regeneration & succession

Logistics support - prioritise and provide the needed technical and scientific back-up for any rehabilitation programme

Inclusion of human ecology - social, cultural, economic and political factors and the interactions between them

Continuing on-the-spot research and development in tightening the link between restored forest and farms - e.g. involves decision to chose farms or spaces in farmed landscape that are not under cultivation, avoid areas where burning is common, encourage permanent settlement by increasing farm productivity thereby discouraging farmland expansion

Discovery of alternative means of providing subsistence goods (food, fuel & housing materials) and alternative commodities to substitute those resulting from environmental destruction

Mapping of the successional patterns of reforestation area - botanical survey, soil and vegetation analysis and mapping, and classification of reforestation area into successional stages

Combining reforestation with agroforestry - for livestock production, tightly restrict access of animals by tethering and stall feeding

Silvicultural methods

a) seed production system - decision to use exotics is sometimes due to lack of knowledge of indigenous species and their seed availability, and their site preferences

b) species-site matching design - classify taxa based on the habitat type occupied by the wildlings
c) direct seeding, use of cuttings and bare root planting materials wherever possible - minimise nursery work and eliminate transport of seedlings from nursery to planting site and thus reduce cost

In summary, the future of using indigenous species for forest rehabilitation does not look bleak. Many research efforts in this field are underway. Although recognising that certain exotic species have a particular ecological or economic role to play, researchers in Malaysia are working on how to make better use of indigenous species. However, it is believed that positive outcomes can only be achieved if policies on sustainable forest management and a sustainable timber trade are comprehensive enough to cover three dimensions: ecosystem, timber yield and people's livelihood.

Abstract

Depending on the degree of degradation, size, and distance to forest, physical and biological barriers can significantly delay natural regeneration in degraded ecosystems. Tropical plantations can fulfill a variety of services including restoration of soil fertility and acceleration of natural regeneration. In a long-term program on ecosystem rehabilitation in the Latin American humid tropics, about half the species tested had positive effects on soils and good growth, making them attractive to farmers for reforestation. In studies of natural regeneration in plantations with indigenous species in the humid lowlands of Costa Rica, forest tree invasion was higher under plantations than in surrounding abandoned areas. Higher plant species richness accumulated under *Vochysia guatemalensis, Virola koschnyi, Terminalia amazonia*, *Hyeronima alchorneoides* and *Vochysia ferruginea,* all species commonly planted by farmers. Natural regeneration was high under mixed-species plantations, with values sometimes equal or higher to those found under pure plantations. The open pastures had the highest proportion of wind-dispersed seeds, while bird and bat seed dispersal was predominant in the plantations. High accumulation of litter on the plantation floor contributed to diminish grass growth and thus encouraged woody invasion.

In regions with larger agricultural fields and farther from sources of propagules, windbreaks and remnant trees in pastures may be important reservoirs of native tree species. Tree recruitment may be higher in windbreaks that are connected to forests. Windbreaks could be made more attractive to birds by including native, fruit-producing trees, by increasing their species and structural complexity, and by positioning them between forest patches to facilitate bird movement.

Examination of the role of strategies for recovery of biodiversity necessitates integrative approaches that consider factors influencing tree regeneration, other potential effects on the ecosystem, and economic, social and environmental constraints.

Keywords: Ecosystem restoration, Mixed plantations, Soil fertility, Succession, Tree species choice, Windbreaks

Introduction

It is becoming widely accepted that the conservation of biodiversity has to take place in managed landscapes as well as in protected areas (Pimentel et al. 1992, Brown and Lugo 1994, Guindon 1996, Lamb 1998, Harvey and Haber 1999). In many regions of tropical America, the landscape consists of a complex mosaic of forest patches, pastures and agricultural fields and is heavily influenced by human activity. Any efforts to conserve biodiversity within managed landscapes must be compatible with local livelihood needs and offer sustainable and economically attractive alternatives to local farmers. Strategies that provide various ecosystem services and fulfil local human needs, in addition to promoting the conservation of biodiversity, will have a higher chance of success (Cairns and Meganck 1994, Lamb 1998).

One strategy that can potentially facilitate the maintenance or recovery of biodiversity within agricultural landscapes is the establishment of native forest plantations on degraded agricultural lands. Tropical plantations can serve diverse economic, social, political and ecological functions. With considerably higher yields than managed native forests, tropical and subtropical plantations can make substantial contributions to world timber and pulp production (Wadsworth 1983, Evans 1992, Evans 1999, Sedjo 1999). Tree plantations can also be a source of cash, savings and insurance for individual farmers. Plantations may help stabilize rural populations in regions where shifting agriculture is the predominant land use. In combination with subsistence and commercial crops (agroforestry) or cattle (agrosilvopastoral systems), plantations have been used as tools in rural development projects worldwide. Plantations are often seen as alternatives to deforestation as they can provide products that otherwise would be taken from natural forests (Fearnside 1990, Mc Nabb et al. 1994, Mc Nabb and Wadouski 1999).

If plantation species are chosen with knowledge of their nutrient-use efficiencies and recycling capacities, they can be highly productive and also serve a function in ecosystem restoration projects. Particularly, tree plantations and tree-crop combinations represent productive land use alternatives for deforested lands with poor natural forest regeneration due to long distance to sources of propagules or intense site degradation. Among the latter, low soil fertility, soil compaction after abandonment from cattle grazing, and invasion by grasses and other agressive vegetation can be serious obstacles to both forest regeneration and conventional agriculture (Lugo 1988, Nepstad et al. 1991). As the area in degraded lands spreads out, emphasis is increasing on the use of tree species which can grow in such conditions and yield economic products (timber, fuelwood and other) as well as environmental benefits (soil conservation, watershed protection) (Evans 1992, 1999).

The initial step in ecosystem rehabilitation projects is to identify the most important constraints to crop or tree productivity, as well as defining the specific land restoration objectives. Some soils can be recovered through the use of fertilizers, others need more drastic rehabilitation techniques, and there are situations of extreme degradation where soils cannot be recovered at all (Dedecek 1992). The recovery of the soils' productive capacity is frequently very expensive, thus the techniques involved must produce financial returns to ensure their adoptability by the local farmers.

The choice of appropriate tree species for plantation forestry or agroforestry is influenced by knowledge on the species' performance and their economic and environmental benefits. Locally, tree species choice is determined by seed or seedling availability and information on silvicultural characteristics and management, including fast growth and the possibility of intercropping during early establishment. Most reforestation or tree planting programs and subsidies promote the use of well-known, often exotic species. About 85% of plantation forestry in the tropics is dominated by three genera: *Pinus*, *Eucalyptus* and *Tectona*, while there may be thousands of indigenous species suitable for similar purposes (Evans 1992, 1999). Native trees can be more appropriate than exotics because (1) they are better adapted to local environmental conditions, (2) seeds and other propagules are locally available, and (3) farmers are familiar with them and their uses. Besides, the use of indigenous trees in productive systems helps preserve genetic diversity and is in better balance with the local flora and fauna.

Rehabilitating Abandoned Lands in the Latin American Humid tropics

A research program to develop alternatives for the rehabilitation and use of abandoned lands took place from 1987 to 2000 in three humid forest regions of Latin America: the Atlantic lowlands of Costa Rica, the Atlantic rainforest of Bahia in NE Brazil, and the sub-tropical forest of Misiones, NE Argentina (Table 1). In these regions, common situations of rapid deforestation, loss of biodiversity, resource misuse and land degradation persist. Similar methods were used in the three locations: soil chemistry and nutrient cycling parameters were measured in pure stands of selected indigenous species, using adjacent areas free of trees (abandoned agricultural field or pasture, secondary/primary forest) for comparison. The size of each project varied with the sites: in Costa Rica the studies were the most complete (soils, above- and below-ground tree biomass, litterfall and forest-floor litter biomass and tissue chemistry), while in Bahia and Misiones the trees were part of a forest reserve or were in private farms and thus destructive sampling was not possible.

Sampling procedures and chemical methods are described in Montagnini and Sancho (1990, 1994a, 1994b), and Montagnini et al. (1995a, b, c). The soils under the species, grassy areas free of trees and adjacent young secondary forest were sampled for soil fertility and nitrogen availability measurements at the three research sites. Litterfall was mesured biweekly with litter traps, and forest-floor litter accumulation was sampled every three months at La Selva, while at Bahia data from existing studies was used.

Impacts of Trees on Soil Fertility

At La Selva, in just 2.5 years soil conditions improved in the tree plantations compared to abandoned pasture. In the top 15 cm, soil nitrogen and organic matter were higher under the trees than in nearby pasture, with values close to those found in adjacent 20-year-old forests (Table 2). The highest values for soil organic matter, total N, Ca and P were found under *Vochysia ferruginea*, a species common in mature and secondary forests in the region (Montagnini and Sancho 1990). Subsequent measurements revealed similar trends in the soil parameters in the three following years.

Table 1. Characteristics of the study sites mentioned in this article.

Location	**Mean annual rainfall and temperature**	**Soil type**	**Previous land use**	**Experimental setting**
La Selva Biological Lowlands of Costa Rica	4,000mm, 24ºC	Fluventic Dystropepts pH 4.3-4.6	1-3 yrs. agriculture, cattle	Pure plantation, 2mx2m, 2-6 yrs. old
Pau Brasil Ecological Station Porto Seguro, Bahia, Brazil	1,700mm, 23ºC	Oxisols (Haplorthox) pH 4.5-5.0	Shifting agriculture	Pure plantation, 2mx2m, 14-15 yrs. old
Eldorado, Misiones, NE Argentina (private farms)	1,700-2,400mm 22ºC	Acid, clayey Ultisols pH 4.5-5.0	50 yrs. of agriculture, pine plantations	Pure stands from natural regeneration, 10-20 yrs. old

Table 2. Topsoil chemical characteristics in pure stands of indigenous tree species at La Selva, Costa Rica; Porto Seguro, Bahia, Brazil; and Misiones, Argentina.

Based on the standards determined by the Ministry of Agriculture of Costa Rica for soil fertility assessments (Bertsch 1986), the cation levels (Ca, Mg and K) under most of the tree species were at or above the critical values for agriculture. In contrast, the cation levels in the adjacent abandoned pasture soils were too low for the subsistence crops preferred in the region (rice, beans). The standards set by the Ministry of Agriculture do not include N or organic matter. However, an indication of the importance of the improvement of the soil organic matter levels is given by the close relation found between organic matter content and the sum of bases (Ca+Mg+K), showing that the organic matter was responsible for much of the cation retention capacity (Montagnini and Sancho 1990). For example, based on this relationship, a 1-2% increase in soil organic matter (in the 4-6% range) would more than double the base content, reaching values in the range recommended for agriculture (Bertsch 1986).

Low crop yields in the humid tropics are often a result in part of unfavorable physical properties such as soil compaction (Cassel and Lal 1992). In our site at La Selva, soil organic matter also had positive influences on soil physical properties: the soil bulk density was lower (i.e., lower compaction) while soil moisture was higher under the trees than in abandoned pasture (Montagnini and Mendelsohn 1996).

The results of standard soil fertility tests used in agriculture (such as those shown in Table 2) may not always reveal the soil's productive potential, because they do not include all chemical forms of nutrients available for plant uptake. For example, although they make up less than 10% of the total soil N pool, mineral N (NO_3-+NH_4^+), are the forms of N available to plants. Nitrogen fertilizers are heavily used in the La Selva region, especially for the most demanding commercial crops such as bananas, in which case capital is available for fertilizer in a more extensive land use system. From the results shown in Table 2, *Stryphnodendron microstachyum*, a N-fixing tree, did not have an important effect on total N, but its litter decomposes faster than the other species, resulting in increased soil mineral nitrogen under its canopy (Montagnini and Sancho 1994a). Evaluating the effects of trees on soil P availability is even more difficult, although experiments with test crops can determine soil impacts. For example, in other experimental research, maize seedlings, grown in plots mulched with *S. microstachyum* and *Hieronyma alchorneoides* versus the other species' litter, showed the greatest initial growth and the highest N and P plant uptake (Montagnini et al. 1993). In these and in other related research at La Selva, the maize seedlings grown without mulch or fertilizer on soils from abandoned shifting agriculture fields grew very poorly, reaffirming the need for soil improvement techniques for growing conventional crops in the impoverished abandoned lands.

In Bahia, positive effects on at least five soil parameters were found under 15 out of the 20 species of the plantations, in comparison with primary and secondary forest (Table 2). Several species contributed to increased C and N, among others: *Inga affinis, Parapiptadenia pterosperma, Plathymenia foliolosa* (leguminous, N-fixing species), *Caesalpinia echinata, Copaifera luscens* (leguminous, non-N-fixing), *Eschweilera ovata, Pradosia lactescens* (of other families) (Table 2). Others increased soil pH and/or some cations, such as *Copaifera luscens, Eschweilera ovata, Lecythis pisonis and Licania hypoleuca* (Table 2, Montagnini et al. 1994, Montagnini et al. 1995a).

In Misiones, NE Argentina, the greatest differences in soil C and N levels under tree species and grass were found under *Bastardiopsis densiflora*, where they were twice those in areas beyond the canopy influence (Table 2) (Fernández et al. 1997). The pH was higher under *Bastardiopsis densiflora* and *Cordia trichotoma*, while the sum of bases (Ca+Mg+K) was highest under *Cordia trichotoma, Bastardiopsis densiflora* and *Enterolobium contortisiliquum*.

Tree Productivity in Plantations Used for Land Rehabilitation

As stated earlier in this article, land rehabilitation programs must use species and designs that not only help in soil recovery but also are productive. If a land rehabilitation system is productive it may represent an economic incentive for the local farmers. At

La Selva, the values of whole tree biomass for the plantations (Table 3) were greater than those reported for 4-year-old *Albizia lebbek* (Parrotta 1989), and for 5.5- year-old *Leucaena leucocephala* (Wang et al. 1991), both growing in dense plantations for biomass production in Puerto Rico. Values of total tree above-ground net primary productivity (calculated by dividing whole-tree biomass by tree age) lie within the ranges reported elsewhere for monospecific plantations in the humid tropics. The value for *V. guatemalensis* is close to that reported for *Gmelina arborea* (12.8 tons per ha/yr) in the Brazilian Amazon (Russell 1987); and to *Gmelina arborea* (12.7 tons/ha) and *Albizia falcataria* in the Philippines (11.3) (Kawajara et al. (1981), in Young (1989)). The increments shown here are however lower than those reported for some of the fastest growing trees in the humid tropics such as *Acacia mangium* (15.5 to 18.0 tons/ha in Malaysia), *Leucaena leucocephala* (20.0-30.0 and even up to 80.0 tons/ha in Hawaii an other tropical sites, Young (1989)). Biomass of the same species planted in other experiments at La Selva was consistent with the results presented here (Montagnini and Porras 1998, Shepherd and Montagnini 1999).

Natural Regeneration in Mixed and Pure Plantations of Native Species

In addition to providing a variety of economic and environmental services (such as timber production, carbon accumulation, soil protection, and land reclamation), plantations may help local biodiversity by facilitating forest tree regeneration and by providing habitats for forest animals (Parrotta 1992, Lamb 1998). Although in humid tropical regions it is often assumed that recovery of the degraded landscape through natural regeneration processes will take place within a time frame acceptable to the foreseen human use, forest regeneration is often significantly delayed by physical or biological barriers (Lugo 1988, Nepstad et al. 1991). The establishment of plantations may overcome some of these barriers by attracting seed dispersal agents into the landscape and by ameliorating local microclimatic conditions within the area, and thereby accelerating the recovery of these lands.

Table 3. Means, aboveground biomass and annual increments for the four native species in plantation at La Selva, Costa Rica[1].

Tree species	Aboveground live biomass, kg/ha				Mean annual Increment, t ha^{-1}yr^{-1}	
	Stem	Branches	Leaves	Total	Total	Stems
Stryphnodendron microstachyum	35,250a	15,250[a]	4,325[a]	54,825a	13.7a	8.8[a]
Vochysia ferruginea	24,750b	14,250[a]	5,925[a]	44,925	11.2b	6.2b
Vochysia guatemalensis	41,750a	6,500b	7,250[a]	55,500	13.9a	10.4[a]
Hyeronima alchorneoides	26,250a	12,250[a]	5,350[a]	43,850	12.0b	6.5b

[1] Differences between sites for a given parameter are statiscally significant (P < 0.05) when means are followed by different letters.

Mixed plantations may have considerably higher conservation value than single-species plantations. In addition, mixed plantations yield more diverse forest products than monospecific stands, helping to diminish farmers' risks in unstable markets, and if planned with consideration of each species' response to mixed conditions, mixed designs can be more productive than monospecific systems (Smith 1986, Burkhart and Tham 1992, Kelty 1992, Wormald 1992, Montagnini et al. 1995, Montagnini and Porras 1998). We are studying natural regeneration in young mixed and pure plantations with eight indigenous species at La Selva Biological Station in the humid lowlands of Costa Rica in order to determine the potential role of plantations in maintaining local biodiversity. The results so far suggest that plantations can accelerate natural successional processes in degraded pastures (Guariguata et al. 1995, Montagnini et al. 1999). Significantly higher plant species richness accumulated under plantations of *Vochysia guatemalensis, Virola koschnyi,* and *Terminalia amazonia* (all species commonly planted by farmers in the region) than in adjacent, unplanted areas (Table 4). In mixed-species plantations, abundance of woody regeneration was intermediate to that of pure plantations.

Natural regeneration was higher in understories with low or intermediate light availability. Most of the seeds entering the open pastures were wind-dispersed, while most seeds entering the plantations were bird or bat-dispersed. This suggests that the plantation may be facilitating tree regeneration by attracting seed-dispersing birds and bats into the area.

Table 4. Average number of individuals of regenerating seedlings in the understory of plantations and in natural regeneration controls, at 7 years of age, at la Selva Biological Station, Costa Rica.

Plantation 1:

Treatment	Number of individuals in 57 m^2
Vochysia guatemalensis	90.3
Calophyllum brasiliense	78.6
Jacaranda copia	57.1
Mixed plantation	87.6
Natural regeneration	28.6

Plantation 2:

Treatment	Number of individuals in 16 m^2
Virola koschnyi	19
Dypterix panamensis	9
Terminalia amazonia	44
Albizia guachapele	0
Mixed plantation	17
Natural regeneration	7

In another plantation with other native species in pure and mixed designs, also at La Selva, the highest abundance of tree individuals was found in the mixed plantation with 32.5 individuals in 32 m^2, followed by *Hyeronima alchorneoides* with 25.2, *Vochysia ferruginea* with 18.2, *Pithecellobium elegans* with 13.5, *Genipa americana* with 4.7 and the natural regeneration control with 2.2. The highest number of species was found in the mixed plantation (11.2), followed by *V. ferruginea* (8.2), *H. alchorneoides* (7.2), *P. elegans* (5.0), *G. americana* (3.2) and control (0.7). The majority of the regenerating individuals were dispersed by birds and bats. The different species of the plantations created different conditions of shade and litter accumulation, determining the abundance of the recruited and the surviving individuals (Carnevale and Montagnini 2000).

Strategies that provide various ecosystem services and fulfil local human needs, in addition to promoting the conservation of biodiversity, will have a higher chance of success (Cairns and Meganck 1994, Lamb 1998). Any efforts to conserve biodiversity within managed landscapes must be compatible with local livelihood needs and offer sustainable and economically attractive alternatives to local farmers. In addition to examining the ecological aspects of forest regeneration within plantations, this project also examines the socioeconomic feasibility of this conservation strategy.

Other Tree-Based Strategies for Recovery of Biodiversity in Deforested Landscapes

In other regions with larger agricultural fields and farther from sources of propagules, windbreaks and remnant trees in pastures and agricultural fields may be important reservoirs of native tree species (Harvey and Haber 1999, Harvey 2000). For example, the effects of planted windbreaks on seed deposition patterns were examined in dairy farms in Monteverde by Harvey (2000). The windbreaks were planted strips of trees about 5 m wide and 9 m tall and were 7-8 years old at the time of the study. Trees and rows within the windbreaks were spaced at 1.5 m. The most common species were *Cupressus lusitanica, Croton niveus, Casuarina equisetifolia* (all exotic species) and *Montanoa guatemalensis* (native). None of these species produce fruits that attract frugivorous birds, and their seeds are wind dispersed except for *Croton* which is gravity dispersed. Windbrekas were found to receive significantly greater densities and species richness of seeds of tree and shrub species than pastures: windbreaks received an average of 39 times as many seeds, and 67 times as many shrub seeds as pastures. In addition, windbreaks received an average of two times as many tree species, and more than two times as many shrub species as pastures. The differences in the seed rain entering windbreaks vs. pastures appeared to be due almost entirely to the enhanced activity of birds in windbreaks: bird-dispersed seeds occurred in greater densities (about 100 times greater), and number of bird-dispersed species was three times greater in windbreaks than in pastures. The high densities of bird-dispersed seeds within windreaks suggests that windbreaks increase forest seed recruitment by serving as habitat and/or movement corridors for seed-dispersing birds (Harvey 2000).

Windbreaks may serve as sources of woody colonists if the agricultural lands are later abandoned. Positioning of windbreaks within the landscape may affect seed deposition patterns by influencing the movements of seed-dispersing birds. Tree recruitment may be higher in windbreaks that are connected to forests. Windbreaks could be made more attractive to birds by including native, fruit-producing trees, by increasing their species and structural complexity, and by positioning them between forest patches to facilitate bird movement (Harvey 2000).

Remnant trees in pastures or agricultural fields may play an important role in conserving biodiversity within agricultural systems because they provide habitat and resources that are otherwise absent from agricultural landscapes (Harvey and Haber 1999). For example, in a survey of 237 ha of pastures in Monteverde, Costa Rica, Harvey and Haber (1999) found over 5000 trees of almost 200 species, with a mean density of 25 trees per ha. Primary forest trees accounted for over half of the species and over one-third of the individuals. More than 90% of the the species were known to provide food for forest birds or other animals. In addition, many of the species were important as sources of timber, firewood or fence posts for farmers. Reasons for leaving trees in the pastures included using them for shade for cattle, timber, fruits for birds, and fence posts. Results of surveys among farmers suggested that farmers in the region would be receptive to programs promoting the conservation of forest trees in pastures, if these programs would fit the particular requirements of shade management for cattle and if they allowed farmers to use a small proportion of their trees for timber, fuelwood or fence posts. The conservation of pasture trees must be part of larger conservation initiatives that includes the conservation of large forest tracts, key habitats, forest fragments, migration routes, and corridors (Harvey and haber 1999).

Conclusions and Recommendations

A number of economically valuable native tree plantation species were found to have positive impacts on soils in three regions of the Latin American humid tropics. Tree productivity and biomass were high for these species, therefore they would be preferred by farmers for reforestation. Studies of natural regeneration entering the understory of established plantations showed that certain species were more effective in attracting seed dispersers and favoring seedling recruitment. Mixed plantations gave good results in accelerating natural succession. Among the factors favoring woody invasion of plantation undestories, high production of leaf litter was most important in helping to suppress herbaceous vegetation and thus favoring competition by tree seedlings.

In addition to conventional plantations, planting trees in windbreaks, and planting or leaving trees in agricultural landscapes may contribute to conserving and restoring biodiversity by offering habitats for birds and other animals, and by enhancing seed dispersal into agricultural landscapes.

Examination of the role of strategies for recovery of biodiversity necessitates integrative approaches that consider factors influencing tree regeneration, other potential effects on the ecosystem, and economic, social and environmental constraints of the proposed systems.

Abstract

In the densely populated area of Central Europe (Germany), landscape in general and forests in particular are faced by an increasing number of different, partly contrary demands of society that can be summarised by the keynotes: wood production, nature conservation and leisure time activities. Besides that, the Central European Forestry has to struggle with political-economic and structural characteristics in the international wood market. Therefore some examples of new research activities are given to outline solutions and effects in multifunctional rehabilitation of forests at different scales: Summarising the results of the studies, a varied afforestation planning and a concept of forest use, which integrates the aspects of aesthetic values and of nature conservation with management systems, in combination with a selected net of total reserves and the creation of biotope-network structures would play an important role in an intelligent, sustainable land-use system for the future - following the intention of AGENDA 21 and the declaration of Rio.

Keywords: Nature conservation, Integrated land-use, Biodiversity, Afforestation, Germany

Introduction

In the densely populated area of Central Europe (Germany), landscape in general and forests in particular are faced by an increasing number of different, partly contrary demands of society.
These social aspects can be summarised by the keynotes: wood production, nature conservation and leisure time activities:

People have realised that a local sustainable wood production shows a lot of benefits, not only for the economy but also for the environment: (renewable raw material, CO_2-fixation, low output of transport energy).

People have become more and more sensitive to the importance of nature protection and the conservation of biodiversity, especially in a system close to nature like forests. Although Central Europe does not belong to the real world-wide „hot spots“ of biodiversity, the region has the international obligation for the protection of the endemic beech forest ecosystem.

People have discovered the forest partly as one of the last areas of silence (to get the experience of wilderness), partly as a place where they can carry out their new outdoor activities (mountain biking, canoeing, para-gliding).

Moreover, the Forestry of Central Europe has to struggle with political-economic and structural characteristics at the international wood market: a high-cost-situation for wood production; the splitting up of the forest area by location and by ownership; the prohibition of clear-cutting and legal provision of creation and conservation of stable, mixed, healthy forests. Besides that, the internal discussion about an adequate system for certification in forestry spoils a lot of time and energy.

In spite of these problems, forestry must face the different demands of the society. Therefore, scientific and practical forestry have to develop different solutions for those multifunctional tasks.

Examples of Multifunctional Rehabilitation of Forests

In the following, four examples of new research activities will be outlined in order to demonstrate solutions and effects in the multifunctional rehabilitation of forests in Germany at different scales:

Example 1: Afforestation Guidelines

Research Approach

During the last 10 years, the agrarian policy of the European Commission had aimed at the reduction of agricultural overproduction in the member states. One way to reach that objective was to increase subsidies for afforestation measures, whereby even productive farmland should be afforestated. In consequence, there was a great discussion about the pros and cons of forestry land-use of these areas. Professionals developed scenarios demonstrating, that the forest surface in Germany would increase by more than one million hectares in the coming years. Nature conservationalists spoke of a "darkening of landscape". In a research project our institute pointed out, which steps and instruments of land-use planning can help to cope with these landscape effects (AMMER 1997).

Results

Although the annual afforestation rates does not increase to the predicted extent, it was and it will be necessary for the future to develop so called *prototypes of afforestation* by including the target group of the planning process.
These prototypes of afforestation should correspond to the heterogeneous morphology of previously described visual landscape units. Besides the primary visual aspect, the prototypical design approach also manages ecological and economical issues in terms of amenity design. Afforestation guidelines may therefore contain verbal and graphic descriptions of prototypical landscape units, including the following parts:

- description of the status quo: basic information about the actual structure of land-use and landscape, the actual distribution of forests or information about geomorphology
- ecological and economical needs (restrictions by laws; preferences set by other ecological plans)
- the results of the public preference for providing food
- potential conflicts of interest (for example between landscape aesthetics and afforestation)
- Solution: recommendation of prototype

The development of prototypes of afforestation does not replace the need for local planning, but it can give the framework. In such an individual plan (for each community e.g.) aesthetic aspects (e.g. the design of forest edges), ecological improvements (e.g. biotope network structures, treatment of marginal sites) as well as forest parameters like tree species selection and mixture, age structure, stability, opening of the stands or the techniques of afforestation must be respected. More than now, the emphasis should lie on the nature-oriented alternative of natural succession (AMMER & PRÖBSTL, 2000).

Example 2: Redevelopment of Protection Forests in the Bavarian Alps

Research Approach

The forests in the high mountains of the Bavarian Alpine Region have always fulfilled a great number of different functions, which are essential for human existence in the Alps. They protect settlements, roads and communication systems against avalanches, falling rocks and landslides, thus providing the people a place for their outdoor activities (skiing, hiking, paragliding) and recreation opportunities in a charmful landscape, protect many rare and endemic species and last but not least supply timber as a valuable raw material.

In the consequence about 60 % of the forests in the Bavarian Alps are protection forests (147 000 hectares). Unfortunately parts of these protection forests have been weakened by air pollution and are overage. In many cases browsing of game prevents natural regeneration and thus intensifies the creeping deterioration of its protection function.

Face to this situation, a programme for restoring the protective capacity was initiated by the Bavarian State Forest Service. On the surface of about 8 % of the protection forests (12 000 hectares), where remarkable degradation of the stand or the menace of erosion and avalanches were obvious, regeneration measures are carried out. This includes according to the degree of necessity, biological measures like afforestation or engineering (various types of wood constructions, figure 1). In four selected areas the activities were investigated by scientific methods. After 10 years of monitoring, some first results of the success of these measures can be stated (AMMER & DETSCH 2000).

Results

Wood constructions

After 10 years the different types of wood constructions against snow movements are in excellent shape. Only 0,5 % of the about 400 investigated snow rakes were damaged, the loss rate of the ground joists (n=1119) were only 1 %. The damage of the snow trestles (11 %) came from a singular avalanche in the test site where the maximum of opening was combined with the minimum of construction intensity.

On the contrary, the results of the evaluation show that snow nets and palings had great problems with snow movements: about two-thirds of the constructions were damaged.

The combination of snow rakes, snow trestles and ground joists lead to a decisive reduction of snow movements and avalanches in the forest stands. However, they cannot guarantee a complete stabilisation of the areas, not even directly in the space between the constructions.

Development of plants

It can be stated generally, that ten years after the starting of the project, the development of plants on these extreme sites is much slower than often predicted. Besides, the plants have grown up differently. The so called pioneer species like *Pinus mugo mugo, Sorbus aria, Pinus syslvestris* and *Larix decidua* can grow up better, the more the stand is opened up, but their contribution towards stabilisation of the snow movement is rather low. The typical species of the climax vegetation unit „Berg-mischwald“, *Fagus sylvatica, Abies alba, Picea abies* and *Acer pseudoplatanus* have some problems with starting but if they are established, the broadleaves can reach height growth rates of more than 50 centimetres per year. Looking at the natural regeneration, *Acer pseudoplatanus* can colonise the stands if the competition of grass is not too high. In each case the expensive building of a fence against browsing of game was necessary. A positive correlation could be shown between the growth of plants and the protection effect of the wood constructions, especially if the plants are positioned right below the construction. Although you can find snow damages also inside of constructed areas, the impact of the damage is less grave than outside. Coniferous species like *Pinus sylvestris* and *Picea abies* suffer from extreme snow pressure especially in the height classes of 1 to 4 meter. According to their flexible shape and to the leafless wintertime, broadleaves (and *Larix decidua*) can stand the snow movements and therefore they get less damaged. Although the development of the young trees after ten years can be described as satisfactory, the complete regeneration of the stands can be found only in one test area.

Example 3: Ecological Effects of The Conversion of Spruce Monocultures Into Mixed Forests

Research Approach

In Germany, large areas of the landscape are dominated by spruce forests (*Picea abies* L.), which are not natural in lower regions. The preference of Norway Spruce in forestry is due to its fast growth, the versatile use of its wood, low demands to soil quality, low sensibility to weather extremes and relative resistance against the grazing by deer.

Figure 1: Snow rakes protect young firs against snow movements

But deterioration of soil quality, gradation of bark beetles and other insects as well as storm damages showed the risks of spruce monocultures. Spruce plantations are also accused of being unsuitable habitats for animals and to be responsible for the reduction of forest invertebrates (Jedicke 1997). As the Bavarian State Forestry has seen the disadvantages of spruce monocultures, spruce stands have been reconverted since the 1950's with the goal to mix about 30-40% deciduous tree species into the spruce stands. This reconversion is realised by planting mainly beech groups (*Fagus sylvatica* L.) under the thinned spruce canopy or into canopy gaps.

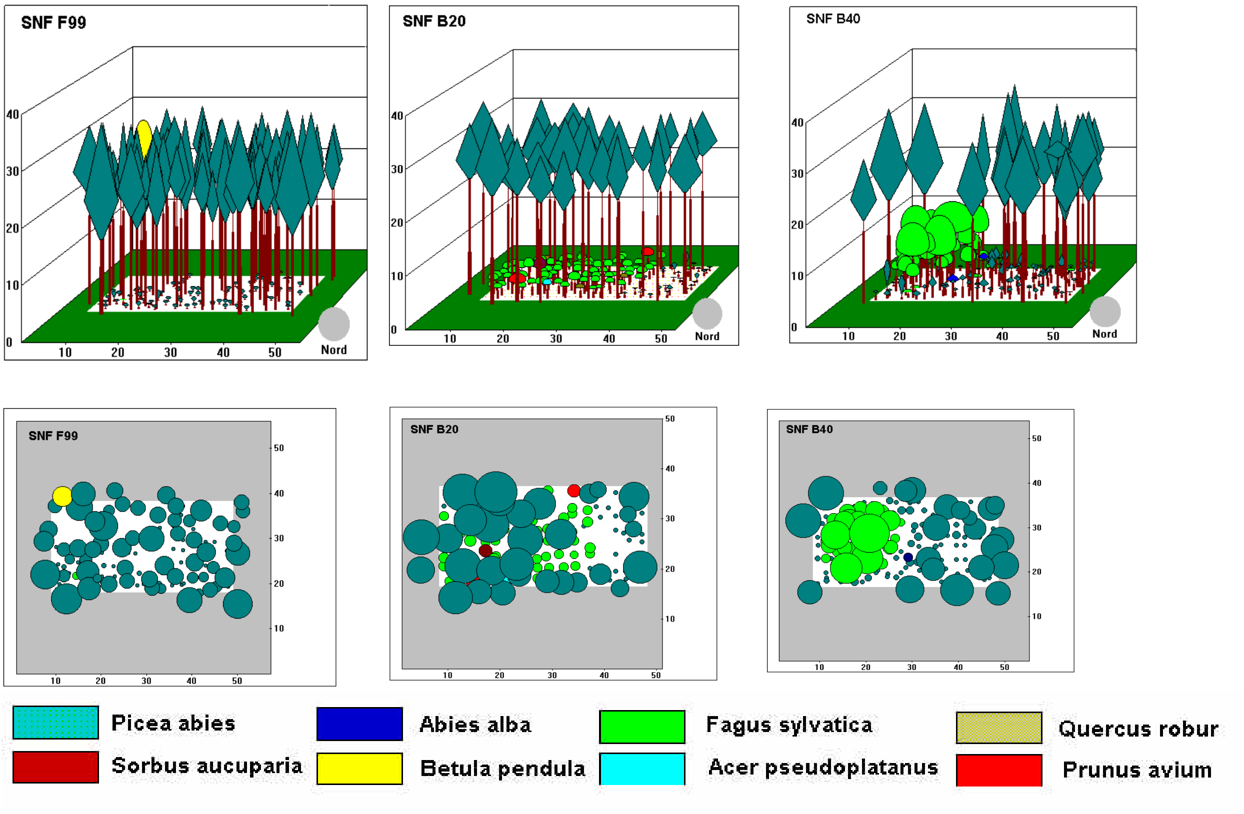
The structural diversity and the invertebrate fauna of different stages of the reconversion process (20- and 40-year-old beech groups; mature spruce monocultures, natural beech stand; 30-year-old spruce stand) were investigated in a space for time substitution" in two test sites in Bavaria (MATTHES 1998; ENGEL 1999).

Results

In summary it has to be stated, that the system of group-wise cutting and starting regeneration beneath the canopy layer is an excellent method to reconvert monocultures into mixed stands. The variability of illumination beneath the canopy layer is necessary for an heterogeneous stand structure and creates ecological niches. Besides the artificially planted tree species (beech, fir), also naturally growing deciduous trees like birch or mountain ash or shrubs of early succession stages appear and increase the species diversity of such stands (see figure 2).

Predators of the mesofauna (Carabidae, Staphylinidae, Araneae, Opiliones, Pseudoscorpiones, Chilopoda, Dermaptera, Formicidae) as well as the saprophagous macroinvertebrates (Diplopoda, Isopoda, Lumbricidae) show a higher abundance and numbers of species in beech woods than in spruce forests. Hence, the reconversion of spruce monocultures is a contribution to higher horizontal and vertical structure in the forest; it increases the mosaic and thus provides a greater number of different habitats for the fauna, especially at the edge of the beech groups.

Figure 2: Development of a conversion stand (3-dimensional model by NAGEL 1996)



although the fauna of most of the beech groups, especially the older stages, is very similar to that of the spruce forests, there are already typical species of deciduous stands immigrating into the isolated groups; some species even show a preference for these stages;

the greater faunistic diversity of the young beech groups compared to the older ones seems to be due to the dense structure and moist microclimate, but the size of the groups might play a role, too, so that planting size should be at least 1000 m^2 , which is also an acceptable size from the operational and economical point of view.

Example 4: Structural and Biological Diversity in a Comparison of Nature Forest Reserves and Managed Forest Stands

Research Approach

In Germany discussions between nature conservation and forestry representative are currently taking place about the issue, which level of nature conservation and natural dynamics can be achieved in managed forests. To de-emotionalise the current discussion we compared nature forest reserves as „indicator areas" for naturalness with managed forests; They are expected to provide information about the integration of nature conservation in forest management concepts.

In a comparative study, two nature forest reserves (beech/oak) and three variants of managed forests (spruce – spruce/beech – beech/oak) were investigated by the same methods, embracing the entire spectrum of ecosystem strata: soil, vegetation and forest trees (stand structure including canopy). Faunistic species groups typical of each stratum were selected and captured by different trap systems. An inventory of macrostructure and their relationships to the biocoenosis completes the research activities

(Detsch 1999; Schulz 1998; Schulz 1996). The project focus on the question: What is the common ground and what are the differences between nature forest reserves and managed forests concerning stand structure and species diversity?

Results

Structural diversity

Several parameters of structure were selected to describe structure-diversity concerning stand composition and macrohabitat provision. The results show that structural diversity is higher in the nature forests reserves than in the managed test areas. The reserves present a wider range of diameters and an exponential structure of stand stock. Another parameter to describe the horizontal structure diversity is the spatial distribution of the trees within the stand. In the nature forests, the values of this index are tending to random or cluster distribution, while the trees in the managed forests are distributed more regularly. However, the indices of intermixture of trees and of vertical structure come to their maximum in the managed test area, stocked with broadleaves (beech, oak). Here, the selected thinning methods create a situation of higher structural diversity than in the unmanaged forests.

Regarding the diversity and richness of microstructures (e. g. dead wood, root plates, brush piles) in the different test areas it can be resulted, that the unmanaged forests show a higher amount and diversity of dead wood (about 200 solid meter/hectare for the reserves versus 10 solid meters/ha in the managed forests). Finally the small-scaled mosaic of natural succession stages in the nature forests (states of decay close to states of regeneration) produce a higher variability in natural edges than in the managed forests with its homogenous age-class system.

Species diversity

An analysis of different organism groups revealed, that the differences between nature forest reserves and managed forests are less grave than expected. But distinct differences were found between the strata (canopy – stem area - ground).

As demonstrated in figure 3, there are organism groups

that follow the supposed degree of naturalness (beetles and fungi). The correlation is evident : both groups find in the nature forest reserves much more of their main habitat structure: dead wood.

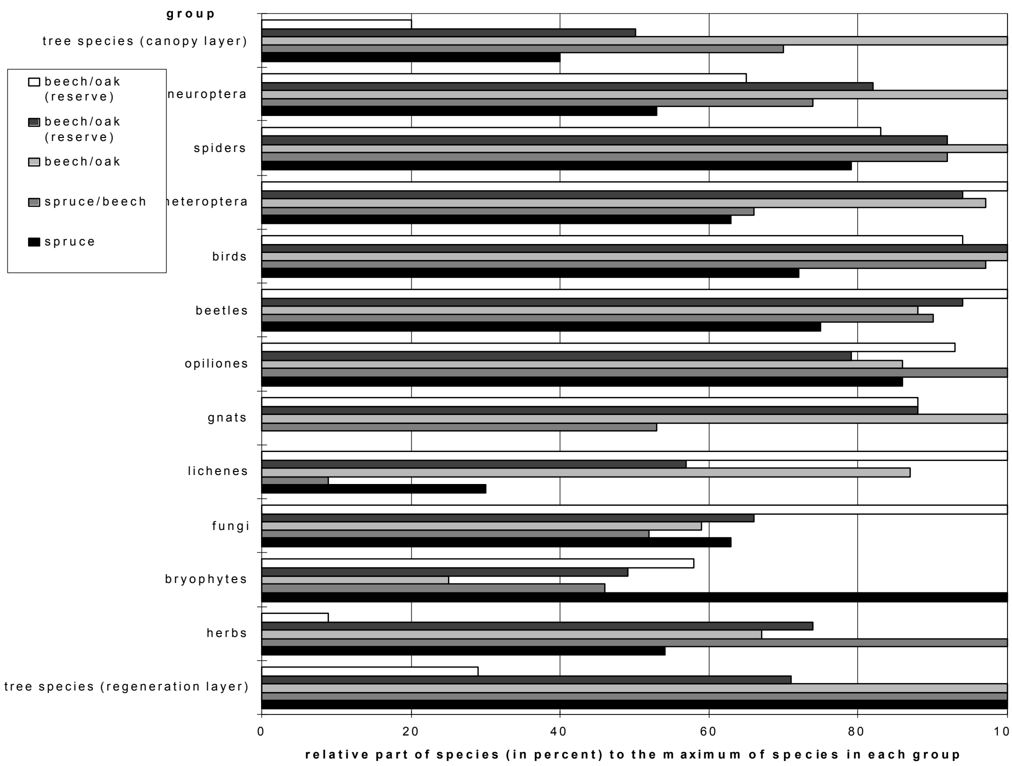
that show no differences in species diversity between the test areas (opiliones, spiders, birds with exception of the spruce area). For invertebrate predators like opiliones and spiders the naturalness of the stand is less important than the existence of micro habitat structures of the surface (brush piles or little branches) which they can find in each stand type.

that were registrated in higher species numbers in the broadleaf variants (managed or unmanaged) than in the coniferous stands (heteroptera, gnats). For the gnats the degradation of the pH-value in the soil caused by the slow mineralisation of coniferous needles seem to be a negative factor. For the heteroptera which mainly prefer the canopy area the broadleaf crowns show more habitat diversity (dead wood, epiphytes).

whose maximum of species diversity has been found in the managed broadleaf forest (neuroptera, lichenes, tree species of the mature stand and of regeneration). It can be estimated that for these groups especially the oak plays an important role for biodiversity within the investigated managed forests. Besides, many other tree species can exist in the neighbourhood of oaks and also the regeneration under the thinned canopy layer of oaks is very diverse.

that present higher species diversity in the test areas dominated by spruce (bryophytes, herbs). The hygrophile group of moss like the high humidity of closed coniferous stands and for the group of herbs it can be said, that in managed mixed forests (with coniferous and broadleaf trees) also a mixture of plant can be found that originate both from broadleaf and coniferous vegeta-tion units.

Figure 3: Investigated organism groups and the relative part of species to the maximum of species found in each group



Nearly the same results are determined by regarding the distribution and the share or rare species (Red-List-Datas). In summary, it is obvious that in our test sites a clear correlation between naturalness of the stand and highest diversity is only given in some cases mostly related to the higher amount of dead wood. Therefore the managed forest and in particular the broadleaf type is of great importance for nature conservation and species diversity.

Conclusions

The stated examples show, that the efforts of forestry are on the right path for the rehabilitation of landscape in Germany.

Even if the rates of **afforestation** remains on a tolerable level, it should be set at a higher value in the planning process than in the past. In such a participative planning process, prototypes of afforestation can help to define the demands of the different actors. In the second step an interdisciplinary approach involved in the landscape planning process will show the best results.

The measures for **regeneration of the alpine forest systems** must be continued even at very high costs and even if the activities will not be blessed by success until several years to come.

The **efforts of conversion** made in the last 40 years in many forests in Germany show first positive effects by increasing structural and faunistic diversity. The conversion program should thus be continued.

A **small-scale, nature-oriented forestry** is able to keep a balance between the maintenance of species biodiversity and the integration of dynamic processes into managed forests.

In any case the **game population has to be reduced** in a way that browsing does not prevent the growth of the young trees. This is important for the Alps as well as in the conversion stands of the lowlands.

Summarising the results of the different studies, a concept of forestry use, which integrates the aspects of aesthetic values and nature conservation with management systems, together with a selected net of total reserves and the creation of biotope-network structures would play an important role in an intelligent, sustainable land-use system for the future - following the intention of AGENDA 21 and the declaration of Rio.

Abstract

Protection forests are forests on steep slopes that have the primary function of protecting people or assets against natural hazards such as snow avalanches and rockfall. In this paper, the current state of protection forests in central Europe, and an approach to managing these forests are presented. If large-scale wind disturbance occurs in a protection forest, fast recovery is needed to restore effective protection. Since silvicultural measures often do not cover their costs with the socio-economic conditions that prevail in central European mountain forests, natural forest dynamics are increasingly being relied since this often ensures sufficient protection. The old view that doing is better than leaving is increasingly being questioned. Decision-making about dealing with wind-disturbed forest areas needs to take into account the decreasing effect of the thrown or snapped trees in preventing natural hazards. Moreover, the increasing effect of the recruitment, especially the advance regeneration, the risk of a bark beetle outbreak when thrown or snapped trees are left lying, and the effects of harvesting on regeneration need to be considered. To choose among different management options, checklists based on the current state of knowledge are used. Since many protection forests are currently far from having the small-scale target stand structure, wind disturbance can also be seen as an opportunity to create forests that will be more resistant to future disturbances, and that will be able to recover from them faster.

Keywords: Protection forest, Windthrow, Regeneration, Silviculture, Central Europe

Introduction

Protection forests are forests that have as the primary function of protecting of people or assets against natural hazards such as snow avalanches, rockfall, debris flow, and floods, or against adverse climate (Plate 1, Brang et al. in press). This definition implies the simultaneous presence of 1) people or assets that may be damaged, 2) a natural hazard or a potentially adverse climate that may cause damage, and 3) a forest that has the potential to prevent or mitigate this potential damage (Wasser and Frehner 1996). On many sites in European mountain forests, site conditions enable forests to offer continuous and effective protection. In the mountain regions of Switzerland, protection forests cover 8-45% of the forest area, depending on the region and the definition of a protection forest (Brassel and Brändli 1999).

The protective ability of a protection forest is mainly provided by trees. Tree stems halt falling stones (Cattiau et al. 1995). Tree crowns prevent, by snow interception and by snow release, the build-up of a homogeneous snow layer that might glide as a compact blanket (In der Gand, 1978). Even dead trees lying on the ground may act as dams to prevent and stop downslope mass transfers (Mössmer et al. 1994). Managing protection forests therefore means maintaining a certain tree cover continuously. The stands should always be a state that meet minimum standards for stand structure. Such standards have been defined for specific natural hazards and site conditions (Wasser and Frehner 1996, Renaud et al. 1994). The ideal structure of a protection forest is often a small-scale mosaic of patches (patch size <0.1

ha) in different developmental stages (Ott et al. 1997 pp. 21, 50), or even a single-tree selection forest (Schütz 1994). On sites where natural disturbance regimes (White and Pickett 1985) create this patchy mosaic, human interference is unnecessary to maintain effective protection. However, on other sites large-scale disturbances such as windthrow prevail, or the current forest condition (e.g., unstable stands with short-crowned, slender trees) favors such disturbances. In such cases, protection forests need to be managed in order to decrease the likelihood of large-scale disturbances, by replacing them with small-scale human forest dynamics.

In central Europe, socio-economic conditions have relieved the pressure on forests as a timber resource. In protection forests, which occur mainly on steep terrain with a slope between 50 and 100%, timber harvesting is costly and may even not cover its costs. Timber is therefore not usually a primary economic factor in European protection forests. In three mountain regions of Switzerland, for instance, no timber harvesting has taken place on 6, 19 and 41% of the forest area for at least 50 years (Brassel and Brändli 1999 p. 187). In many stands, management therefore aims not to maximize revenues, but to minimize losses from timber extraction. Natural forest dynamics are relied on as long as they successfully provide effective protection. However, it is difficult to decide when this is the case. In this paper, we present an overview of the factors to be considered when deciding whether or not to interfere with natural forest dynamics after wind disturbance.

The Current State of Protection Forests in the European Alps is Far from Ideal

Natural disturbance regimes would create the small-scale mosaic desirable in protection forests on the majority of sites in European mountain forests (Zukrigl 1991). However, most stands are far from having an ideal structure since they have been strongly shaped by human impact during centuries (Ott et al. 1997 p. 24). The current deviations from the ideal condition include too little structural and species diversity, insufficient regeneration and too little coarse woody debris.

Plate 1. The protection forest of Curaglia in central Switzerland 1 year after the storm Vivian. The area was harvested and planted, and temporary avalanche barriers were constructed.

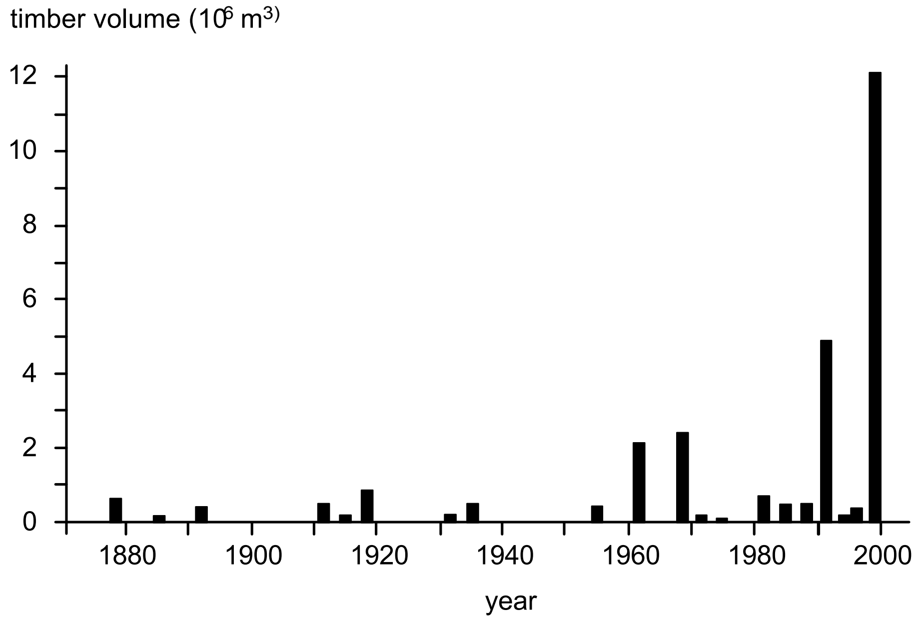
The stand structures are much more uniform in the current man-made forests than in old-growth forests. In the Swiss Forest Inventory the stand structure was classified as uniform on 68% of the plots (Brassel and Brändli 1999, p. 117). There are no representative data from old-growth forests on similar sites. However, a site-specific analysis of many case studies in Slovakian old-growth forests (Korpel' 1995) suggests that, without human interference, over three quarters of the Swiss forests would be structurally diverse (including *Fagus sylvatica* forests, mixed *Abies alba-Fagus sylvatica* and *Picea abies-Abies alba* forests, and subalpine *Picea abies* forests; Brassel and Brändli 1999, p. 67). In comparison to what is assumed to be the natural vegetation, *Picea abies* is over-represented in Swiss forests. This was shown using a site-classification model and tree inventory data, on sites where deciduous trees would be dominant without human interference (Kienast et al. 1994). On these sites, *Picea abies* occupied more than 75% of the total basal area on 21% of the plots. The proportion of another coniferous species, *Abies alba*, has been reduced by human impact. This shade-tolerant species is not competitive on large open areas and is much more heavily browsed by ungulates than most other tree species (Liss 1988). Its distribution has been greatly reduced by extensive clear-felling and grazing in the 19th century, and by high browsing pressure in recent decades (Eichenseer 1997). The volume of coarse woody debris currently amounts to 11.9 ± 0.5 m3/ha (mean ± SE, Brassel and Brändli 1999 p. 290) in Swiss forests, while in Slovakian old-growth forests, volumes of 50-280 m3/ha have been reported on similar site types (Korpel' 1997). Moreover, tree regeneration has been impaired by grazing, browsing (Brändli 1995), and a lack of coarse woody debris which is an important seedbed for several tree species (Mayer and Ott 1991 p. 14). In an analysis of Swiss National Forest Inventory data it was estimated that the regeneration cover is below target values on about 30% of the area on sites where *Picea abies* is assumed to be dominant (Brang and Duc, unpublished data).

Structurally homogeneous stands are less resistant to wind disturbance (Schmid-Haas and Bachofen 1991). Furthermore, the higher proportion of *Picea abies* means lower resistance to bark beetle disturbance since this species is most susceptible to this type of disturbing agent. Insufficient regeneration and coarse woody debris as a seedbed mean longer recovery periods after disturbances. In conclusion, deviations from an ideal stand composition and structure mean that with the current stands, effective protection is more likely to be impaired by natural disturbances, and will take longer to be regained after impairment by disturbances.

Wind Disturbance in Central Europe

Wind is a major disturbing agent in many forest ecosystems (Brünig 1973, Oliver 1980/1981, Canham and Loucks 1984, Martinez-Ramos et al. 1988, Foster and Boose 1995, Mitchell 1995, Vasenev and Targul'Yan 1995). In old-grown forests in central Europe, 8-15% of the forest area show visible signs of wind disturbance (Falinski 1976, Skvorzova et al. 1983 p. 172). In secondary forests in western Russia with large-scale wind disturbance, this percentage can reach 30% (Skvorzova et al. 1983 p. 172). This must be regarded as an extreme value for secondary forests. At the other end of the scale are two large districts in the Urals in Russia. Wind disturbance affected only 0.12% of the forest area in the 8400 km^2 district and 0.19% in the 8100 km^2 one over a 30 year period. In contrast, the storm Vivian in 1990 alone affected 0.4% of the forest area in Switzerland (Schmidtke and Scherrer 1997). The timber volume affected by wind disturbance has increased in recent decades in Switzerland (Fig. 1). The main reason for this is probably an increase of the standing volume (Brassel and Brändli 1999 p. 76). In contrast, there is not yet any empirical evidence for an increased frequency and/or magnitude of storms in central Europe (Schiesser et al. 1997).

Fig. 1. Development of timber volume affected by wind and snow load disturbance in Switzerland. The volume has increased in recent decades.



After the storm Vivian in 1990, 90% of the windthrow areas (size >0.2 ha, and with less than 20% canopy cover left) in Switzerland were smaller than 1.8 ha, and comprised 50% of the total windthrow area (Schmidtke and Scherrer 1997). Less than 1% of the areas were larger than 10 ha, but these made up 18% of the total windthrow area. In old-growth forests in central Europe, the individual areas affected by wind disturbance tend to be smaller than in secondary forests (Zukrigl 1991), although firm evidence is difficult to find since the remaining old-growth remnants are very small (Leibundgut 1982, Mayer et al. 1989, Korpel' 1995).

Wind disturbance often triggers other disturbances, especially by bark beetles (Strunz 1995, Schopf and Köhler 1995, Schmidtke and Scherrer 1997, Forster et al. 2000) which feed on weakened trees. After the storms in recent decades, the timber volume affected by secondary damage amounted to 30-60% of the initial wind disturbance (Forster et al. 2000).

The patterns of wind disturbance found in European mountain forests, especially protection forests, are similar to those presented above. In comparison to lowland forests on flat terrain, aspect has a greater influence on the occurrence of wind disturbance (Foster and Boose 1995). Although wind speeds are generally higher in mountain areas than in the lowland (Schüepp et al. 1994, Finnigan and Brunet 1995), there is no evidence for higher levels of disturbance in mountain forests. Several effects seem to counteract higher wind speeds in mountain areas: the adaptation of trees to wind (Mattheck 1989), lower tree height connected to lower site productivity (at least in a regional comparison), and a higher frequency of internal stand edges which are highly resistant to wind (Ott et al. 1997 p. 21).

Restoration After Wind Disturbance in Protection Forests

There are two principal ways of reducing the impact of wind disturbance in forest management: by enhancing the resistance of the stands to wind, and by promoting fast recovery. Managing for resistance, which should aim at preventing undesirable disturbances, is widely practiced (for even-aged stands, see Nielsen 1995 and Slodicák 1995, for uneven-aged stands, see Ott et al. 1997). However, there are always wind speeds higher than what the stands can resist. If such a disturbance occurs, fast recovery is needed until the recruitment ensures effective protection again. In this paper, we focus on the second case of managing for fast recovery after wind disturbance.

To determine the degree of human intervention, necessary in protection forests, a consistent procedure has recently been adopted in Swiss mountain forests, and several checklists have been developed (Wasser and Frehner 1996, Ott et al. 1997, BUWAL 2000, Brang et al. in press). The basic idea is to make use of natural forest dynamics as long as undesired effects are unlikely to occur, and to limit human interventions to those that are effective, justifiable (cost-effective), necessary, and feasible (Wasser and Frehner 1996, Brang et al. in press). The most important short-term management alternatives are: leaving trees (with the bark, or stripped bark of) in place vs. harvesting trees, planting vs. (or as a supplement to) natural regeneration, and using avalanche and rockfall barriers vs. relying on the effects of downed trees and surface roughness. Scientific evidence that can be used to underpin management decisions is increasing, but much of the procedure is still based only on the experience of forest managers.

Several factors need to be taken into account in applying this procedure to areas affected by wind disturbance, aside from the potential costs involved in any silvicultural measure (see also BUWAL 2000). First, the downed stems usually provide effective protection for at least one decade (Lässig and Schönenberger 2000), although empirical evidence about how long this effect lasts is lacking. Second, it takes 30-80 years until protection from the new generation becomes effective in subalpine protection forests (Ott et al. 1997 p. 33), and still 20-50 years in montane forests. While natural forest dynamics will, under most conditions in the European Alps, create stands that provide effective protection after wind disturbance, the time needed may be unacceptably long (Fig. 2). Given this uncertainty, an interventionist approach is still appropriate to protect people or assets directly threatened by natural hazards (direct protective effect, Brang et al. in press). In such cases, precautionary measures should be taken to ensure continuous effective protection.

Third, leaving trees in place may trigger bark beetle damage in adjacent stands, although a "clean" management, with immediate removal of every attacked tree, is in many cases unfeasible. Fourth, harvesting trees may damage advance regeneration (Fig. 3, Alexander 1957, Timoney and Peterson 1996). However, harvesting also creates exposed mineral soil, a safe site for the establishment of the seedlings of many conifers (e.g., Alexander 1984, Prévost 1992, Brang 1998). Fifth, downed trees are an impediment for browsing ungulates and therefore protect seedlings and saplings from browsing. Sixth, we can be more certain about the spatial distribution, growth and mortality of seedlings if they have been planted.

Managing for fast recovery must start before a wind disturbance occurs. A crucial element in fast recovery is the presence of established seedlings and saplings that wait for release (advance regeneration, Fig. 3). After a windthrow, the regeneration of climax species is often primarily from advance regeneration, while most of the seedlings of pioneer species re-establish after the disturbance (Fig. 3, Fischer 1992, Lässig and Moèhalow, in press). Lack of advance regeneration delays recovery or at least effective protection, especially on large areas. The pioneer species invading a windthrow area (Fig. 3), such as *Betula spec*., seem to be less effective in providing protection against avalanches than evergreen conifers, such as *Picea abies*. The patchiness that is usually observed in natural regeneration on wind-disturbed areas (Lässig et al. 1995) is not a problem but rather an advantage in protection forests, as long as the distance between individual patches is smaller than about 30 m. A diverse stand structure in the recruitment facilitates the development of structural diversity. In contrast, overly dense stands, especially those planted with regular spacings, are most likely to become structurally homogeneous with low individual tree stability, or require high tending costs to avoid this development (Ott et al. 1997 pp. 83-92). Planting is only used if advance regeneration is insufficient and coniferous seed trees are further than about 100 m away (Lässig et al. 1995), and if fast recovery is essential since planted seedlings usually grow faster than those from natural seedling establishment (Mosandl and El Kateb 1988).

Fig. 2. Schematic development of the protective effect after wind disturbance. Time steps: (0) disturbance, (1-4) and (8-11) protection effective, (4-8) protection ineffective since the sum of the effects of the downed logs and of the recruitment is insufficient. The period from 0 to 11 lasts 50-150 years.

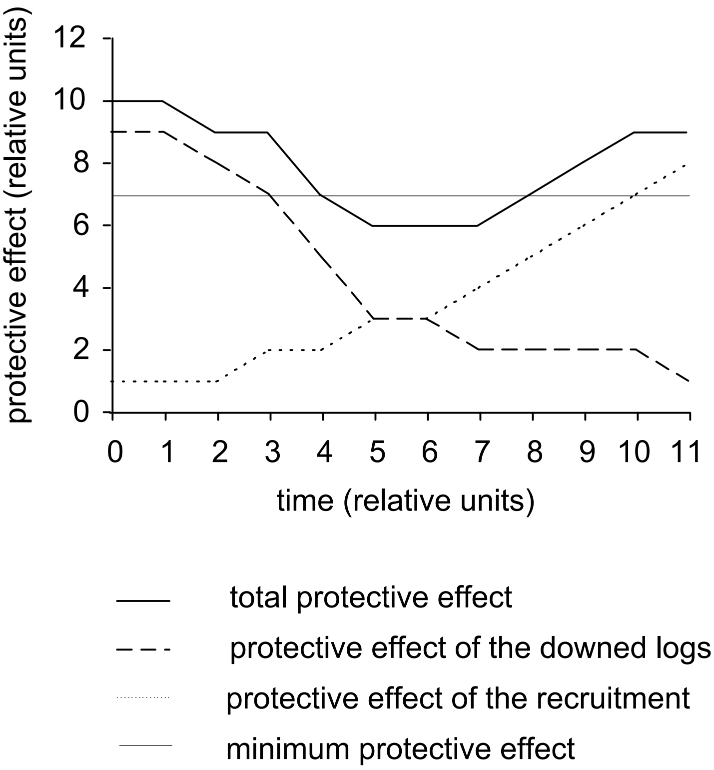


Fig. 3. Species-specific abundance of naturally established tree seedlings (height >20 cm) in cleared and uncleared parts of the windthrow area Šajtanka (central Ural, Russia) and in the adjacent forest, one year after a storm. *Picea obovata* and *Abies sibirica* are unable to grow to 20 cm height within one year; therefore, they are from advance regeneration in all areas.

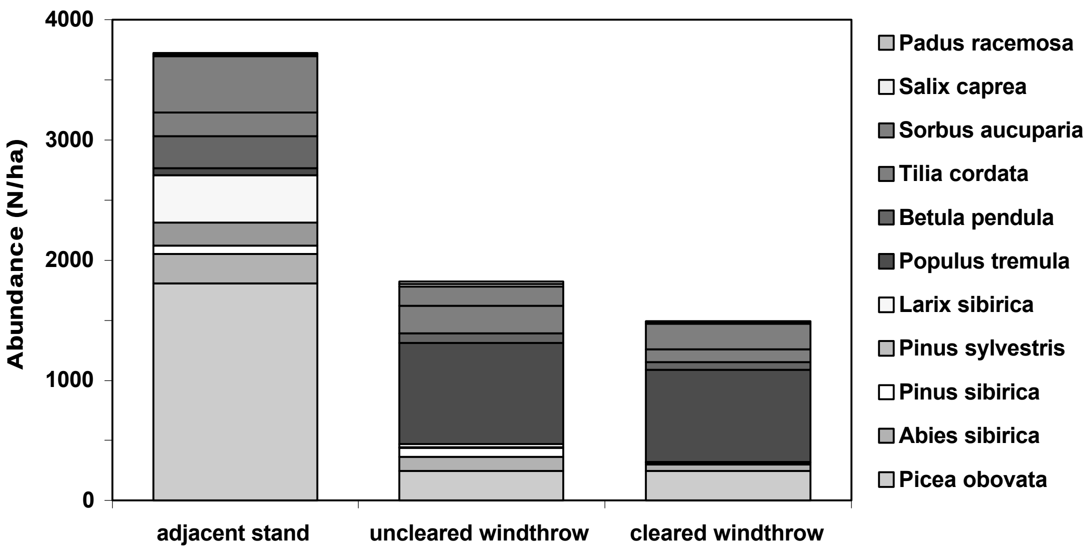

In any case, the old practice of planting areas in regular grids has been abandoned to avoid structural homogeneity.

Conclusions

Over the past 20 years, the management of protection forests in Switzerland has changed profoundly, There was a strong belief that silvicultural measures would always be required in any situation to ensure continuous effective protection (Leibundgut 1982 p. 186). This belief was only partly based on scientific evidence. Socio-economic changes have caused a revision in silvicultural thinking. Since "leaving" is in many cases cheaper than "doing", a "smart laziness" (Ott 1990) has been adopted, meaning interfering with natural forest dynamics only if this is effective, justifiable (cost-effective), and necessary to ensure sufficient protection. "Doing" and "leaving" are now accepted as equally valid management options.

A stand damaged by wind obviously creates problems, especially in a protection forest. However, wind disturbances must also be seen as a silvicultural opportunity (Kasper and Schönenberger 1991) since stands that are far from having the ideal structure for effective protection may be transformed to structurally diverse stands that will be continuously effective. Moreover, wind disturbance seems to reduce the browsing pressure in adjacent stands because these areas are highly attractive to browsing ungulates. Finally, monitoring after wind disturbance (Schönenberger et al. 1992) helps us to understand forest dynamics better, including interactions among disturbances such as wind and bark beetles, and helps to scientifically underpin our approaches to the management of protection forests.

The general line of thinking about management options to restore wind-disturbed forests has been elaborated. Some simple decision support tools, such as checklists (BUWAL 2000), are available. Applying these tools helps us to avoid management failures. Current knowledge about the processes that take place after wind disturbance has been utilized tin designing these tools. However, we are far from having an adequate risk management approach (Quine et al. 1995, Valinger and Fridman 1999). The challenge lies in widening our knowledge in order to enable us to manage the risks associated with alternative management options. The storms, Lothar and Martin, which hit central European forests in 1999, have provided new opportunities for improving our approaches to dealing with wind-disturbed forests.

Abstract

Landscape conservation and management are increasingly important goals in rural land-use planning. Integration of landscape management into natural resource planning is tied to possibilities of illustrating the impacts of activities. The different approaches to include scenic values to forest and land-use planning include landscape preference studies, preference modeling and participatory planning. In all approaches visualization can be a good instrument.

For routine planning efficient and inexpensive tools are needed. Today digital image editing and virtual landscape simulators offer the most sophisticated means of visualization. Digital image editing enables public evaluation of forest management alternatives for example in recreational areas or in urban forests. However, forest landscape simulators are less labour-intensive than image editing and offer flexible movement between different viewpoints. The greatest advantage of landscape simulators is that they can be linked to actual planning systems and to different type of forest data. In the future, participatory planning calls for more realistic illustrations , integration of visualization with different sources of spatial data as well as high interactivity of planning tools. Furthermore, additional research is needed to evaluate and compare the usability of different visualization media in forest planning.

Keywords: digital image editing, forest landscape simulators, landscape planning, multimedia GIS, visualization.

Introduction

Rural landscapes provide many amenity benefits such as experiential and ecological values. Landscape quality is also shown to have economic dimesion and for example to reflect in property values (Willis and Garrod 1993, TyrvŠinen 1999). Moreover, in many regions rural tourism becomes for a second or third economic area besides agriculture and forestry. Environment is evaluated mainly as a landscape (Zube et al. 1982) and its quality is a key element for the development of rural tourism (e.g. TyrvŠinen et al. 2000). Therefore, in forest management a balance between traditional economic and less tangible amenity benefits, important for the new means of livelihoods has to be developed.

In the forests are as much part of the nature as the rural cultural landscape. Because approximately 87% of the total land area in Finland is forested. Forest management practises, in particular forest regeneration has long-term impacts on landscape (e.g. Benson and Ulrich 1981, Karjalainen and Komulainen 1999). Furthermore, field afforestation and agricultural intensification have great effects on the visual landscape character as well as biodiversity values. In a country such as Finland with little open agricultural land (7 %), afforestation will hide the agricultural landscape of farm-houses and other traditional land marks behind a forest cover and may close up important distant views such as lakes. Cultural landscapes will become unrecognizable (e.g. Tahvanainen et al. 1996). Visual changes will be immediately and directly experienced by the public However, the quality of impacts of afforestation and forest regeneration depend on the landscape character and negative effects can be mitigated by landscape planning.

Recently, at the forest policy level the social sustainability has been increasing emphasis besides the economical and ecological aspects (e.g. Lisboa 1998). The national Forestry Law in Finland sets social sustainability as a parallel goal to economic and ecological sustainability in forest management (MetsŠlaki

1998). In addition to the traditional socio-economic objectives such as job opportunities and preservation of landscape beauty, The concept includes besides enhancing the opportunities for outdoor recreation and diversification of the means of livelihood in the rural areas. In the future, the multifunctionality will be emphasized in the EU's common agricultural policy, which means among other things, that in food production, cultural landscape heritage and landscape management needs will be considered (Kola 1999). Prerequisite for EU subsidies is that afforestation of land should be adapted to local conditions and compatible with the environment (Council Regulation 1999), which implies that the scenic impacts of afforestation should be addressed in the planning.

Although the landscape conservation and management may be recognised as a strategic objective, they are less successfully put into practise. The legal regulations addressing visual aspects of land-use planning leave wide space for interpretation and in forestry the visual impact analysis has evolved little so far. One of the main reasons is that at present there is no adequate and efficient tools for measuring and integrating landscape values in land-use planning and policy-making (McCormack et al. 1998, Nousiainen et al. 1999). However, objective measurement would place scenic beauty, as a resource, on a more equal footing with other more tangible resources, and would also provide better justification for land-use decisions.

Two main factors have increased the need for realistic visualization tools. i) A general trend towards smaller scaled forest management practices in many countries and ii) public concern about environmental impacts and tighter management guidelines which demand better and more accurate planning (e.g. Buckley et al. 1998). Traditionally, in Finland planning is carried out on one farm at a time. However, administrative borders rarely join physical, ecological or visual borders of the landscape. Often the activities of neighboring farms are as important as activities on the object farm. Therefore, landscape planning should preferably be made simultaneously both on the landscape level and on the farm level. The scale of planning should be chosen according to the scale of changes and the type of landscape. A uniform landscape needs larger evaluation than a small-featured or scattered landscape.

Participatory planning provides the citizens and interest groups a possibility to influence in decision-making in forestry. In Finland the method has been used in strategic forest planning at national level, but also in planning of state owned forests as well as in urban forest planning (e.g. Kangas et al. 1996, Loikkanen et al. 1997, FNFP 1999). The benefits of broad-based community involvement are many and there include promoting stronger sense of commitment of citizens, increasing user satisfaction, creating realistic expectations of outcome and building trust (e.g. Al-Kodmany 1999). It is important that the participants are equally informed on the impacts that land-use or natural resource management may have including their effects on scenery, recreation and other amenities. To avoid the problems of misunderstanding, information should be easily understood by all participants. Visualization is required in participatory planning of rural areas, where larger groups of people are involved. It is the key to effective public participation, since it is a common language in which all participants - technical or non-technical can relate (e.g. King et al. 1989).

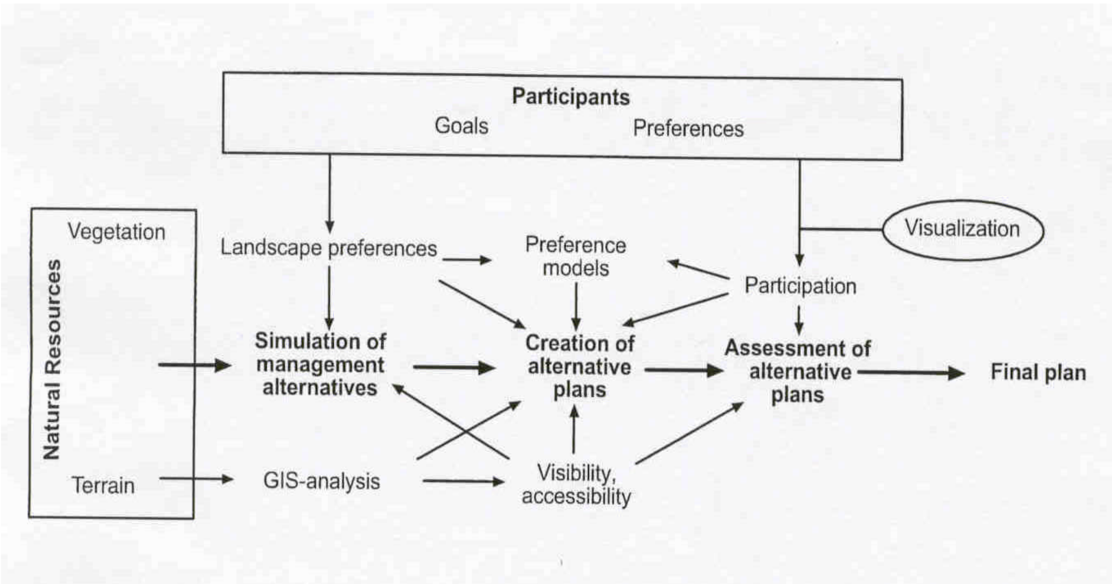
Conflicts in the use of natural resources may often arise from the fact that people have different mental images and ideas of the proposed activities. The attitudes towards forest management seem to depend to certain extent on the presentation format. Amount of verbal information is also shown to have an affect on the people’s acceptance of various management actions in relation to the forest environment (Jensen 1998). A study of Tahvanainen et al. (2000) indicate that preconceptions concerning different silvicultural measures in general did not consistently correspond visual perceptions. People may oppose certain management options although the impacts on landscape may be unnoticeable or even beautiful. Therefore visualization may decrease potential conflicts related to forest management.

Requirements for Visualization

The main part of landscape perception occurs through the sense of sight and therefore, integration of landscape management into natural resource planning is tied to the possibilities of illustrating the impacts of activities. The different approaches to include scenic values to forest and land-use planning include landscape preference studies, preference modeling and socio-economic studies. In all approaches visualization can be a good instrument. Furthermore, in multi-objective forest planning methods such as numerical optimisation procedures and choice models have been developed (Kangas and Kristiansen 1995, Pukkala et al. 1995). Although the the scenic beauty may be difficult to predict and express numerically, the impacts of management plans can be visualized for decision-makers (Fig. 1).

Landscape planning is unlikely to be successful without being linked with other forms of planning. Even when it does operate independently, it must usually take into account social and economic factors which condition these other forms of planning . Therefore forest visualization should preferably be linked to operational planning systems and tools such as GIS (e.g. Nousiainen et al. 1999). For public participation forestry experts and land-use planners need an interactive visual planning tool that enables the interest groups an citizens to fully participate in the process. In the planning meeting the planner and/or participants may interacting themselves or through a consultancy (Kangas et al. 1996.).

Figure 1. Different approaches to integrate scenic values to forest planning (adapt. from. Nousiainen et al. 1999).



Many interest groups, besides landowners, are interested in landscapes. The number and quality of groups vary according to the planning areas. The possible groups may include interested citizens local residents, tourists, NGO's , administrators and enterprises. There are different levels of participation. At its highest level the participant will make the decisions and the responsible organisation will only implement the plan. At the lowest level the focus is in delivering information during the public meetings (e.g. Loikkanen et al. 1997). The role of visualization is especially important if people without special expertise are involved in planning. It is important that changes both in landscape structure and vegetation can be recognised. The illustrations should be able to capture the details such as special shapes of trees, undervegetation and stones, which attract the viewer's attention and create experiences. The required level of realism is very high if the person knows the landscape thoroughly. This is the case with local residents and people frequently visiting a particular setting (e.g. Karjalainen and TyrvŠinen 2000).

Visualization is not only cheaper than on-site visits but it also offers laboratory conditions where many aspects affecting site evaluation can be avoided (e.g. heat, cold, rain, wind). However, landscape illustrations should correspond to the conditions in nature. Although many studies have shown that slides and photographs are acceptable substitutes for on-site visits if they include most of the scenic elements of the landscape (e.g. Shuttleworth 1980), opposite results have also been obtained (e.g. Hull and Steward, 1992). Visualization has also been criticized because it is not able to represent the whole richness of real nature. Photographs, for example, are not only less complex and less multidimensional but they also offer less interaction than real scenes (e.g. Karjalainen and TyrvŠinen 2000).

Visualization should also simulate the way people move in and perceive the environment. A good visualization tool enables flexible choice of viewpoints and the perspective of illustrations should be realistic. Perceptions are also dependent on the rate of speed, on the means of transport (e.g. on foot, by bike) and on the activities performed (e.g. Zube et al. 1982). In order to be able to account for this kind of variation simulation of different ways of moving in landscape is needed.

In forest planning the decisions concern the future and are impacts of silvicultural treatments are probably difficult for the ordinary residents to comprehend. In order to determine the effect of any particular change such as regeneration or afforestation, it is important that the visualization medium allows only one aspect of the landscape changing at a time. The desired changes in images should preferably be automatized, but at least they should be relatively easy to make. The method should enable to control variables such as light, colours and shades. Furthermore, visualization should be accurate and scientific. It is often important to know the exact size of the logging area and the amount of timber removed or trees planted to guarantee that the illustration corresponds to the reality. Therefore, the visualization medium should be linked with different kind of spatial forest data.

Moreover, the planning costs are limited and therefore visual impact assessment in forestry should not generate too much extra costs. The price of visualization package and the requirements for its running environment must be reasonable. Expenses can be restricted if the use of visualization tool is easy and not labor-intensive.

Visualization Methods in Forest Planning

Forestry professional and scientists have been investigating visualization techniques for many years addressing a range of forest management problems. The recent methods for illustrating changes caused by management include photographic manipulations and video techniques and multimedia GIS. Furthermore, sophisticated technological innovations such as computerized visual landscape simulations have been introduced (Zube et al. 1987, Karjalainen and TyrvŠinen 2000).

Digital image editing techique uses computer software in the manipulation of digital images which have been either digitized or originally taken with a digital camera. Digital image editing makes it possible the study of the effect of a particular change in landscape and control other variables such as amount of open space. The images produced are photorealistic, but also static and the method cannot be easily automized. Detailed changes in original images are time-consuming and costly to make (Fig. 2). There are, however, many factors affecting editing speed. For example, how accurately the original pictures are to be visualised, what is the quality requirement and for what purpose pictures are to be made (Tahvanainen et al. 2000). Furthermore, the pictures produced are, to a certain extent, open to inaccuracy because of the subjective evaluations present in the modification of the original pictures. Without the use of spatial data it is difficult to estimate the effect of change in the landscape accurately.

The available methods to simulate movement include *video* and *animations* (e.g. Vining and Orland, 1989). Using video simulation participants can actually see their comments and suggestions taken into in account. This feedback reinforces the participatory process and promotes the exchange of ideas. While video images are photorealistic and inexpensive, the simulation of change is labour-intensive. Furthermore, although animations are relatively easy to prepare with present computing equipment and freely available software, photorealistic animations are also laborious to produce.

Figure 2. The impact of forest management can be illustrated by digital image-editing are photorealistic, however detailed changes in original images are laborius to make.

Furthermore, GIS has been used in visual impact assessment in forestry, in particular, the aesthetics of forest cutblock shape, size and location are an primary interest. However, current GIS technology has not provide visualization functionality affording realistic presentations of the 3-D landscape. So far there has been relatively little integration of the scientific visualization techniques with commercial GIS software (Buckley et al 1998). However, with increasing functionality and hardware developments capabilities to represent and animate 3-D images of the landscape in real time are coming on-line within commercial GIS applications. Moreover, *multimedia GIS* have been recently tested in land-use planning (e.g. Weidenbach 1999, Weidenbach and Pršbstl 1999) This approach includes the use of digital video and sound, combined with graphic files and zoning maps. However, the use of multimedia GIS in participatory planning must be looked critically, because digital presentation with audiovisual effects may influence the audience more than a conventional analogue presentation of the land-use plan (Weidenbach and Pršbstl 1999).

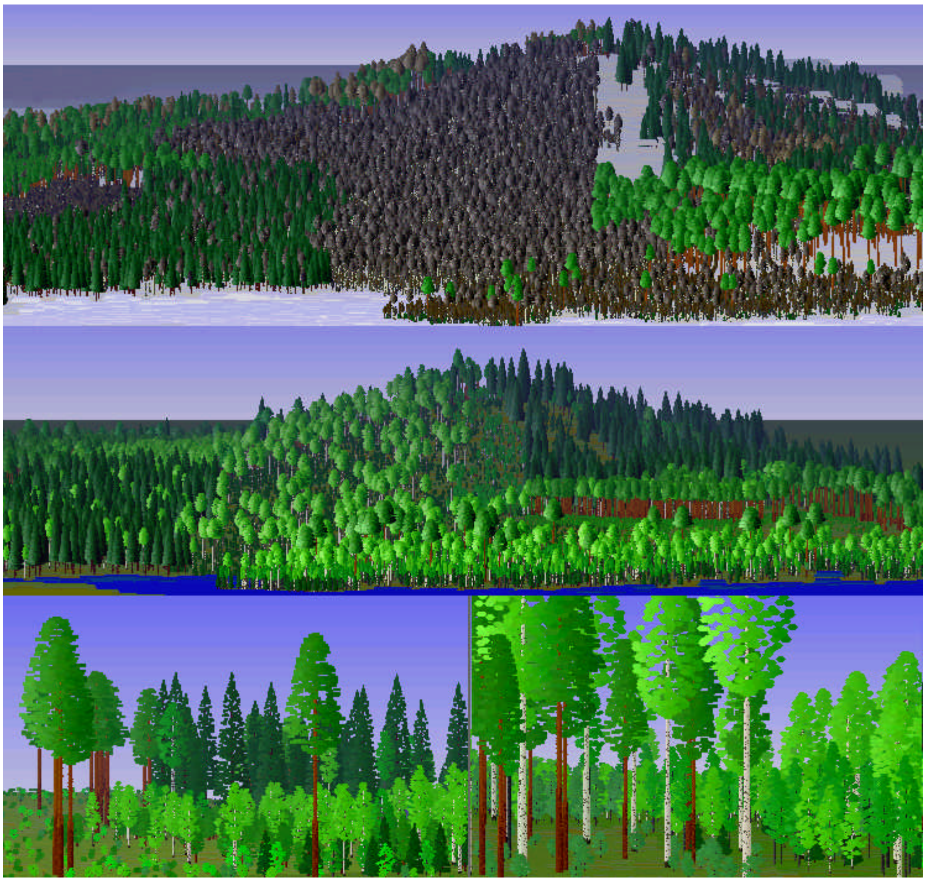
Virtual forest landscape simulators are based on the use of a digital terrain model, some kind of a map and forest data (Orland 1997, Uusitalo et al. 1997, Pukkala 1998). Examples of systems developed in Finland include the multiple-use forest management planning system, MONSU (Pukkala, 1998) and a commercial landscape simulator FORSI developed by private consultant and development enterprise Plustech Ltd. Other example include, Smart Forest –program, an interactive, three-dimensional visualization system developed by University of Illinois (Dept of Landscape Architecture) and the USDA Forest Service for visualizing scenic effects of use and treatment decisions (Orland 1994). The functions of the programs are rather similar and are based on map information, an elevation model, compartment data of the target area, and visual objects.

The illustrations of forest landscapes in the MONSU system are automatied computer line graphic drawings based on tree and site parameters, included in present forest planning systems. Trees can be illustrated by three different quality levels. The tree symbols are differently coloured two- or three-dimensional graphic symbols, whose species and size distribution correspond to the local tree populations as described in inventory data (Fig. 3). In FORSI and Smart Forest programs the two-dimensional visual objects generated from digitized photographs represent the main elements of a forest landscape (trees, shrubs, undervegetation, logging residue).

One advantage of the landscape simulators in visualization of forest plans is their flexibility; the observer is not limited to any predetermined viewpoints. They display topographical variation and perspective from a chosen vantage point. The programs enable a flexible assessment of both close-ups and long-distance scenes with updated forest data. The assessment of landscape from several viewpoints is possible. They also enable the simulation of a real-time movement in the landscape, but at present the capacity of current PCs limits the use of this property (TyrvŠinen and Karjalainen 2000). The programs are also able to illustrate the effects of seasonal change and atmospheric effects such as fog. Moreover, automatized visualization reduces the production costs of illustrations.

The visualization tool can be connected with a forest planning system, which means, among other things, that the evaluation of the scenic impacts of alternative plans is easy. Because MONSU program is developed for forest planning, the simulation of landscape changes by different management regimes is easy both at forest stand and forest area level. In FORSI and Smart Forest programs the simulations of forest operations are less easy to conduct; they are realized through a manipulation of the compartment or tree data.

Figure 3. An example of the near-view and long-distance view illustrations of a forest area produced



One of the disadvantages of landscape simulators is that the images may not correspond to the real world well enough (Karjalainen and TyrvŠinen 2000). Although the illustrations include some elements of the undervegetation such as berries and mushrooms, the special features and details of a particular landscape (buildings, shrubs, stones, special shapes of trees and single trees) are absent. Thus the forest simulators produce more or less standard landscape pictures. However, the quality of the illustrations depends to large extent on the viewing distance. Moreover, rare tree species and additional objects such as houses and recreational facilities can be added to the object library or added into the pictures manually.

At present rather very is known how well the visualizations correspond to the reality in different planning situations. There are some studies in which two or three visual presentation methods have been compared to each other (e.g. Pukkala et al. 1988, Nousiainen and Pukkala 1992, TyrvŠinen and Tahvanainen 1998). In the study of Nousiainen and Pukkala (1992), computer graphics and slides proved to be almost equal methods for the ranking of forest trails on the basis of scenic beauty and variation. However, it was found out that the recreational value of forest trails cannot be easily evaluated on the basis on computer graphics, presumably because low bushes, dwarf shrubs and obstacles on the ground were omitted from the illustrations.

Some studies suggest that computer graphics may be an adequate presentation format for public evaluation al.1998). In the study of TyrvŠinen and Tahvanainen (1999) images illustrating impacts of afforestation produced by an early version of the MONSU (multiple use forest planning system) and panoramic slides were evaluated by land-use experts and landowners. Nousiainen et al. (1998) tested the use of vector graphic illustrations in a participatory planning context in North-Karelia, Finland. Both studies suggest that computer vector graphics is an adequate medium in the comparison of different management alternatives in large-scale agricultural landscapes. In large-scale views, small landscape elements are not so important and merge easily with the background scenery.

Conclusions

Scientific visualization in forest planning systems allows planners to work effectively with landowners from wide variety of backgrounds and perspectives. The visualizations have to be tied to underlying databases and the links between visualization and data are verifiable, reliable and accurate. Currently visual simulation of forest may be only descriptive. The difficult task of evaluation remains for the planner and the participants. Visualization should be used more in decision-making process. It is often now regarded as decorative in function and is done to sell the resulting proposals in planning. Moreover, visualization can only be an important tool if it is integrated early in the planning process.

Presently, digital image editing and virtual landscape simulators offer the most advanced visualization methods for the needs of forest planning. The advantages of landscape simulators include that the landscape illustrations are automised and that they offer flexible movement between different viewpoints. Furthermore, virtual landscape simulators are able to link images both with forest inventory data and with the planning systems of forestry and agriculture. However, participatory planning calls for more realistic illustrations as well as integration with different sources of spatial data, real-time movement in the landscape and high interactivity. In addition, a good visualization tool illustrates the changes in the environment in a realistic manner both from the near and the distance. While many of these properties exist in current landscape simulators, they are not at present all incorporated in the same program. However, computer graphics systems are under rapid development.

Often the areas which are of main interest for landscape visualization are visually sensitive areas: urban forests, recreation areas, national parks, and other scenic environments. In such landscapes the illustration of details (e.g. the special shapes of trees and the spatial variation of undervegetation) remains very important. Detailed illustration is also necessary when the respondents are familiar with the environment, as the case is in urban forests. So far original or manipulated photographs are the best means of visualization -in particular when assessing visual impacts of forest management on close-ups with their special features.

There are technical problems in the visualization of landscape change and methodological problems in the evaluation of landscape beauty and lack of clarity in integrating the visual aspects in the planning process. For example because of the limited resources available in forest inventory, forest data do not have the details and richness, i.e. information on forest edges, undervegetation, individual big trees and their shapes, required if we are to create realistic images. One solution is to use mixed techniques. For example, illustrations could be produced by forest simulators and edited by image editing technique or using techniques such as image draping available in GIS.

The future prospects for landscape visualization in forest planning include a use of virtual reality techniques with multi-stimulus representations of landscapes. Nevertheless, it must be remembered that even at its best the visualization of the landscape cannot fully convey the real landscape experience. Illustrations are an additional tool and not replace the field work in environmental planning. Moreover, additional research is needed to evaluate and compare the usability of different visualization media in rural land-use planning.

The Social and Economic Impacts of Plantation Forests

by
Roger A. Sedjo
Resources for the Future
Washington, DC, USA

Abstract

The rapid increase of plantation forests is an important phenomenon. Fifty years ago plantation forests for wood production were quite rare. Most regeneration was natural, not planted. Since that time planted forests have become common throughout much of North and South America, the Nordic countries, and increasingly in parts of Asia. The onset of industrial forest plantations as a major component in the world's industrial wood supply can probably be dated from about the 1960s.

Planted forests now account for an estimated 34 percent of the world's industrial wood production . The portion coming from planted forests will certainly increase over the next few decades as more natural forestlands are set aside for environmental purposes and harvesting restrictions become increasingly stringent, thereby driving up the costs of wood from natural forests. Thus, the economic advantages of forests, which are planted in desirable, accessible locations, and in selected species will become increasingly attractive vis-a-vis wood obtained from natural forests and difficult sites in marginally accessible areas.

The social and economic impacts of plantation forests become increasingly important as the contribution of plantation forests to the timber supply continues to grow.

Keywords : Forest plantation, Social and economic impact.

Introduction

The rapid increase of plantation forests is an important phenomenon. It represents a fundamentally different way of providing for society's wood needs. The gathering of the bounty of the natural system is gradually being replaced by the introduction of an agricultural mode into wood production. Fifty years ago plantation forests for wood production were quite rare in most of the world; parts of Europe and Japan might have been the exceptions. While some forms of forest management were commonly practiced, most regeneration was natural, not planted. Since that time planted forests have become common throughout much of North and South America, the Nordic countries, and increasingly in parts of Asia. In earlier work I have argued that the onset of industrial forest plantations as a major component in the much of the world's industrial wood supply can probably be dated from about the 1960s.

Planted forests now account for an estimated 34 percent of the world's industrial wood production (Table 1). The portion coming from planted forests will certainly increase over the next few decades as more natural forestlands are set aside for environmental purposes and harvesting restrictions become increasingly stringent, thereby driving up the costs of wood from natural forests. Thus, the economic advantages of forest, which are planted in desirable, accessible locations, and in selected species will become increasingly attractive vis-a-vis wood obtained from natural forests and difficult sites in marginally accessible areas.

This paper examines the social and economic impacts of plantation forests. Although the literature on this topic is small, some studies touch on aspects of this situation and there are anecdotal events that provide some insights.

Overview

Figure 1 provides a long-term overview of the changes in forestry. For millenia humanity relied on the production of nature to meet its wood needs. Although there is evidence of some tree planting and silviculture back to the B.C. period, tree planting for wood products probably was not common on a larger scale until after 1800, and then only in parts of Europe. However, in the latter part of the 20th century things changed dramatically. Planting began in earnest after WW II and especially after 1960. The 1950s saw large-scale tree planting in Japan, restoring much of the forest that was depleted during the war. The Nordic countries also became active in tree planting as they recognized that lands abandoned by agriculture had substantial tree planting potential.

The late 1950s saw major tree planting in the U.S., precipitated by excessive agricultural production, through a program to take lands out of agriculture. However, by the mid-1970s, large scale planting was underway driven not by government programs, but by market forces. The 1970s and 1980s saw the intensity of the planting increase and move to a variety of new countries including Brazil, Chile, Argentina and Colombia in Latin America, as well as New Zealand, South Africa, Indonesia, Malaysia, the Philippines, China, and elsewhere. Much, but not all, of the activity was focused on industrial wood products. For example, both China and South Korean had large programs driven by protection and environmental objectives.

Most of this activity was in terms of fairly large-scale operations. Much of it was financed, at least in part, by government. Much of the tree planting occurs in government forests and incentive programs for tree planting on non-government lands are common worldwide.

Table 1. Global Harvests by Forest Management Condition

Forest Situation	**Percent of Global Industrial Wood Harvest**
- Old-growth	22
- Second-growth, minimal management	14
- Indigenous second-growth, managed	30
- Industrial plantations, indigenous	24
- Industrial plantations, exotic	10

Planted, Intensively managed	1960 - current
Planted, Superior trees, Traditional breeding	
techniques	**1970 - current**
Planted, Superior trees, Genetic modification	1999? - future

[1] This estimate has been revised to reflect the dramatic demise of Russian timber production.

These range from some programs, such as those that were once common in Brazil, that provide most of their benefits for large corporations and land holders, to the programs once common in New Zealand (but now discontinued), which provide subsidies to all tree planting. There are also some programs aimed at smaller wood lot owners. These include small-owner programs in Finland, the US South, as well as small-owner eucalyptus planting in Thailand.

Overarching Economic Impacts

There is no question but that the economics of plantation forestry are becoming more favorable through time. Clearly the competitive position of the forest plantation countries is improving, especially those with intensively managed, rapidly growing forests, compared to that of the countries producing from primary and secondary growth stands. As noted above, the availability of timber from natural forests is diminishing relatively, not so much from excess harvesting, but rather due to policy changes. It has been estimated that about 50 percent of the world's forests, most of it primary and old-growth forests, is inaccessible for harvesting under current conditions. Additional protection from harvesting is being provided through the creation of new set-aside and protected areas. Furthermore, forest management practices codes are becoming more stringent. For example, it is estimated that the new code in British Colombia adds 50 percent to harvest costs.

In the U.S. harvests from National Forests are less than 20 percent of what they were one decade ago. All of this raises the costs of wood from natural forests and improves the economic advantage of planted forests. Additionally, innovations in planted forest establishment, harvesting and biological stocking have improved the economics of planted forests. Thus, we observe that tree planting worldwide is estimated to be near 10 million ha annually, much of it in the establishment of new planted forests. In a study I undertook two decades ago (Sedjo 1983), I showed that the economic returns to plantations were very favorable *in some regions of the world.* Over the ensuing 20 years these areas have exhibited large increases in planting and wood production. Some, like Brazil, have progressed to be one of the world's leaders in pulp production (Sedjo 1999a). For many other of these countries forestry has become very important. These include New Zealand, which is exporting sawnwood; South Africa, a producer of pulp and paper; and Chile, which is producing both solidwood and pulp products for world markets. Today, Uruguay is moving ahead with the large establishment of plantations and is intent on becoming a major producer and Argentina is gradually shifting from meeting its wood needs from native forests to relying on plantation wood.

Thus, planted forests are fulfilling an important economic need in providing readily available industrial wood without large costs and price increases.

Additionally, they are providing a desired social function by deflecting some of the logging pressure away from fragile natural forests to planted forests, where their environmental impact is small. Finally, since plantations are established only on low productivity agricultural lands, plantation establishment does generally not require the destruction of natural forests.

.

Plantation Impact on Local Communities

Concern is often expressed about the impact of plantations on local communities, especially when large external firms enter the region. From the perspective of the community, the large firms often invest large amounts of capital, some of which results in the creation of local employment and wealth. However, where external funds are provided, most of the proceeds to this investment are withdrawn from the community. Thus the local community experiences some positive effects but also some negative effects. Furthermore, within the local community there are likely to be winners and losers. Owners of land have the potential to benefit. However, users of land, such as sharecroppers and users of common property resources are likely to lose their use rights and may be disadvantaged.

Local labor may be benefited or disadvantaged depending on what the new industry does to overall labor and the demand for specialized labor skills.

I know of no systematic study that has tried to objectively assess the impact of the establishment of a forest plantation on the local community and its economy. Nevertheless, we do have some related and anecdotal information. It is clear that planted forests employ workers from the local community. Planting, management and harvesting require human services, as is transport to a processing facility or shipping point. Where large forest resources are present, wood processing facilities are commonly introduced. Sawmills, veneer mills and other processing facilities are common. Many of these activities can be undertaken on a small scale thereby often providing product for the local community while generating employment in the wood-processing industry. Additionally, of course, large-scale pulp and paper mills are associated with planted forests. These however, tend to be capital intensive and utilize relatively little labor.

Where the forestland and timber are owned by local people, the economic benefits accrue to the local owners and the community as stumpage payments (rents). Thus, planted forests surely generate local employment in forestry and related activities. Also, wood payments to local wood lot owners can add income to the local economy.

In some regions, such as the US South, forestry has been an activity that occupied farmers during the year when agriculture was slow, e.g., period other than agricultural planing and harvesting. In these situations, much of the agricultural equipment was adapted to forestry (Sedjo 1999b). Forestry, in this context, provided additional income and employment to the community, especially during periods of low economic activity in the major industry. This situation probably continues to persist in parts of the south where agriculture and forestry are both important economic activities. However, as plantation forestry becomes more specialized, the skills and equipment of the average farm worker will become less relevant.

How prevalent is the situation where agriculture and forestry coexist on fairly large scales in countries in which plantations have recently been established, e.g., South America or New Zealand, has not been systematically assessed. However, such a situation appears feasible.

A different type of situation has existed in northern Sweden. There, much of agriculture is not viable. Investments were made in mechanization so as to provide incentives in the form of high wages so that labor would remain in this region and not be drawn off to high paying urban employment. The government and the industry worked together to develop equipment appropriate to the task, and especially appropriate to loggers (Sedjo 1999b). Such an approach, however, is likely to be less viable in many of the regions where new plantations are being established, since many are in regions with plentiful low wage labor.

In some regions, however, forestry has replaced agriculture, e.g., Chile and New Zealand. Although this could be viewed as employment and income reducing, this need not be the case. In New Zealand, for example, forestry has replaced sheep paddies in many parts of the country. This shift was precipitated by the withdrawal of subsidies on sheep after a permanent decline in sheep prices worldwide. Thus, forestry proved to be a “godsend” in that it provided an alternative economic use of the land and human resources that were displaced from their earlier use. In Chile, the agricultural land converted to forestry was very marginal, thus its opportunity cost was low and it could readily be converted to forestry. Although, again, I know of no overall assessment, it is clear that the economic activity in the forest plantation region of the country is very substantial, and much greater than when the earlier agricultural regime prevailed.

There have been problems in some places, however. In coastal Brazil, there is concern that plantation forestry is displacing agricultural families and generating local hardship. And pressure is being directed to limit the areas established in plantations. In some regions, tropical forests, de facto, are being converted to plantations. Concerns have been expressed about the situation of indigenous peoples and the local community.

Conclusions

Like other changes in land use and economic activity, plantation forests have effects on the society in which they operate. Often, the influence has been positive, providing employment and income in regions where earlier economic activities are no longer viable. In many cases the nature of the plantation forests is significantly altered to adapt to local conditions including labor and capital availability.

However, where the land ownership is external to the region the impacts may be muted in that the land rents are transferred out of the region. Nevertheless, if the capital required for the plantation is imported and/or processing facilities are introduced to complement the forest resource base, net economic benefits probably accrue to the local community.

Abstract

The aims of this paper are 1) to understand the production and consumption of fuelwood over the world and the need of plantations for fuelwood production, and 2) to estimate the amount of CO_2 absorption by the world's forests and 3) to provide status of fuelwood plantation and forest biomass with its contribution to CO_2 absorption in Korea. In 1995 world fuelwood consumption was amounted to 1.7 billion m^3. India, the Peoples' Republic of China, Brazil and Indonesia – all developing countries with large population – had occupied the highest shares. Tropical regions accounted for three quarters of both production and consumption of world fuelwood and charcoal in 1994. By 2000, deficit amount of fuelwood production was expected about one billion m^3; 500 million m^3 in Asia, 300 million m^3 in Africa, 140 million m^3 in Latin America and 60 million m^3 in other countries. To meet the deficit, about 25 to 105 million ha of fuelwood plantation is required in developing region for the next 10 years. The total amounts of CO_2 absorbed by world's forests (above-ground biomass only) and its annual growth were 226.3 billion tons and 16.3 billion tons, respectively. In Korea, the total and annual CO_2 absorptions in the forests were 516.8 million tons and 37.2 million tons in 1990, respectively. Present biomass of forest in Korea was estimated at 317 million tons with 22 million tons of annual growth.

Keywords: Fuelwood, CO_2 Absorption, Biomass, Plantation

Introduction

Global warming and climate change have become a serious threat to the survival of biological organisms and the well-being of people around the world. The world's forests are habitat for diversity of life and yet they are increasingly suffering from human-induced stresses such as industrial pollution, large-scale clearing and land use changes for agricultural and urban development. Global warming poses an additional threat to the forests. According to the United Nations' Intergovernmental Panel on Climate Change (IPCC) in 1996, the most likely cause of warmer temperature is increased concentrations of greenhouse gases in the atmosphere. Depending largely on limited, non-renewable energy such as fossil fuels around the world adds significantly to the build-up of greenhouse gases. The main greenhouse gases are CO_2, CH_4, N_2O and CFC, of which CO_2 is the biggest contributor to global warming.

It is estimated that 76 percent of the CO_2 emissions are the result of fossil fuel combustion. Tropical deforestation and forest degradation account for an estimated 23 percent and the remaining 1 percent comes from cement manufacture (Food and Agriculture Organization of the United Nations; FAO 1997). Therefore, controlling the burning of fossil fuels and conservation or creation of forests as sinks of CO_2 can both contribute to reducing CO_2 emissions and mitigate climate change.

Much effort is being proposed to reduce CO_2 emissions and various forestry-based strategies have been carried out. Reforestation schemes, reduction of carbon tax by plantation, fuelwood plantation and substitution with alternative renewable energy sources have been suggested as strong ways of reducing carbon emissions. In this regard, the use of biomass energy in efficient and sustainable manner can offer many advantages for the environment and the economy. The potential of biomass as a renewable green source of energy has been widely studied as a means of mitigating global warming. Besides, biomass production is used diversely from immediate serve for food and medicines to socio-economic purposes (van Gelder and O'Keefe 1995).

The aims of this paper were to understand the production and consumption of fuelwood over the world and the need of plantations for fuelwood production, and to estimate the amount of CO_2 absorption by the world's forests. Status of fuelwood plantation and forest biomass with its contribution to CO_2 absorption in Korea was also provided.

Change in the World's Forest

According to FAO, the world's forest area was 3,454 million ha, covering about 27 percent of the earth's land surface. Of these, closed forests covered 2,858 million ha, comprising about 83 percent of the world's forest. However, between 1980 and 1995, the extent of the world's forests decreased by some 56,000,000 hectares (Table 1). Tropical forests covered nearly 50 percent of the world's forest, but they are disappearing by 12,600,000 ha per year during the recent years.

Table 1. Change in forest cover during 1990-95 (FAO 1997)

	Total forest in 1990 (10^3 ha)	Total forest in 1995 (10^3 ha)	Total change in 1990-95 (10^3 ha)	Annual change (10^3 ha)	Annual change rate

Former USSR	813,381	816,167	2,786	557	0.1%
Oceania	91,149	90,695	-454	-91	-0.1%
Tropical Oceania	42,659	41,903	-756	-151	-0.4%

The significance is that large-scale deforestation occurs in most developing countries, particularly in tropical Asia and Central America, showing the highest loss at an annual rate of over 1 percent. Currently, the world's forests are estimated to be net sources of CO_2 primarily due to deforestation and forest degradation in the tropics. Conservation of forests from deforestation and forest degradation in the tropics would reduce the current CO_2 emissions substantially and would also reduce the release of other greenhouse gases. The IPCC estimates that about 12 – 15 percent of the projected CO_2 emissions from fossil fuel consumption from now until 2050 could be offset by slowing deforestation, promoting forest regeneration and increasing the area in plantations and agroforestry systems.

Status of World Fuelwood Production and Consumption

Fuelwood production over the world showed continuously stable trend after sharp drop in 1985. This was resulted from improving energy efficiency and replacement of energy sources in industrialized nations from wood to fossil fuels such as oil, gas and electricity. Korea showed substantial downward in fuelwood production, while the most developing countries and tropical countries did continuous upward in recent years (Table 2).

In its proportion rate per total roundwood production, most developing countries in Africa, Asia and Latin America showed much higher share than that of developed countries (Table 3). Comparing production and consumption patterns in tropical vs. non-tropical countries, tropical regions accounted for three quarters of both production and consumption of fuelwood and charcoal in 1994. By contrast, they accounted for only 17 percent of production and 20 percent of consumption of industrial roundwood.

Global consumption of wood reached almost 3,400 million m^3 in 1994. Nearly half of the consumption was used for fuelwood, and the rest for a variety of industrial purposes. Over the last 30 years, fuelwood consumption expanded more rapidly than industrial roundwood consumption, growing by 60 percent to 1,707 million m^3 in 1995, while industrial roundwood consumption grew by 15 percent to almost 1,500 million m^3 (FAO 1997). Considering current growth rate of fuelwood consumption over the world, the amount of fuelwood consumption in 2010 is estimated at 2,487.7 million m^3. In response to increasing demand of fuelwood in near future, creation or enhancement of fuelwood plantation should be encouraged, particularly in developing regions.

Population and income are considered as the major factors influencing the consumption and production of wood. Consumption usually rises with an increase in both population and income. However, in the case of fuelwood, an increase in income tends to lower consumption. In developing countries, the growth rate of fuelwood consumption is nearly equal to that of population. Table 4 shows continuous increase in fuelwood consumption of Asian countries. Particularly, four countries lead fuelwood consumption, which are in developing world with large population; India was the largest consumer with 226 million m^3 per year, China with 174 million m^3, Brazil with 172 m^3 and Indonesia with 129 m^3 (Table 5).

Needs for Fuelwood Plantation and its Contribution to CO_2 Absorption Over the World

People rely more on biomass than on all hydroelectric dams and nuclear fuel plants as their main source of energy for cooking and heating in the world combined. Estimates suggest that the number of people relying on wood fuel will increase to 3 billion by 2000. Among theses, perhaps 100 million users face fuel shortages as supplies of wood fuels dwindle. By 2000, deficit amount of global fuelwood production is estimated at one billion m^3; 500 million m^3 in Asia, 300 million m^3 in Africa, 140 million m^3 in Latin America and 60 million m^3 in other countries. To meet the deficit, about 25 to 105 million ha of fuelwood plantation is required in developing region during the next 10 years (German Bundestag 1990). In response, various approaches are being proposed to ensure sustainable supply of fuelwood and to identify alternative renewable energy sources. Creation of global biomass reserves through fuelwood plantations can provide opportunities principally in environmental and economic aspects.

Total	…..1,680		

Furthermore, it is considered as a practical application for enhancing CO_2 fixation capacity over the world and for reducing CO_2 emissions from burning of fossil fuels. Recent estimation suggested that CO_2 emission in the atmosphere generated from tropical deforestation was 1.5±1.0 billion tons and CO_2 emission from combustion of fossil fuel was 5.3±0.5 billion tons in 1980 (German Bundestag 1990). Based on the growing stock of the world's forests for 277,670 million m^3, biomass of the world's forests was estimated at 138,835 million m^3, which was calculated by multiplying growing stock by the estimated value of dry-specific gravity of tree species, 0.5. World's forests contained 226,301 million tons of CO_2 and absorbed 16,291 million tons per year, with 11,843 million tons of O_2 emission per year (Table 6).

Status of Fuelwood Plantation in Korea

In Korea, forests cover 6.4 million ha, which is about 65 percent of total land area. However, forests have been severely degraded during the Japanese colonization from 1910 to 1945 and Korean War from 1950 to 1953. The predominant causes for the forest loss were coming from large-scale clearing of forests and exploitation of forest resources for food and fuel. Besides, substantial amount of fuelwood was required for house heating in winter season. In response to critical demand of wood for fuel energy in local communities, Korean Government implemented massive plantation plan with some fast-growing trees during 1960s to 1970s. Of the total forestland areas, 30 percent is man-made plantation. This has greatly contributed to the fuelwood supply and to expansion of forests as carbon sinks (Table 7).

In the past, fuelwood supply for cooking and heating at the rural households was the very important function of the forests. The Government initiated national fuelwood plantation in 1945 at the end of Japanese colonization but halted at the start of the Korean War in 1950. Large-scale plantation was actually implemented from 1959. The target area was 1.2 million ha and at 0.5 ha of planted area per household enough for 2.4 million households in rural areas.

Table 6. Amount of CO_2 absorption and O_2 emission by forests and their annual growth in 1988 (German Bundestag 1990)

	Growing stock (10^6 m^3)	Growing stock (m^3/ha)	Biomass (10^6 tons)	CO_2 absorption (10^6 tons)	O_2 emission (10^6 tons)	Annual CO_2 absorption (10^6 tons)	Annual O_2 emission (10^6 tons)
World	277,670.0	77.1	138,835.0	226,301.1	164,519.5	16,290.8	11,843.3

Europe	15,418.0	112.5	7,709.0	12,565.7	9,135.2	628.3	456.8
Former USSR	66,996.0	84.6	33,498.0	54,601.7	39,695.1	1,638.1	1,190.9

However, the accomplishment was far less than the target. Over 6 years of implementation, plantation was 420,000 ha. Thus, the Government modified the plantation area to 364,000 ha, about one third of the original target, to be reforested by 1967. In 1973, the first 10-year Forest Development Plan for Rehabilitation and Restoration was developed. With this plan, 207,000 ha of plantation was additionally created and total plantation area reached 643,000 ha by 1977 (Table 8). The plantation was continuously expanded year by year. During 1976 to 1977, 127,000 ha of plantation – 20 percent of total plantation area – was developed through IBRD loan of US$ 4.4 million (Korea Rural Economics Institute 1978). Fast-growing trees such as *Pinus rigida, Robinia pseudo-acacia, Alnus* species and *Quercus acutissima* were plantedmostly from 1962 to 1972 (Table 9).

Table 7. Forestland area and growing stock by year (Ministry of Agriculture and Forestry, Republic of Korea 1998)

Year	Area (10^3 ha)	Growing stock (10^3 m^3)	Growing stock (m^3/ha)
1960	6,700	63,995	9.55

Forest Biomass and its Contribution to CO_2 Absorption

Forest biomass in Korea was estimated by measuring net absorption of CO_2 by the growth of biomass in the forest including roots. Present biomass and annual growth of biomass in the forest was estimated from with the sum of biomass in trees, saplings, shrubs, grasses and herbs. Biomass in each group of species was divided into stem, branch and root.

Biomass in tree stems was estimated by multiplying growing stock of different stands, excluding I-grade stands, with dry-specific gravity of *Pinus koraiensis* and *Quercus mongolica*, 0.44 and 0.80, respectively. As of 1990, present biomass in tree stems was estimated at 143,566,000 tons (dry weight tons) with annual growth of 9,083,000 tons. Using ratio of branches, branch volume rate per stem volume, biomass in tree branches was estimated by multiplying growing stock of different stands by dry-specific gravity of tree branches. Present biomass in tree branches was 40,525,000 tons with annual growth of 2,617,000 tons.

For the estimation of biomass in tree roots, dry weight of root was used. For conifers, 23.96 tons per ha of mean root dry weight was estimated from 18 – 55 year-old *Pinus koraiensis*. For broadleaves, 23.85 tons per ha of mean root dry weight from 20 year-old *Quercus mongolica*. Assuming annual growth rate of tree roots was the same as that of tree branches, biomass in tree roots was estimated by multiplying present biomass in tree roots with growth rate of stem dry weight. Present biomass in tree roots was 111,805,000 tons with annual growth of 7,694,000 tons.

For the estimation of biomass in saplings, stem volume and annual growth of saplings were estimated by multiplying volume and annual growth of 5 year-old saplings, indicated in the stand yield table, with I-grade stand area shown in the Statistical Yearbook of Forestry. Present biomass in sapling stems and its annual growth were 5,931,000 tons and 712,000 tons, respectively, which were estimated by multiplying stem volume and annual growth of saplings with dry-specific gravity of sapling stems.

Due to deficient research data on the volume of sapling branches in Korea, ratio of sapling branches was not measured. Instead, ratio of shrub branches multiplied by volume of sapling stems was used, assuming annual growth rate of saplings was same as that of shrubs. Present biomass in sapling branches was 1,883,000 tons with annual growth of 127,000 tons. Applying same calculation method for the estimation of biomass in tree roots, present biomass in sapling roots and its annual growth were 5,148,000 tons and 345,000 tons, respectively.

Assuming shrub biomass estimated from pine stands located in Kwangju-gun, Kyunggi-do and from broadleaved stands in Mt. Baekwoon, Chollanam-do, was mean value of biomass in shrubs, present biomass in shrubs was 8,171,000 tons with annual growth of 2,164,000 tons. For the purpose of calculation, annual growth rate of stems and branches in shrubs in conifers was assumed at 17.6 percent, which was that of stems and branches of shrubs in broadleaved trees. Annual growth rate of shrub stems and branches was estimated by multiplying annual growth rate by with present biomass in shrub branches. Supposing leaves of shrub were newly grown every year, biomass in shrub roots and annual production measured in natural broadleaved forests of Mt. Baekwoon was applied. Estimation of biomass in herbs and grasses was based on the paper reported by Park (1986). However, his data were considered underestimation of its value. Supposing present biomass of herbs and grasses was same as annual growth of herbs and grasses, present biomass of herbs and grasses was 76,000 tons. Taken together, present forest biomass in Korea was estimated at 317,061,000 tons (Table 10) and annual growth of forest biomass was 22,818,000 tons (Table 11).

To produce 1g of biomass, forests absorbed 1.630g of CO_2 and released 1.185g of O_2 as of 1990. Total biomass, its annual growth and CO_2/carbon absorption in the forest were as follows: 516.8 million tons of CO_2 and 140.9 million tons of carbon absorbed by total biomass, and 37.2 million tons of CO_2 and 10.1 million tons of carbon by annual growth(Table 12).

Table 10. Total biomass in the forest (Korea Forestry Research Institute; KFRI 1996)

Conclusion

World fuelwood production was 1,707,329,000 m^3 in 1995, showing stable trend after sharp drop in 1985. This was resulted from improving energy efficiency, replacement of energy sources in industrialized nations from wood to fossil fuels such as oil, gas and electricity, while fuelwood was still prevalent in most developing countries and tropical countries. Comparing production and consumption patterns in tropical vs. non-tropical countries, tropical regions accounted for three quarters of both production and consumption of fuelwood and charcoal in 1994. By contrast, they accounted for only 17 percent of production and 20 percent of consumption of industrial roundwood. World fuelwood consumption was the highest in four countries, which are in developing world with large population; India was the largest consumer with 226 million m^3 per year, China with 174 million m^3, Brasil with 172 m^3 and Indonesia with 129 m^3 as of 1986. As a whole, tropical countries in Africa, Asia and Latin America leaded fuelwood consumption. Considering increasing growth rate of fuelwood consumption in current years, fuelwood consumption in 2010 was estimated at 2,487.7 million m^3.

By 2000, deficit amount of fuelwood was estimated at one billion m^3, due primarily to massive consumption in developing countries with large population. To cope with such fuelwood demand, a development of 25 million to 105 million ha of fuelwood plantation is required in developing regions. In response, various approaches to ensure sustainable supply of fuelwood and to sequester greenhouse gas emissions are being made through sustainable forest management, reforestation and fuelwood plantation establishment. Growing stock of the world's forests was estimated at 277,670 million m^3 and biomass of the world's forests was estimated at 138,835 million m^3 in 1988. Estimation indicated world forests contained 226,301 million tons of CO_2 with 16,291 million tons of annual absorption.

In Korea, large-scale plantation was implemented by the Government during 1960s to 1970s and 643,000 ha of plantation was successfully achieved with some fast-growing trees including *Pinus rigida, Robinia pseudo-acacia, Alnus* species and *Quercus acutissima*. This has greatly contributed to fuelwood supply and to expansion of forests as carbon sinks. Today, this plantation is no longer supplying fuelwood due to replacement of alternative energy. CO_2 absorption of forests in Korea and its annual absorption were 516,809,000 tons and 37,193,000 tons, respectively. Present biomass of forest in Korea was estimated at 317,061,000 tons with 22,818,000 tons of annual growth.

Abstract

Although many of the issues raised about forest plantations are non-trivial, there are a number of significant environmental advantages of plantation establishment that appear to outweigh concerns, *if* plantation management practices can be developed to address concerns regarding sustainability. Foremost among the advantages is that establishment of highly productive forest plantations can provide large quantities of wood and fiber from relatively small land areas, raising the possibility that pressures for harvesting within natural forests can be markedly reduced. Moreover, assuming that forest plantations are carefully established and managed, they have the potential to produce a continuous, renewable stream of industrial raw materials that results in less overall environmental impact than other types of raw materials. Assessment of total environmental impacts over product life cycles show that structural and non-structural wood and wood fiber products made from plantation-derived raw material yield markedly lower impacts than similar products made from metals, cement, petroleum, or other raw materials. Similarly, examination of total environmental impacts of papermaking fiber production in forest plantations versus fiber production using annual agricultural crops shows significant advantages to wood fiber. Thus, forest plantations can yield environmental benefits that extend well beyond the geographic location in which they are located.

Keywords Environment, tree plantations, forest plantations, wood

Introduction

This paper examines the forest plantation balance sheet from an environmental perspective. Positive and negative aspects of plantation forests are identified and briefly examined. Particular attention is focused on life cycle impacts of wood production and use. Although given little attention in forest plantation literature to date, careful examination of environmental life cycle data for wood, and for materials that might be used as substitutes for wood, gives forest plantation establishment a new imperative.

The term "forest plantations" is widely used to describe 1) natural forests in which regeneration following selective harvest has been accomplished by planting seedlings of native, genetically modified, or exotic species, 2) native forests in which enrichment planting has been done, 3) secondary forests that have been planted, usually in rows, using native, genetically modified, or exotic species following clearing of natural forests, and 4) forests that have been planted on savannahs or degraded lands following mining or agriculture. Remarks herein focus primarily on plantations as described in 3) and 4) above.

Why Plantations?

Rising Raw Material Needs

One of the most compelling reasons for establishment of forest plantations is that consumption of industrial wood and wood for cooking and heating is rising steadily at the same time that efforts to reduce harvesting in natural forests are also increasing (Sutton 1999). As long ago as the 1960s Marsh (1962) observed that "natural forests grow too slowly to meet bulk forest products demands." In the decade of the '90s, the specter of record population growth led many to take note of rising demand for forest-derived resources. Lyons (1993), for example, observed that "large increases in demand for wood and fiber are coming by 2010." A year earlier, Leslie (1992) had suggested that the forest plantation area would "have to be increased by 30 percent in the immediate future" in order to meet needs for fuelwood and industrial wood. Given the plantation area in existence at the time (approximately 100 million ha), Leslie's suggestion translated to a global need for new plantations covering an additional 30 million ha. These estimates were followed by a stunning conclusion reached by the World Energy Council (1995) which indicated that between 700 million and 1350 million ha of land will be needed for biomass energy production by 2050. This figure implies a need for as much as a seven- to thirteen-fold increase in global forest plantation area, excluding what might be needed to provide increased volumes of wood for industrial uses. If these estimates did not in themselves provide a strong case for substantial forest plantation establishment, projected impacts of the current movement toward certification of managed forests would seem to suggest a mandate for increased plantation investment. For instance, one of several studies of the impact of certification (Lundstrom et al. 1997) suggests a decrease in long-term timber supply of 12-15 percent if Forest Stewardship Council management guidelines are applied to managed Swedish forests. Together, these kinds of estimates have served to greatly intensify interest in forest plantations.

Forest plantations are typically highly productive as compared to natural forests. Evans (1992) reported that plantations often produce 10 m^3 of wood/ha annually, that wood yields of 20-25 m^3/ha/yr are not uncommon, and that annual yields as high as 45 to 60 m^3 have been attained with some hardwood species. Sedjo (1999), using figures adapted from Clapp (1993), cites annual plantation yields averaging 10-40 m^3/ha, with some values as high as 70 m^3 ha. High plantation productivity has been well documented by many others (Hakkila 1994, Pandey 1995, Sedjo 1999, Steen 1997, Tiarks et al. 1998). In contrast to plantations, natural tropical moist forest commonly yields 1 to 2 m^3 /ha annually, which can be increased to perhaps 6 m^3/ha with management (Wyatt-Smith 1987); similar yields are recorded for natural forests in temperate regions (Sedjo 1999). Yields of up to 15 m^3/ha are reportedly attained in some types of managed dipterocarp forests (Wyatt-Smith 1987).

Restoration of Degraded Land

Land degradation as an impetus for forest plantation development is not unique to the tropics. Unsustainable agricultural practices in parts of the southern United States in the early 1900s, for example, led to establishment of large areas of tree plantations in the 1930s (Schultz 1999).

Today, it is widely accepted that forest plantations have great potential for restoring degraded sites in the tropics (Evans 1999, Parrotta 1992, Sawyer 1993). Evans (1999) observes that such plantings can be "astonishingly successful." Brown et al. (1997) note that the profit potential of forest plantations provides opportunities and incentives for implementing intensive management techniques as well as initiation of site rehabilitation activities. Evans (1999) points out that forest plantations not only have future potential, but that tree planting to achieve soil erosion control, whether on steep hillsides or as part of shelterbelts to reduce wind erosion, is already widely practiced.

A Source of Minimal Impact Renewable Materials

The Carbon Sequestration Issue

It has long been recognized that liberation of carbon dioxide and other gaseous emissions, as a result of combustion of fossil fuels and other human activities, has the potential to warm the earth's atmosphere. This potential was formally recognized in 1997 in Kyoto, Japan at the United Nations Framework Convention on Climate Change. Also given formal recognition in Kyoto was the capacity of forests to capture carbon from the atmosphere and to store or sequester it for extended periods. The fact that forests can capture carbon from the earth's atmosphere has led to a number of initiatives to preserve existing forests and to create new forest plantations for the purpose of carbon storage. There are many examples of forest plantations having been created for this purpose.

It is widely acknowledged that stored carbon stocks increase rapidly when a forest is established on land that was previously not forested (Harmon et al. 1990, Marland and Schlamadinger 1999). As dry wood is 49 percent by weight carbon, substantial carbon storage accompanies the growth of trees and the accumulation of woody debris on the forest floor (Figure 1). Carbon accumulation appears to be more rapid when a portion of the wood harvested is used in long-lived products, as opposed to short-lived products such as paper.

Scientific evidence also indicates that a net loss of carbon over the short term may accompany plantation establishment when mature forest is cleared beforehand. In this case, stored carbon is liberated as standing trees are removed, and as decay processes in the soil and litter layer accelerate (Harmon et al. 1990, Marland and Schlamadinger 1999). A net short-term loss appears likely even when a portion of the harvested biomass is incorporated into long-lived products. Over the longer term, assuming efficient conversion of a portion of woody materials into long-lasting products, net storage gains occur after thirty to forty years, even when the planted forests are periodically harvested.

Although it is often assumed that trees grown to offset CO_2 emissions need then to be preserved in order to keep the CO_2 from returning to the atmosphere (Marland 1993), recent research shows that carbon storage can be significantly enhanced by periodic harvest of trees and their use in long-lived products. Marland and Schlamadinger (1999) list four ways in which forest growth, harvest, and subsequent use of harvested biomass can impact carbon storage: 1) Growing trees can capture carbon dioxide from the atmosphere and store carbon as woody biomass, 2) Carbon can be stored for long periods of time in long-lasting wood products, and in wood-derived products buried in landfills, 3) Liberation of carbon contained within fossil fuels can be prevented by generating energy from biofuels, and 4) Because the production and use of wood products is highly energy efficient compared to alternative products, such as those made of steel, concrete, or plastic, wood use avoids liberation of carbon that would result from increased energy consumption associated with alternative materials (Figure 2).

Figure 1. Cumulative in Carbon Stocks in Soil, Forest Litter, and Standing Trees after Afforestation

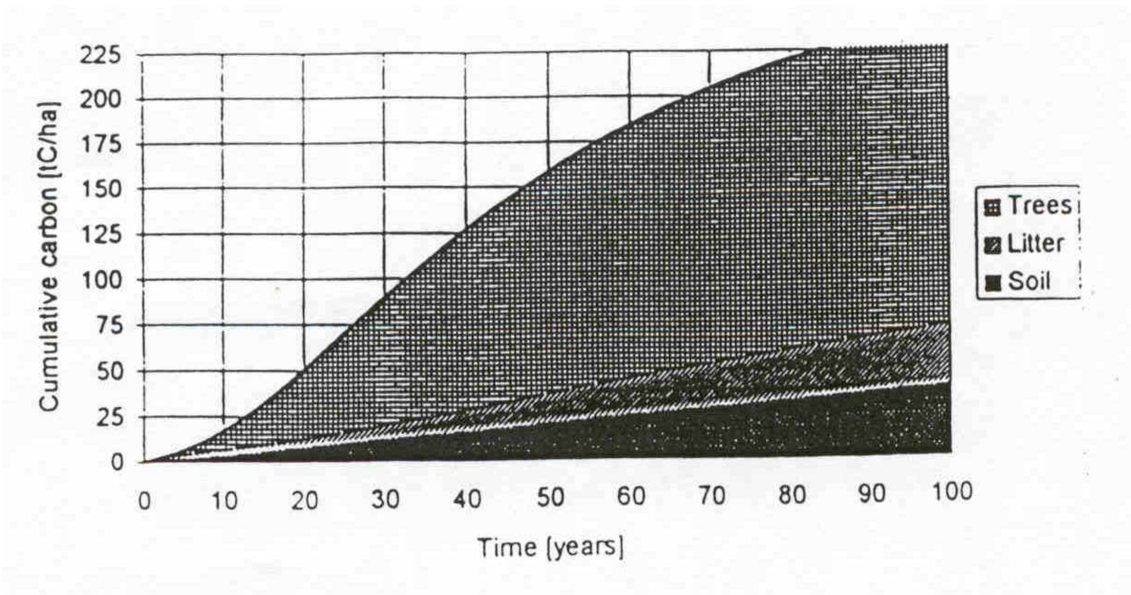

Figure 2: Cumulative Changes in Carbon Stocks with Afforestation and subsequent Harvest

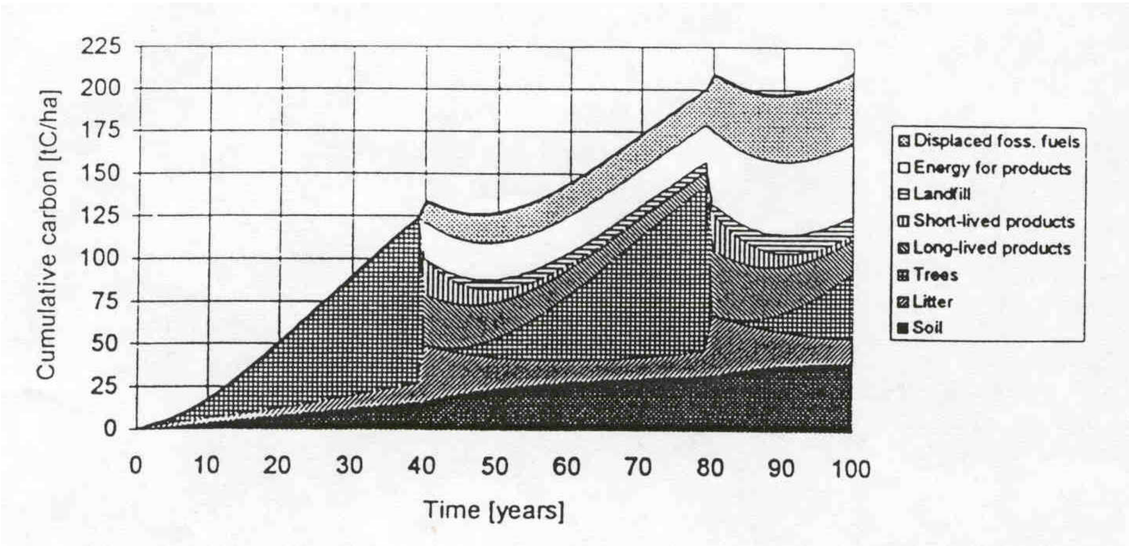

Though not well understood, this latter point is extremely important, not only in terms of carbon liberation avoided, but from an overall environmental perspective as well. This topic is examined in more detail in the following section.

Environmental life cycle analysis (LCA) involves systematic examination of all environmental impacts associated with a given product. A thorough analysis considers impacts resulting from extraction, transportation, primary processing, conversion to semi-finished and finished products, installation, maintenance, and disposal or reuse. A key part of a life cycle analysis - the life cycle inventory (LCI) - examines all *measurable* raw material inputs, products and by-products, emissions, effluents, and wastes at all stages of extraction, production, use, and disposal.

Extensive LCA/LCI analyses have been completed since the mid 1970s, especially in western Europe, Canada, and Oceana. A few of these studies have examined wood and common substitute products; the results dramatically indicate the advantages of wood as an industrial material. Although a number of studies could be cited, findings from three recent analyses will be used to illustrate the environmental benefits of producing and using wood as a construction material.

Meil (1994) compared the manufacturing emissions and effluents associated with constructing a wood-framed, non-load bearing interior wall vs. a steel-framed, non-load bearing wall of the same dimensions. All effluents and emissions associated with all steps in the process were tracked, from forest harvest or mineral extraction, through to construction of the wall. The results demonstrate that selection of building materials can have very substantial environmental implications. Construction of the steel-framed wall was found to require 3.2 times more energy than construction of the wood-framed wall. Even larger differences were found in associated emissions and effluents (Table 1).

Table 1: Comparative Effluents and Emissions Associated with Constructing 90m^2 Wall Sections Using Wood vs. Steel Framing

Type of Emission/Effluent	**Wood Wall**	**Steel Wall**
CO_2 (g)	313,333	971,000
CO (g)	2,533	11,950
SO_2 (g)	370	3,694
NO_x (g)	1,011	1,575
Particulates (g)	187	591
Suspended solids (g)	12,180	495,640
Nonferrous metals (mg)	62	2,532
Cyanide (mg)	99	4,051
Phenols (mg)	17,715	725,994
Ammonia and Ammonium (mg)	1,310	53,665
Halogenated organics (mg)	507	20,758
Oil and grease (mg)	1,421	58,222
Sulfides (mg)	13	507
Iron (mg)	507	20,758

Another study by the Athena Sustainable Materials Institute (Canadian Wood Council 1997) examined energy consumption and CO_2 emissions in constructing a large office building. Three designs were evaluated: 1) a wood building (wood structural beams, wood cladding, wood-framed interior walls) on a concrete foundation, 2) a steel building (steel structural beams, steel cladding, steel-framed interior walls) on a concrete foundation, and 3) a concrete building (reinforced concrete beams, concrete panel exterior, concrete block interior walls on a concrete foundation. Differences in total energy use and carbon dioxide liberation associated with creating each building are shown in Table 2.

The environmental advantages favoring the use of wood in construction, as well as for other purposes, are many and substantial. In addition to the environmental advantages, wood is the only widely available industrial raw material that is renewable.

The inescapable conclusion to which LCI/LCA studies such as those referenced above lead is that assuming contemporary levels of efficiency in processing, and technically attainable durability in use, wood should be used to the greatest extent possible consistent with assurance of sustainability. As noted by Marland and Schlamadinger (1999), the greater the manufacturing efficiency and useful product life, the stronger the case for wood becomes. Thus, among the advantages of forest plantations managed to provide wood for long-lived products is vastly lower environmental impact per unit of industrial raw material produced.

A final point with respect to life cycle comparisons of various raw materials has to do with various options for producing papermaking materials. Paper production worldwide has soared in recent years, with production outstripping both population and GDP growth rates. This has served to stimulate interest in a variety of alternative papermaking materials, from agricultural crop residues, to agricultural crops planted specifically for the purpose of producing papermaking fiber. While the use of crop residues (in excess of those needed in sustainable farming) as papermaking raw material has long been practiced in many parts of the world and makes a great deal of sense, the specific planting of agricultural crops for this purpose is highly questionable from an environmental point of view. A recent analysis of the environmental impacts associated with papermaking fiber production using annual crops of kenaf, vs. fiber production in intensively managed tree plantations again suggested very significant advantages of wood fiber production (Bowyer 1997); differences in landscape impacts were particularly notable.

Table 2: Total Energy Use and Carbon Dioxide Emissions Associated with Constructing a Large Commercial Office Building of Different Materials

Construction	Total Energy Use[1]	Above Grade Energy Use[1]	CO_2 Emissions[2]
Wood	3.80	2.15	73
Steel	7.35	5.20	105
Concrete	5.50	3.70	132

1 GJ x 10^3
2 Kg x 10^3

Do Plantations Take Pressure Off Natural Forests?

There is disagreement about whether plantations take pressure off natural forests.

Perhaps the most pointed criticism of the natural-forest-saving role of plantations comes from Sargent (1992) who notes that production of large volumes of plantation wood will tend to drive down the price of wood in general, thereby stimulating demand for wood from plantations and natural forests alike. Mathur (1993) also suggested that plantations might do little to help protect natural forests, pointing out that production of wood is only one of many functions of natural forests. Ironically, Sargent's questioning of the environmental role of plantations is given credence by Lovejoy's observation regarding the potential impacts of a boycott of tropical timber (Lovejoy 1990). Lovejoy documented the findings of a workshop that included an assessment of the impact of a loss of timber demand on the value of natural forest. It was concluded that such a development would reduce the value of forests, making more likely a conversion to pasture or cropland. Following the same reasoning, should high wood production in forest plantations, in fact, result in reduced timber value, then the effect on forests could well be similar to that of a boycott.

The possibility for adverse impacts arising from timber demand shifts has led some to suggest that regulations and formal agreements may be needed to protect natural forests in conjunction with plantation establishment. Some, in fact, are now calling for the set-aside of vast areas of forest land in natural or non-managed reserves, with wood production shifted entirely to privately owned natural or modified forests or to intensively managed plantations. That is precisely the strategy that was pursued in both New Zealand and Australia as part of efforts to significantly increase the area of forest plantations.

Regarding the possibility of protection of natural forests as part of a plantation strategy, some authors have questioned whether seeking to abandon timber production in natural forests is a wise idea. More than 40 years ago Dawkins (1958), for example, wrote "Even where plantations are justified, it does not necessarily follow that all remaining naturally regenerated forests are best left unproductive. If they are, they may become vulnerable to destruction . . ."More recently, Sedjo and Botkin (1997), for example, gained a great deal of attention from the observation that we [society] could produce all the wood we want on very little land. Less noticed was their caution that it is not necessarily a good idea to prevent any harvesting in native forests. Whitmore (1999) echoed this theme, stating that although plantations can diminish pressure on native forests, the native forests should, nonetheless, continue to be managed extensively. Thus, the debate about whether forest plantations can take pressure off natural forests appears to have come full circle. An emerging view is that it would be a mistake to leave vast areas of natural forests in a non-managed state.

Environmental Issues Associated with Forest Plantations

Negative Impacts on Soil Moisture and Water Yield

Concerns about the impact of plantations on soil moisture and water yield are mostly related to apparent high transpiration rates and impacts on soil moisture depletion, increased moisture interception and evaporation at the canopy level, and reduced stream flow. Many references can be found in the literature to situations in which plantations have been established on pastureland, or on plots adjacent to land used for agriculture. Observations such as the following, from Calder et al. (1992) indicate great impact of plantations on site hydrology: "When eucalyptus is planted in areas where the roots have access to groundwater, as for example when planted next to irrigation canals, there is no doubt that growth rates are higher by a factor of at least five, and that water consumption is likely to be roughly commensurate."

Similar trends, although smaller in magnitude, have been reported in New Zealand in conjunction with establishment of pine plantations (Fahey and Rowe 1992, Fahey 1994). Schultz (1999) also reported reduced water yields from loblolly pine plantations in the U.S. It should be noted that all studies do not show that plantations reduce streamflow. Whitmore (1999) cites several studies that found either no change or higher stream flow associated with plantations as compared to other types of vegetative cover.

Erosion and Soil Degradation Resulting from Plantation Establishment

As noted by Whitmore (1999), the prospect of lowered yields as a result of site deterioration under intensive management of short-rotation tree crops has been a concern of foresters for decades. Recent literature suggests that this is still a major concern. Lai (1997), for example, expresses concerns about the effects of plantation establishment, pointing out that deforestation and change in land use associated with initiating plantation forests can lead to soil compaction, erosion, and depletion of soil organic matter, and thus degradation of physical and nutritional properties of soil. Evans (1992) observes that plantations tend to be kept in an early successional stage, with maximum removal of biomass from the site at harvest. He also reports that plantations are less efficient at trapping released nutrients, due in part to the existence of fewer roots near the surface. The result, he notes, may be significant nutrient loss from sites where trees are harvested. Binkley and Giardina (1997) strongly link a continued supply of soil nutrients to long term sustainability of high productivity in tropical plantations. They then note that rapid growth of tropical plantations leads to high rates of nutrient accumulation in biomass, and that harvesting at short rotation intervals removes large quantities of nutrients which may, over time, lead to depletion of soil fertility.

Will (1984), discussing the subject of monocultures in both temperate and tropical regions, indicated that where soil deterioration problems have occurred, poor forest management has usually been to blame. Lai (1997) said much the same thing, explaining that plantation forestry can lead to soil degradation as a result of soil or tree mismanagement, but that judicious soil and vegetation management can improve soil properties, minimize soil erosion risks, and enhance soil quality and productivity. He reports that growing leguminous crops in association with trees is a useful strategy for improving soil properties and controlling erosion. Evans (1999) has written extensively on the soil degradation question. Evans suggests that the evidence that has been gathered seems to indicate that productivity loss may not be as serious a problem as many have feared, and that instances of yield decline in the tropics and subtropics often reflect weed mismanagement or mismatching of species to site, rather than inherent shortcomings of plantation forestry practices.

Risks of Pests and Disease

One of the best discussions of the risks of pests and disease in natural versus plantation forests is found in a recent FAO Forestry Paper (Swedish Agency for Research Cooperation with Developing Countries 1992). On the one hand, it is noted that there are many documented instances of insects and disease causing extensive damage in natural forests, as well as an increasing number of examples of plantations that have been grown over many cutting cycles with few problems. The more than 100-year history of exotic rubber plantations in Malaysia is cited as one example of successful long-term plantation operation. On the other hand, a strong case is presented to support the contention that plantations, and particularly single species plantations, are at much greater risk to catastrophic insect and disease losses than are natural forests.

Strong criticism of even-aged, single species plantation forestry comes from Schultz (1999), who reports "Damage from pests and environmental stresses have become increasingly severe in [U.S.] southern pine forests over the past 50 years. This is principally the result of human changes in ecosystems from mixed species to rapidly growing even-aged stands of a single species such as loblolly pine. Research has shown that such development has altered many natural balances that previously kept pathogenic organisms in check in ecosystems." Perry and Maghembe (1989) and Widagda (1981) have expressed similar views.

There appears to be increasing recognition in the literature that the genetic base of a forest plantation is more important than the number of species that comprise it. Zobel and Talbert (1984) raised this issue, commenting that a monoculture established from rooted cuttings or clonal material would be at considerable risk over any extended time frame. In contrast, a plantation comprised of genetically diverse planting stock does not present great risk, even if composed of a single species.

As with other environmental concerns, many view pest and disease problems as due to factors other than use of exotic species or the planting of monocultures. Burdon (1982) listed four such factors: 1) inappropriate site choice, leading to stress-induced changes in the trees that increases their vulnerability to pests and diseases, 2) use of a poorly adapted seed source, 3) poor silvicultural practices, such as careless pruning and thinning, which can leave scarred live tissue open to infection, and 4) inadequate attention to nutrient and water requirements.

Impacts on Biodiversity

Hakkila (1994) describes plantations of the southern hemisphere and tropics as, in general, monocultures of introduced species that are of uniform size and spaced geometrically. Thus, he concludes, they are not capable of supporting biodiversity characteristics of native forests. Widagda (1981) also refers to complex versus simple structure within natural forests as a central reason for reduced biodiversity within plantations.

Few authors dispute that forest plantations support reduced levels of biodiversity than natural forest stands, but an increasing number challenge the contention that plantations necessarily have vastly lower biodiversity than surrounding native forests. Evans (1992) acknowledges that there is little diversity within individual plantation stands, but points out that production plantations usually consist of several age classes, with the result that the "forest" as a whole tends to contain different habitat types, such as open ground, areas of young trees, closed thickets and mature open stands. He explains that an additional source of habitat diversity within plantations is attributable to unplanted areas, including roads and tracks, gullies, rocky areas, and firebreaks that normally account for about one-fifth of the total plantation area.

Another part of the biodiversity debate involves the role that plantations play in restoring biodiversity to an impoverished landscape. Evans (1992) provided several examples of this, noting that planting of caribbean pine on poor savannas in Venezuela has led to a substantial increase in the deer population and the return of the jaguar, that planted cypress forests in Kenya and Tanzania are the home of thriving populations of the Sykes monkey, a species once driven to near extinction, and that the leopard is again found on the Nyika and Vipya plateaus of Malawi as a result of afforestation in these regions. Another study in the Canterbury plains area of New Zealand found the presence of many plant species that had been mostly absent prior to afforestation (Norton 1989).

Discussion and Summary

Were the human population small, and demands upon the world's resources negligible to modest, there likely would be few concerns about natural forests, and no forest plantations or even discussion of them. However, the population is anything but small, and population growth is dizzying. Moreover, consumption of natural resources is growing even more rapidly than population, and pressures on all of the world's natural systems, including forest ecosystems, are growing daily. Given this situation, concern about growing demands on the world's natural forests is certainly understandable. Understandable as well are concerns about development of vast plantations of often non-native tree species. Yet, at a time when it is increasingly obvious that bold initiatives are needed in order to balance the reality of human wants and needs with the necessity of protecting the environment, it is difficult to understand how one can realistically oppose *both* the exploitation of natural forests and development of forest plantations.

Despite environmental concerns and problems associated with the establishment and sustainable management of some forest plantations, the benefits that accrue from plantations of rapidly growing trees are so significant that further development of forest plantations is virtually assured. Benefits include high commodity production on relatively small land areas, vastly reduced overall environmental impact associated with wood production and use in comparison to available alternatives, and potential for concomitant restoration of degraded land areas and associated biodiversity.

To recognize the tremendous advantages of forest plantations or the inevitability of further development does not mean that environmental concerns linked to plantation development should be dismissed. Rather, it is to the advantage of everyone that forest plantations operate sustainably in every sense of the word, and that they provide the greatest possible array of benefits. In view of the size and recent growth of the forest plantation enterprise globally, and the nature of problems that have been encountered in conjunction with development and maintenance of some plantations, it is imperative that steps be taken to address known problem areas and concerns.

Recent findings suggest that many problems associated with plantation establishment and sustainability are traceable to poor planning and/or inadequate management. Research also indicates that questions about a number of issues do not yet have definitive answers. It is clear that great care will have to be taken in plantation management to ensure sustainable high-yield harvest over successive rotations. Given the scale of the emerging plantation enterprise, an aggressive and ongoing program of research should be given high priority.

Abstract

The world's natural forests are under increasing pressure to meet demands for wood and fibre, while continuing to provide a vast array of environmental and social services. Future increases in demand for wood are likely to be met largely from forest plantations. This paper reviews the current extent of the global forest plantation resource, provides an assessment of the key wood production parameters (species, growth rates, rotation lengths), identifies a range of priority areas for future plantation research, and provides discussion and assessment of likely future wood supplies from plantation forests.

Keywords: Plantation forests, Resources, Wood production, Scenarios.

Introduction

Globally, the dominant trends for forest products are increasing demand for wood (resulting from increased populations and incomes) from diminishing, or more restricted, forest supply base. As forests are cleared, degraded, or withdrawn from production for conservation purposes or other reasons, the burden placed on the remaining production forest increases commensurately. Questions consequently arise as to the capacity of forests to continue to meet consumption demands, and these can only be answered by increasingly detailed analyses of sources of supply. During the past thirty years an evident decline in natural forest resources in a number of countries and the difficulties in accessing increasingly remote areas of natural forest available for wood supply, has resulted in an intensified focus on plantation forests. Plantations provide a potential means for alleviating potential future wood shortages and providing continuity of supply for existing industrial enterprises or household woodfuel needs.

Over the past several years FAO has intensified its efforts to quantify the potential extent of future wood supplies from forest plantations. Considerable effort has been applied towards collating and refining data on forest plantation areas, species, age-classes and yields. Nonetheless, the ideal of global plantation woodflow modelling being done with real precision remains elusive. Not only is much of the base national forest inventory data (area, age-class, increment, species, yield) incomplete, inaccurate, obsolete or otherwise unreliable in many countries, but many of the other key variables, for example, impacts of intensified management regimes, genetic gains from tree improvement programmes, and harvesting and processing technologies remain unmeasured or unreported. Data relating to qualitative change in forest resources and wood and fibre production are particularly scarce.

The data collection and refinement process is, however, ongoing and provisional data must necessarily be used in modelling to enable progress and key trends to be benchmarked and disseminated.

Current Plantation Forest Resources: Species and Areas

The Global Forest Resource Assessment 1990 estimated the world's total forest area to be 3.4 billion hectares with an additional 1.7 billion hectares classified as Other Wooded Land[1]

Plantation forests make up only a very small proportion of global forest area. It is estimated[2] that in 1995 the global area of plantation forests totalled 123.7 million hectares, approximately 3.5 percent of global forests.

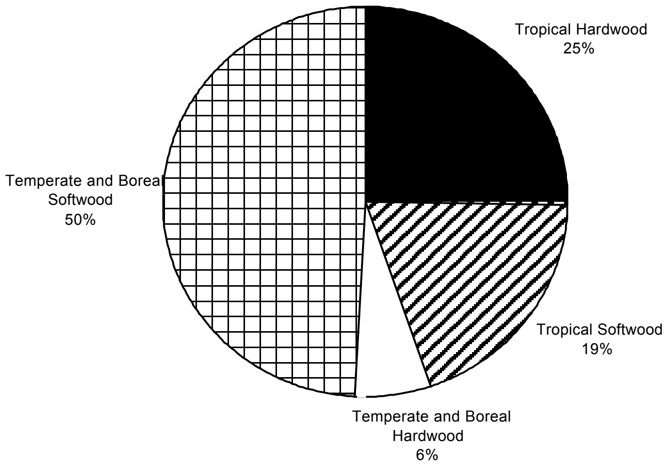
Table 1 shows that the Asian region has the largest proportion of plantation forests, with 45 percent of the total. More revealing is the dominance of a handful of countries in global plantation forest establishment. Five countries - China, United States, Russian Federation, India and Japan - have each established more than 10 million hectares of plantation forests. These five countries collectively account for 65 percent of the global plantation resource. The overall concentration of plantation resources in a handful of countries is further shown by the fact that only an additional 13 countries have an area of plantation forest exceeding one million hectares. Thus, 18 countries account for 87 percent of the world's plantation forests. Note, however, a number of European planted forests have reverted to semi-natural status due to the time elapsed since establishment.

At the broadest level, global plantation forests can be separated into tropical (including sub-tropical) and non-tropical plantations, and into hardwoods and softwoods. The global distribution of these areas is illustrated in Figure 1. Plantation forests in temperate and boreal countries are reported to cover 68 million hectares. Softwood species dominate in temperate and boreal plantation forests. Temperate and boreal softwoods are estimated to cover 61 million hectares and constitute 89 percent of the temperate and boreal plantation forest resource. Temperate and boreal hardwood plantations are estimated to cover almost 8 million hectares.

[1] Other wooded land: Land either with a crown cover (or equivalent stocking level) of 5-10 percent of trees able to reach a height of 5 m at maturity *in situ*; or a crown cover (or equivalent stocking level) of more than 10 percent of trees not able to reach a height of 5 m at maturity *in situ* (e.g. dwarf or stunted trees) ; or with shrub or bush cover of more than 10 percent.

[2] Sources: Pandey (1997) for tropical countries; ECE-FAO (1998) for temperate countries.

Figure 1: Global plantation forest resources by type and area 1995 (123.7 million hectares)



Sources: Tropical forest plantations: Pandey (1997): Temperate and boreal forest plantations: compilation

Tropical and subtropical forest plantation resources are estimated[1] at 55 million hectares, (about 45 percent of the global resource) for 1995. Tropical hardwood species are estimated to occupy 31 million hectares (about 57 percent of tropical plantation forest area). Tropical softwood species cover 24 million hectares.

Globally, the dominant forest plantation genus is *Pinus*. More than 40 percent of the world's forest plantations are planted with pines. This dominance largely emanates from temperate regions where large pine estates in the United States, the Russian Federation, and the southern plantation countries: Australia, New Zealand, South Africa and Chile, collectively contribute to a temperate pine plantation estate of almost 40 million hectares. *Eucalyptus spp.* are the most common tropical forest plantation species, with 10 million hectares planted. Brazil and India account for more than half of this area.

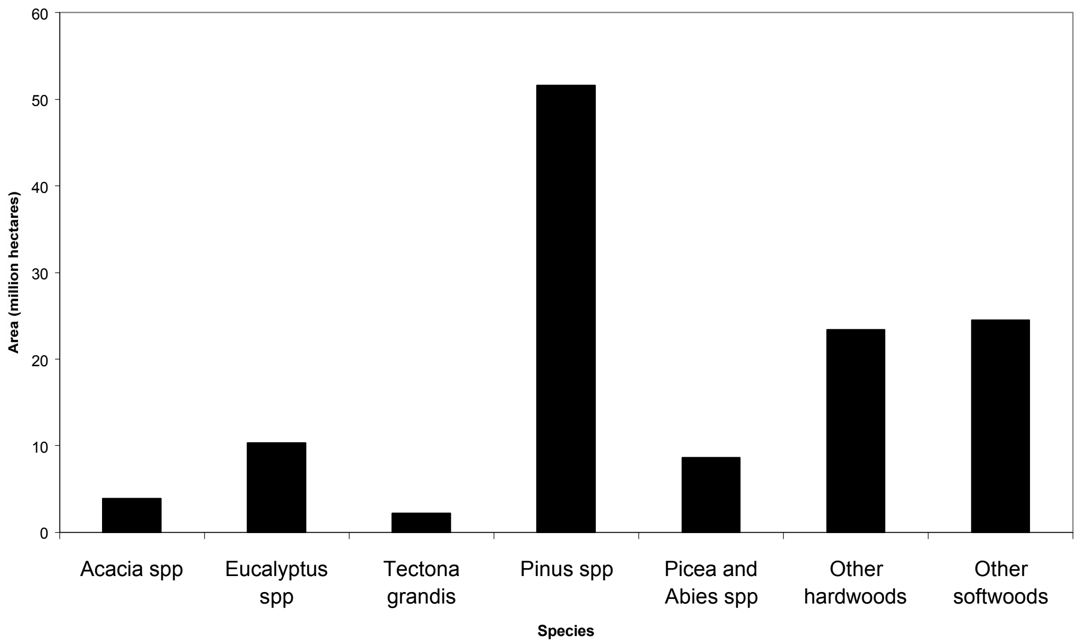
Other major forest plantation genera include *Picea*, *Abies*, *Larix*, *Acacia*, and *Tectona*, while the more than 6 million hectares of *Cunninghamia lanceolata* planted in China may make this the single most extensively planted forest plantation species. Figure 2 illustrates an approximate global species distribution for plantation forests.

Current Plantation Resources – Age Classes, Volume Increments, Rotations and Planting

Discussion of roundwood production, and the key variables that determine it (age-class, increment and rotation) is primarily relevant for the production of industrial wood.

[1] Tropical and subtropical plantation areas are drawn from Pandey (1997). The areas quoted throughout this paper are Pandey's Net Areas as opposed to Reported Areas. In an attempt to provide more accurate assessments of actual plantation areas Pandey, in some instances, applies a net down factor to the area of plantations reported to be present in particular countries. "Estimation of the net area, that is, the actual area of the stocked plantations excluding failed, harvested or doubly counted plantations, has been done by applying a reduction factor/success rate derived from inventory or survey of plantations". A more complete description of the process is provided in Pandey (1997).

Figure 2: Global distribution of plantation genera and species



Sources: Tropical plantations: Pandey (1997): Temperate and boreal plantations: compilation

Fuelwood production is often much less concerned with stem harvest volume, than with biomass production, notably branches, twigs and tops.

The discussion here will, consequently, focus only on forest plantations with a primary purpose of supplying roundwood for sawntimber, veneer and pulp (industrial plantations). If all forest plantations in Europe and the former-USSR are assumed to be for industrial purposes[1], then global area of industrial forest plantations in 1995 is estimated at 103.3 million hectares (83.5 percent of the total forest plantation area).

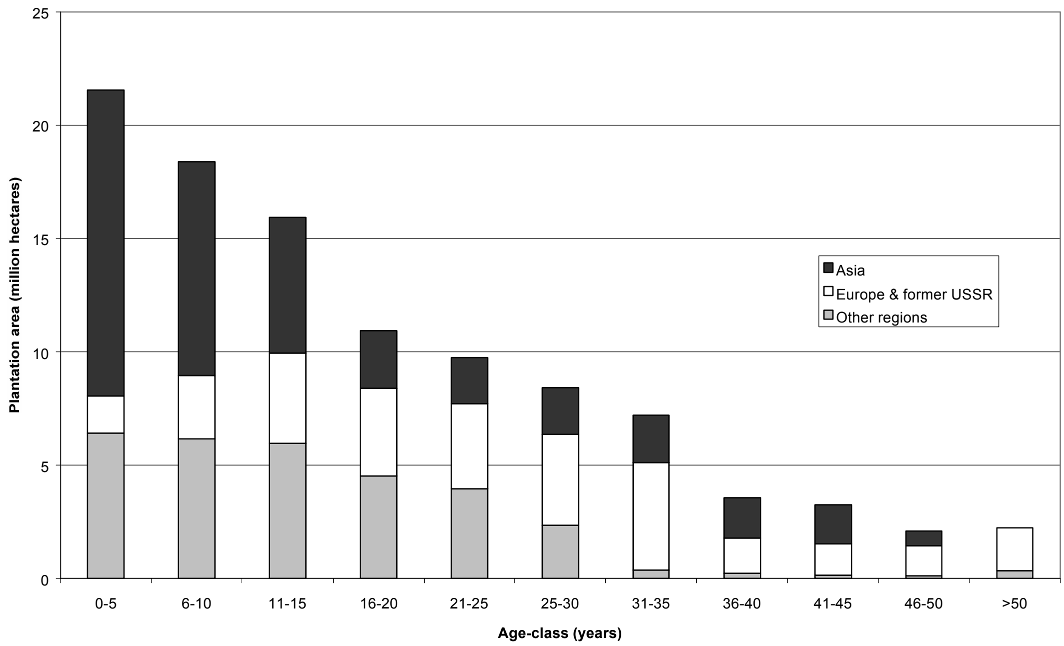
Age Classes

An absence of aggregated national plantation inventories for most countries means there are considerable difficulties in compiling detailed age-class structures on a regional or global basis. Nonetheless, forest plantation age-class information is of considerable importance since it enables more accurate assessment of the current level of wood production from plantations and likely future changes in production levels. Despite the scarcity of forest plantation inventories there is still much information available in various forms, the reliability and timeliness of which varies across countries and regions. FAO has commissioned a study[2] that derives representative age-class structures on a country-by-country basis, consistent with published information. It should be emphasised that these age class structures have been developed using a significant amount of data manipulation, the intention being to obtain structures that are representative of the "shape" of national data. The derived global age-class classification for industrial plantations, by region, is illustrated in Figure 3. Two dominant trends are apparent in Figure 3. Firstly, the preponderance of Asian plantation forests compared with the other regions is clearly evident.

[1] An assumption that ignores, for example, the establishment of, for example, recreational forests in countries such as United Kingdom, Holland and Denmark, and protection forests in mountainous countries such as Switzerland and Austria.

[2] Brown (1999)

Figure 3: Derived industrial forest plantation age-class structure by region 1995



Source: Brown (1999)

This is particularly the case for forest plantations established in the past decade. Asian plantations constitute 40 percent of the global total and 57 percent of the forest plantations established since 1985.

A second conspicuous feature of Figure 3 is the very high proportion of plantations aged less than 15 years, particularly in developing countries. Overall, 54 percent of industrial plantation forests are less than 15 years of age, with 21 percent planted between 1990 and 1995. Only 2.2 percent of plantation forests are aged more than 50 years. A further 16 percent are between 30 and 50 years of age.

This is largely the result of an acceleration in the rate of new plantation forest establishment, but also reflects the harvesting of mature forest plantations in the older age-classes and a general shortening of rotation lengths in many countries. Forest plantations aged more than 50 years are almost exclusively in temperate and boreal regions. Countries with significant areas of plantation forests established prior to 1946 include the Russian Federation, Ukraine, France, Portugal, Denmark, Ireland and South Africa.

Volume Increments

Forest plantation yield data, at a suitably aggregated level for global modelling, are both scarce and imprecise. While a vast body of literature assesses the yield of different species in research trials, the actual yield achieved on a commercial/operational scale are generally lower as the land is more variable, and the quality of establishment and silviculture is more difficult to control. Climate, altitude and geomorphology, matching of species to site, pests and diseases can have marked effects on tree growth at local levels. And small variations in annual yields can have major implications for final harvest volumes. For example, if a plantation estate yields 7 cubic metres/hectare/annum it will produce 40 percent more wood than at 5 cubic metres per hectare. Thus, at a global level, any consistent bias in yield data can badly distort the results. Initiatives such as the Tree Growth Potential Information System (TROPIS)[1] and the Sistema de Manejo de Informacion sobre Recursos Arboreos (MIRA) [2]are making

[1] Developed by CIFOR.
[2] Developed by CATIE.

significant improvements to the availability and quality of data, as well as the efficiency of research efforts.

Tropical regions may offer greater potential for future productivity gains than temperate regions. For example, while eucalyptus species, in the field, rarely yield more than 25 cubic metres per hectare per annum at present, significant advances may well be achieved in the not too distant future. In Brazil, for instance, hybrids of *E. grandis* with *E. urophylla* have, on some sites, attained growth rates of 70 cubic metres per hectare per annum (Campinhos, 1994). The extent to which such results can translate to the field, and particularly, whether other problems (for example, wood quality, or susceptibility to disease or windthrow) may arise from focussing mainly on growth and yield attributes remain important question-marks.

Rotation Lengths

Figure 4 illustrates comparative average yield data for temperate and boreal forest plantations. As shown, the highest yielding species are generally *Eucalyptus* and *Pinus* species, though these have a high degree of variability among various species and locations. At the other end of the scale are species adapted to very dry or very cold climates, which may produce only 1 cubic metre per hectare per year (at a national scale).

Rotation lengths in industrial wood plantations are determined by a number of factors: rate of wood and fibre production; desired wood and fibre properties; and maximisation of site productivity. However, the over-riding factor determining rotation lengths is generally profitability. Growth rates and wood properties should form part of an investment equation that marries costs and prices to determine the optimal length of time that the plantation investment should be "held". In terms of profit maximisation, rotation lengths, for single forest plantation blocks[3], are easily varied within a moderate time-span to capitalise on market conditions. Harvesting can be brought forward, or deferred according to prevailing market prices.

In terms of modelling[4], changes to rotation lengths can have significant impacts on predicted wood yields, but they are likely to be less important source of error than, for example, errors in estimated Mean Annual Increment, which will be compounded through the span of the rotation.

Planting

The question as to what role forest plantations might play in meeting future wood demands is inextricably linked to past and current patterns in plantation establishment. Plantation production, through to 2010 is almost exclusively dependent on trees already in the ground. Beyond 2010, future rates of planting will be increasingly important in determining the level of forest plantation production. Rates of plantation establishment vary annually in most countries and are driven by a range of factors including government finances, general economic conditions, incentives offered to private sector interests, perceptions of forestry profitability, successes of previous planting programmes, and perceptions of future supply-demand imbalances. Some of this planting (an unknown but, perhaps, large proportion) is, however, replanting of harvested areas. The current annual rate of new plantation establishment in temperate and boreal countries is estimated to be around 750,000 hectares, although this estimate does not include significant areas of enrichment planting and seeding in semi-natural forests.

[3] Profit maximising strategies will vary according to the size and age-class structure of a plantation estate, and long-run objectives of an investor. For example, a forest corporation owning multiple plantations of varying age-classes will have different cash-flow requirements and strategies to a single age-class, sole stand plantation owner.

[4] The modelling in Brown (1999) allows for harvesting to be distributed around an average rotation length and thus mimics some of the uncertainty between planned and actual rotation.

Forest Plantation Production

Current Harvest from Forest Plantations

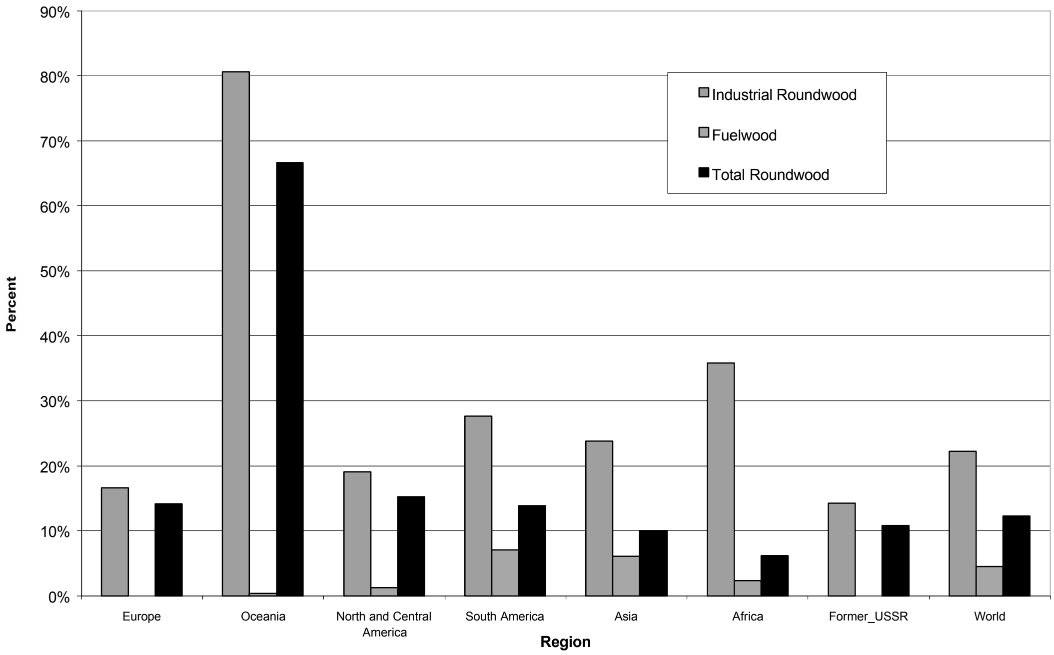
Current annual industrial roundwood production from forest plantations is estimated to be 331 million cubic metres, based on mature age-class production potential. Fuelwood production is estimated to be 86 million cubic metres (Brown, 1999).

Figure 5 shows an estimate of current industrial and non-industrial forest plantation harvests as a percentage of the total harvest of natural forest and plantation-grown industrial roundwood, fuelwood and total roundwood. A number of interesting features are evident from the graph. The "bottom-line" shows that current plantation production for industrial and fuelwood purposes could[1] be supplying around 12 percent of the world's total roundwood harvest. The harvest from forest plantations designated "industrial" constitutes, however, a far greater proportion of reported industrial roundwood production, than does the proportion of non-industrial plantation relative to fuelwood production. Industrial forest plantations are estimated to contribute 22 percent of global industrial roundwood production, compared with non-industrial plantations' 4 percent share of fuelwood production. It is important to note that these estimates are for over bark standing timber. Delivered mill-gate volumes of industrial roundwood may be significantly lower.

Forest plantation production for industrial roundwood is particularly important in the Oceania region, where 80 percent of industrial roundwood is plantation-grown. Africa (35 percent), South America (27 percent) and Asia (23 percent) also have above average proportions of industrial roundwood produced in plantation forests.

[1] That is, the global plantation age-class structure under the assumed national harvesting profiles would suggest that 417 million cubic metres of plantation-grown roundwood had reached maturity (i.e. its assumed rotation age) in 1995.

Figure 5: Estimated forest plantation wood supplies as percent of total roundwood harvest – 1995



Sources: FAO (1997), Brown (1999)

Production from forest plantations in a handful of countries in each of these regions – Australia, New Zealand, Chile, China, Japan and South Africa – is sufficiently large to put these regions ahead of the global average.

Future Forest Plantation Harvest Scenarios[1]

Comprehensive modelling of production, consumption and trade in forest products has been carried out as a core component of the Global Forest Products Outlook Study (GFPOS)[2] using the Global Forest Products Model (GFPM), a price endogenous linear programming system. Three scenarios for future wood supply from forest plantations have been modelled as part of the subsidiary GFPOS Thematic Study on Plantations, but independently of the GFPM analysis. The three forest plantation scenarios are:

Scenario 1 provides a baseline forecast, by assuming that forest plantations are not expanded beyond their current area and that all areas are replanted after harvesting.

Scenario 2 assumes that new planting will increase the forest plantation area at a constant rate of 1.2 million ha per annum in total (equal to 1% of the current area of forest plantations).

Scenario 3 assumes that the annual rate of new planting estimated in 1995 (4.71 million ha in total) is maintained until the year 2010, after which it is reduced by 940,000 ha at the start of each of the following decades (i.e. until it declines to zero in 2050).

The implications of these Scenarios in terms of plantation establishment by region and for major countries are shown in Table 2.

Scenario 2 is notable for requiring only relatively modest, and seemingly plausible, increases in plantation areas. For example, the 27.1 million hectares proposed for China in 2050 under Scenario 2 is markedly less than the 40.35 million hectares currently planned in China to 2050. Scenario 2 implies a 55 percent increase in current plantation forest areas.

[1] Note the assumptions behind the modelling and a more detailed discussion are found in Brown (1999).

[2] Results are published in Shushuai et al (1998).

Table 2: Industrial forest plantation areas under new planting scenarios (million hectares)

Country	Area 1995	Area 2050 Scenario 1	Area 2050 Scenario 2	Area 2050 Scenario 3
North and Central America	**18.9**	**18.9**	**29.3**	**43.2**
United States	*18.4*	*18.4*	*28.5*	*41.2*

Source: Brown (1999)

Plantation development is, however, unlikely to be uniform across countries. Countries such as Chile and New Zealand have, for example, achieved isolated increases in forest plantation areas of 5-10 percent in a single year. Other countries have gone for extended periods with little or no forest plantation establishment. South Africa, for example, is not encouraging further afforestation, with a preference to maximise water yields from catchments. Conversely, Australia has targeted the development of a 3 million-hectare plantation estate (a trebling of the current) by 2020. The impacts of subsidies and other incentives could play a major role in distorting competitive advantage in forest plantation establishment away from current patterns.

The areas implicit in Scenario 3 also seem to be generally achievable in physical terms. Institutional and policy constraints may, however, play a highly significant role in limiting planting below the indicated levels. Two notable cases are China and the United States, both of which would be required to maintain rates of plantation establishment higher (or for longer) than seems likely at present. Some of this "excess" planting could, however, be spread across other countries without markedly affecting the results of Scenario 3.

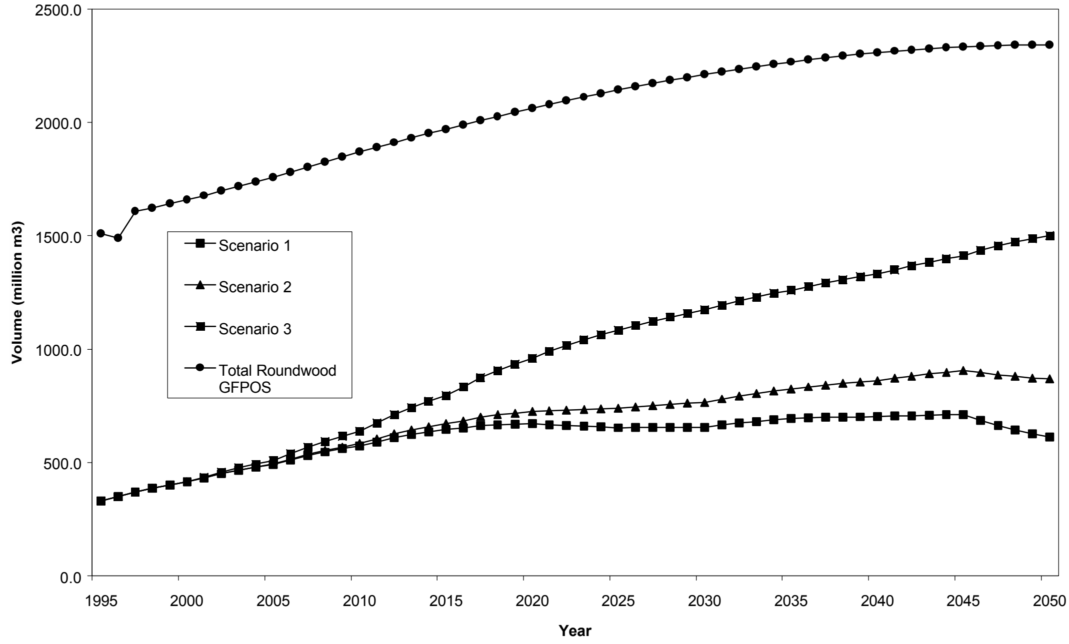
Several issues are likely to be of substantial importance in determining actual rates of plantation establishment. Perhaps most important will be the suite of government policies that impact on plantation establishment. A key change over the past 30 years has been national policy shifts away from centralised government planting programmes, with governments taking less direct means of encouraging tree planting.

A variety of incentive policies, privatisation, management devolution and government promotions, have contributed to this change in a variety of countries. An important future trend, in at least some countries, may be a form of "private sector devolution" whereby forestry companies take a lesser role in plantation establishment, and outgrower-type schemes assume much greater importance.

Future Forest Plantation Wood Production

Future wood production from industrial plantations under each of the three scenarios is compared with a forecast of industrial roundwood consumption derived using the GFPM until 2010 and long-term trend analysis, beyond to 2050 in Figure 6.

Figure 6: Comparison of projections for industrial roundwood production with three plantation scenarios



Source: Brown (1999)

Several Points of Interest Can Be Noted From The Graph

1. There is little difference between the three forest plantation scenarios until 2010. This is because trees already in the ground will determine production over the next decade.
2. The heavy weighting towards the youngest age-classes in the global distribution means that even Scenario 1 (zero new planting) shows a significant increase in wood production from forest plantations. Scenario 1 shows an increase in production from 331 million cubic metres to 712 million cubic metres. Note, however, this growth in plantation production would be insufficient to keep pace with the forecast growth in roundwood consumption, and additional new sources of wood or fibre would need to be found to supply additional new demand.
3. Scenario 2 increases at approximately the same rate as projected new demand for roundwood. Scenario 2 shows an increase in plantation wood production to 906 million cubic metres. Note, however, that current levels of harvesting in natural forests, recycling, etc. would need to be maintained if no other new fibre sources are found, or efficiency is not significantly improved.
4. Only Scenario 3, with its relatively large landuse implications, would enable forest plantations to substitute for wood production from natural forests. Scenario 3 expands plantation production to 1.5 billion cubic metres, approximately equal to current levels of global industrial roundwood consumption. Under Scenario 3, the industrial forest plantation share of industrial roundwood production is estimated to increase from the current 22 percent, to 64 percent in 2050.

The long-term production forecast from forest plantations is very sensitive to the assumptions made about future forest plantation establishment rates. Consequently, much is likely to be determined by the future availability of land for new planting and perceptions of supply-demand balances for wood and fibre. In general, it should be expected that plantations will supply a high proportion of feedstock to fibre based industries and for the production of utility sawntimber (particularly, outside Europe). High quality hardwood timbers, especially, are likely to continue to be sourced from natural forests, although plantation grown teak can be expected to become increasingly important.

Priority Areas For Forest Plantation Research

The analysis to this point highlights a need for continued focus on forest plantation research. If future supply shortfalls are to be avoided, or harvesting in natural forests be reduced, then forest plantation areas are likely to need significant expansion or plantations will need to come significantly more productive. The following offers a brief suite of potentially rewarding research topics.

Data deficiencies: Problems relating to incomplete, inaccurate and obsolete plantation inventory data have already been highlighted. Currently, data weaknesses have significant implications for the accuracy and reliability of production modelling and forecasting. In turn, doubts over the reliability of modelling create uncertainty in public policy setting and for the private sector.

Silviculture and management: Silviculture and management have considerable room for improvement in many countries, particularly in terms of mortality and general neglect. Broader dissemination of best practice techniques for various species and continuing site-specific experimental trials could lead to extensive improvements in productivity.

Species-site matching: Significant improvements in productivity could also be achieved through greater attention to matching species, provenances and clones to sites. Often successful plantings of a particular species or provenance are merely extended across a range of sites, where varying the species selected or testing other provenances could improve harvests. At the same time, a primary driver of species selection should be intended end-use. The species that grows best may not necessarily yield the highest financial returns or have a recognised use or market.

Genetics: The broad field of genetics offers substantial opportunities for improving forest plantation productivity, though activities such as genetic modification (small scale in forestry) are fraught with controversy. Much work may be required to secure acceptable levels of risk to the environment and allay public fears over controversial activities.

Tree-breeding: There is considerable potential for increasing wood yields though tree-breeding and other fields of biotechnology, though effectively translating the results of laboratory or small-scale research plots to the field is doubtless a major challenge. In view of this, it is distressing that still today, seed for planting in the tropics is generally procured or purchased from the most readily available sources, due to lack of information on consequences and potential losses, due to lack of knowledge of within species diversity and its adaptation to varying environmental conditions, and due to unavailability of quality seed, stemming from institutional weaknesses and lack of technical knowhow in seed collection and handling in many countries which possess these valuable genetic resources (Palmberg 1989). Even more disturbing is the fact that countries, at times, will embark on tree breeding programmes based on haphazardly introduced genetic materials, sometimes of unknown origin and genetic base. Such action can only lead to disillusion and economic losses. Amidst excitement over potential improvements in yields and uniformity of products, sight must not be lost of the dangers posed to forest plantations by climatic variation, abiotic factors, pests and diseases.

Issues of wood quality: Plantation grown timbers are often perceived as being inferior to natural forest timbers, particularly in high value applications or for applications where strength or elasticity are important. In some instances this may be more a marketing issue. From a research perspective, many of these issues may be overcome by applying (or developing new) wood engineering techniques. For example, the development of laminated veneer lumber enables plantation grown timber to be used in high load bearing applications where ordinary sawn beams are insufficient.

Wood utilisation: Much small dimension roundwood is produced in forest plantations, as thinnings, top-logs, or due to economics of short rotations. Much of this timber is used for low value purposes such as posts and poles, low quality sawn timber or pulp. Recovery rates for solid wood processing of small logs tend to be low, and often the wood or fibre is of low quality. In many areas utilisation could be improved by better distribution, or by introducing new processing techniques or technology.

Tree-growing in low forest cover countries: Far greater attention needs to be applied for experimental trials in low forest countries, particularly those where there is a weak "forest culture". Considerable strengthening of research into social, policy and legislative issues, as well as strengthening technology transfer and information dissemination may be required in a number of countries.

Revitalising degraded land: Plantation forests are often proposed as a means of rehabilitating or utilising degraded lands. Further attention needs to be given to species-site matching in this regard, as well as more study of the economic and/or environmental efficacy of such rehabilitative efforts. The need for Environmental Impact Assessments to be carried out prior to implementing afforestation projects on "wastelands" should be noted.

Forest plantation sustainability: Considerable controversy continues over the long run sustainability of forest plantations. While most research indicates that plantations meet "narrow sense" definitions of sustainability (notably maintaining productivity across multiple rotations), considerable further work is required to demonstrate that plantations meet broader sustainability criteria. These will be a key consideration if extensive increases in plantation forest areas are to be achieved. Activities that, for example, promote greater biodiversity in plantations may provide fruitful areas for research. Similarly, attention to multifunctional uses of forest plantations can enhance their social and environmental values.

Policy-related: On-going study and research across a broad spectrum of topics will be required to support national plantation policy development. Diverse issues such as land availability, effectiveness of incentive policies, appropriate ownership structures, social impacts of plantation establishment, and mechanisms for carbon offset schemes require study or monitoring.

Conclusions

The analysis suggests a central conclusion that the role of plantation forests in meeting future wood and fibre demands will increase during the next 30 years, irrespective of future rates of plantation establishment. Forest plantation wood supplies for the next decade are already largely determined by trees in the ground and, in many countries, a considerable increase in areas of plantation forests reaching harvestable age is expected. Thus, by 2010, the annual yield of plantation grown industrial roundwood is estimated to increase from the current 331 million cubic metres to around 600 million cubic metres. Production of plantation-grown fuelwood is expected to double from the current 8 million cubic metres.

Beyond 2010, plantation production forecasts are increasingly dependent on assumptions of new planting rates, and on assumptions of improvements in annual increments. There is scope, depending on policy decisions and markets, for forest plantations to play a dominant role in industrial wood and fibre supplies. A more likely scenario is probably that the proportion of forest plantation-grown wood will increase, but natural forests will continue to supply a modest majority of industrial roundwood.

The question of where future plantation forest development is most likely to occur remains unclear. At present, many governments remain active in plantation forest establishment, either directly, through state planting programmes, or indirectly, by providing incentives to the private sector. In some instances plantations realising non-market values can justify incentives. In other cases the incentives are merely maintaining wood supply capacity. In any event, under these circumstances, competitive and comparative advantages are not clearly emerging.

The most significant forest plantation increases in the immediate future will be in countries where specific public planting programmes are in force, most notably China and India. In Europe, plantation establishment is likely to be mainly dictated by the life span of incentive policies. Europe is largely self-sufficient in terms of wood-fibre volumes and development of a larger than present plantation-based export trade seems a relatively unlikely development.

South America and Oceania are likely to continue to expand forest plantation areas under the perception that real competitive advantage in plantation growing is held in these regions. The extent to which forest plantations increase in these regions is likely to be dictated by the extent to which this perception is sustained. If plantation revenues are unsatisfactory then afforestation rates in these regions are likely to slow.

Plantation profitability in the southern countries is likely to be determined by conditions in North American and Asian markets and by wood and fibre supplies from forests in these regions. Similarly, if the current trend toward increasing regulation of natural forests increases then forest plantation establishment in both North America and Asia is also likely to accelerate. Of key interest will be natural forest wood supply trends in the US Pacific-Northwest, Canada, Indonesia and Malaysia.

Plantation forest establishment in the former-USSR and Africa seems unlikely to accelerate in the immediate future. In the former-USSR countries, economic difficulties are likely to mean plantation investment will be of relatively low priority, particularly given the extensive natural forest resource in several of these countries. In Africa, the absence of strong infrastructure is likely to remain a significant competitive disadvantage for many countries. It is difficult to see true competitive advantage in plantation investment emerging in many countries, even those that have important industries based on natural forests.

Abstract

Non-wood forest resources particularly bamboo, rattan and other related species, form a very important source of livelihood for the rural folks, especially those who are at the bottom of the economic level. This is particularly true for large segments of the population in many Asian countries. In the last few decades, the accelerated rate of forest conversion and logging has led to a decimation of these non-wood resources, sometimes to the point of their disappearance. Despite their importance in the socio-economic and cultural contribution to the marginalised people, little effort has been given to manage these resources on a sustainable basis through proper harvesting, restocking, and artificial propagation. The lack of scientific knowledge of these non-wood forest resources especially the taxonomy, silviculture, technological properties and processing methods, has partly resulted in their desultory development. With more concerted efforts, backed by deeper scientific investigations, it should be possible for industries based on these underdeveloped resources to supersede the timber industry in several parts of the Asian region. There is considerable opportunity for further development in furniture manufacturing and other novelty items. This paper presents a summary of some of the important findings and the ongoing research efforts, with particular reference to production and utilization of some selected non-wood resources and products in Peninsular Malaysia.

Key words: Non-wood , Management , Research , Developmental considerations

Introduction

Malaysia is one of the twelve "megadiversity" countries of the world. These countries together contain 60 percent of the world's known plant and animal species. The flora of Malaysia, for example, is conservatively estimated to contain between 12,500 to 15,000 species of flowering plants, more than 1,000 species of ferns and fern allies. The fauna composition comprises more than 100,000 species. Both flora and fauna of the country are mostly located in the natural forest, wherein are found the important non-timber resources .

The most important non-timber forest resource in Malaysia (and also several Southeast Asian countries) is rattan, with bamboo next. These two groups of plants have received attention (in terms of silvicultural management) by the scientific community around the region. The forests in this region have the greatest concentration of rattan in the world with 12 genera and about 600 species. In this respect, there is great potential for value added processing of rattan. Trade in rattan has been on the increase especially in the furniture industry.

Bamboo has often been termed the **Poor Man's Timber** or **Friend**. Bamboo has been harvested from natural stands for constructional purposes and other uses such as flooring, walls, frames, shingles, doors and in other components of the house. In modern living, bamboo is found as curtains, paneling, picture frames and in a host of other products. Bamboo shoots are eaten in many Asian countries. Management of this resource is important in order to sustain the productivity and the industry.

Apart from rattan and bamboo, there are also other non-timber resources that are being used by the village community for their daily needs or to supplement their income. Amongst them are forest species producing oil bearing seeds, resins, medicines and fruit. The forests of Southeast Asia are extremely rich in such species.

Past and present activities such as logging or conversion of forests to agriculture or other non-forest uses can permanently destroy the non-timber resources. Exploitation or harvesting of non-timber resources is seldom strictly managed or controlled. This is mainly due to the difficulty in enforcing regulations in the forest. This will in the long run result in total depletion of the resources. There is little available information on non-timber resources, especially on the technical aspects related to their management and silviculture. Information on the available species and their distribution is also scanty. Hence, basic research must be undertaken to provide the much needed information so that these resources could be managed in a sustainable manner.

Non-Wood Forest Resources

Non-wood forest resources as defined in the FAO Forestry Paper No: 97 (1991) refers to market or subsistence goods and services for human or industrial consumption derived from renewable forest resources and biomass, bearing promise for augmenting real rural household incomes and employment. The products include the use of plants for food, beverages, forage, fuel and medicine (Table 1); animals, birds and fishes for food, fur and feathers (Table 2); and the services of land for conservation and recreation (Table 3). The area covered is so wide that the list can be endless. This shows the importance of non-timber forest resources which can give cash earnings and "intangibles" to each country having "forest" that produces wood and other goods.

Status of Current Resources

The current and potential plant resources of the forests are many. They range from timber to other minor forest products such as rattans, dyes, gums and resins. They are being exploited depending on the location and the people surrounding the forests. The most notable forest products that are being harvested/collected are rattan and firewood. There is, however, no large scale organised efforts in their extractions as compared with timber. The fast rate of disappearance of the tropical vegetation underscores the need to study the forests in more detail, especially into the potential of the forests as a source of major and certain minor forests products. The following section highlights some of the important resources exploited and found in the tropical forests and discusses the status of the resources in some of the countries.

Table 1: List of non-wood forest products according to category

Food -	wild, domesticated, semi-domesticated plants, usable weeds, fungi, etc. and their edible roots, tubers, bulbs, stems, leaves, shoots, flowers, fruits, seeds, etc. to provide cereals, vegetables, edible fats and oils, spices and flavorings, salt substitutes, sweeteners, rennet substitutes, meat tenderizers, beverages, cordials and infusions, thirst quenchers, etc.
Forage -	food for livestock and wildlife, including birds, fishes, and insects such as bees, silkworms, lac insects, etc.
Pharmaceuticals -	drugs, anesthetics, slaves, ointments, lotions, purgatives, etc. for both human and veterinary use.
Toxins -	for hunting, ordeal poisons, hallucinogens, pesticides, fungicides, etc. (Note: some may have a pharmaceutical potential, especially as anesthetics.)
Aromatics -	essential oils for cosmetic and perfume industries (international market highly specialized and vulnerable), unguents, incense, etc..
Biochemicals -	non-edible fats and oils, naval stores, waxes, gums and latex, dyes, tannins, biochemicals for plastics and coatings, paints and varnish industries, etc.
Fibre -	cloth, matting, cordage, basketry, brooms, stuffing for pillows, cork, etc.
Wood -	wood for handicrafts.
Ornamentals -	aesthetically pleasing plants for horticultural and amenity planting, cut- and dried-flower trades, etc.

Source: FAO Forestry Paper No: 97 (1991)

Table 2: Faunal Non-wood forest products

Wild animals -	meat, hides, skins, fibre, horn, bone, pharmaceuticals, etc.
Birds -	meat, eggs, feathers, edible nests, guano, etc.
Fishes -	food, fish oil, feed protein, etc.
Reptiles -	food, hide, skins, shell, toxins, pharmaceuticals.
Insects -	edible insects, plant exudates (manna), honey, wax, propolis, silk, lac, insect pests, etc.

Source: FAO Forestry Paper No: 97 (1991)

Table 3: Forestry Services

Range -	grazing, browse, shade and shelter for domestic livestock and wildlife, etc.
Soil improvement and protection -	green manure, humus, N-fixation, soil stabilization, shade, shelter, hedges, etc.
Parks and reserves -	for conservation of flora and fauna, tourism, recreation, hunting, shooting, fishing, photography, bird watching, bug collecting, etc.
Aesthetic -	scenic or historic sites, etc.

Rattan

Rattans are spiny climbing plants belonging to the palm family. There about 600 species in the world, of which 106 species are found in Peninsular Malaysia. Based on the third National Forest Inventory (1990-1993), the estimated rattan resource was about 825 million sticks (Note: each stick is 3 m length). If the data is true, then Peninsular Malaysia will face a shortage of raw material supply by the year 2020. Based on another report (Kiew & Hood 1990), the supply of manau and sega are much lower. Rattan harvesters have to track deeper into the forest to collect rattan.

The planting of this resource, mainly that of *Calamus manan*, is conducted by the government and private sector. To date more than 31,000 ha have been planted. Out of this, 7,000 ha have been planted in rubber plantations throughout the country (Aminuddin & Salleh 1994, Abd. Latif & Aminuddin 1996). Other large plantations in Sabah are planting mainly *C. caesius* and *C. trachycoleus*. So far more than 10,000 ha have been established. Other rattan species that have been looked into include *C. scipionum* and *C. palustris*.

Indonesia is one of the countries in the region rich in rattan, providing about 80% of world's rattan supply. Indonesia with about 300 rattan species, has about almost 50% of the known total number of rattan species worldwide. Most of the rattan supplied (90%) to the market are obtained from the primary forests. The rest comes from rural small holdings and plantations. There has never been an inventory of rattan resources for the country but the natural rattan resources are fast dwindling.

Bamboo

Bamboo is next to rattan in terms of economic importance especially in Malaysia. It is one of the non-wood resources found growing wild in the forests. Many Asian countries have a long tradition in the use of bamboo for the manufacture of a wide variety of products such as blinds, chopsticks, mats and baskets, farming implements etc. Other uses include scaffolding, houses and bridges. In some countries like India, bamboo is one of the important raw materials for pulp and paper making. In Malaysia, bamboo has not been utilized as extensively and its use is limited to the production of poultry cages, vegetable baskets, utensil products etc. In Asia, there are 320 species (Liese 1985). Fifty species are known to be found in Peninsular Malaysia but only 13 species are being utilized commercially (Aminuddin & Abd. Latif 1994).

Bamboo usually occurs in significant quantities in disturbed situations such as logged-over forests, wastelands or in marginal localities fringing the forest. So far, there has been no report on the inventory of bamboo resources in any country in the world. However, Abdul

Razak and Abd. Latif (1988) estimated that bamboo covers an area of about 320,000 ha in Peninsular Malaysia with an estimated standing stock of about 7.0 million tons, of which 6,000 tons valued at RM 3 million are of commercial species.

Other Non-wood Forest Products

Besides rattan and bamboo, there are other non-wood forest products that are being exploited. That they are being dealt with less comprehensively here does not necessarily indicate their lack of importance. It only reflects the infant stage of the related industries.

Medicinal Plants

The forest has been the source for man's medicinal needs since time immemorial. This fact is well documented in a number of early publications detailing the uses of various plant parts for numerous ailments (Tavera 1892, Brown 1921, Burkill 1966). The use of plants for medicine has been clouded by superstition and magic, but the basis of the pharmaceutical properties lies in the alkaloids present in the plant tissues. Currently there is a renewed interest in seeking cures for various diseases using active compounds present in plants. The World Health Organization (WHO) has established 21 collaborating centres worldwide to strengthen research and development effort on traditional medicine. The United Nations Industrial Development Organization (UNIDO) has agreed to undertake the task of developing guidelines to assist developing countries in achieving improved supply of medicinal plants.

Systematic screening programs have been initiated since the fifties. In countries like Malaysia, Indonesia, Thailand and the Philippines, thousands of species were examined and screened leading to the detailed studies of promising species (Santos 1957, Kiang *et al.* 1964).

Chemicals from Wood

A large number of chemicals, present in various parts of plants, have found commercial application. A good example is latex from the rubber tree which has demonstrated its commercial importance. The bark of certain mangrove trees like *Rhizophora mucronata* contains a high percentage of tannin and is used in the tanning industry. *Caesalpinia sappan* (kayu sepan), produces a red dye in the wood, which was once extensively used to colour foodstuffs and to dye mattings and fabrics (Burkill 1966). The demand for natural dyes has gradually diminished with the development of synthetic substitutes. Resins are collected from old and new wounds on the tree trunks of some of Dipterocarpaceae especially *Dipterocarpus* and *Shorea* species. The limited supply coupled with the availability of synthetic resins have reduced the trade.

Fruit Trees

In most villages in this region we can find domesticated fruit trees like *Nephelium*, *Mangifera*, *Sandoricum* and *Eugenia* being grown (Wee & Rao, 1980). They have been domesticated through the centuries from wild forest species. Their progenitor and relatives still exist in the forest. Many are known and the fruits are collected and sold in rural markets. A good example is *Baccauria*. *B. motleyana* is an established fruit tree of village gardens. The other two species *B. macrocarpa* and *B. puberula* are known but not properly grown. Of the many species of *Mangifera*, *Durio* and *Garcinia* that exist in Southeast Asia, only a handful are grown in rural orchards, although many more species with edible fruits exist in the forest. Another fruit tree that is known to many in Peninsular Malaysia is *Parkia speciosa* (petai). Petai can be found in encroached forest, logged-over forest, shifting cultivation areas and cultivated agricultural land. In such habitats and management systems, the number of pods produced per tree per year varies. It ranges from as high as 873 pods in encroached forest to 136 pods per tree per year in cultivated agricultural land. This shows that the nature of land uses affect productivity.

Status of Current Utilization

At present, the most important non-wood resource that is being harvested heavily is rattan, followed by bamboo. In countries where bamboo is more prominent such as India and Bangladesh, the reverse is true. Nevertheless, these resources are being depleted and steps are being taken by the respective government agencies of countries in the region to plant them on large scale. In this section, utilization of the important resources are discussed with reference to Peninsular Malaysia.

Rattan

The rattan furniture industry for Peninsular Malaysia is quite dynamic. There are about 700 rattan mills and 525 are engaged in manufacturing activities, with about 13% of the latter being export oriented (Abd. Latif & Aminuddin 1996, Abd. Latif 1997). The rest are mainly cottage and small-scale industries. The rattan industry requires about 12 million 3m-length sticks of the prime cane species *Calamus manan*, and 45 million 6m-length sticks of the small diameter cane *C. caesius*, annually (Appanah *et al*., 1998). Shortages of these high-quality canes are being felt. Other canes of lesser quality are also being used by the industry. While the widely dispersed rattan processing mills tend to be concentrated in the state having large forest areas where rattans are commonly found, the manufacturing industry is predominantly located in the west coast areas where large market and basic amenities are readily available (Aminuddin & Abd. Latif 1991a, Abd. Latif & Aminuddin 1996). Peninsular Malaysia has an abundant supply of raw rattan. The total gross value collected could amount to over RM 5 million a month. The value can increase to more than 21-25 times if the manufacturers concentrate on downstream processing as in furniture or semi-processed products such as ropes and binds which are traditionally imported from Singapore, Hong Kong, Indonesia or Taiwan (Abd. Latif 1989b, Abd. Latif & Aminuddin 1996). Since the ban on the export of raw rattan and the imposition of high import duty for the semi-processed products in 1989, a shift from the traditional practice of exporting the raw and semi-processed products to more value-added finished products has increased the foreign exchange earnings as well as the employment opportunities in the rural urban sectors.

Bamboo

As reported by Aminuddin and Abd. Latif (1991b), there are 1,032 bamboo-based industries of various sizes in Peninsular Malaysia but only 104 mills have appropriate machines producing products such as skewers, chopsticks and toothpicks (32 mills), furniture (2 mills) and craft (70 mills). While these 104 mills are categorised as medium and large-scale, the remaining 928 mills are classified as cottage and small-scale enterprises. Although the bamboo industry in Peninsular Malaysia began in 1950's, activities were confined to traditional handicrafts, while the machine intensive industry was introduced only in the last decade.

Cottage industries making handicraft items are mainly found in the west coast states of Peninsular Malaysia, whereas industries making poultry cages and vegetables baskets tend to concentrate around vegetable plantations around Tapah in Perak . The local market for bamboo products is worth about US$3 million annually (Aminuddin & Abd. Latif 1994). Lately, there has been an increased utilisation of bamboo by the industries. This could probably be associated with increasing level of difficulties in gaining commonly used timbers from the forest, hygienic concerns especially for cheap disposable items used in contact with food; and the awareness to sustain the healthy surrounding green environment within the society. The popularisation of bamboo as an environment friendly material (fast growing, high yielding renewable resource and a secondary forested species) has also resulted in the resurgence of bamboo industries (especially those machine-intensive) from its seven static years in 1988 to 1995. The domestic demands for machine-intensive products such as skewers and single chopsticks, for example, have considerably increased to about US$5 million in 1996 onward compared to the average of US$3 million per annum within those static years (Abd. Latif 1989, Abd. Latif & Abd. Razak 1994, Abd. Latif & Abd Razak 1998).

Fruit tree

In Southeast Asia there are 130 species of domesticated fruit trees belonging to 29 genera and 17 families. Almost all of them have their wild or nearest relatives in the forests. Because wild fruit trees have scattered occurrences, about less than 10 trees per 40 ha, their existence can only be detected with intensive search over a long period of time. The trade in wild fruits in the local markets appears to be tremendous but there is a lack of quantitative data on non-wood resources. In one study on Petai, the magnitude of the trade is fairly large in the domestic markets. The trade can be between RM 336,000 to RM 900,000 per annum depending on the locality (Woon *et al.* 1995). It is therefore necessary to look at evaluating other non-wood resources which will eventually lead to a fair assessment of its economic value.

Non-Wood Forest Resources Management

International funding agencies are willing in their own way to work on these resources but national programs must lead the way. Priority therefore should be given to the further development of non-wood resources that provide socio-economic benefits at the domestic levels. Multi-purpose tree species must be managed at all levels. A selection of the specific non-wood resources is described in general terms.

Rattan

In order not to rely so much on the supply from the wild, large scale planting of the resource is deemed necessary. This is supported by the fact that for *Calamus manan*, Peninsular Malaysia required about nine million 3-m length sticks per annum and this requires planting of about 5000 ha per annum. For other commercial species, planting is also needed in order to supplement its requirement as an alternative material for the highly sought after species. If such activities are not carried out, supply in the near future will be difficult. Planting can be either in the logged-over forest areas or in rubber plantations. Assistance can be provided by the government to provide incentives in other aspects of the plantation management.

Bamboo

In countries where the demand for bamboo is large, silviculture management of the species already exists. This is practically so in countries like China and Taiwan where monopodial bamboo is dominant. In Peninsular Malaysia where most of the bamboos are sympodial (clump-forming type or so-called pachymorph) and wild, management of the natural stand as a plantation crop is imperative in order to ensure continuous supply of the raw material demanded by the industry. It is understood that for *Gigantochloa scortechinii* (the highly sought after bamboo species in the country) which is abundantly found in the northern part of Peninsular Malaysia, about 12 - 15 culms (of age classes less or equal to three years old) per clump should be left behind and the harvesting should be systematically practiced. The optimal number of clumps per hectare should also be maintained between 220 - 250 clumps (Abd. Latif & Abd. Razak 1994).

Fruit trees

For management purposes, it is essential to zone the potential producing areas depending on the fruits. This will provide data for long term management purposes. Intercropping of the fruit trees with other crops to maximise the land-use is another approach to contribute for the higher income generation of the species. In a study by Woon *et al.* (1995), petai and durian land use option provides the highest net present value (US$ 11,173.85 per ha) compared with primary forest (US$ 70); and petai and banana (US$ 262). Planting of some of the fruit trees should be encouraged as the increased income generated will be significant.

Quantification of Non-Wood Forest Resources

There is a growing awareness on the importance of forest and the services it can provide either for conservation or recreation. In terms of non-wood resources, several items listed below can be considered to have tangible benefit and shows that the forest is an important resource to be preserved and conserved by mankind.

Recreation

At present there is almost one forest recreation area in one district but it is difficult to quantify the significance of the area. There has been some studies indicating the number of visitors going to the place (day trippers, campers, etc.), facilities available and so on, but there is no attempt to relate this recreational area to monetary values. Questionnaires and fees charged to people using such facilities could probably provide some information whether such facilities are useful.

Hydrology

Hydrological studies have proven that water production from forests is greatly affected by deforestation and quality. There has been no attempt to look at the economic impact of water in the forest.

Problems and Prospects

Rattan

Peninsular Malaysia has an abundant supply of raw rattan. Abd. Latif (1989a) reported that the total gross value of raw rattans collected amounts to over US$ 1.3 million a month. The value can increase to more than 21-25 times if the manufacturers concentrate on downstream processing as in furniture or semi-processed products such as ropes and binds which are traditionally imported from Singapore, Hong Kong, Indonesia or Taiwan (Abd. Latif 1997). Since the ban on the export of raw rattan and the imposition of high export duty for the semi-processed products in December 1989, a shift from traditional practice of exporting the raw rattan to semi-processed and finished product has resulted. This has increased the foreign exchange earnings as well as the employment opportunities in the rural-urban sectors. There was in fact a significant increase in the export value of rattan products from Malaysia in 1990 (almost 200%) as a result of the total ban. The Federation of Malaysian Manufacturers projected that revenue from the export of rattan furniture would reach RM 150 million (US$ 40 million) before the 21st century.

Rattan has the potential for industrial development especially in the form of finished products (Abd. Latif 1991). Therefore, Malaysia should exploit these resources fully. Concerted efforts, however, must first be spearheaded towards overcoming immediate problems encountered by the industry such as inadequate supply of skilled and trained workers, unavailability of original contemporary designs, technological improvements, know-how such as low-cost automation and mechanisation, lack of quality control and insufficient operational capital. Besides giving incentives such as soft loan and sales tax reduction, establishment of an information and service centre for better marketing strategies, business opportunities and design trends should also be given immediate attention (Aminuddin & Abd. Latif 1991b). The establishment of village industries or service centres at district level focusing on the economic support of complementary activities will highly benefit many traditional entrepreneurs as these could also serve as training centres for new entrepreneurs to learn basic production techniques. With government support to develop the industry, there is no reason why it should not succeed. With careful planning and cooperation among the industrialists and government agencies, rattan entrepreneurship should continue to develop and the industry will eventually become competitive with those from the rest of the exporting countries.

Bamboo

There are several problems that need immediate attention if the bamboo industry is to be developed further. The misconception that bamboos are weeds interfering with the growing timber and regeneration of trees (Ng 1980) or free goods of nature has to be redefined. Bamboo plantations should be established to ensure a continuous supply of high quality raw material and at the same time exploit the possibility of growing bamboo for shoots and commercialising them. Commercially utilisable bamboo species grow mainly in northern Peninsular Malaysia, in logged-over forest, and on river banks and hillsides. The large areas of bamboo forest within this region need to be designated as bamboo estates, and leased out to private sector agencies to manage on a sustained yield basis. With intensive and careful management, these natural bamboo resources can be gradually converted to equivalent plantation stand. With proper silviculture treatment and harvesting practice, sustainability of bamboo supply can be ensured.

A reliable estimate of total bamboo areas and production especially the magnitude of useful bamboo species available within the country (especially Sabah and Sarawak of East Malaysia) should be carried out thoroughly in order to facilitate planning for development of the industries. Only with a continuous and regular supply of the raw material would the industry be able to develop properly. To a certain degree, drastic steps should also be taken to revise the current institutional systems and procedures pertaining to bamboo resources. This also means that the current policy of issuing permit for bamboo extraction should be retailored to include the provision for the licensees in managing the natural bamboo stands within the given area.

More attention should be devoted towards training-cum-production centres. In such centres, besides ensuring all the government funded facilities remain in good condition, the maintenance of machines used on a rental basis could easily be handled by the selected industrialists.

Concerning employment of foreign skilled workers, an incentive for lower levy should be introduced. This is particularly importance with the current serious shortage of workers in both the plantation and industrial sectors within the country. Besides obtaining various knowledge on manual artistic skill work from foreign sources to be delivered to the interested local work-force, more diversified value-added products integrated from different cultures could also be expected.

Information on the technological properties of Malaysian bamboos particularly in relation to their industrial application should also be expanded. Since many bamboo species remain unutilized, research effort is needed to determine the properties of such species and develop their appropriate utilization technology. Emphasis should also be given to encourage locally fabricated machines designed to process local species not only to achieve higher recovery rate but also to reduce the cost of imported machinery. There is also a need to provide a team of industrial designers to produce new and attractive designs (either in combination with other materials such as plastic, metal or less popular cultivated woody species) which can maintain and upgrade the products without sacrificing its original identity as well as to sustain the interest of the buyers. Furthermore, to extend the utilization of bamboo, consideration should be given to promote or upgrade the existing research and development institutions involved in patronizing the small-scale bamboo industries.

Another aspect that could help improve the industry is by reducing its processing waste. The range of wastage (28 - 47%) generated by the industry is very high. If the industry cannot avoid the high labour and other material costs, the waste generated should be reduced by utilizing the waste for other products such as pulp and paper, flooring and advanced materials (for instance the particle and thermoplastic fibre board) which could tremendously increase the profit margin (Abd. Latif *et al*. 1988, Abd. Latif & Liese 1995).

Priority Research Areas

To enhance the importance of non-wood forest based resources to the economy and improve the utilization and production, an intensified research and development programme should be initiated and expanded.

Inventory

There has been no serious attempt to quantify the non-wood resources of any country. The only serious attempt is done by Forestry Department of Peninsular Malaysia in their National Forest Inventory which conducted every 10 years. The National Forest Inventory in 1981-1982 and 1990-1993 indicated that clusters of commercial rattan species appear to be located in the north-west of Peninsular Malaysia. In the south, there seems to be less canes available in the forest probably due to over exploitation. The report by Abd. Latif and Shukri (1989) further revealed that rattan processing mills are concentrated in states having bigger forest areas and better infrastructural facilities, in the west coast states. Stocks of rattan species harvested and the amount required by the industry are well reported by Tan (1989) and Abd. Latif *et al.* (1990a) , respectively.

There has been no attempt to quantify the bamboo resource using the data available from the inventory. The only serious attempt was done for the state of Kedah revealing there are about 179 tonnes and 185,000 tonnes of air-dried bamboo for *Gigantochloa* spp. (Betong type) and for the other bamboo species (non-Betong), respectively. There has also been no attempt to inventorize the stocking of other non-wood resources in Peninsular Malaysia probably due to budget constraints and inadequate inventory techniques. Thus, in addition to rattan industrial survey, bamboo and *Pandanus* are the only two non-wood resources inventoried so far (Abd. Latif *et al.* 1990a; Abd. Latif *et al.* 1990b).

Silviculture and Management

The cultivation of rattan is imperative to sustain the depleting resource. The growth rate of several rattan species was monitored and four important exotic species were planted and studied. The feasibility of planting 'manau' under rubber and forest plantations has been established (Aminuddin & Nur Supardi 1986; Aminuddin *et al.* 1990).

Since propagation of bamboo using seeds is not practical due to its rare phenomenon of flowering and fruiting, vegetative propagation from culm cutting of selected *Gigantochloa*, *Schizostachyum*, *Bambusa* species and *Thrysostachys siamensis* has been initiated. The growth and yield of these species using rhizome offset on degraded soil, and response of bamboo regeneration to harvesting intensities and fertilizer application have also been investigated (Aminuddin & Abd. Latif 1994).

Properties

The usage of non-wood forest resources has long been exploited traditionally. However, further research on the utilization of waste derived from processing and manufacturing processes either for furniture, parquetries and panels (Abd. Latif & Hilmi 1991) is required involving studies on their physical, mechanical and anatomical characteristics. Studies have and are still being conducted to determine optimal harvesting age of bamboo and rattan, in relation to anatomical, chemical, physical, mechanical, and processing properties. These data are important as they help the harvester in selecting suitable material for its intended end-use (Abd. Latif *et al.* 1990c, Abd. Latif & Liese 1995, Abd. Latif & Liese 1998a, 1998b).

Analysis of chemical composition of bamboo, particularly starch and total sugar content, and in relation to fungal and insect attack, was reported by Abd. Latif *et al.* (1990d). The effect of bleaching on mechanical properties and colour quality of bamboo and bamboo products were investigated (Abd. Latif *et al.* 1989). Further studies on the properties of bamboo, particularly on its absorption and retention characteristics (Abd. Latif *et al.* 1990e) and high pressure sap displacement preservative treatment (Choo 1989) were also envisaged to encourage/promote its life-service. Studies on the usage of bamboo for pepper-vine support (Choo 1989), engineering application for soil embankment in highway construction (Low 1990) and soil stabilizer (Abd. Razak 1989) would certainly improve their commercial application.

While some bamboos are commercially utilised, there is still an abundance of other species yet unexploited. The use of less popular species of bamboo for furniture, chopsticks and machine intensive products charcoal and vegetable basket and lesser known rattan species for semi-processed products such as cores, ropes and binds will surely be beneficial to local industrialists. Published Guidelines on selection, preparation and factors related to rattan products quality (Abd. Latif 1991) will definitely be appreciated by entrepreneurs in this field.

Innovation

The development of innovative technology in the non-wood forest based industry in Malaysia has been very encouraging. Research is now being directed towards upgrading the quality and productivity by means of low-cost mechanization and_automation. At present, 47 machines on diversified usage of rattan, bamboo and *Pandanus* have been fabricated, of which 12 of them were registered for patents. A series of jig and mould for mechanical testing of rattan and bamboo were also made (Abd. Latif *et al*. 1996).

Dissemination of Information

With financial support of the Canadian-based International Development Research Centre (IDRC), the Rattan Information Centre (RIC) was established in FRIM in March 1982 with the aim of setting up a comprehensive depository of rattan literature, document and retrieval system, publishing quarterly news bulletin and disseminating information to interested parties (Kong 1989). FRIM will respond to any request for information pertaining to all aspects of rattan biology, silviculture and utilization. The production of the Bamboo Bulletin since 1992 has also contributed to the dissemination of bamboo resources within the country.

Training and Extension

The Small-scale Entrepreneurs Development Unit (SSEDU) for non-wood forest based industries was officially established in June 1985 with the financial support from the World Bank and Malaysian Government. Its main objective is to encourage the involvement of Malaysians in industrialization. The unit also functions as a technical agency by providing industrial guidelines, technical and advisory services and to assist newly established entrepreneurs and to the public.

Since 1985, the unit has conducted training programmes involving 1500 rattan and bamboo entrepreneurs and more than 75 series of entrepreneurship lectures. As a result of intensive training and services to the industry, the unit was able to initiate the establishment of a commendable number of factories. They include 13 bamboo mills, 24 rattan and 3 palm-based industries (Abd. Latif *et al*. 1996).

Besides the SSEDU, the Bamboo and Rattan Agroforestry Unit of FRIM has also conducted several courses on the planting of rattan. Seven series of technology transfer seminars on rubberwood, rattan and bamboo to the rubber small-holders have also been initiated in various states since 1992.

Future research considerations for upgrading the non-wood forest based industries

A summary list of some of the future research priorities in upgrading the related industries:

A. Inventory of Resources

- techniques and methodologies
- species, availability, distribution
- supply and demand
- phenology and taxonomy
- potential areas to be developed

B. Plantation/ Cultivation/ Harvesting

- management and silviculture techniques for natural stand
- selection of potential and suitable species
- planting techniques
- control of harvesting - regeneration and growth performance of cultivated rattan and bamboo on degraded land and tin-tailing areas
- improvement of harvesting methods

C. Properties

a. Anatomical - schedule/key/method of identification
  - fiber dimensions, rations and particle geometries

b. Chemical - extractives, polysaccharide and medical aspect

c. Mechanical - strength, gluing, acoustical and combustibility

d. Physical - moisture, specific gravity, dimensional stability and movement

D. Preservation

- natural durability
- seasonal influences on carbohydrate and chemical contents; susceptibility to borers and fungal attack
- table of fungi, pest and diseases

- cost effective method – traditional and chemical
- resistance to indoor, outdoor and marine use
- determination of permeability or fluid flow law for monocotyledon.

E. Drying/Seasoning

- cost effective method – traditional and advance such as high frequency0, kiln- and forced air- drying
- schedule of drying
- effectiveness of drying methods against defects

F. Processing and manufacturing

- criteria of selection
- machining, workability and rate of recovery
  for both commercial and less popular species
- *operational manual on machineries and methods of processing*
- cutter tool technology - suitability of metal and alloy for efficient processing
- diversification of product design
- bill of costing
- jointing and binding technology
- mould, jig fabrication, low cost mechanization and automation

G. Boiling of rattan

- standardization of method and medium
- rationale of different preliminary processing practices
- effects of boiling and boiling medium on technological properties, durability, quality

H. Finishing
- cost effective methods and materials
- effect on strength and quality
- adhesive and absorption properties
- resistance to environmental stresses
- type and combination of finishing materials and components

I. Grading

a. Processed and semi-processed products (especially rattan)
- table of grading guidelines
- uniform grading rules based on agreeable parameters such as species, length, appearances, allowable defects and strength

b. Finished products
- furniture testing
- wear resistance
- hardness
- jointing

J. Products development

- waste utilization
- polymerization of less popular species
- modification and advancement of materials forthermoplastic composite, hybridization and filler
- panel, wall, flooring, ply, flattened and laminated
- engineering application such as reinforcement, piling, structural and acoustical purposes.

K. Inventory

- impact of the industry on the socio-economics
- inventory on the industries - profile, status,
  distribution
- rate of consumption and production
- market outlets/strategies in relation to products quality, design and acceptance
- employment generation potential

L. Dissemination of information to industries/public

- via non-wood forest products information centre
- homepage and entreprenews

Institutional Responsibility for Non-Wood Resources

Non-wood forest products have been in the limelight for quite sometime. There are various international agencies that are involved, or have taken the lead, in promoting these resources. These include agencies like IDRC, INBAR, ICRAF, IPGRI, UNESCO, UNIDO and WHO. They collaborate with the relevant national programmes in conducting selection and propagation for either agroforestry work or other kinds of plantings. Their responsibility depends on the specialists involved in promoting the resources. It may range from ethnobotanist right through to processing technologist. The action to be taken by the respective experts may include collection of herbarium specimens, communication, liason with other relevant experts and of course analysis.

Approach to Development of Non-Wood Resources

The development of non-wood resources must be a multi-disciplinary approach carried out by appropriate experts in the national programmes and the funding agencies. This kind of collaboration is essential as it creates awareness on any shortcomings that might happen within any research activity.

Another approach is to look at the three necessities, namely food and beverage, forage and medicine. Product development must therefore be geared towards these necessities as it would be expected to benefit a wider range of people. Products that promise to increase rural incomes and employment as well as provide for these three basic needs should receive highest priority.

The stages of development of a product must be coordinated at every level. New product development can then be identified from within a larger project. Collaboration with other departments or agencies can give/provide a better guide in the process. This can only be done if the present status regarding the product is known pooling information not only from within the diversity of the plants or animals involved, but also that related to the sustainable management of the resources. There is also a need to educate the people to be more appreciative of the value of their own natural resources by strengthening some of the training and research facilities.

E-mail: jachambe@vt.edu

Abstract

Over the last decade, there has been a growing interest in the economic and ecological potential of non-timber forest products. In the United States, much of this increased interest stems from drastic changes in forest practices and policies in the Pacific Northwest region, a region that produces many non-timber forest products. The forests of the eastern United States, however, also produce many non-timber forest products. This analysis focuses on the status of non-timber forest products in management plans of the national forests in eastern United States. Of the thirty-one national forest plans examined for coverage of non-timber forest products, only seven plans addressed the management of these resources. A review of national legislation that affects national forests reveals that non-timber forest products are not recognized as a management objective. But, they are considered as "special products" in key policy documents. There is legislation under consideration that could significantly change how these products are managed. This paper identifies and discusses key issues that could affect decisions to manage for non-timber forest products.

Keywords : Non-timber forest products, Eastern United States, U.S. forest service, Forest management.

Background

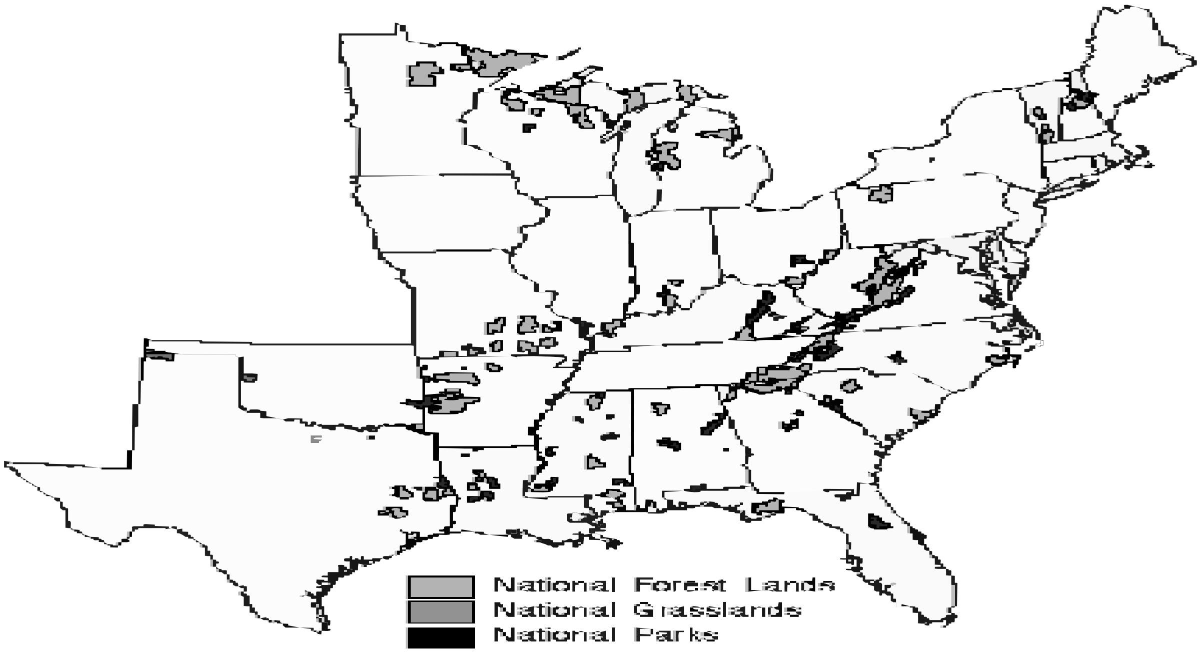
The early inhabitants to the eastern United States brought with them the tools and resources (food, seed, and medicine) needed to sustain their lives. When these stores were depleted, the settlers turned to the forests as the source for many of these essential items. The forests of eastern U.S. are still an important source for many non-timber forest products (NTFPs). Many of the species from which NTFPs are harvested, grow only in the region.

Concern for the management for non-timber forest products has increased, in-part due to the changes in forest policies and practices on the national forests in the early 1990s. With a decrease in logging on national forests, and an increase in demand for many non-timber forest products, there are tremendous possibilities to realize the economic development potential of these resources. At the same time, demand on the forest resources could exceed the capacity to supply non-timber forest products, which could have unfavorable economic and ecological impacts.

The Forests of Eastern United States

The eastern United States has not been the focus of much of the dialogue concerning non-timber forest products, even though the region includes more than 50 percent of the U.S. population and more than half the states. Eastern U.S. hardwood forests are one of the most extensive forests of this type in the world (USDA Forest Service 1984). The biological diversity of some forests of eastern U.S. may surpass that found in tropical and temperate rainforests. The broadleaf forests of the Appalachian and Blue Ridge Mountains ecoregion form one of the most biologically rich temperate forest regions in the world (Ricketts et al. 1999). According to Constantz (1994) "no other region in North America hosts so much living diversity than Appalachia." Figure 1 illustrates the region defined as eastern United States. It includes 33 states, from Minnesota south through Texas and east to the Atlantic Ocean.The eastern states are the source of many forest resources. Most of the eastern States have a high percentage of forest cover and a low percentage of rangelands (USDA Forest Service 1980). All but four of the states have more than 25 % of the total land area in forest.

Figure 1. Eastern United States with National Forests and National Grasslands identified (Adapted from USDA Forest Service 1997)



More than 60 % of the states in the East have more than 50 % forest cover. While the region has low a percentage of land in range, the eastern U.S. forests produced 100 % of the wild-harvested ginseng in 1998, and eight states in the region supplied approximately 85 % (25,739 kg.) of total harvest (Robbins 1999).

Non-Timber Forest Products

Many important products are harvested from eastern forests that are not timber-based, but are plant or fungal based. Various terms have been used to describe these products, including non-traditional, secondary, minor, non-wood, and special or specialty. In many cases, NTFPs are neither minor nor secondary. The collection and sale of NTFPs may be a major source of income for some rural inhabitants. Often, NTFPs are not specialty products, but move through distribution channels as commodities. Many non-timber products have as long of a tradition in human society as do timber products. Hunters and gatherers were collecting edible products from the forest long before they had the technology to cut timber. Some wood-based NTFPs have an important niche in the craft and specialty furniture industry.

Non-timber forest products are plants, parts of plants, fungi, and other biological material that are harvested from within and on the edges of natural, manipulated or disturbed forests. Plants may include fungi, moss, lichen, herbs, vines, shrubs, or trees. Many different plant parts are harvested, including the roots, tubers, leaves, bark, twigs and branches, the fruit, sap and resin, as well as the wood. NTFPs can be classified into four major product categories: culinary, wood-based; floral and decorative, and medicinal and dietary supplements (Chamberlain et al. 1998).

Culinary non-timber forest products include mushrooms, fruits, saps and resins, ferns, tubers and herbs. In many parts of the region, local economies are improved and enhanced by the marketing of edible forest products. Wood-based forest products are considered non-timber if they are produced from trees or parts of trees, but not from commercially sawnwood. For example, burls, twigs, branches, and cypress knees are processed directly into handicrafts, carvings, turnings, utensils, containers, furniture, tools and musical instruments. Floral and decorative products are used in flower arrangements, for wreathes, swags, garlands, roping, as well as in the landscape industry. Plant-derived medicinal products that have been tested for safety and efficacy, and meet strict U.S. Food and Drug Administration standards may be marketed as medicines, otherwise they are legally considered food items and are marketed as dietary supplements.

Eastern United States is the source of many non-timber forest products, some of which are found only in the region. Figure 2 illustrates the geographic distribution of *Cimicifuga racemosa* (Black Cohosh) and *Hydrastis canadensis L.* (Goldenseal), two important medicinal plants (Small and Catling 1999). Though *Acer saccharinum L.* (Sugar Maple) is widely distributed throughout the eastern U.S. (Harlow et al. 1991), the major source of syrup is New England. *Taxodium distichum* (Baldcypress), the knees of which are harvested for woodcarving is distributed throughout the coastal plains of southeastern United States (Harlow et al. 1991). Some states (e.g., Florida) are the primary worldwide sources of important products, such as *Serona repens* (saw palmetto).

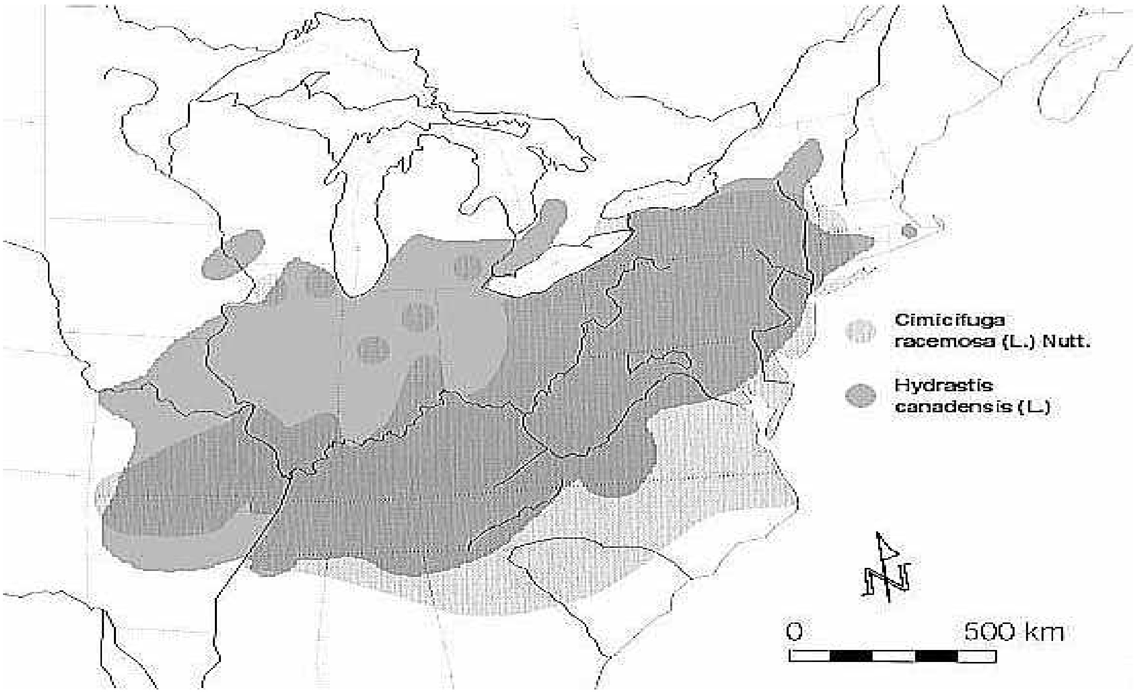
Many species are valued for their therapeutic qualities. Foster (1995) identifies more than 25 tree species, 65 herbaceous plants, and 29 shrubs that have been listed by the U.S. Pharmacopoeia for their medicinal values. More than 500 plant species with medicinal value have been identified in eastern and central North America (Foster and Duke 1990). TRAFFIC North America, a division of the World Wildlife Fund (1999), identified approximately 175 medicinal plants native to North America that are marketed in the United States, many of which are found in forests of eastern United States. Krochmal et. al. (1969) identify more than 125 medicinal plant species that grow in the Appalachian region of the eastern U.S. As the demand for medicinal NTFPs and other products expands, there is potential to realize greater economic benefits, but also potential for increased pressure on the resource base

In the early 1990s, a series of major factors helped spark an increase in interest in non-timber forest products. As a result of major forest fires, bumper crops of edible mushrooms appeared on many National Forests in Oregon and Washington (Freed 1994). Perceiving the potential for economic development and increased revenues, the federal and state forestry departments as well as private companies commissioned market studies on the opportunities for non-timber forest products (Mater Engineering 1992, 1993, 1994).

The findings of medical research also helped to increase market demand for non-timber medicinal forest products (Eisenberg 1993, Le Bars, et al. 1997, Stix 1998). The 1996 estimated value of the global markets for herbal medicines was approximately $14 billion (Genetic Engineering News 1997). Europe was the largest market representing one-half of the global trade. Asia commanded approximately 36 % of the global market. In 1998, the total retail market for medicinal herbs in the United States was estimated at $3.97 billion, more than double the estimate for North America in 1996 (Brevoort 1998, Genetic Engineering News 1997).

The mass-market segment for herbal medicinal products, which constitutes approximately 17% of the U.S. market, is growing at an annual rate of over 100% (Brevoort 1998). The growth in exports of forest-harvested ginseng from 1993 (69,000 kg) through 1996 (191,500 kg) is illustrative of the trend in demand for many medicinal NTFPs (USDA 1999). Though exports of forest-harvested ginseng decreased in 1997 (144,000 kg) and 1998 (109,000 kg), demand for other species continues to expand (USDA 1999). For example, the estimated growth in the mass market for St. John's wort and black cohosh, for the 52 week period ending July 12, 1998, were approximately 2,800 % and 500 %, respectively (Brevoort 1998).

Figure 2. Geographic distribution of two popular medicinal non-timber forest products (adapted from Small and Catling 1999)



Management Agency for National Forests

As steward of the national forests, the U.S. Forest Service has a responsibility to manage for all natural resources found on national forest lands, to meet the public's needs without degrading the environment (USDA Forest Service 1999). Under the National Forest System (NFS), the U.S. Forest Service manages 155 national forests and 20 national grasslands and is the steward of more than 192 million acres of public lands (USDA Forest Service 1999). The NFS is partitioned into 9 divisions, including Wildlife, Fish and Rare Plants, Forest Management, Recreation, Heritage and Wilderness Resources, Range Management, Minerals and Geology Management, and Watershed and Air Management (USDA Forest Service 1997).

The U.S. Forest Service divides the eastern United States into two regions. U.S. Forest Service Region 8 – The Southern Region – includes 13 states (Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Mississippi, North Carolina, Oklahoma, South Carolina, Tennessee, Texas, and Virginia). The U.S.F.S. Eastern Region (Region 9) includes 20 north-central and northeastern states. In Region 8, the NFS contains 35 National Forests and 2 Grasslands. These are organized into 17 forest land management planning units (USDA Forest Service 1984). The National Forest System in Region 9 includes 16 National Forests that are organized into 15 management planning units (USDA Forest Service 1983).

No fewer than 82 laws affect Forest Service activities on national forests (Floyd 1999). Four laws provide the main direction on which, and how, the natural resources will be managed. The practice of forest management of the national forests was initiated by the Organic Administration Act of 1897 (U.S. Code 30 Stat. 35). The act directs that forests be established to improve and protect the resources to secure water and to furnish a continuous supply of timber (Organic Administration Act of 1897, U.S. Code 30 Stat. 35). More than thirty years later, the Multiple-Use Sustained Yield Act (MUSYA 1960) authorized and directed the Secretary of Agriculture to manage the national forests to ensure the multiple-use and sustained yield of the renewable surface resources of the forests. MUSYA defines the purposes for which the national forests are established and administered: "outdoor recreation, range, timber, watershed, and wildlife and fish" (MUSYA 1960).

The Forest and Rangeland Renewable Resources Planning Act (RPA) of 1974 institutionalized land and resource management planning in the Forest Service (RPA 1974). The legislation requires the Secretary to prescribe land and resource management planning regulations that incorporate standards and guidelines which are fully integrated into each national forest management plan. In particular, the legislation directs that plans to address recreation and wilderness, range, timber, watershed, and fish and wildlife.

The National Forest Management Act (NFMA) of 1976 amended the RPA to provide additional statutory direction on preparation and revision of Land and Resources Management Plans (LRMPs). The NFMA restated that such plans include "coordination of outdoor recreation, range, timber, watershed, fish and wildlife, and wilderness" (NFMA 1976, section 6 (c)(1)). Plans "determine forest management systems, harvesting levels and procedures in light of all of the uses set forth in subsection (c)(1)" (NFMA 1976, section 6(c)(2)). The LRMP provide management direction through a combination of activities for the use and protection of the natural resources within the bounds of the national legislation. To accomplish this, forest plans: 1) establish goals and objectives for a 10-15 year period; 2) Prescribe standards and guidelines, prescriptions, resources needed, and; 3) monitor and evaluate management impact (White Mountain NF LRMP 1985).

The stimuli for this research are the growing interest in non-timber forest products, and the fact that the forests of eastern U.S. are a major source of many valuable NTFPs. With the full support of the USDA Forest Service, this research is designed to improve our understanding of the status of NTFPs in the management of national forests. The objectives are to determine the extent that NTFPs are addressed in the forest management plans and, to examine policies and legislation that affect management of national forests, for opportunities and constraints to include NTFPs in forest management.

Research Methods

This research adapted a methodology developed to analyze the contents of newspapers, presidential speeches, and other printed material (Holsti 1969, Carney 1972, Krippendorff 1980). The content analysis focused on the forest management plans for the national forests in eastern United States, and measured the area in square centimeters (cm^2) devoted to the management objectives or problem issues identified in the LRMP. Measurements were limited to the discussion (text) devoted to each objective or issue. Measurements were not made of tables and figures, because of the potential to bias the analysis by giving more attention to an objective that required more figures or tabular data. For example, the analysis of timber management requires a large number of volume tables and figures. Also, the units of measurement of tabular data vary tremendously between management objective, making comparisons problematic.

The area of text was measured for three general categories: 1) Natural resources mandated by national legislation; 2) Management objectives identified in the Forest Service Manual (USFS FSM 1998) or as a major public issue, and; 3) Non-timber forest products. Legislation mandates that national forests be managed for certain natural resources: timber, range, minerals, recreation and wilderness, water, and fish and wildlife. In addition, national forest plans address other management objectives as identified in the Forest Service Manual (USFS FSM 1998). These include transportation (e.g., roads), special uses (e.g., power lines, military installations), protection (e.g., fire management, pest control), and facilities (e.g., buildings). Major public issues might include ecosystem management, biodiversity conservation, and old-growth forest. As a management objective, non-timber forest products include discussions about one of the four major product categories.

The research first examined the forest management plans for 31 national forests in eastern United States. Plans that addressed NTFPs to some extent were selected for more in-depth analysis. Forest plan revisions also were examined for coverage of NTFPs. The investigation examined current and proposed legislation and policy analyses that impact national forests management.

Findings

Non-Timber Forest Products in Forest Management Plans

Non-timber forest products are not recognized in national legislation as a natural resource to be included in multiple-use management. In the 1980s when the first forest plans were developed the management of non-timber forest products was not a public issue. Though the markets for many of these products were established, demand on the resources was not sufficient to raise public concern. Even though management for these products was not identified as an issue, seven out of thirty-one national forest plans addressed them to some extent. This section summarizes the extent of coverage afforded to NTFPs in the seven forest plans.

Approximately 23 % of the national forest plans in eastern United States address non-timber forest products to some extent. Seven of the thirty-one national forests in Regions 8 and 9 addressed the management of forest resources for non-timber forest products. Of these, six were located in the eastern region (R9). The only national forest plan in Region 8 (Southern) to address NTFPs at some level was The National Forests of Florida (Florida LRMP 1985).

Table 1 describes the extent of coverage for each of the management objectives addressed in the seven national forest plans that included non-timber forest products. Percent coverage was based on the area devoted to a management objective relative to the total coverage. Overall, the amount of attention afforded to non-timber forest products is insignificant compared with other natural resources. No national forest plan provided NTFPs more than one percent coverage. The amount of coverage provided to legislatively recognized management objectives exceeded 68 %, with the exception for the Hoosier National Forest Plan. Problem issues commanded more than 26 % of each plan. All plans, except for the Hoosier LRMP, addressed management of rangeland resources even though range is a relatively minor resource.

The seven national forest management plans that addressed NTFPs varied in extent of coverage. In general the coverage focused on the recreational opportunities and the research needed to better address these products. Berry production and collection were identified in all but one management plan as a management opportunity. While all seven national forest management plans provide general forest-wide guidance for NTFPs, only three have prescriptions for maintaining or enhancing NTFP production.

Chequamegon National Forest Plan: This plan for this forest, which is located in Wisconsin, devoted approximately 0.4 % of its coverage to non-timber forest products. The primary focus of the coverage was on research needed to better manage NTFPs. The specific coverage dealt with how to restore wild rice beds to their former abundance (Chequamegon NF LRMP 1986). These resources were recognized for their wildlife habitat and for recreational opportunities, but not as a revenue generating natural resource.

Additional coverage was provided to non-timber forest products in the management prescriptions for five management areas. The desired future condition in four management areas was to provide increased access to the collection of NTFPs (Chequamegon NF LRMP 1986, p. 4.108, p. 4.128). One purpose of management area 8.1 was to “create and/or maintain a berry crop” (Chequamegon NF LRMP 1986, p. 4.162). The desired future condition of this management area was to provide for more berry-pickers. The plan recognizes berry picking as an opportunity along with bird watching, hunting, fishing, and trapping.

Table 1. Percent coverage for each management objectives addressed in national forest plans.

Management Objectives	Chequamegon NF (Wisconsin)	Finger Lakes NF (New York)	Florida NF (Florida)	Green Mountain NF (Vermont)	Hoosier NF (Indiana)	Nicolet NF (Wisconsin)	White Mountain NF (New Hampshire)
Legislated							
Timber	25.60%	19.19%	19.32%	17.43%	6.29%	23.46%	15.72%

Total Not Required	29.94%	26.62%	28.03%	30.92%	58.95%	27.35%	28.58%
Total Coverage	100.00%	100.00%	100.00%	100.00%	100.00%	100.00%	100.00%

The Finger Lakes National Forest: This small (13,200 acre) national forest is located in New York state (Finger Lakes NF LRMP 1986). The primary focus of the coverage devoted to NTFPs (0.64 %) was to provide for the recreational collection of blueberries. The plan provided a vision for the management of these resources, as well as prescriptions on how that vision would be achieved. Supply and demand analysis for blueberries provided the general context by which the prescriptions were developed. The major research question defined for this resource was how to keep a desirable mix of blueberry varieties productive with prescribed burns. The plan directed that 5 acres of blueberry patches be provided annually for recreation purposed (Finger Lakes NF LRMP 1986, p. 4.09) and acknowledges the benefits of managing the blueberry resource for forest wildlife. Management prescriptions focused on maintaining and promoting fruit production, including apples. The plan provides forest-wide standards and guidelines for management of this natural resource in accordance with national legislation.

National Forests of Florida: The management plan for the national forests in Florida includes four national forests (Apalachicola, Choctawhatchee, Osceola and Ocala) and covers approximately 1.1 million acres (Florida NF LRMP 1985). The management of NTFPs is afforded approximately 0.08 % of the plan's discussion. The major focus of the coverage was the research needed to develop a way to deal with the expected increased demand for NTFPs, particularly Christmas trees, firewood, and berries (Florida NF LRMP 1985, p. 2-19).

The Green Mountain National Forest: Located in Vermont, the Green Mountain National Forest covered about 325,000 acres in 1986 when the plan was adopted. An explicit goal for the national forest was to "maintain existing areas that provide blueberries for picking and valuable habitat for wildlife" (Green Mountain NF LRMP 1991, p. 4.07). The plan established forest-wide standards and guidelines for the management of fruit and berry production and prescribes eliminating vegetative competition, pruning and fertilizing to maintain productivity. To maintain and increase blueberry production, the plan prescribes burning 1/3 of each patch every 3 years. The plan calls for maintaining 2/3 of each patch in vigorous growth (Green Mountain NF LRMP 1991).

The Hoosier National Forest: This forest is located in Indiana and covers approximately 196,000 acres. During the development of the forest plan environmental pressure on how the Hoosier National Forest was to be managed grew substantially. The well-organized and motivated environmental community was instrumental in directing how the forest resources were to be managed. The low amount of coverage afforded to timber management (6.3 %) is a result of these efforts. At the same time, substantially more coverage is afforded to problem issues in the Hoosier plan (58.95 %) than any other plan.

The original plan (Record of Decision – 1985) for the Hoosier National Forest was significantly amended in 1991 (Hoosier NF LRMP 1991). The amount of coverage afforded to non-timber forest products, in the amended plan, was approximately 0.54 %. The plan recognizes management of mushrooms and berries as an issue of public concern. The discussion professes an abundance of edible forest products on the forest and suggests that some areas have been managed for NTFPs, particularly blackberries. Yet, NTFPs are not addressed in the management areas nor accompanying prescriptions.

The Nicolet National Forest: The forest plan for this 655,000 acre national forest in Wisconsin was accepted in 1986 (Nicolet NF LRMP 1986). The plan provides approximately 0.54 % of the management discussion to non-timber forest products. The major focus of the coverage is forest-wide standards and guidelines that deal with sensitive species. Throughout the forest, "harvesting of ginseng without a permit (Form 2400-14) is a violation of 36 CFR 261.6(h)" (Nicolet NF LRMP 1986, p. 62). District Rangers are directed not to grant permits for harvesting ginseng. Embedded within a table, and therefore not measured as part of the coverage, is a proposed activity to manage 50 acres of blueberry annually.

The White Mountain National Forest: The plan for this 750,000-acre national forest, in New Hampshire, was accepted in 1986 (White Mountain NF LRMP 1985) Non-timber forest products are addressed in the discussion (0.16 %) of forest-wide standards and guidelines. The general direction provided for "other forest products" in the plan is to consider applications for collection on a case-by-case basis. The plan recognizes maple sap, Christmas trees, and evergreen boughs.

Forest Plan Revisions

The National Forest Management Act requires that all forest plans be revised "when the agency finds that conditions on a forest have significantly changed, or at least every 15 years" (NFMA, section 6(f)(5)). Following this legislation, all national forest plans in eastern U.S. should be revised by 2002. Only 13 national forests in regions 8 and 9 have submitted a "Notice of Intent" to revise the forest plan prior to August of 1997 (USDA Forest Service 1999a).

Of the seven national forest plans that addressed NTFPs, four are in the process of, or have completed the plan revision. The plan for the national forests in Florida, the only completed revision, has forest-wide standards and guidelines for special forest products. It designates the District Rangers as the responsible party for establishing appropriate restrictions on the collection of seventeen recognized special forest products (Revised Florida NF LRMP 1999). The Chequamegon and Nicolet National Forests, which are combining efforts to produce one plan for two forests, have the most comprehensive "Analysis of the Management Situation" for special forest products (USDA Forest Service 1998). It summarizes current outputs and activities, assesses demand for special forest products, and recognizes the need to "manage these resources" (USDA Forest Service 1998, p. 10).

1995 Resource Planning Assessment

The 1995 RPA program identifies ecosystem management as the strategy by which the Forest Service can reach the goal of sustainable forest management by 2000. This new strategy will require the Forest Service to "move beyond traditional approaches to include a broad range of values" (USDA Forest Service 1995, p. ES-1). Four fundamental elements (ecosystem protection, restoration, multiple benefits, and organizational effectiveness) are identified as necessary for the success of the strategy (USDA Forest Service 1995).

All of the fundamental elements have direct implications on how forest resources are managed for non-timber forest products. A greater diversity of ecosystems creates potential for greater diversity of forest products. Conserving species before they are protected under the Endangered Species Act helps to assure productive populations of harvestable NTFPs. The use of native species in restoring ecosystems suggests that the gene pool for NTFPs could be conserved. Accelerating natural processes could help to restore NTFP species that have been extirpated from certain forests. For example, Forest Service research efforts to restore the pine/bluestem ecosystem in the Ouachita National Forest may prove beneficial to *Echinacea spp.* (purple coneflower), a plant harvested and marketed for medicinal purposes (Guldin 1999). A priority management activity of developing a system to charge fees for harvesting and using the natural resources that is based on fair market value could significantly change the permit system for collection of NTFPs. Further, an emphasis on restoring and sustaining strong and diversified rural economies could lead to greater assistance to NTFP harvesters.

In the 1995 RPA special forest products are a main concern under the priority management area "economic action programs" (USDA Forest Service 1995, p. III-31) and are identified as compatible with sustainable forest management. The Forest Service uses the term "special forest products" to describe products derived from biological resources, collected from forests, grasslands, and prairies for personal, commercial, and scientific uses. Special forest products exclude sawtimber, pulpwood, cull logs, small round wood, house logs, utility poles, minerals, animals, animal parts, insects, worms, rocks, water, and soils (National Strategy 1999). The RPA commits the Forest Service to "develop these products to strengthen rural communities" (USDA Forest Service 1995, p. III-31).

"One of the most important ways the Forest Service can contribute to special forest products is to collect information" (USDA, Forest Service 1995). This includes identifying and describing the ecosystems and habitats from which NTFPs are collected. Information is needed on defining what materials are collected, the methods of collection, and how much is collected. More economic and market information on NTFPs is needed. Finally, the

RPA recognizes the need for management strategies that include NTFPs to protect the health, diversity and productivity of forest ecosystems.

National Strategy for Special Forest Products

The Forest Service is developing a "National Strategy for Special Forest Products" (National Strategy 1999) that recognizes the need to manage for special forest products. The principles and priority areas set forth in the strategy are intended to provide "a solid conceptual foundation for an action plan" (National Strategy, p. 3). To guide and direct management of the renewable resources that produce special forest products, the strategy establishes five strategic goals: 1) availability within ecosystem limits; 2) integration into forest management; 3) consistent and effective policies and plans; 4) inventory and monitoring of resources; and, 5) collaboration with stakeholders.

National Legislation for Special Forest Products

In February of 1999, the U.S. Congressional Subcommittee on Forestry and Public Land Management convened a hearing to explore opportunities and constraints on increased harvesting of non-timber forest products on national forest land. In October of 1999, there was national legislation in front of the President that could drastically change how the US Forest Service manages national forests for non-timber forest products. The Bill (H.R. 2466) provides for establishment of a pilot program to charge fees for the harvest of "forest botanical products" from National Forest System lands (H.R. 2466, Sec. 339). Forest botanical products are defined as mushrooms, fungi, flowers, seeds, roots, bark, leaves, and other vegetation that grow on NFS lands, but does not include trees. The Bill requires the Secretary of Agriculture to determine sustainable harvest methods and levels and to establish methods to ensure that revenues from the issuance of permits for collecting these products reflect the fair market value.

Though the first round of forest plans did not, in general, address management of NTFPs, there is potential that these resources will receive greater attention in the future. The 1995 RPA provides explicit direction to the Forest Service concerning non-timber forest products. The national strategy on special forest products contributes to the institutionalization of management for NTFPs. The legislation that is under-consideration could provide further acceptance of these products in forest management.

Issues and Implications

Based on this review of forest management plans and polices, a number of key issues are identified that could significantly affect how the national forests are manage for non-timber products. Societal pressures on how, and for what purposes, national forests are managed continue to intensify. Economic issues are driven by demand for the products and include questions of macro and micro scale. Environmental concerns range from the impact that harvesting has on the species to the impact on the ecosystem from where the products were collected. There is a wealth of knowledge on how to mange for timber, wildlife, recreation, and water resources, but in general there is a lack of technical information and expertise for managing for non-timber forest products. How to incorporate NTFPs into the ecosystem management paradigm remains an issue. Institutional barriers must be removed to allow NTFPs to be well managed.

Social

For the most part, the collectors of NTFPs are under-represented stakeholders in the planning process. They are not organized nor represented by any group, but are individuals who may be apprehensive of getting involved in government activities. They may not want others to know how much is collected nor the collection location. But none-the-less, the collectors are stakeholders in how the national forests are managed, as management decisions can drastically affect these people's livelihoods. For some collectors the income gained from the sale of NTFPs could be a major portion of their annual income. Certainly, for many collectors, income generated from NTFPs is "extra money" and is an important component to the overall household budget. A ban on collection of NTFPs, or an increase in permit costs could have significant impact on the collectors' lives. Special efforts are needed to identify the collectors and to get their input. The sustainable management of NTFP resources will require understanding of how these people view and use the resource.

Economic

Unlike timber, the economic value of non-timber forest products, in general, is not well defined. Though the overall value of some sectors (e.g., herbal medicinal) is documented, little information is available on forest-harvested products (e.g., forest-harvested medicinal plants). Defining the value of non-timber forest products at the forest and district levels is necessary to determine sustainable management levels. Though demand figures for some products (e.g., ginseng) are available, in general very little is known about the demand for most products. As a whole, very little information is available on the supply of non-timber forest products. Forest inventory data for NTFPs is generally non-existent. Without accurate information on the supply and demand for non-timber forest products, it is difficult to determine sustainable economic harvest levels.

Environmental

The environmental issues, if not addressed, could result in a management strategy based on protection of the NTFP resources and not conservation or utilization. If the population of a NTFP species degrades to a level that initiates the statutes of the Endangered Species Act the Forest Service would be required to pursue a protection strategy. To manage for conservation and utilization the status of NTFP species can not drop to the level that requires management under ESA. The effect that harvesting has on local plant populations, as well as the impact on the associated ecosystem is an issue that truly affects how the Forest Service manages these resources.

Institutional

To address the issue of technical management of the NTFP resource will require creating new information through research, broadening horizons beyond traditional forestry, and expanding the expertise involved in management. The research needed to develop the knowledge on how to manage for NTFPs is boundless. In general, there is a lack of information within forestry on how to manage the NTFP resources. But, expanding the inquiry to include knowledge of herbal medicine and gardening could provide valuable information on reproducing some NTFPs. The technical management of NTFPs will require more information on the status, characteristics, and requirements of the habitats and species. To include NTFPs in forest management will require developing the expertise to understand the ecology (biological and social) and botany of the natural resource.

From an institutional standpoint, the economics of management must be defined to determine the investment needed to ensure sustainability of the resource. Over the last decade revenues from timber sales, as well as appropriations from the U.S. Congress have decreased. The decline in fiscal support has put tremendous pressure on the Forest Service to deal with the most important issues. The issue of "below-cost" management could impede Forest Service efforts to manage the NTFP resources. At this point, the costs of managing NTFPs may exceed the revenues generated from the sale of collection permits. To incorporate NTFPs into forest management will require either additional fiscal support or a shift of funds from other management objectives.

National legislation is being considered that would lead to increased revenues from the sale of collection permits and development of sustainable harvest levels. But, until NTFPs are recognized as a natural resource, "more important" issues will subsume the amount of effort devoted to managing them. Legislation that recognizes NTFPs as a management objective for national forests, along with those identified in current legislation, would institutionalize management of non-timber forest products.

Conclusions

In the 1980s, when the first round of national forest plans were developed, non-timber forest products, in general, were not recognized as a management objective nor as a issue of public concern. A few national forests identified NTFPs as a resource and incorporated them into management plans. Still, the coverage devoted to NTFPs was insignificant compared to other management objectives. Much of the coverage focused on recreational collection and research needed to conserve the resource base.

Over the last decade, interest in, and concern for, NTFPs has increased drastically. Today, NTFPs are receiving a great deal of attention in natural resource policy dialogue. The U.S. Forest Service is leading the way on defining how national forests will be managed for non-timber forest products. A great deal of research, analysis and support are still needed to have NTFPs fully integrated into national forest management plans and practices.

Non-timber forest products are economically and ecologically important. The collection and sale of NTFPs from the forests of eastern U.S. have local, regional, national and international economic impact. Collection of these products also, may have significant impact on the health of the forests of the region. To realize the maximum economic benefits and to have the minimum ecological impact, the natural resources that produce NTFPs need to be managed.

The Forest Service strategy of managing national forests as ecosystems can not be fully realized until NTFP resources are sufficiently integrated into management plans. The goal of sustainable forest management will remain elusive if NTFPs are not managed as a natural resource. Certainly, the paradigm of multiple-use management needs to be expanded to include these forest products. Perhaps, the ecosystem management paradigm needs modification as well.

Hiccups/Problems with Inequitable Distribution of Profits from Non-Wood Forest Products and Their Remedies

by
D. D. Tewari,
Professor, Division of Economics,
School of Economics and Management
University of Natal, Durban, South Africa
E-mail : Tewari@nu.ac.za

Abstract

The nonwood products, or nontimber forest products (NTFPs), have become important forestry outputs as their economic significance is being perceived by forestry experts and policymakers at large, all over the world. For example, some US$ 90 billions worth of NTFPs are extracted worldwide every year. And, more than 300 million people, specially tribal and underprivileged, are dependent primarily upon them for earning their livelihood. This has initiated, and enhanced where initiation had already taken, the process of commercialization of NTFPs. Commercialization has augmented the values of NTFPs on one hand but has also added to the rapid extraction of NTFPs on the other. The enhanced process of extraction of NTFP resources has thus generated large profits for large corporate companies but at the same time have heightened the concerns about subsistence and livelihood for a large poor tribal and low income earning population. The commercialization of NTFPs has thus engendered more inequity and has raised concerns about the sustainable use of the resource in the future.

In the wake of this unequal and unsustainable development, the policy questions that loom large are: How should we develop this resource and how can we benefit the most poor and unprivileged people of the world? Are there some remedies on hand or need to be invented? This paper would attempt to answer these questions and highlight the issues of commercialization of NTFPs and its impact upon the distribution of profit between poor tribal population and the large profit-seeking enterprizes. The paper would delve into various aspects of inequity generated as a result of commercialization and its implications for social welfare. One of the various remedies that can be proposed to attenuate the escalating inequity is to promote NTFP-based small-scale enterprizes in the rural areas. The paper hypothesizes that small-scale enterprises generate income and employment in the local village economy and thus reduce poverty, unlike large companies which export jobs from villages to cities and big business centers of the country or world. The small-scale enterprizes thus generate economic growth with equity, and are also sustainable in terms of scale of operation, and have spill-over effects in promoting entrepreneurship skills among tribal people. The paper would emphasize upon the development of NTFP-based small-scale enterprises, document their characteristics and constraints, and finally list the benefits and costs of developments of small-scale economic institutions. The study would identify various types of constraints and discuss ways to relax them in order to promote small enterprise development, and would explain how to promote entrepreneurship skills among tribal people in rural areas. The study would be based upon the cross-country review of various enterprises and data. Various countries that would be reviewed are India, Pakistan, Indonesia, South Africa, countries covering the Amazon region, Malaysia, and others. Finally, the paper would provide a framework to develop NTFP resource without jeopardizing the welfare of tribal and underprivileged people in rural areas of much of the Third World countries.

Keywords: Non-wood products, Non-timber forest products, Small-scale enterprise, Sustainability

Introduction

During the last 10-15 years, the world at large has discovered the economic significance of non-wood forest products (NWFPs) which were in the past belittled by identifying them as “minor forest produce”. Several studies around the globe now confirm the significance of NWFPs. For example, in India, the recorded revenue from sale of NWFPs was about Rs100 million (US$2.5 Million) per annum in 1958-59 and it has now increased to Rs 20000 million (US$500 million) in 1990s (Shiva, 1998, 35). Further, NWFPs constituted some 13% of total exports of India in 1990-91--one of the major categories of foreign exchange earning commodities (Shiva, 1998, 36). The Indian trade in NWFPs is now estimated to be around US$1000 million (Freese, 1998). In terms of employment, some 500 million people living in and around forest in India depend on NWFPs for their sustenance and supplemental income (Tewari, 1994). Likewise, in Pakistan, the Northwest Frontier province abounds in NWFPs, especially honey and mushroom; and, about US$ 1 million worth of NWFPs are annually harvested (Iqbal, 1991). Large quantities of NWFPs are harvested in Nepal and Bangladesh too. Some US$ 529000 worth of NWFPs are exported into India from Nepal every year (constructed from Edwards, 1993). In Bangladesh, some US$250 million worth of NWFPs are extracted annually from Sundarban region which employs some half a million people every year (FAO, 1999). It is believed that, in the Indian subcontinent alone, the total value of NWFP harvested every year is estimated to be more than US$ 2000 million (personal estimate).

In Southeast Asia, including Indonesia, Malaysia, and other neighbouring countries, the trade in rattan alone is estimated to be more than US$3 billion per annum (World Watch,1991). In Brazil, exports of palm heart and Brazil nuts generate some US$20 million per annum (World Watch, 1991). In the Western United States, several NWFPs are commercialized and play a significant role in the economy. For example, the value of maple syrup production in 1995 was estimated at US$ 25 million, and the value of mushroom production in Oregon, Washington and Idaho was approximately US$41 million (FAO, 1999). In the Eastern United States, the Applachian region abounds in NWFPs; the total recorded value of NWFP industry in Virginia has been estimated at US$ 35 million (FAO, 1999).

In overall, the NWFPs have become a big business around the globe. It is estimated that some US$ 90 billion worth of NWPS are extracted every year (Pimental et al, 1997). Further, some US$ 11 billion worth of NWFPs are internationally traded, and $55 billion worth are traded within the national economies of the world, and the rest one-third is consumed in the local village economies of the world (Tewari, 2000). In terms of employment, NWFPs support more than 300 million people in the world, most of whom belonging to underprivileged and tribal populations (FAO, 1998). These estimates are, however, believed to be rather conservative, the real size of world NWFP economy is believed to be larger than above. The multiplier impacts of the same are hence to be much larger and significant than otherwise thought. The World Health Organization estimates suggest that some 80% of the population of the developing world use NWFPs for health and nutritional needs (Vantomme, 1999).

The wheel of commercialization has augmented the value of NWFPs and made them more profitable to big companies. This has brought mixed sets of results. On one hand, there are large soaring profits that big businesses are enjoying. On the other hand, this is adversely affecting the original user population, i.e., the tribal or indigenous population which primarily depends upon NWFPs for their food, medicine, and income. In turn, it has heightened the concerns about their subsistence and livelihood. The trade–offs are very large. The commercialization of NWFPs has thus engendered more inequity and more poverty and more unsustainable use of NWFP resources.

In the wake of this unequal and unsustainable development, the policy questions that loom large are: Is “big business” approach to develop NWFPs the right one? How should we develop this resource otherwise? Are there some remedies on hand or need to be invented? In the past several studies on NWFPs have expressed concern over the “big business” syndrome among the NWFP sector (Tewari, 1994, Tewari and Campbell, 1995). However, a comprehensive understanding and analysis is lacking. This study aims at fulfilling this gap. The major objective of the study is to throw light on the inequities created by the “big business” syndrome and suggests remedies to thwart the impending dangers. More specifically the study aims at:

1. Understanding the process of “big business” syndrome in the NWFP sector;

2. Discussing the impacts of "big businesses" and concerns of original users of NWFPs;
3. Suggesting some remedial policy measures to thwart the "big business" syndrome;
4. Recommending some operational policy guidelines to promote equitable and sustainable use of NWFP resources.

The Big Business Syndrome

The process of commercialization and formation of big businesses in the NWFP sector are intricately related. The original consumers of NWFPs are the forest dwelling population -- tribal/indigenous in nature – who lived in a subsistence economy. Formal health care was more or less absent and people resorted mainly on to indigenous medicare which used NWFPs intensively. In addition, NWFPs also provided various other forms of food such as wild fruits/berries, etc. and thus, ensuring food security to the tribal population. The NWFPs thus met the personal or household needs of tribal population; resource in general was well protected as there were no opportunities for personal gains in this subsistence economy, finally ensuring the sustainable extraction of NWFPs. For almost many centuries, the cycle of subsistence economy remain undisturbed and exploitation of NWFPs went on a sustainable basis. But things began to change as trade in NWFPs increased around the world. Increasing trade led to the enhanced demand for the NWFP resources. This opened new markets for NWFPs and thus a new alternative to generate income by selling in local and faraway markets emerged. The process of marketization went on over the years and brought three significant changes in the business of NWFPs.

Firstly, the product which were once used by indigenous population are now being demanded in the faraway places in the regional, national and international economies. Most of this demand for NWFPs originates from the developed world including U.S.A., E.C., and Japan. Some 60 percent of annual imports of NWFPs originate from the above three regions (Iqbal, 1995). For example, Brazil produces some 42 thousand metric tons of raw brazil nuts per annum at an estimated value of US$ 34 million; of this total, approximately 80% is exported to USA, Canada, U.K., Australia and Germany (Lafleur, 1992, 1-22). It is believed that some 150 NWFPs are of major commercial significance in the international trade (Iqbal, 1995, 3). Many more would be of commercial significance in the national and regional economies. In other words, the center of consumption has moved from local village economy to faraway national or international economy. Thus, to meet the needs of distant urban consumers, changes in the product quality and information systems were necessitated. Changes in product quality demanded new techniques and strategies for product processing, transport, and storage. Similarly the new information systems which can cover large areas and multiple consumers, producers, and traders were also needed.

Secondly, as the demand for NWFPs increased, the pressures on the resource increased and sometimes reached the threshold of economic extinction. Therefore, to meet the extra demand, some of NWFPs are required to be cultivated or domesticated; thus, a shift in production from natural stands to the domesticated production is happening. A large number of NWFPs are now being domesticated.

Thirdly, during the last 15 years, the world has been swept by many macro changes such as rising wave of privatization or promotion of free enterprise economy, more freer trade and trade liberalization and so on. These changes have imparted more control of resources in the hands of individuals, firms, and other marketing entities, leading to a sophisticated marketing system in the global economy. The marketization of NWFPs has enabled the original user population to harvest the resource for personal monetary gains resulting a shift from local economy to a regional/national/international economy. The change-over to market economy has thus promoted the big businesses to take over the command of NWFP economy. The size of market economy is much larger than subsistence economy thus requires a larger volume of NWFPs to maintain a sustainable profitable business. This leads to the enhanced extraction of NWFPs, often pushing the system toward the threshold of un-sustainable extraction. Various studies done lately confirm this conviction (Tewari, 1999; Singh, 1999; Parameshwarappa, 1992).

Impacts of Big Business Syndrome

As the business in NWFPs grew over time, the small businesses were replaced by large ones because of their better access to national and international markets and better co-ordination of information. This brought a variety of changes which can be classified primarily into two categories; 1) people-related changes, and 2) resource-related changes.

The people-related changes refer to those that affect the people or tribal collectors primarily. People can be impacted in various ways such as by income and employment transfers created by big businesses, promoting migration from centers of production to centers of consumption of NWFPs, reducing food security to local villages, heightening the income differential between rural and urban people, and so on.

Various studies confirm that NWFPs generate income and employment for tribal or indigenous collectors as the business in NWFPs grows (Tewari, 1999; Pimental et al, 1997). This happens primarily by increased labor absorption in collection of NWFPs. The income and employment generation potential is increased tremendously when NWFPs are processed and value is added. Most times this is done in big cities, far away from areas of collection of NWFPs. It is believed that income and employment generation potential through value added activities is many times greater that from sheer collection of NWFPs. The value addition in places distant to rural areas (where raw NWFPs are collected), also exports jobs and incomes to cities. This displacement of income and employment has thus far-reaching effects on rural areas.

Lack of adequate employment opportunities in villages drive people out in cities, contributing to the congestion and more pressure on municipalities. Marketization of NWFPs has also reduced the food security to village people. Prior to takeover of NWFPs by big businesses, ample quantities of wild fruits and berries were available to meet the needs of hungry village people. However, with increased access to market, villagers now sell everything that is available in the forest and try to make as much money as possible. Since the NWFPs are common property resource and tribal collectors do not pay any price for it, the resource is extracted too soon from the forest, and very little is left to meet the needs of hungry people.

Commercialization of NWFPs has also brought a change in the collection strategy. For example, in subsistence economy, individual families harvested plants for domestic use only. But, with market economy, the incentive to collect maximum is high and now 2 to 4 households group together to collect maximum possible for monetary gain (Singh, 1999). Further, people now start harvesting early and end it late, thus stretching the collection period. This finally damages the resource, in particular, its regeneration capacity (Singh, 1999). Besides above, the monetization of NWFPs has widened the gap between rich and poor. The capital-rich large businesses can take advantage of this natural resource whereas the capital poor tribal people can only get a meager income.

The resource related changes entail the over-exploitation of resource and thus has raised concerns for the its sustainability per se. Some of the trends are not fully visible at this time but would be recognized a few years from now and by then most of the damage would have been already done. Many studies confirm this conviction; for example, increased demand for NWFPs has led to the increased pressure on extraction, and, as a result, many NWFPs are on the verge of economic extinction. For example, Salai (Boswellia serrata) gum trees in north Gujarat are diminishing rapidly. During 1970s the average extraction of Salai gum was about 4000 quintals and the total population of economically yielding trees of Salai gum was about 80000. In the late 1990s, the average annual extraction had declined to 1500 quintals and the number of Salai gum trees per hectare declined from 100 to 38 (Tewari, 1998). Kadaya (Sterculia urens) gum trees met a similar fate. During the 1970s, some 2000 to 3000 quintals per annum of Kadaya gum were extracted from north Gujarat. But by the 1990s, there was no collection of Kadaya gum at all and the population of economically yielding trees was basically nil.

Other examples include the extensive loss of Gulmavu (Machlus marcarantha) trees in Coorg and Malanad districts in karnataka, India, due to unscientific or over-exploitation (Parammeshwarappa, 1992). In central India, Mahua trees (Madhuca indica) are burnt repeatedly in order to harvest petals-- this kills the regenaration. As a result, young Mahua trees are getting scarce and believed to be extinct by 2200 (Wasteland News, 1992). Evidence also exist that most medicinal plants in different parts of the world are over-exploited (Joshi and Edington, 1990; Cunningham, 1991; Farooquee and Saxena, 1996).

Remedies : Small is Sustainable and Beautiful

The NWFPs collected by the rural poor are sold out to middlemen or government agencies which sell them in the national or international markets at high prices. Only a small proportion of final price goes to the original users of the NWFP resource. This happens for three possible reasons. Firstly, some NWFPs are bulky and they are transported in raw form to distant markets/collection points; since transportation costs are high, it finally reduces net price to the tribal collectors. Secondly, most collectors have very little knowledge of access to improved processing technologies, which gives high margins to middlemen (Poffenbergen et al, 1990). Thirdly, in many developing countries, the NWFPs markets and marketing channels are not well developed. As a result, the marketing margins are very large for those who indulge in this business. This finally translates into low price to NWFP collectors; but, at the same time, it promotes exportation of jobs and income to far away places.

To boost income and employment in local economy, we need to reverse the process by promoting value addition activities in the local village economy. This would give (a) higher net prices to collectors, (b) stop the migration of rural people to urban areas in search of jobs, (c) improve quality of life in village economy, (d) provide security in terms of food and income. Bringing value addition activities in local economies would also be consistent to sociocultural values of people; for example, recruitment of wood-carvers from far-away places for an urban-based small scale NWFP-based enterprise in Java (Indonesia) did not take the progress too far, mainly because of chronic absenteeism (Karr, 1991).

The best way to initiate value addition activities in local village economy is to promote the small-scale enterprises. Processing adds a considerable value to the raw NWFPs. For example, from experience in West Bengal, it has been noted that Sal leaves grow in value and become ten times more valuable when stitched into plates and pressed with polythene inserts. In the absence of value addition villagers sell raw products at 5 to 20% of market price (Poffenberger et al, 1990). Likewise, Cashman (1987) found that palm oil small-scale processing enterprises, among various income generating activities such as selling cola nuts, fruits, vegetables, meat and fish, maize, locust beans processing and soap making, were the most profitable activity in southwest Nigeria. Also, processed NWFPs fetch higher export prices as well; for example, the value of rattan re-exported from Hong Kong was found to be 17 times higher than the price of raw rattan exported from Indonesia (Business News, 21/10/81). The forest-based small-scale enterprises (FBSSEs) are thus considered to be better for value addition for their efficient handling of collection, processing, and marketing of NWFPs, as opposed to large-scale enterprises.

In the collection and processing of NWFPs, the large-scale enterprises do not have comparative advantage due to their higher private cost of collection and processing; and, at the same time they cause large environmental costs to the society as well (Campbell, 1991). This is because NWFP resources are scattered and hard to reach, thus mass extraction and transfer costs are high, and extraction of NWFPs is less likely to be sustainable. The FBSSEs are seen by local indigenous people, who gather or collect NWFPs, as part of their livelihood strategies. The major objective of FBSSEs is hence to provide a steady or supplemental income and help meet subsistence need of the indigenous people over the long run. On the contrary, large enterprises are interested in short -run profit maximization and may have less or no concerns for sustainable extraction of NWFPs. Large scale enterprises require a large amount of NWFPs in order to break-even, or their minimum scale of output is very large. In addition, the large scale enterprises have a greater propensity to move in and out of the market thus induces instability in the market and uncertainty to tribal collectors.

The higher mobility potential of large scale enterprises also mitigates against the sustainable extraction. As opposed to large business firms, the local people are less inclined to move to other occupations and can operate with small outputs of NWFPs, without destroying the regeneration capacity of the forests. For example, indigenous rattan collectors in Indonesia have been collecting and processing raw rattan out of dense local rain forests for hundreds of years to feed the growing non-wood industry (Campbell, 1991). Similarly, Sal-leaf plucking in West Bengal and in Madhya Pradesh, India, has been found to be a sustainable practice (Deb, 1990). It has been also found that women are more concerned about the sustainability of leaf production than men. For example, women are found to pluck leaves, not to break twigs, so as to preserve the leaf renewal capacity.

Small-scale enterprises are also more efficient in serving local markets, particularly when certain market infrastructures such as roads and other fast communication channels are absent. The small-scale enterprises do well as they have cheaper means of accessory market information and can quickly respond to demand signals received from the immediate processing or manufacturing units. For example, small scale splint and veneer producing enterprises in southern India provide a reliable supply of intermediate goods to thousands of small enterprises scattered within the region. The Sal leaf plates making household industry in West Bengal is mainly run by women and is found to be meeting demand very cost-effectively (Dutta and Adhikari, 1991). The wood carvers and rattan crafts people in central Java (Indonesia) are able to claim a large market share which large mechanized furniture factories could not do (Campbell 1991). This however should not be mistaken to mean that FBSSEs have always got a competitive advantage over large-scale enterprises. For example, the traditional umbrella making industry in Indonesia has become less viable compared with cheaper factory-produced plastic substitutes from Taiwan. Many NWFPs have been marginalized by chemical and synthetic substitutes, and this potential threat may exist for many NWFPs.

Case studies from India, Indonesia, and Latin America and African countries reveal that FBSSEs have some common characteristics. The most common characteristics are their small size and based in household; they are frequently seasonal in nature, providing seasonal employment and supplementary income to local people. All of FBSSEs are labor-intensive and based on simple technologies. In addition, they have low capital requirements. That is why they are accessible to low income and socially disadvantaged groups and are most often managed by women (Campbell, 1991; FAO, 1987).

The small-scale enterprises do not always perform well as they face various types of constraints. It is imperative to take cognizance of these so that a proper environment can be created for them. Various constraints can be classified into six categories: (1) diminishing supplies of NWFPs, (2) problems with access to institutional finance and lack of tax incentives, (3) highly market environments and poor infrastructural support systems, (4) income-sharing problems, (5) poor management capabilities, (6) poor availability of appropriate technology and skills. Knowledge of these constraints is one step towards improving the FBSSEs in the industry (FAO,1987).

As the demand for the NWFPs is rising with increasing trading opportunities, the impacts are being felt on the stocks of NWFP resources too. Some of the NWFPs are being over-exploited. Unlike, in the past, extraction of NWFPs is no longer a part-time activity of many tribal collectors; rather it has become a major source of income to some people and it is a part of a more formal, market oriented enterprise, competing with major forest products such as timber. For example, the Indian match industry is finding it increasingly difficult to meet raw material demand from these timbers also used to produce fuelwood. Similarly, rattan collectors in Indonesia find themselves helpless in fighting against large timber extracting companies which destroy the NWFPs resource base. The long-term survival of FBSSEs depends on well-balanced management plans which limit removals, focusing on growth and regeneration strategies which increase production rates instead.

Although investment in FBSSEs is small, the rural poor have very few assets to keep as collateral, a prerequisite for getting loans from any institutional source of finance. This is because banks are very risk-averse when it comes to financing FBSSEs. Banks should rather use the productivity or income generation potential as collateral and extend loans to the FBSSEs. Tax incentives are also important policy instruments for promoting the small businesses in NWFPs. Any easy access to finance and tax incentives could produce very promising results. For example, the small-scale sector of match industry in India has been very successful on account of government's tax incentive policies (Campbell, 1991).

Markets faced by small-scale enterprises are local, small and uncertain. FBSSEs hence need to be diversified, or swings in demand can destroy their existence because of their very low risk-bearing capacity. Despite instability in demand, they face competition from international markets and from the manufacturing sector in terms of innovating and producing substitutes. Adaptability to new market situations and diversification of activities is therefore essential for improving the risk-taking capacities of small enterprises. For example, due to its adaptability the carved wooden furniture industry in Indonesia has been able to recognize new demand and new designs and has survived. On the other hand, the traditional umbrella and craft industries in Indonesia have given way to plastic substitutes.

Income-sharing within FBSSEs depends upon who owns them. A concentrated ownership is not of much advantage. For example, the ownership of medium match factories in India is concentrated in the hands of 18 families who hire women and under-aged children at very low wage (Campbell, 1991). The lack of government support forces this to continue. The share of NWFP-gatherers in consumer's rupee is very small; a large proportion goes to intermediaries. The NWFP gatherer's share can be increased by checking the exploitation by intermediaries and increasing extraction efficiency through improved harvesting, storage, transport, processing of NWFPs (Wickens, 1991).

The poor management skills are a big constraint and this results into a failure of business; up to 80% of small enterprises go out of business; within five years due to poor management (FAO, 1987). The major reasons for failure is that most times FBSSEs are run by one person as owner-cum-manager who has to deal single handedly with all activities, ranging from creation of enterprise, identification and procurement of inputs, organization of production, finding markets and then marketing, planning future course of action, etc. Also, unlike large enterprises, FBSSEs do not have hard market data, and planning very much rests on intuition and causal understanding of market factors. A large number of FBSSEs (up to 10 workers) do not use machinery and depend upon simple tools (El-Namaki, 1987). As a result, their labor productivity is very low, which in the long term hampers the growth of FBSSEs.

Required Policy Initiatives

From the above discussion, it is obvious that promotion of FBSSEs would meet the objective of securing more equitable distribution of profits and also sustainable extraction of NWFPs. The major concern hence is to outline policy measures which would promote the development of small-scale enterprises. A five-pronged strategy is suggested. This would certainly require initiatives and efforts from governments of respective countries. The strategies include: (1) transfer of management and organization skills to the collectors of NWFPs; (2) promotion of value addition activities at the local and regional level; (3) improvement in marketing channels so as to pass benefits on to collectors of NWFPs; (4) exploring the regional and national markets; and, (5) strengthening the local institutions.

The first and foremost strategy for regenerating the FBSSEs is the development of skills among the rural people. Many collectors who pursue the small-sale enterprises do not have the skills required for running a business; these include skills of organization, marketing, and bookkeeping and so on. This is because many of these collectors are iliterate and not exposed to the outside world. The non-governmental organizations ot NGOs can fulfil this role .

The second most important task is to promote the value addition activities in local village or regional economy, thus saving the exportation of jobs and income to faraway areas. This also gives a higher net price to the local collectors. The value can be increased by sorting produce by quality grades or by performing simple value adding operations such as separation of dirt, pulverizing, powdering, and making tablets and so on. For example, the Gujarat State Forest Development Corporation (GSDFDC) in India enforced the standardization and grading of NWFPs and thus passed on large benefits to tribal collectors. It is interesting to note that price differential between lowest and highest grade of of NWFPs varied from Rs 55 per quintal in the case of Doli (seeds of Madhuca indica) to the highest of Rs 1383 per quintal for Musli (Cholorophytum tuberosum) (Tewari, 1999). Similarly the GSFDC undertook various simple processing operations on NWFPs of medicinal value and at times this resulted into as high as 4000% increase in the value of raw NWFP through simple technology (Tewari, 1999). Another good example is the efforts of Kalahan Educational Foundation (KEF) in Philippines. In 1980, the KEF members started a food processing center and began making jam and jellies from forest fruits, with an intention to capture 10% of the high-end market in Manila. By 1995, the center was providing cash incomes to some 150 local families (Rice, 1995). Several such success stories exist and teach us that local processing is a key to the sustainable management of NWFPs.

The third important change is to revamp the marketing system. Currently there exist many middlemen in the marketing chain from collectors to final consumer. This finally reduces the net price to the NWFP collectors as marketing margins constitute a big proportion of consumer's price. The higher marketing margins can be associated with high risk involved but they can be exploitative if middlemen use their bargaining power to their advantage. In these circumstances, the co-operative or community-based enterprises have worked better. For example, the trade in medicinal plants in Nepal is very large to the tune of US$10 million per annum but large benefits from this in the past had gone to the middlemen and least to the collectors. So much so that some of the species are believed to be locally extinct. An important herb , known as Jatamasi (Nardostachys grandiflora) was saved by a concerted action by local people with the assistance of a non-governmental organization. The locals took control of the market by processing it locally and thus cutting the large margins charged by middlemen (Taylor, 1999).

The fourth most important strategy is to explore the regional and national markets. International demand alone is likely to yield short-term benefits unless the product in question is well-established. Search for regional and national markets can be more rewarding, for it is cost-efficient and hassle-free. Regional markets can thus serve as key to the NWFP trade (FAO, 1995). For example, Amla (Emblica officinalis) a fruit tree which grows in the forests of Gujarat, India, is an important NWFP; tribal collectors sold its raw fruits at a very low price as they could not store it long. But, once they learn to dry the fruits, the prices climbed up. Thus, simple processing allowed them to store it long and also to sell their produce throughout the province of Gujarat (Tewari, 1998). Neem (Azadirachta indica) is another example; previously Neem seeds were purely crushed for oil but when their insecticidal properties were later discovered, a large regional market was exploited. Similarly, in Cost Rica, traditionally the bitterwood (Quassia amara) was used for medicinal uses; later it was found to be a source of a bio-insecticide and strong demand existed for this in the region. But, its extraction was found to be unsustainable for the export purposes (Taylor, 1999). In Thailand, the extraction and processing of catechu (Acacia catechu) flourished well when they found a regional and export market in India(Wanida et al, 1993).

The fifth most important strategy is to provide a set of local institutions which can help the change to take place in the rural setting. The strong local institutions and supportive national policies are crucial for making small-scale enterprises a success. Strong community-based traditions are a plus factor which augur with the success of local businesses. These can be in terms of some collective and co-operative venture.

Summary, Conclusions and Guidelines

Non-wood forest products have become an economically important output in terms of their economic significance and trade. It is estimated that some US$ 90 billion worth of NWFPs are extracted every year and some $13 billion worth of products are traded internationally. However, the commercialization of NWFPs have benefitted more the big companies than the poor collectors who depend on NWFPs for their livelihood and food security, and medicine. The rights and privileges of these collectors are hence encroached by big companies and no mechanism exits for resolving this issue. Commercialization has thus engendered more inequity and more poverty and more unsustainable use of NWFPs. These symptoms-- inequity, poverty, and unsustainability-- are part of, what I would define as, the Big Business Syndrome. The big business syndrome is characterized by increasing value addition away from the center of production, increasing monetization of the resource, and increasing poverty and inequity in the local village economy, increasing unsustainable extraction of the resource as such.

The forest-based small-scale enterprises are suggested to be a solution to counter the impacts of big business syndrome. For various reasons the small-scale enterprises are considered to be more efficient than large scale enterprises and they are also found to be using the NWFP resources on a sustainable basis. However, they are besieged with various constraints such as access to credit, poor management capabilities, uncertain markets, and so on. But they can be made effective if sufficient policy initiatives are taken. A five pronged strategy is suggested to increase the share of small-scale enterprises in the profits from NWFPs and manage them on a sustainble basis. These include: (1) transfer of management and organization skills to the collectors of NWFPs; (2) promotion of value addition activities at the local and regional level; (3) improvement in marketing channels so as to pass benefits on to collectors of NWFPs; (4) exploring regional and national markets, and (5) strengthening the local institutions.

Abstract

Non-timber forest product-based enterprises have been viewed as possible vehicles for reconciling the livelihood needs of forest dependent populations with the larger societal goal of sustainable forest management. In India, village-initiated efforts and state-sponsored programs for collective forest protection during the past decades are reconfiguring the context and institutional landscape for such enterprise. Increasingly, local institutions for forest management are becoming focal points for village development and resource governance. Proceeds from NTFP sales, fines and fees from a variety of products from village protected forests are also creating pools of common funds which are becoming significant sources of liquidity and investment capital for rural enterprise.

Despite their appeal and considerable promise, experience in India and other countries has shown that relatively few conservation-oriented NTFP enterprises have become viable. It takes time and in most cases, subsidies, especially during the early years for an enterprise to achieve viability. Fewer still have demonstrated significant equity and poverty alleviation impacts and for many, their conservation benefits remain unproven. In many cases, economic success has resulted in resource over-exploitation since generally low levels of capital and skills requirement often make them contestable. High returns tend to invite new entrants and increase pressure on NTFP resources unless rights of access are clear and enforceable. For these enterprises to achieve their multiple goals, complementary developmental inputs and strong policy support are essential.

Keywords: NTFP enterprise, Conservation, Collective action, Cooperatives, Community and economics

Introduction

The potential of non-timber forest product (NTFP)-based enterprise to reconcile the livelihood needs of forest-dependent populations with the larger societal goal of sustainable forest management has been the subject of much discussion during the past decade. Reasons often cited for their potential derive from the observation that many NTFPs: involve non-destructive harvesting of annually renewable plant parts; depend on intact forest systems for their continued viability; tend to be small-scale, spatially and temporally dispersed; and usually engage people from the poorest socio-economic groups (FAO 1995; Perez and Arnold 1995). The growing recognition that knowledge of NTFPs is integral to local cultures and to the character of local ecosystems has also raised interest in patterns of resource use that are at the same time economically profitable, empowering for local people and affirmative of their cultural heritage (Gupta et al 1995; Malhotra, 1998). This thinking has developed in tandem with the idea that forests need to be sustainably managed for both timber and non-timber products to satisfy the needs of multiple users. It fits comfortably with the two-decade-old paradigm of participatory, decentralized management of common property natural resources at a time when greater market liberalization worldwide holds out the promise of significant economic returns (Isaak, 1999). Moreover, it intersects an on-going shift in international development thinking, namely, the refocusing of developmental goals from poverty alleviation to sustainable livelihoods and asset creation (Jazairy et al 1992; Robinson and Tinker 1998; Granfelt 1999). In this reformulation, particular attention is paid to a class of intangible assets such as institutions and social networks, which provide poor people with instruments of empowerment and expanded economic opportunities, thus enabling them to collectively improve their livelihoods and better manage their natural resource base (Bebbington 1999). Within this conceptual landscape, conservation-promoting, NTFP-based enterprises that can be managed profitably and sustainably by local communities and forest-dependent households find a very hospitable niche.

However, while recognizing the attractive features of the concept of inter-linking livelihoods and conservation through enterprise, a number of concerns have been raised about the possible adverse implications of commercializing NTFPS, especially those that are key inputs to household production. Commercialization and the prospect of increased returns could attract more powerful groups into NTFP-based activities at the expense of women and disadvantaged groups (Dove 1994; Perez and Arnold 1995). For many NTFPs, the long-term outlook may not be optimistic because of competition from lower cost synthetic products or higher quality substitutes. Demand and market sizes for some NTFPs may fall as consumption standards or incomes rise if the products are considered "inferior goods". On the other hand, NTFP-based activities with good prospects for growth and returns often require levels of skills and capital investments that the poorest segments of the community may not possess (Arnold and Townson 1999). Local markets for NTFP products tend to be thin, while markets farther away, including international "green" markets, tend to be volatile and unreliable (Hyman 1995). Sustainability is an amorphous concept that is not easily marketed to final consumers who, in most cases, are unwilling to pay price premiums for conservation (Rice and McLean 1999).

Given that the bulk of NTFPs traded worldwide are still collected from the wild, questions are increasingly being raised about the validity of the implicit assumption underlying conservation-promoting NTFP enterprise, i.e., that NTFP stocks are sufficiently abundant to withstand increased harvesting. The ecological and genetic diversity impacts of long-term harvesting especially when the enterprise involves collection of roots, fruits, seeds or whole plants are issues of concern (Godoy and Bawa 1993; Peters 1997). Several authors have noted that even in the absence of destructive harvesting, the collection of commercial quantities of fruits and seeds can cause notable changes in the structure and dynamics of a plant population (Hall and Bawa 1993; Peters 1994; Murali et al 1996; Muraleedharan et al 1997; Muraleedharan et al 1999). Data showing that in the case of some species even small-scale harvesting of foliage and twigs can lead to regeneration failure if done continuously over a long period of time (Singh 1998), lend credence to some of these questions. The numerous cases of failed conservation-oriented enterprises have prompted others to call for a rethinking of the concept (Oates 2000).

Indeed, available evidence suggests the difficulty of simultaneously meeting livelihood and conservation objectives through enterprise. Results from two recently completed cross-country studies indicate that many factors determine the economic viability and conservation outcomes of NTFP enterprises. A multi-dimensional analysis of NTFP enterprise cases from nine countries showed that resource conservation goals can be achieved only under certain circumstances. Successful outcomes tend to be associated with: positive state-sponsored regulations that offer clear and well-known rights to people; a harvesting intensity and/or technique that does not put excessive pressure on the resource; a transparent market; well-organized gatherers; and the existence of external support groups (Perez and Byron 1999). Similar conclusions were drawn from the Bio-diversity Conservation Network's seven-year experiment with twenty projects on bio-diversity conservation through enterprise development in seven countries in Asia and the Pacific (Salafsky and Margoluis 1999; Salafsky et al 1999). Their results indicated that an enterprise strategy can lead to conservation, but only under limited conditions, and never on its own. Factors that influenced enterprise viability included: good book-keeping skills; working in markets that are established but not too competitive; good market research; and focusing on simple enterprises that used skills local community members already possess. Their findings showed that local involvement in the enterprise and effective conservation were strongly associated and that cash incentives may not be as important as non-cash benefits as initially supposed. Among the major lessons learned was the importance of providing complementary development work and environmental education to enhance enterprise viability and conservation success. That an enterprise strategy may need to be subsidized yet still create a net gain for conservation was another important lesson.

Over the past decades, attempts have been made in India to promote conservation-oriented, collective NTFP enterprise schemes that included developmental elements to varying extents and with varying degrees of success. While initial efforts were organized around state-initiated cooperatives with a pronounced focus on livelihood generation, later efforts increasingly involved non-governmental organizations (NGOs) as facilitators and intermediaries between local communities and state agencies within collaborative forest management arrangements. This paper discusses the evolving context of collective NTFP enterprise in India and emerging opportunities for more effective linkage among economic empowerment, community development and sustainable forest use. It highlights a few enterprise cases and draws wider implications for policy.

Context of NTFP Enterprise in India

The collection, processing and trade of diverse NTFPs has been an important, although until recently, largely unrecognized sector in India's economy. The NTFP sector is estimated to contribute more than 50 % of total forestry output value and 70 % of export earnings. It generates over 1600 million person-days of employment annually, mostly through household or small group-based NTFP collection from public forests and trading involving mainly women and forest-fringe dwelling tribal populations (Khotari et al 1998). Earnings from NTFP enterprises contribute from 5 to almost 60 % of total household income (Shiva and Mathur 1996). As in other countries, NTFP enterprises are a key component in Indian rural households' multiple sourced livelihood strategies. The income they provide, though meager, is critically important especially during lean agricultural periods and times of famine. NTFP enterprises are typically seasonal, small-scale, undertaken within complex, usually conflict-ridden conditions of resource access, dependent on individual or household labor, use relatively simple technology, mostly oriented to local markets, and generally non-remunerative (Tewari and Campbell, 1995). They are usually labor intensive and have limited overhead costs, fixed assets or raw material inventories. With labor as the most significant input, NTFP enterprises tend to be contestable. High rates of profit invite new entrants and increased pressure on the resource unless there are effective institutional safeguards and clear, enforceable rights of access.

Out of the 16,000 recorded plant species in India, 3000 yield NTFPs. Except for NTFP species of high commercial value, most (about 60 %) are consumed locally. Those that are traded are mostly sold or exported in their raw form with little, if any, value adding processing (Shiva 1998). There is considerable scope for increasing NTFP utilization and for adding value to already traded products. But lack of access to capital, markets and market information; weak technology and extension support; inadequate storage and transport facilities; and depleting or unreliable raw material supplies have been serious constraints. In the absence of alternative means, most NTFP collectors and entrepreneurs are locked into highly exploitative relations with middlemen who are often their only source of inputs and their sole gateway to more distant markets. NTFP collectors' share in their products' market value typically ranges only between 10 and 20 %, even much lower in the case of perishable commodities (Shiva and Mathur 1996; Verma 1998). The lion's share goes to middlemen, mostly in the form of monopoly profits. These iniquitous arrangements, in turn, have encouraged resource over-harvesting especially when combined with pervasive policy-induced insecurity in NTFP access rights and strong competitive pressures from other collectors.

Ostensibly to protect both collectors and NTFP resources from over-exploitation, state governments have organized NTFP enterprise around the idea of cooperatives and have taken over the marketing of the most commercially important NTFPs. Between 1970s and 1980s, the Indian government nationalized key NTFPs such as mahua (*Madhuca indica*), tendu (*Diospyros melanoxylon*) leaf and sal (*Shorea robusta*) seeds, making trade in these and other nationalized products a monopoly of the state. Regulations on processing and transport were also put in place for some products. State forestry development corporations (SFDCs) were created to manage NTFP collection, marketing, resource conservation and development and to help ensure fair prices for collectors. In addition, the SFDCs were supposed to provide training in resource management, credit and other inputs. To harness the unified strength of NTFP collectors, the government encouraged the formation of NTFP collectors' cooperative societies and apex organizations and the adoption of a system of cooperative governance of NTFP resources at the village level. Since the mid-1980s, many tree growers' cooperative societies were also created for watershed rehabilitation and afforestation on degraded lands to satisfy local fuel, fodder, small timber and other NTFP needs. Cooperatives could bid for SFDC contracts to harvest nationalized NTFPs. Contractors would then pay state governments royalty on the NTFPs they collect. Through this system, in theory, cooperatives could generate employment for their members, have a ready buyer for their harvests, and in some cases, receive bonuses based on the values realized from NTFP sale.

Although notions of democracy, autonomy, self-governance and self-reliance are often thought to permeate the cooperative ideal, ironically, in practice, instead of being voluntary, member-led institutions, many cooperatives in forestry are state-funded, bureaucratically controlled, inefficient and non-transparent set-ups with little accountability to their members (Jain and Coelho 1996; Singh and Ballabh 1996). Participation by members is often limited to merely serving as hired laborers. Through a system of patronage and sub-contracting to private agents, state monopoly has generally translated into private monopolies by influential individuals. Except in a few states, the system of state monopoly and NTFP cooperatives has proven to be largely ineffective from the standpoint of both livelihood enhancement and resource conservation.

Evolving Institutional Landscape

Village-based efforts and state sponsored programs for collective forest protection initiated during the past decades, however, are now slowly reconfiguring the Indian institutional landscape and the context for rural enterprise. The numerous self-organized village-based forest protection groups that have emerged to counter severe forest products shortages, while far from ideal, are probably the closest approximation of the cooperative concept. Their membership tends to overlap with that of village level NTFP collectors' and other forestry-related cooperatives. They are estimated to number in the tens of thousands, with at least 10,000 in the state of Orissa alone. In some states, they have begun to federate for purposes of conflict mediation and policy advocacy on behalf of their members, often with the support and facilitation of development-oriented professionals and NGOs. In Orissa, they are demanding ownership rights over state forests which they have been protecting for decades (Mahapatra 1999). Some are venturing into livelihood augmenting activities, such as collective NTFP marketing and trading.

A similar pattern of evolution is becoming increasingly apparent among village institutions set up during the 1990s in the context of collaborative forest management programs, notably Joint Forest Management (JFM) in degraded forests and Eco-development (ED) in protected areas. JFM and ED have been the main vehicles for implementing the concept of people's participation in forest management articulated in India's National Forestry Policy of 1988. Both programs involve a formal agreement between state forest departments and village-based groups which protect degraded public forest lands from fire, grazing and unauthorized use in exchange for usufruct rights to non-nationalized NTFPs and, in the case of JFM, a share in timber harvests. Currently, there are an estimated 35,000 JFM groups protecting 7 million hectares of degraded forests. Many of the JFM and ED groups have benefited from the assistance of NGOs in group formation, leadership training, resource management planning, basic book keeping and organizational management, and in forging links with government agencies and external partners. Where NGOs are absent, foresters have often performed some of these functions.

In some locations, neighboring groups have federated and are beginning to carve out niches in the NTFP economy (Raju 1998; Mahapatra 1999). For example, in Gujarat, SAKSHAM, a state-wide federation of 12 federations consisting of village forest protection groups and tree growing societies, has been formed to advocate the cause of grassroots institutions engaged in forest protection and management. With a combined membership of 49,000 men and women protecting nearly 53,000 hectares of forest and wastelands, and a strategically designed program for peer learning, capacity building and advocacy, SAKSHAM is becoming an increasingly important force for the political and economic empowerment of its members (VIKSAT 1999). High on SAKSHAM's agenda is a campaign for greater share in the NTFP economy through increased contracts for member-federations to become SFDCs' NTFP collection agents. Through federation-formation, it is becoming increasingly possible for forest protection and NTFP collectors' groups to achieve economies of scale in production and marketing and to improve the efficiency of technology access and application. Albeit still limited, public and private research and development efforts have yielded a wide range of technologies that can be adapted for NTFP processing (Shiva and Tangri 1996).

Where collective action has been effective, degraded forests and wastelands have begun to regenerate. From 1972 to 1995, the area of regenerating forests nation-wide increased by 14 % or about 7.82 million hectares (CSE 1999), largely due to village-based protection. Participatory monitoring of vegetation changes conducted by villagers and NGOs in several states indicate generally increased availability and diversity of NTFPs in different types of forests. Effective village forest protection, self-regulation and management are also contributing to increased liquidity and savings in rural areas, thus, helping to somewhat relax the credit constraint on entrepreneurship. In many states, village funds are being accumulated from fines, penalties and sales of timber and NTFPs. Investments made using these common funds have not been limited to forestry, but have included road construction, school building, drinking water facility installation and other village development projects (ETS 1999).

In many villages, self-help savings and credit groups (SHGs) which mobilize members' savings for revolving loans have also been formed to complement JFM and ED programs. For example, in Andhra Pradesh, all 115 villages covered by the ED program in and around the 11,000- hectare Srisailam Tiger Reserve have at least one SHG. The 362 SHGs operating in the area serve around 5500 members and together have accumulated net savings of Rs. 2,040,530 (US$48,600) (AP SFD 1999). These pools of funds represent significant resources in a country where per capita income is only Rs 11649 (US$ 277) per year. SHG funds are usually deployed for emergency needs or invested in individual assets and small businesses, including NTFP enterprises. Although SHG savings tend to be limited and often unable to provide enterprise capital requirements beyond a small scale, through these funds, villagers are increasingly able to qualify for matching funding from the formal banking sector under the Indian government's various livelihood-oriented loan programs. Hence, they are widening the space for NTFP enterprise and other more profitable activities. In addition, they are facilitating empowerment through enhanced financial autonomy especially for women. Building on these institutional and technical possibilities, a number of innovative enterprises designed for mutually advantageous, resource conserving partnerships between the business sector and grassroots federations are now in the process of development (Boaz 1999; Phansalkar 1999). Recent legislation that vested village assemblies in predominantly tribal areas with ownership and management authority over NTFP resources, if implemented, could further expand the scope for such enterprises in the future.

Enterprise Cases

The increased supply of NTFPs from regenerating forests, more effective local institutions for forest resource planning and management, stronger leadership and organizational capacity, expanded networks and alliances, growing pools of investable funds, and increased access to technical, financial and marketing support are making NTFP-based enterprise increasingly feasible. But whether or not they would also result in greater resource protection remains an open question. Previous experience with state-initiated and NGO-facilitated NTFP-enterprises has shown that it takes time and, in most cases, subsidies, especially during the early years, for a collective enterprise to reach economic viability. An enterprise can be economically profitable and provide enhanced employment and income, yet fail to mitigate, and sometimes even encourage, resource depletion. The ability of groups to effectively manage their common resources and enforce their rights in the face of increasing contestation crucially determines outcomes. This, in turn, depends to a large extent on the policy environment and their web of alliances that could be mobilized in times of need. While early state-initiated efforts tended to be paternalistic in their approach, NGO and private sector efforts that have come up in recent years have tended to emphasize capacity building to enable communities to better manage their resources and interface with the market. This difference in approach is illustrated in the following cases which also underscore the difficulty of meeting multiple goals of economic viability, resource conservation, equity and empowerment.

Kerala Tribal Cooperative Societies. After the state of Kerala granted its tribal population exclusive rights over NTFP collection in 1978, Tribal Service Cooperative Societies were established to ensure that collectors receive fair prices for their products. In 1981, a federation of cooperative societies was formed and entrusted with the right of monopoly procurement and sale of all NTFPs collected by the societies. All decisions relating to collection, allotment of territories to be harvested, setting royalty payments and purchase and selling prices of collected NTFPs, are made by a committee chaired by the state's Chief Conservator of Forests. Acting on the instruction of the committee, the federation's branch managers and the State Forest Department's Divisional Forest Officers award collection contracts to cooperative societies which in turn employ tribal people to harvest specified types and quantities of NTFPs.

Although the cooperative societies merely act as collection agents with no resource management authority, collectors have nevertheless benefited through increased employment and income and improved product prices (Thomas 1996). Total quantity of NTFPs collected and marketed by the federation increased from 3 to 24 million kilograms between 1982-83 and 1997-98. Data from the Kerala Forestry Research Institute's long-term socio-economic and ecological monitoring in two forest divisions indicate a similarly increasing trend of collection and marketing for many individual NTFPs within individual cooperative societies, as well as a fairer distribution of proceeds from NTFP sales. Payments received by collectors for different NTFPs on a per kilogram basis increased by as much as 190 to 4200 %. However, because of high rates of inflation, collectors' real incomes rose only up to 239 % [Muraleedharan et al 1999]. While the federation has not been immune to unexpected price fluctuations, which have caused losses from certain products in some years, it has generally been able to make profits from NTFP marketing.

However, rising NTFP prices and market demand have led to dramatically increased harvesting not only by authorized tribal collectors but also by illegal, non-tribal private collectors. The lack of members' participation in the functioning of their cooperatives, their inability to fend off illegal collectors, and more attractive procurement prices offered by private traders, have given the latter effective control of about 40% of the market with virtual monopolies in some locations. Only half of the commercially exploited plant species were found to still have reasonably good density and population distributions. Regeneration rate was found to be negatively related to harvest intensity and to be high in vegetatively propagated species, but poor in seed propagated species. The regeneration index of species propagated vegetatively was 100 % even when harvest was as high as 95 %, but in seed regenerated species, a harvest rate of 35 to 50 % would be the sustainable limit (Muraleedharan et al 1997). The combination of intensive commercial harvesting and poor regeneration, especially of species regenerated through seeds, has apparently negatively affected biodiversity in the study areas. A similar scenario can be drawn from detailed analysis of the SFDC and NTFP collectors' cooperative societies in Gujarat (Tewari 1998).

Tree Growers Cooperatives. The National Tree Grows Cooperative Federation (NTGCF) is a national level apex organization established in 1986 to provide technical inputs, marketing and liaison support to village-based tree growers cooperative societies (TGCS) which are its members. It is a non-governmental, membership organization governed by an elected board of directors composed of representatives from state-level TGCS and from the National Dairy Development Board. Through a proactive campaign for environmental education, organization and training, the NTGCF has established over 520 TGCS in six states with total membership of almost 40,250. Together, they have revegetated more than 10,720 hectares of mostly state-owned wastelands leased by the societies for plantation of timber and NTFP species.

Funds for the TGCS are raised through membership fees and issue of shares as well as through loans, donations, subsidies and grants. The NTGCF provides each newly organized TGCS with a loan of Rs. 458,000 (US$ 10, 900) to establish mixed tree plantations. Profits earned by the TGCS from sale of members' produce are allocated as follows: 25 % for its reserve fund; up to 12 % for shareholder dividends; and a certain amount stipulated by law for a cooperative education fund. Out of the remainder, 65 % is proportionally distributed as bonus to members based on the value of products they sold through the society; 10 % as bonus to TGCS staff; 15 % for a soil, water, energy conservation and wasteland development fund; and 5 % for cooperative promotion and publicity. Resource conservation, economic incentives and social responsibility are thus tightly intermeshed in this program which Singh (1999) rated highly in terms of economic efficiency, equity, people's participation and sustainability. However, a typical TGCS will take about 15 years to achieve financial viability and will most likely need subsidies during the initial years. But Saxena and Agrawal (1997) argued that conventional financial accounting does not capture the value of environmental services produced by TGCSs and, hence, provides a distorted assessment of their worth. Using an expanded accounting framework, they showed that a TGCS with a financial net worth of only Rs. 7089 (US$ 170) was in fact worth Rs. 568,000 (US$ 13,525) when the value of its social and environmental services are considered.

Soliga Enterprises. The Vivekenanda Girijan Kalyan Kendra, a community development-oriented NGO working with other NGOs and university-based researchers, established a cluster of NTFP enterprises in the Biligiri Rangaswamy Hills, a 540 sq. km. sanctuary populated by the 4,500-member Soliga tribe in the state of Karnataka. The first enterprise, a 30-ton capacity honey processing unit (HPU) established in 1995, involves collecting and processing honey from wild (*Apis dorsata*) and domestic apiaries. Although operating at less than full capacity, it made profits of Rs. 200,000 (US$ 4,760) in 1997 and Rs 340,000 (US$ 8,100) in 1998. The second enterprise, a food processing unit (FPU) also established in 1995, produces jams and pickles for sale, using *Phyllanthus emblica* and other fruits of forest species. In 1998, it generated over Rs 145,000 (US$ 3,450) in sales. Together, these two enterprises, which are located within the sanctuary, provide full-time employment to 14 people and annual earnings of more than Rs 100,000 (US$ 2380), a considerable sum compared to the Soligas' average annual household income of Rs. 13,000 (US$ 310). The third enterprise, a herbal medicine processing unit (HMPU) located 24 km away, produces and markets herbal medicines using both domestically grown and wild herbs collected from the forests. This unit is only just beginning to become profitable. The enterprises have been supported by strong biological research and monitoring to determine the impacts of enterprise-related extraction and to ensure that harvests are kept within sustainable levels (ATREE 1999). Complementary activities were also in-built to promote community participation, management capacity strengthening and equitable benefit sharing.

The Soligas have now taken over management of the HPU and the FPU. The enterprise manager, also a Soliga, reports to a managing committee consisting of NGO and Soliga community representatives. The Soligas decide profit distribution. For example, they decided to distribute 30 % of the HPU's 1998 profits to NTFP collectors and enterprise shareholders within the community. The HMPU is gradually increasing Soliga participation and adopting profit-sharing mechanisms to support community development programs. Although the enterprises are now performing well financially and the Soligas are increasingly sharing in the benefits, determining sustainable harvest levels continues to be a challenge. Over-all rates of NTFP extraction remain high. For example, average levels of *Phyllantus emblica* fruit removal per tree range from 87 to 95 %. These high levels of fruit harvest appear to be an opportunistic response to uncertainties in the entire process of bidding, selling, payment and harvesting adopted by the state-sponsored cooperative with monopoly rights over NTFPs in the sanctuary (Lele et al 1998). Harvest rates were significantly lower where NGOs and researchers have undertaken environmental education compared to areas where no education had been undertaken (ATREE 1999). However, despite this hopeful sign, thus far, the conservation benefits from the enterprises have yet to be conclusively demonstrated.

Conclusion

Despite their appeal and considerable promise, experience in India and in other countries has shown that relatively few conservation-oriented NTFP enterprises have been able to achieve their multiple goals. It takes time and in most cases, subsidies, especially during the early years, for an enterprise to become viable. Fewer still have demonstrated significant equity and poverty alleviation impacts. The conservation benefits for many such enterprises have remained unproved. In many cases, economic success has resulted in resource over-exploitation. The generally low levels of capital and skills requirement for NTFP enterprises often make them contestable. High returns have tended to invite new entrants and increase pressure on NTFP resources. The strengthened institutional capacity and new channels for critical inputs being created in rural India present greater opportunities for NTFP enterprises to meet livelihood needs while promoting sustainable resource use. However, unless present restrictive policies and the system of state monopoly and centralized control over key NTFPs are reformed, sustainable resource use would remain an elusive goal. Strong policy support and well-defined and enforceable rights for those most dependent on forests and NTFP resources are essential if these resources are to be effectively and sustainably managed.

Abstract

Rural and urban people in Africa are heavily dependent on non-wood forest products (NWFP) for a wide range of needs including food, medicines and construction materials. Many of these NWFP are important sources of income and employment at the local level, with some being traded at the international level.

In order to determine the sustainable level of any commercial utilization of a given NWFP, accurate information is needed on the status and regenerative capacity of the resource providing the product, in addition to information on the socio-economic and cultural aspects affecting the use of the NWFP.

Practical methodologies for assessing socio-economic and biological factors of NWFP utilization are not widely available. Such methodologies are needed to collect information both at the forest management unit level as well as at the national level.

This paper analyses the factors to be taken into consideration when planning an assessment of the forest resources providing NWFP. It discusses current gaps in knowledge and presents some of the main activities of the FAO Forestry Department aimed partly to fill these gaps at the local and national scale.

Keywords: NWFP, Forest inventory, Assessment methodologies, Africa.

Introduction

A variety of definitions exist for non-wood forest products (NWFP) and the related term non-timber forest products (NTFPs), corresponding to different perceptions and different needs. For the purposes of this paper, the following definition of NWFP is used: "Non-wood forest products are goods of biological origin other than wood derived from forests, other wooded lands and trees outside forests" (FAO 1999).

This definition makes a distinction between the forest resources and the products, which are obtained from these resources through direct human intervention. An assessment of the resources providing NWFP, therefore, will not aim to quantify all biological resources (other than wood) found in a forest but only those which are actively used by people for particular purposes or which have a potential for exploitation. In this sense, assessment of NWFP resources is aimed at assessing the status of exploited resources and evaluating the potential or otherwise of NWFP utilization for economic development at local and/or national level within the framework of sustainable forest management. NWFP can be collected from the wild or produced in plantations, in agroforestry systems or in intermediate systems. The knowledge of the prevailing production system is an important factor in planning a sustainable promotion of NWFP.

This paper deals principally with NWFP which are already used in Africa, and in particular those which are traded. The discussion on assessment methodologies is limited to plant resources providing NWFP.

The last decade has witnessed a steep increase in interest and activities concerning NWFP. There are numerous ongoing projects in African countries and globally to promote NWFP use and commercialization as a means to improving the well being of rural

[1] FAO Consultant

populations and at the same time conserving existing forests (FAO 1995, Wollenberg and Ingles 1998, Ros-Tonen 1999).

In order to determine the sustainable level of any commercial utilization of a given NWFP, accurate information is needed on the growth and regenerative capacity of the resource providing the product, in addition to information on the socio-economic and cultural aspects affecting the NWFP use. Although there is often considerable indigenous knowledge for specific NWFP, there is often a lack of documented or scientific information suitable for the determination of sustainable yields readily available to forest users.

At the national level, the full recognition of the socio-economic value of NWFP to people and national economies is still hampered by the lack of good national data on NWFP production, consumption and trade. At the same time, increasing demands are being put on countries to report on the status of forest resources and their biological diversity (which includes NWFP and their use) at the national level as part of reporting requirements under international initiatives, such as for the Convention on Biological Diversity, for initiatives on Criteria and Indicators for Sustainable Forest Management, and for reporting to international agencies like the Food and Agriculture Organization of the United Nations (FAO), World Trade Organization and International Tropical Timber Organization.

Although significant advances in research on both the socio-economics and the biology of NWFP have occurred in the last few years, methodologies for NWFP assessment at the national as well as the forest management unit level are still not widely available in practice. The multitude and variety of NWFP, the multiplicity of interests and disciplines involved in NWFP assessment, organizational and financial constraints, the lack of globally, or even nationally, recognised common terminology and units of measurement (FAO 1998a), all contribute to make the assessment of NWFP and of the resources providing them a difficult task.

According to its mandate, FAO shall collect, analyse, interpret and disseminate information related to nutrition, food and agriculture (including forestry). FAO is mainly concerned with the national, regional and global levels. Within this mandate, the FAO Forestry Department is carrying out a number of activities aimed at addressing gaps in knowledge and field application of NWFP assessment at various levels, so as to contribute towards the achievement of sustainable forest management in its member countries.

Materials and Methods

The results and discussions in this paper are based on information obtained through desk studies, literature reviews and a number of expert consultations in which the Non-wood Forest Products Programme of FAO has taken the lead or been actively collaborating.

Recent activities related to the potential of NWFP exploitation and assessment of resources providing NWFP in sub-Saharan Africa include those outlined below.

The Importance of NWFP in sub-Saharan Africa

A series of international consultations, conferences and workshops have been held in recent years. Those in which FAO has been involved and which are relevant to the current paper include the following:

> The International Expert Consultation on NWFP held in Yogyakarta, Indonesia in 1995 (FAO 1995)
>
> The International Conference on Domestication and Commercialization of NWFP held in Nairobi, Kenya in 1995 (Leakey at al. 1996).

With particular reference to Africa, a Regional Expert Consultation on NWFP for English-speaking African countries was held in Arusha, Tanzania in 1993 (FAO/CSC 1994). The Central African Regional Programme for the Environment (CARPE)-FAO workshop held in Limbe, Cameroon in 1998 specifically addressed the issue of ecological assessment of NWFP, identified gaps in knowledge and recommended actions on a number of priority key species (Sunderland *et al*. 1999).

Assessment of NWFP and Non-wood Forest Resources at the National Level

Within the framework of the EU-FAO Partnership Programme on "Data collection and analysis for sustainable forest management in African, Caribbean and Pacific (ACP) countries: linking national and international efforts", quantitative and qualitative information was gathered during 1998/99 on the exploitation practices and production levels of major NWFP in collaboration with 42 African countries. The preliminary findings were discussed in four regional workshops: East Africa (Kenya, 1998), Southern Africa (Zimbabwe, 1998), Central Africa (Gabon, 1999) and West Africa (Côte d'Ivoire, 1999). The most important NWFP in Africa, on which further development efforts should be concentrated, were also identified during this process and include: gums, mushrooms, forest fruits, bushmeat and medicinal plants.

More specifically, information was collected on a country basis on major NWFP, the plant or animal sources from which they are extracted (and part used), the habitat in which they are found/produced, their destination (subsistence/trade), main uses and economic value.

The data collected under this effort were also used as input to a Special Study on NWFP for the Global Forest Resources Assessment 2000 (FRA 2000), spearheaded by FAO. Methodological work preceding the actual gathering of available information for this study concentrated on the information requirements for data collection of NWFP at the national level.

Assessment of Non-wood Forest Resources at the Forest Management Unit Level

In addition to information obtained from the above activities, this paper also builds on information obtained from the two recent literature reviews indicated below and a number of case studies commissioned by FAO on the assessment and management of forests providing NWFP.

As part of the development of a set of guidelines for the management of tropical forests for the provision of non-wood goods and services (FAO *in press*), an extensive literature search was undertaken. The guidelines, which focus on the tropical moist forests, include a specific chapter on the aspects of assessment of resources providing NWFP at the forest management unit level. Several case studies were commissioned from around the world, including one on the assessment and management of wildlife resources providing bushmeat in West Africa.

In a study commissioned by the Forest Research Programme of the UK Department for International Development (DIFD), Wong (2000, in prep.) analysed 95 case studies on assessment of non-wood forest resources mainly from English language literature. Of these, 28 were from 16 African countries. Based mainly on the results of this review, a detailed structure for quantitative surveys of NWFP is under development and will form part of a new forest inventory manual being prepared by FAO.

Results

NWFP and Their Potential in Africa

Rural and urban people in Africa are heavily dependent on NWFP for a wide range of needs, including food, medicines, construction and shelter materials, fibres, dyes, resins, gums, oils, aromatics and a variety of animal products such as honey, beeswax and bushmeat. Many of these NWFP are important sources of income and employment at the local level, with some being traded at the international level[2].

Various criteria can be used to identify key NWFP. At the aforementioned CARPE-FAO workshop on NWFP for Central Africa, two

[2] An overview of major NWFP in Eastern and Southern Africa is described in a separate voluntary IUFRO paper: "The significance of NWFP for tropical societies: an analysis of statistical data on NWFP utilization in East and Southern African countries", by Killmann et al., 2000.

criteria were used to draw a short-list of key NWFP: firstly and most importantly, those products which are highly valued for domestic consumption, or as a product for the market; secondly, those where the demand for a "high value" NWFP is exceeding supply. Therefore a two step selection process is recommended: step one to identify NWFP with a high value, step two to define those that are intensively harvested and consequently risk unsustainable exploitation. At the local level, resource assessment studies are most urgently needed for NWFP species meeting the above criteria. However, for national assessments, a wider range of products and species may be of importance.

Assessment of Forest Resources Providing NWFP

The above-mentioned activities have provided some useful information on the trade and consumption of the main NWFP for 42 countries in sub-Saharan Africa. However, the study also highlighted the fact that there is a serious lack of data at the national level on the resources providing these products.

The reviews of cases studies and other reports of assessment of non-wood forest resources at the forest management unit level (particularly the above mentioned DFID study) concluded that the range of assessment methods used so far in tropical moist forests has been limited and many assessment methods in use are not biometrically valid (Wong 2000 in prep.).

Discussion: Towards a Better Assessment of Forest Resources Providing NWFP

The discussion below focuses on the biological and technical aspects of non-wood forest resources assessment. The political and legal context of NWFP use (ownership, tenure and access to the resources, legal restrictions), the social profile and welfare of the collectors/users, current and future demand for a given product, market assessments etc., also affect the sustainability of forest resource use. However, such analyses lie outside the scope of this paper.

Information Needs at the National Level

The recognition of the socio-economic value of NWFP to people and national economies requires information on the collection, validation and analysis of national level data on NWFP production, consumption and trade. Increasing demands are also put on countries to report internally on the status of their forest resources and biological diversity (and therefore, incidentally, reporting on the status of resources).

This calls for a two-pronged approach to obtain information on both products and resources at the national level.

<u>Products</u>

Product information needed at the national level are production and trade data (quantities and values) of major NWFP for their inclusion into national and regional level country statistics, including the FAO Forest Products Statistics Yearbook. These data are essential to assess the full contribution of the forest sector to the economy of the country, and may be complemented with other descriptive information on the importance of NWFP for sustaining subsistence livelihoods, particularly their contribution to food security and /or their income generating role.

<u>Resources</u>

At the national level, improved assessment of forest resources providing NWFP require information on:

- the identification, prioritization and knowledge of the plant and animal species from which major products are obtained;
- the extent, frequency and status of the species, based on national inventories; and
- habitats in which the species are found.

The above information should be available, as far as possible, in a standard format to allow comparisons both among countries and products.

Management Information Needs at the Forest Management Unit Level

Abundance, distribution, population structure and growth rate data are among the most fundamental pieces of information required for sustainable management of a given forest resource. Data can only be obtained through quantitative forest inventories combined with growth and yield studies. Such inventories also provide the baseline data necessary to monitor the impact of harvesting and management practices.

Main Factors to be Considered in the Assessment of Forest Resources Providing NWFP

Assessments should concentrate on priority NWFP. Initial screening of NWFP for further study at the local level can be done through a participatory appraisal and may include information from harvesting records, household consumption analysis and market studies. At the national level, information on traded products, e.g. taxation records and/or preliminary information on the status of the resource, can be used for initial screening.

Due to the great variation of NWFP and the settings in which they occur, it is not possible to prepare specific prescriptions, which are valid for the assessment of all the forest resources providing NWFP. However, some general considerations to ensure that such assessments are biometrically sound are presented below.

The discussion is limited to the biological and technical aspects of non-wood forest resources assessment. Other aspects, such as the economic feasibility and socio-cultural suitability of each approach, should be carefully considered in the context of local conditions before choosing a specific approach. Techniques must be refined and adapted to suit location-specific ecological and socio-economic circumstances, needs and priorities.

General Approach for Forest Resources Assessments

Few assessments will have to start from scratch. At the national level, results from previous inventories, recent aerial photos or satellite imagery at a large scale and existing maps may be available.

At the local level, collectors and users often have long-established and detailed knowledge of the resources of which they make use. This may include knowledge of their life history, distribution and abundance, and variation of productivity in time and space and with respect to harvesting practices. Although this knowledge is rarely quantifiable, it can be very valuable if used together with sketch maps drawn by experienced collectors during a preliminary participatory appraisal.

Where possible, the delineation of different forest types should be undertaken based on available information prior to conducting the inventory.

Local users undertake many NWFP inventories at the forest management unit level. In a participatory inventory, techniques must be tailored to the abilities and resources available to the communities.

The methodologies for resource assessment vary according to the type of forest resources in question. Plants and animal resources, more often than not, are thus treated separately. It should be kept in mind, however, that an assessment of plants that are important food sources or habitats for animals might be needed for the sustainable management of the forest animal resources. Likewise, an assessment of the status of animals that are important pollinators and seed dispersers might be needed for successful management of forest plant resources. Although valuable information on plants may be obtained from an inventory of forest animals and vice versa - and should be used as far as possible – few examples exist of successful efforts at combining the assessment of plant and animal resources in, for example, a multi-purpose resource inventory (Lund 1998).

Bushmeat is an important NWFP in sub-Saharan Africa. Yet, the assessment of forest animal resources poses several specific problems due to their mobility, habitat (e.g. tree canopies), life cycle, seasonality (caterpillars/butterflies, migratory birds) and diurnal pattern (many species are nocturnal) and fall outside the scope of this paper.

Resource Assessment Designs

Assessments can either be undertaken as total counts or by sampling. Total counts are expensive and time-consuming and can only be justified if the resource is very valuable and the area relatively small. Most assessments are carried out through some form of sampling.

Several different sampling designs exist. The choice between sampling designs depends mainly on the type of forest and resources to be assessed, the existing information and knowledge of the area and the skills of the assessors. Systematic sampling provides a regular distribution of observations, is easier to lay out and is better for mapping purposes than random samples, but the risk of bias is greater.

In tropical forests being surveyed for the first time and/or for a number of different resources, a systematic sampling design, usually laid out in grid fashion, is generally recommended to ensure that all parts of the forest are covered. Where prior knowledge about different forest types and distribution of desirable species is available, each type can with advantage be sampled independently using a stratified design. This is often combined with random sampling. Particular difficulties are related to the rareness and clumped species distribution, which are characteristics of tropical forest species.

The sampling units may be transects with or without fixed boundaries, plots – usually square or circular, sample points, or measured in time. The choice between these depends on the type of resource(s) involved.

The size of the individual sampling units depends on the size and density of the resources being assessed. Where several different plant resources that vary greatly in size are to be included in one inventory , nested quadrants may be used. For statistical purposes, the optimum sampling unit should contain an average of 10 to 25 individuals.

The sampling intensity employed for sampled counts varies according to the purpose of sampling and the degree of accuracy needed and on the funds and time available. It also depends on the size and abundance of the resource and according to whether information on the local distribution of animal/plant populations is available or not. Where distribution is clumped and the locations known, the sampling may be concentrated at known sites and the overall sampling intensity (sampling area in percentage of total area) may be very low. If the resource is small and abundant, a low sampling intensity may also be used.

Timing of the assessment depends on the type of resource and its life cycle and seasonality. The issue is most critical with regard to ephemeral resources such as flowers, fruit or mushrooms. The inventory should take place, where possible, just prior to the harvesting season or when flowers are available to facilitate taxonomic identifications.

The parameters to be measured depend on the purpose of the assessment, the type of resource(s) and the product(s) to be obtained.

The inventory of forest plant resources at the forest management unit level should provide the following information (Peters 1999):

- a reasonably precise estimate of the density of harvestable plants;
- data on the current population structure or size-class distribution of adult plants; and
- a preliminary assessment of the regeneration status of the species.

What is FAO Doing?

Assessment of NWFP and Non-wood Forest Resources at the National Level

A prerequisite for compiling national level statistics on NWFP of countries for inclusion into the Forest Products Yearbook is the availability of a global, applicable and agreed upon classification system for NWFP. This was initiated by FAO (Chandrasekharan 1995), which continues to work with its member countries to develop further practical mechanisms for countries to report on NWFP production and trade data, including supporting efforts towards harmonization of related definitions, concepts and classification systems (FAO 1999).

Few NWFP are significant at global level, which is one of the reasons why they are not reported in the global forest products statistics published by FAO. The publication of regional forest statistics, where important NWFP at the regional level could be featured, and the identification of low-cost, easy and applicable methodologies to improve the collection of national data on NWFP, are initiatives supported by FAO (FAO 1998b).

The FAO-EC partnership programme mentioned above supports capacity building in participating countries to provide improved statistical data on forestry and specifically NWFP. The information obtained is being used to prepare a regional synthesis on NWFP, while also contributing to 'NWFP country reports' as a Special Study under the FAO "Forest Resource Assessment 2000" programme. In addition, information on the current use of main NWFP and on likely trends will be the basis for the formulation of the NWFP section of the recently initiated Forestry Outlook Study for Africa, which is coordinated by FAO and funded by the African Development Bank.

Within the FAO-EC partnership programme, 'pilot studies' have been initiated in four countries (Uganda, Cameroon, Madagascar and Zimbabwe) to develop and test methodologies for the collection and analysis of data on NWFP. These methodologies should provide reasonable estimates of the production, consumption and trade in NWFP, and should be cost-effective and widely applicable and relevant to other countries in the region. During the pilot studies, all available information related to NWFP in the respective country is analysed and NWFP of major national importance are identified. The coverage of NWFP by national statistics is evaluated and all institutions involved in the collection of statistical data, as well as the methods used for data collection, are identified. Finally, necessary steps to improve statistical data availability on NWFP are suggested.

Assessment of Non-wood Forest Resources at the Forest Management Unit Level

Guidelines for the management of tropical moist forests for the provision of non-wood goods and services have recently been prepared (FAO *in press*). This document provides general guidelines for the assessment and management of forest resources providing NWFP, complemented with several examples and case studies on this subject.

A "Forest Inventory Manual" (working title) is currently under preparation in FAO. This manual aims to provide an overview to natural resources users and managers on inventorying and monitoring techniques, which will enable readers to access other references for details and in-depth studies. The final result will be a "forest inventory package" where single chapters will be set up as inter-linked, self-contained units, which can be updated, reviewed and compiled over time by various individual or corporate authors. This modular format, while potentially also linearly structured, will allow more dynamic access to users, timely modification and revision of the content and closer collaboration of inventory specialists in sharing knowledge and experiences. The NWFP section is structured so as to guide the user to a set of recommendations, which can be used as the basis for a locally specific and relevant protocol.

Within the framework of another and recently initiated partnership programme between FAO and the European Commission, NWFP resource assessment methodologies at the forest management unit level are being tested for important, selected NWFP in each of the major sub-regions in sub-Saharan Africa. The project will develop guidelines that will enable national forestry administrations to implement improved and regular monitoring of the NWFP resource base and develop sustainable management plans in partnership with local and indigenous communities. This endeavour will draw on existing knowledge through the review of ongoing and completed work on NWFP resource assessment.

Conclusions

Rural and urban people in Africa are heavily dependent on NWFP for a wide range of needs, including food, medicines and construction materials. Many of these NWFP are important sources of income and employment at the local level, with some being traded at the international level. However, the full recognition of the socio-economic value of NWFP to people and national economies in sub-Saharan Africa is still hampered by the lack of national level data on NWFP production, consumption and trade.

The assessment of NWFP, and the forest resources providing them, is an essential tool for the sustainable management of these resources.

In spite of recent interest in and research work on the ecology and socio-economics of NWFP, practical methodologies for the assessment of NWFP at the local and national levels are still largely unavailable to the main resource users (local communities) and to the institutions that are responsible for centralized planning, monitoring and national reporting.

Various approaches exist to carry out NWFP assessment: those drawing on indigenous knowledge and ethnobotany, and those drawing on quantitative inventory. However, the range of assessment methods used so far in tropical moist forests is limited and more attention should be given to ensuring that quantitative inventory assessments are biometrically valid.

The mandate for work on NWFP often falls across several disciplines, institutions and land-use categories. While this may represent a constraint in the implementation of inventories, it also presents an opportunity for devising much needed innovative approaches to NWFP assessment, drawing on the experiences of different disciplines and sectors (forestry, agriculture, ecology, social sciences, etc.).

Due to the great variation of NWFP and the settings in which they occur, it is not possible to prepare specific prescriptions that are valid for the assessment of all the forest resources providing NWFP. However, in the forthcoming FAO Forest Inventory Manual, practical information on the main factors that should be taken into account to ensure biometrically sound NWFP resource assessments is included.

The economic feasibility and socio-cultural suitability of resource assessment approaches should be carefully considered within the context of local conditions, and methodologies and techniques should be refined and adapted to suit location-specific ecological and socio-economic circumstances, needs and priorities.

FAO, in close collaboration with other international and regional organizations and institutions in member countries, supports the development, testing, adaptation and dissemination of improved methodologies and practices for the assessment of forest resources providing NWFP through a number of specific activities in sub-Saharan Africa, as well as in other countries.

Abstract

This paper discusses cultural differences and similarities in forest recreation and other amenity uses between a Northern (Finland), a Central (The Netherlands) and a Southern (Italy) European country. The behavior, meanings and values related to forests for different European populations are discussed in order to understand the future demand on forests and other natural resources for recreation and nature-based tourism. Nature-based tourism is predicted to become one of the major, increasing, uses of forest resources in the future. It is important for a host country to know how it should deal with visitors that have varied cultural backgrounds.

Different types of recreational forest uses are described in terms of participation rates and the intensity of participation in different activities, as well as in terms of time-use patterns and the types of areas used for recreation. Attention is also paid to the differences in meanings and values of forest and nature between countries and regions. The effects of differences in the supply of natural resources for recreation are also discussed.

In the North, there are many natural areas available for recreation, and there is much interest in also providing those resources as a basis for nature-based tourism for other European peoples. In Central Europe, people are interested in increasing the amount of nature in their residential areas. The total participation rate in outdoor recreation is as high in the South as in the North, but people make fewer visits to forests. In Southern Europe, there is a growing pressure to use nature protection areas for recreation, which causes serious problems for the protection of nature.

Keywords: Outdoor recreation, Ecotourism, amenities, Service functions

Introduction

The Aim of the Paper

In many Central and Southern European countries, forests have lost their predominant role of timber production in the last decades. In the Nordic countries, forestry still has an important role in national economies. At the same time, other functions of the forest have come to interest the public, economic operators and governments. These are water and soil protection, biodiversity preservation and recreation. The role of forest in social and cultural life cannot be measured only in economic terms. Many kinds of direct or indirect enjoyment of the forest involve our emotional, psychological and spiritual sphere. In Europe, such non-economic components of forest functions play a great part in people's lives.

This paper analyses the present state of forest recreation in three European countries (Finland, the Netherlands and Italy) which, because of their geographic position and cultural features, are assumed to represent the European situation well. The main purpose of the work is to draft a common European framework for forest recreation, highlighting similarities and differences among the countries, which will allow the formulation of proposals and hypotheses for the future development of forest recreation in Europe from a common perspective.

Forests for Recreation in Finland

Forest areas are abundant in Finland, covering 86 % of the land area. The total area of forests is 26.3 million ha, which means 5.1 ha per person. State owns 33.2 % of the forestland, private families 54 %, and the commercial sector 7.8 %. The national economy is strongly dependent on forest industry, which produces about 29 % of total foreign income. In Finland, all forested areas are available for recreation according to the doctrine of 'everyman's rights', but there are a large number of designated recreation areas as well. The forested land includes 2.67 million ha of protected areas and about 0.2 million ha of urban forests and recreation areas, which are about 10 % of the total forested area. The protected areas include 32 national parks and 7 national hiking areas. The capital area has a concentration of large urban populations (0.9 million persons, 18 % of the population). Of the total population, 36 % live in cities with more then 50 000, and 64 % in smaller towns or in the countryside.

Communities manage most recreation sites which are located close to residential areas. Designated recreation areas are facilitated by trails with signs and information boards, and in many areas with on longer trails there fire rings, camping facilities, shelters, huts, etc. All forested areas are suitable for recreation but the areas most used for recreation are forests in urban fringes, lake and seashore forests (close to summer houses), forested islands in the archipelago as well as lake districts national parks and wilderness areas in Northern Finland. Family-owned summer cottages are an important basis for the recreational use of many timber production forest areas. At the nationwide inventory of the area the listing of recreation areas as well as monitoring the services and the quality of recreation resources are in progress (Sievänen 2000).

Forests in Italy

Forests cover 28 % of the territory in Italy. Almost 8.7 million ha (MAF-ISAFA, 1988), or 35 % are plain forests, 37 % hill forests and 28 % mountain forests. They are very important element from the landscape and social point of view, and less important for economic purposes especially in the last decades. Italy imports about 50 % of the rough timber. The forested areas comprise of forests (71 % in total; high-forests, 27 %; coppices, 44 %), other woodlands (mainly scrubs, 26 %), and plantations such as fruit chestnut and cork oak woods (3 %). The plantations have no recreational function.

About one-third of the wood resources are public forests. At present, around 10 % of the national territory is protected (19 national parks and over 800 protected areas). Forest availability for the population averaged, 0.16 ha per person but the area is not uniformly distributed. While there is about 0.7 ha per person in some alpine regions, it decreases to 0.05-0.10 ha per person in some Mediterranean regions. Almost 47 % of the Italian people live in urban areas with more than 30 000 inhabitants, and 53 % live in small cities (< 30 000 inhabitants) or in the countryside.

Due to its large north – south latitudes, Italy enjoys wide climatic diversity, which determines many different forest typologies on its territory. From the alpine forests of conifers, similar to those of central Europe, they change through the broadleaved woods of the Apennine up to the coastal woods situated in the central-southern peninsula and in the islands, which have a strong Mediterranean mark. Different forests determine different behaviour and recreation approaches. In the North forests are very often the main environmental attractions', the alternatives being in some way linked (and close) to the woods: lakes, rivers, mountains and grasslands. In the Centre and South, the sea and the beach are the most important attractions.

In Italy, at present, there is not really an "everyman's right" or an equivalent tradition of open access, but most forest areas are freely accessible for "low impact" recreational use. Some limitations may apply to the protected areas (permanent or seasonal prohibition to access some zones or to walk outside marked paths). Limitations concerning activities such as hunting, fishing, free camping, out-of-paths skiing and, overall, accessing forest roads with motorised vehicles are quite frequent.

Forests in the Netherlands

The total forested area in Netherlands is 355 000 ha of which 60 % are coniferous and 40 % deciduous. Most of the forests are found in the higher and dryer parts of the Netherlands, located more inland. Together with 141 000 ha of other natural areas, they cover about 11 % of the Dutch territory. Currently 36,700 ha of these natural areas are within one of 10 national parks. Six more (land-based) national parks are being formed. On average, the nature availability is about 300 m^2 per person. Nature availability, however, is not uniformly distributed. When using a 3-kilometer radius, the amount of nature available within this radius ranges from less than 20 m^2 per capita for census tracts located in large cities such as Amsterdam and Rotterdam, to over 840 m^2 per capita in more forested and less densely populated areas.

The three major organisations that own or managed nature areas are the State Forest Agency (220 000 ha), the Federation of "Provincial Landscapes" (80 000 ha) and "Nature Monuments" (78 000 ha). The latter two are private organisations that are primarily dedicated to nature and landscape conservation. These organisations are very popular within the Netherlands. For example, "Nature Monuments" is an association with about 900 000 households as members. Although in the Netherlands there is no "everyman's right", most natural areas are open for recreation (about 80%), although access is often restricted to roads and paths (70 %), and sometimes for members only (Grontmij 1995). Timber production is a minor industry in the Netherlands. For example, the State Forest Agency produces about 300 000 m^3 a year, which is considered a substantial part of domestic production. Another important function, besides nature conservation, bio-diversity, recreation and timber production, is water retention.

Recreational Use of Forest and Other Natural Resources

Forest recreation in Finland

Participation in Outdoor Recreation Activities

Forest recreation is an essential part of the Finnish way of life. According to a recent population study, a preliminary estimate of the total participation rate among the Finnish population is 96 % (Sievänen 2000). The most popular activities are walking, picking wild berries and mushrooms, swimming outdoors, bicycling and studying nature (Table 2). Typically, urban people keep the tradition of picking berries at a family-owned summer cottage, to which about half of the population has access. Berry picking is an everyman's right. Hunting is three times more common among men in Northern Finland than among men living in southern Finland. Hunting is one of the few activities that shows some type of rural vs. urban difference in nature-based recreation. An average number of visits is three to four times a week, each visit lasting about one hour at a time. Finnish people use an average of 4.4 hours per week for recreation and sports according to the national time use survey (People and Pääkkönen 1989). About 40 % of the make a nature trip during each year. A nature trip is defined as a trip, in this the main purpose is to participate in outdoor recreation, and which includes an overnight stay.

Access to Recreation Resources

For the site areas used for day visits (does not include overnight stay), 85 % is forested areas. About half of them or are located by near lakes or seashores. Around 40 % of all day visits are in municipality-managed recreation areas, 5 % on state recreation areas, and approximately 50 % in areas used according to "everyman's right". The average distance to a day-visit area managed by municipality is 3 km, and 25 km to a state owned area. Most people have a forest suitable for recreation within one kilometre of their homes. Three out of four day visit areas have a paved or gravel road for walking and bicycling, and about one out of three has constructed trails and signs (Sievänen 2000).

In areas which are destinations of nature trips, 90 % have forest and almost 80 % are located by the sea or lake, (include smaller lakes or ponds). Majority of nature trips in the countryside(over 80%) and designated for recreation (50-60%); e.g., they are multiple-use areas (Sievänen 2000). About half of the destination areas have constructed trails, signs, information boards and constructed sites for open fire and shelters for visitors. The state-managed areas have a special role in providing recreation opportunities for vacation and weekend leisure time. People travel quite long distances in order to get to some of the state-managed areas. The average distance between a visitor's residence and the state recreation area is about 500 km, (Sievänen 2000). The reason is that state-managed areas are mainly located in northern and eastern Finland, but the majority of the population is in southern Finland. The state managed recreation areas, which are located in southern Finland, the average distance traveled by visitors is between 80 and 90 km (Ovaskainen et al.1999).

Forests are an essential part of the Finnish landscape. Often the forested landscape is fairly dark and closed, dominated by conifers. The hardwood forests, particularly birch forests, are favourite the among and Finnish (Savolainen and Kellomaki 1984). The people give a great value to forest as a recreation and also appreciate fields, meadows and, particularly, water elements in the landscape (Sievänen 1995).

Access to Nature and Some Policy Issues

In Finland, a new forest law (1997) emphasizes also the social sustainability of forest uses, including recreation. The Ministry of Agriculture and Forestry has developed a basic list of criteria and indicators, which should be used to evaluate the sustainable use of forests. Recreation is one of the criteria of social sustainability and recreation research is recognized as the means to provide information and monitoring.

There are several different kinds of national programs and projects, which give new guidelines to forest management. Some guidelines are developed particularly to improve forested environment for recreation and others consider landscape management as an aspect related to recreation. In these programs, integrated forest planning is developed. Such planning includes economic use (timber production), ecological sustainability (biodiversity) and social sustainability (recreation).

Table 1. A summary of forest resources in Finland, Italy and the Netherlands.

	FINLAND	HOLLAND	ITALY
Total country area (land and water areas) (million ha)	33.5	4.1	30.1
Inhabitants (millions)	5.2	15.8	57.6
Forest (million ha)	26.3 *)	0.34	8.7
Forest area per capita (ha)	5.1	0.02	0.7
Public forest area rate (%)	33.2	46.9	33.9
Free accessible forest area rate (%)	99.9	80	n.a.
Protected areas (million ha)	2.7	0.01 **)	3.0 ***)
Timber production (million m^3 per year)	77	1.2	8.5
Timber exported/imported	Export	Import	Import

*) In Finland, also high altitude areas and peat lands with scrubs are included.
**) Figure applies to State Forest Agency only
***) Not only forests. Protected forest area can be estimated as about 0,9 million ha

Table 2. Recreation activities: participation rates and frequencies, on average, during the last 12 months in 1998-1999 among the Finnish population. LVVI-study/ Sievänen 2000 *).

Activity	Participation rate %	Frequency (times or trips per 12 last months)
Walking	68	110
Hiking	19	10
Bicycling	55	46
Jogging, running	16	49
Walking the dog	25	229
Staying in summer cottage	56	30
Camping	18	6
Picnicking	28	7
Hunting	8	21
Picking wild berries	57	7
Picking wild mushroooms	41	7
Cross-country horseback riding	2	28
Studing and enjoying nature	51	7
Swimming outdoors	64	23
Boating	46	23
Fishing	44	24
Cross-country skiing	40	20

*) The first nation wide population survey of outdoor recreation, the total sample is 12 000, respondent rate 84 % (population by 15-75 years old).

In Finland, one of the actual policy issues is to determine how a large supply of recreation services is needed in recreation areas and whether the costs of services should be paid from tax money or from user fees. Funding from the state budget has not developed in terms of the number of areas and services that are to be maintained. There is a discussion about developing a fee system to cover the expenses of recreational services. According to recent surveys, only one in ten Finns clearly supported the introduction of user fees to maintain the current level of recreation services and facilities (Sievanen and Ruuska 1999).

In Finland, rural areas are now looking for possibilities to provide resources and services for nature-based tourism. There are a large number of EU-projects, which support the construction of new facilities such as trails, farm-based accommodation and restaurant services, and program services in rural villages. Village planning is a key method to integrate agriculture and forestry, landscape management, and tourism in a way, which offers possibilities for employment and income in rural communities.

Forest Recreation in Italy

Participation in outdoor recreation activities

At present, a periodical survey of the recreational use of forests in Italy does not exit. So far, only a unique study by Scrinzi et al. (1995) has evaluated, throughout the whole country, the role of the forest in Italian people's recreation demand in quantitative terms. Featuring parameters such as length of events, type of forests and the activities concerned, the study referred above exclusively concentrated on direct exploitation inside forest environments, and did not consider all those kinds of events and activities generally addressed to 'green areas' (attendance of urban parks and gardens, camping, snow-based and water-based activities, etc.) in which, however, the forest plays an important role. Almost all (96%) of Italian people participate in recreation activities involving the forest. The median time from the last forest-related recreational event for the Italian population is about 66.2 days (compare the method of Koch 1978, Koch and Jensen 1988). Each Italian has, on average, about 4 events per year with a mean duration of 3 hours and 45 minutes or about 1.3 days/visitor according to the Schreuder criteria (Schreuder et al. 1975).

Italian forest areas host a total of 170 to190 million events per year (including also the young, the elderly and foreigners), corresponding to 50-58 million days/visitors, 40 % of which involved protected areas. Italian forests are subject to a human pressure of about 20 events per year per hectare (70 events/year/ha in protected areas, 13 events/year/ha in other forest areas) with an average value of about 6 days/visitor per hectare, per year. The time spent on recreation in forests is less than 1 % of total free time and about 5 % of free time spent outdoors (Table 3). Italians have, on average, 4.7 hours of free time per day. Outdoor activities (including sports) take, on average, 0.8 hours per day (ISTAT 1993). Most recreational use (60 % of events) occurs on festive days. An increasing number of events have been recorded during holiday periods (25 % of the total number of events with a frequency ten times higher than in working periods). About 70 % of events occur exclusively on road networks (forest roads, paths, etc.). Users travel an average of 32 km from their starting point (home or temporary residence) to reach the forest site.

Preferred recreation environment

Users prefer “pseudo-natural” forests that are not too intricate, with good visibility on the ground, low-density stands, and even vertical stems of intermediate or big size (Scrinzi et al. 1996). Forestry interventions have the most negative effect on preferences, at least when their consequences are evident (cut or cracked stems, scattered residuals, stumps).

The results also showed that the great impact of users on protected areas (40 % of the total use on 7% of the total area) could cause compatibility problems between recreational use and preservation. Italian forest legislation lacks measures concerning the social function of the woods. The main national forest law (quite outdated, being issued in 1923) focused on soil and water protection including a number of limitations to be respected in forest activities. Management plans are compulsory only for public forests while on private property they are optional and therefore being very rarely an additional cost to the owners. In the absence of a management plan, the law acts according to its most restrictive dictate.

Table 3. Activities, participation rates and recreation use of forests estimated for Italian population.*)

Activity	People practicing the activity (%)	Times the activity is prevailing, %	Time dedicated to the activity, %
Walking (without a specific destination)	40.1	21.9	17.0
Hiking	38.1	21.7	19.7
Picnicking	44.6	16.0	20.6
Mushroom picking	20.9	9.9	10.2
Wilderness watching (incl.photography)	20.9	8.2	8.4
Picking of other products	19.4	6.3	7.7
Bicycling	5.7	2.9	2.1
Tourist facilities, attending	6.9	2.1	2.9
Running	3.9	1.7	1.3
Hunting	3.9	1.7	1.9
Horseback riding	3.0	1.1	0.8
Fishing	2.8	1.1	1.0
Climbing	2.5	1.0	1.1
Free camping	2.4	0.8	1.1
Cross-country skiing	1.8	0.6	0.6
Other activities (not specified)	7.0	3.0	3.5

*) a mail poll questionnaire on a sample of 3000 citizens (18-75 years old) distributed over a variety of demographic criteria and representative of the whole Italian population.

Forest Recreation in the Netherlands

Participation in Outdoor Recreation Activities

Within the Netherlands, nation-wide surveys on outdoor recreation are conducted regularly though Statistics Netherlands. These surveys focus on day-trips of at least two hours in length. Data are gathered by means of a diary (Statistics Netherlands (CBS) 1997). This survey focuses on activities much more than on destinations. About 50 % of the 60 million visitors make day-trips and 30 % of the 40 million cycling day-trips takes place in forests and heath. For walking, over 70 % of the day-trips take place in natural surroundings (besides forests and heath, also beaches and dunes, and along lakes, pools, and rivers). For cycling, agricultural areas are also important as a location (about 30 % of trips).

In the last version of the CBS-survey, conducted in 1995-1996, participation levels were asked for the first time without referring to a minimum of time spent on the activity. The results for activities that belong to the category of outdoor recreation are depicted in the table 4. According to the Social and Cultural Planning Agency (SCP 2000), in 1995, the Dutch people spent on average about one hour a week on outdoor recreation. This is about the same amount of time as they spent on this type of activity in 1975.

Preferred Recreation Environment

Within the Netherlands, forests are generally considered to be the most attractive natural environment (Reneman et al. 1999). From the rank order of 11 different types of natural environment, the forests have a mean score of 9.6 on an eleven-point scale. Sea, beaches and dunes come second, with a score of 7.5. The third place is for lakes and pools (M = 5.9). The lowest scores are for large-scale agricultural landscapes (M = 1.5). The most attractive aspect of a forest is silence (the absence of noise), the second most is alternation with other types of nature. The third most attractive aspect is space (‘large’), the fourth is solitude (‘quiet’, i.e., few other people), and the fifth is being within walking distance from home. Beech, birch and oak forests stands of full growth are considered most attractive. Generally forests with undergrowth are considered more attractive than forests without undergrowth. However, the undergrowth should not be too dense. Variation in overgrowth has a high attraction value (Heytze and Herbert 1991).

Table 4. Outdoor recreation participation levels and frequencies in the Netherlands (based on CBS-survey 1995/’96).

Activity	Participation rate (%)	Frequency (how often in last 12 months)
Walking	74	63
Bicycling	68	46
Touring (by car or motor)	39	21
Jogging, running	16	51
Surfing, sailing, rowing, canoeing	14	11
Horseback riding (outside)	6	30
Visiting playground (large), zoo, attraction park	57	3

NB: frequencies are the average for participants

Access to Nature and Other Policy Issues

In the Netherlands less forested areas are less available, certainly on a per capita basis, compared to the other European countries. One of the goals of the Dutch government is to increase the forested areas by 75 000 ha within the next 25 years. Although forests take a less dominant position in people's life than in Finland, they form a very popular destination for short outdoor trips, as well as for vacations. Together with the small supply, this may be one of the reasons that access can not be taken for granted and is often restricted to roads and paths. Recently the need for 'roaming nature', (i.e., nature areas in which there are fewer restrictions on behavior within the area and one is allowed to walk wherever one pleases), has become a policy issue.

The issue of user fees was on the political agenda a few years ago. Besides problems related to the feasibility of implementing such a measure in a cost-efficient way, also some negative side effects may be expected. Introducing entrance fees has a strong negative effect on visiting behavior to the extent that the expected length of the visit is shorter, the present frequency of visitation is higher, the visitor visits other locations more and the household income of the visitor is lower. There is also a relationship with the mode of transportation: the negative effect of introducing entrance fees is smaller for people that come by car. Presumably these people are used to having to pay for parking. Consequently, parking charges are likely to meet less resistance and have less negative effects on visiting behavior than entrance fees (De Bruin and De Vries, 1997). Nowadays more attention is paid to indirect mechanisms for marketing nature, such as leasing or letting out land. By combining ‘red’ (commercial, man-made) and ‘green’ (resource-based) facilities in this way, the ‘red’ facilities can pay for (their location in or near) the green facilities (see Hansman, Borgstein and Kolkman, 1999).

Within the Netherlands a change in policy has taken place. Until recently nature conservation and ecological policies used to look at recreation as a threat, and adopted a “no, unless” attitude towards recreation in natural areas. This meant it was up to the recreation sector and its proponents to show that recreational use of the area had no negative impact on nature. Nowadays there is more attention to the societal function of nature, such as nature-based recreation.

Recently, the Dutch ministry of Agriculture, Nature Management and Fisheries also has become more output-oriented. As a consequence, the State Forest Agency now has classified all of its grounds according to ‘recreation target type’. Each type has its own level of recreational facilities and intended level of visitors. Governmental financial support depends on the assigned type of the area. The agency has to monitor visits in order to show the ministry that intended levels of visitation are met, to ensure the financial support is maintained at its present level. At present, the tendency is for policy-making to become more integrated and participatory. Among other things, this leads to (more) multifunctional forests and (experiments with) integrated forest management (Van der Jagt et al. 1996).

Discussion

Comparison of recreation opportunities and recreational use of forests

For Finns, the accessability to nature-based recreation services is fairly easy and the supply is evenly distributed among the population. Those who live in the northern parts of the country have better opportunities for activities which demand large forested areas, such as hunting or snowmobiling. The common interest in outdoor activities among urban and rural populations offers an important insight when discussing the preferences and values which people assign to rural landscapes and natural recreation environments. Large forested areas, lakes and rivers, and even wilderness are highly appreciated by the Finnish. Naturally, not all of the forested land has the qualities of good recreation environments but together with the supply of designated recreation areas, the Finnish have ample opportunities to enjoy nature in their leisure time.

Finland can provide high quality recreation opportunities to other Europeans, who are interested in recreation in forested environments, and particularly in snow-based activities. Today, forest planning and management policies include aspects of landscape and recreation issues much more than before. Recently, special efforts have been taken to produce a good information basis for landscape management and the recreational use of forests. It is a future challenge to develop nature-based tourism. Tourism could offer new sources of income and employment to people in rural areas who are dependent on the natural resources.

In Italy, visiting a forest is not a "daily" component of life in comparison with central or northern European countries, but visiting a forest is a annual festive event. Picnicking is the most popular activity, which describes the social character of forest visits in Italian culture (89% of visits being group activities). Picking mushrooms also belongs to the Italian tradition of countryside visits, being a significant economic resource as well. If compared to Northern Europeans, Italian people have much less forest area available, even though there is a great variety of forest environments. Furthermore, people are very interested in visiting nature protection areas. The high recreational pressure is a problem in those areas, which are founded for nature conservation. On the other hand, over the last decades Italian public opinion, aware of the need to safeguard nature, has often identified such needs with an absolute denial in forest interventions for timber production in ordinary timber managed forests. Such cultural and social concerns have caused a very prudent style of forestry action, often based on a low level of interventions. Consequently, though suitable enough for recreation activities from an intrinsic point of view, many Italian forests are not very specialised for such a function. Because of the increasing importance of non-material functions of the forest ecosystem, coupled with a concentration of recreation use in few specific forest areas, a deep revision of traditional forest management criteria is currently taking place in Italy.

In the Netherlands, visiting a forest is not a daily activity. However, it does seem to be an important part of leisure, or of life in general. When the local supply of forested areas is poor, people will go out of their way to visit a forest. The number of kilometers traveled to the most often visited forest site ranges from less than 7.5 in well provided areas to more than 30 kilometers, on average, in poorly supplied areas (De Vries, in preparation). Not surprisingly, many people in these latter areas are not satisfied with the amount of forested areas within their immediate environs. Of desired changes within the own living environment, over 50% have to do with more forests and/or other natural areas within this environment (Reneman et al. 1999). This is often at the expense of industrial and business sites, roads, dwellings and large-scale agricultural landscapes. More nature within the living environment is considered (very) important by about half of the respondents. This almost universal positive valuation of nature seems to justify the use of public finances on securing its societal functions. Given the strong association of nature with silence and quietness, it remains to be seen whether the proposed marketing of nature is not in direct conflict with what makes it attractive: a sphere that is not dominated by people, in whatever way.

Summarizing and comparing the situations in Northern, Central and Southern Europe, forests are important recreation environments in all studied countries, but the supply of forested recreation environment varies greatly. In the North, there are many natural areas available for recreation and there is much interest in providing those resources also as a basis for nature-based tourism for other Europeans. In Central and Southern Europe, particularly in the Netherlands and other places where the population density is high, there is shortage of natural environment for recreation and people are interested in improving their environment by introducing more of nature into their residential areas. Participation rates in outdoor activities are comparatively higher in Northern compared to in Central Europe. The only difference is that natural areas are more commonly used in the North. In the South, participation in outdoor activities in nature is different. The total participation rate is as high in the South as in North, but people make fewer visits to forests and more often use other natural environments, and the activities are more social in character, such as picnicking. In

Southern Europe, there is a growing pressure to use nature protection areas for recreation, which cause serious problems for the protection of nature.

Final Considerations and Conclusions

In European nations where large natural or semi-natural forests still exist, such as Finland, most preservation and protective tasks are not in conflict with recreation functions. On the contrary, in countries where fewer natural forest areas are available, as in the Netherlands or Italy, it is necessary to identify and specialise those sites to be used for recreation in the future. Forest areas of a high importance from a natural and ecological point of view, currently subject to human pressure, could be better safeguarded. In the Netherlands, politicians have started to favour a multiple-use policy, in order to combine nature conservation and recreational use on a limited amount of land. In Italy, the huge public interest in protected areas makes the principle of multiple use a more complicated matter. Other forested areas than protection areas should be developed for recreation in order to shift the recreation pressure from protected areas. In Finland, restrictions of recreational use on protected areas are very seldomly demanded.

Development of forest areas for nature-based tourism has to take into account the ecological and economic peculiarities of those areas. This also means that the neighbouring communities and local people have to be given an active and participatory role in the management of these areas. Policy and legislative actions have to be taken to improve the integration between primary economic activities and other functions in the use of forest resources. Finland has developed methods of multipurpose forest planning, which help in this task. For example in Italy, the conversion of coppices into high forests, provides many benefits: economic (timber assortment), ecological (i.e., biodiversity), protective (side stability, water tapping), and suitability for recreation.

In many European countries, wood does not constitute an exhaustive source of income in rural areas. It is necessary to stimulate rural development where farms are running different parallel activities: forestry, agriculture, breeding, wild products gathering, tourism and recreation services. This may be possible in many regions without changing the farm structures too much. In Italy, an already existing law offers fiscal discounts and contributions for "holiday farms". In the Netherlands, private owners receive a subsidy for opening their forest for recreational use. A desired development should provide recreation services while maintaining the predominant role of primary rural activities. The same type of rural development is an objective in Finland, too, where landscape protection is becoming an important aspect of rural land-use. In most European countries, the present forests are a result of centuries of human action (both in a positive and a negative sense). Forests need to be cultivated and managed by man in a balanced manner and according to the latest criteria of forestry. As a common feature for European people, forest recreation can constitute not only a source of psychophysical relaxation and a way to know the natural environment of other countries, but also a means to get closer to their traditions, cultures and ways of life, becoming a precious instrument for integration. Each European country, in particular those, that have a quantitative and qualitative richness of forest environments, should therefore supply forest recreation services to its own citizens, but also acknowledge opportunities for foreign visitors.

Abstract

Forests of North American provide many social benefits and services for people. These range across a wide range of leisure, environmental, amenity, and economic benefits and services including recreation and leisure, water and wildlife, cultural and spiritual, and employment and income services. Resulting from these interests has been intense interest in parks, wilderness, wild rivers and other special places, exploitation of forests for a variety of services, a preservation orientation to counter exploitation, and clashes between interests. The result has been development of a mosaic of land uses and classes to provide opportunity for realizing a variety of services from North American forests and a constant tension among competing interests to have their service needs met. Clearly, North Americans recognize that forests provide many and diverse social and environmental services.

Abstract

The various social services provided by the forests of industrialized Japan and Malaysia, a developing country, are discussed. The large population, increasing urbanization, diversity of cultures and geography, distinct national environmental policies and administration in the region have influenced the location of forests and their conservation, their socio-economic uses and recreation preferences and demand. The discussion is based on themes such as types of amenity forests and facilities available, recreation policies, use and demand statistics, growing demands for nature/ ecotourism opportunities, impacts of use and issues arising. Several suggestions are given for sustainable management and utilization of forests for recreation, ecotourism and conservation in light of the socio-political and economic conditions of the two countries. Common trends in both countries are highlighted.

Keywords: Amenity resources; Forest recreation; Sustainability; Ecotourism; Asia

Introduction

Asian forests as well as people are more diverse than other regions of the world. Furthermore, the population density in many parts of Asia is very high. These populations depend not only on forest products and forestlands for economic livelihood but also on recreational opportunities provided by forests. This situation is contributing to the overuse and deterioration of ever decreasing areas of Asian forests. Very often, non-commodity values tend to be neglected as immediate demands such as food and timber supply are given more importance. However, concern over global environmental issues such as biodiversity loss and increases in greenhouse gases emissions has compelled Asian nations to take immediate measures against the further degradation of their forests.

The authors discuss the various social services, in particular, amenity services provided by the forests in Japan and Malaysia. Criteria for comparison include the following: the forest environment, recreation policies, legal instruments, some use related statistics and national survey results, facilities, and recent hot issues. Various suggestions are given for sustainable management and use of forests for recreation, ecotourism and conservation in light of the socio-political and economic conditions of the two countries.

Forest Recreation and Related Services in Japan

Japan's forested areas have been increasing since the 1950s when dependency on fossil fuels accelerated as a result of "energy revolution". Now they occupy over 25 million hectares (Forestry Agency 1999). That means almost 68% of Japan's land area is forested. This percentage is much higher than the Asian average ratio of 18% and equivalent to that of Finland. However, there are several problems from the viewpoint of social services.

Japan's Forests as Amenity Resources

Japan's forests have several characteristics from the standpoint of amenity resources. First, 41% of them are plantations represented by cypress planted in the 1950s. Such forests are not only dark and monotonous but also relatively low in biodiversity. Such plantation forests can be attractive if occasional thinning is done. However, current timber prices are too low to invest money in managing them. Second, the lack of management of wildlife populations, for example, the rapid increase in deer population is causing serious damages to agricultural products as well as plantations.

Third, most forested areas are located in steep mountain areas. These mountainous regions contributed to the protection of Japan's forests which otherwise would be under heavy population pressure. However, steepness makes access from urban areas difficult and expensive. Once developed, both trails and forest roads require intensive care to overcome the damages caused by occasional landslides or erosion. Activities in such areas are also demanding and high risk. For example, Mt. Tanigawa has claimed more than 500 lives of climbers. Fourth, heavy rains accompanying the monsoon make some recreational uses uncomfortable and dangerous. For the same reason, the undergrowth of forest is dense and full of undesirable bugs enough to discourage activities in the summer season except for the alpine zone. For instance, hornet attacks are causing more casualties than elephant attacks in Kenya; every year more than forty lives are lost.

In short, Japan has relatively abundant forests, but their quality and location are not preferable as amenity resources. Still, these natural disadvantages can be turned into attractive factors by various adaptation measures. Indeed, the Japanese developed a sustainable forest culture since the eighth century and have not only been using the forest sustainably for thousands of years, but also have been enjoying it as amenity resources. Such non-commodity values of the forest were recognized by not only the ruling class but also by ordinary people.

Social Issues related to the Forest

Forest culture is diverse and changing from traditional wise use to biodiversity protection and recreation (Ito 1998b). The Japanese have developed a sustainable relationship with the forest after several critical periods (Totman 1989). However, such relations have been getting weaker since the 1950s, and several social issues related to the forest are occurring.

First, because of higher cost of domestic timbers, Japan depends heavily on imported ones; more than 88 million cubic meters (80%) of timber resource are imported annually. Such dependence on imported timber is partially contributing to the increase in biomass in Japan, but forestry is becoming a diminishing industry. The population of mountain villages is decreasing, and plantations are not managed. As a result, traditional forest culture related to wise use of forest resources is disappearing. At the same time, the accumulated deficit of national forest management reached 3.7 trillion yen (equivalent to 34.6 billion U.S. dollars) by 1997.

Second, because of the uneven location and resulting lack of direct contact, urbanites have little real experiences in forests. They tend to believe in forest information supplied by the mass media with little doubt. This is causing serious problems in the understanding of forest conditions among city dwellers. Most Japanese prefer natural forests to man-made forests when asked in questionnaires, but they choose the picture of the latter (Shidei *et al.* 1981). Thus, ignorance of forest and forestry among the Japanese is further compounded by images. This trend is clear from the national surveys on forest and forestry (Prime Minister’s Office 1999). Almost 90% of Japanese have some interests in the forest, but more than one third of them did not visit the forest at all. Even among those who visited, they just enjoyed sightseeing drives and other activities not directly connected to the forest environment.

Third, those with little experience in the forest tend to depend on modern tools and facilities to enjoy forest recreation (Ito 1994). They purchase a variety of camping equipment as advertised in outdoor magazines and carry them in overloaded cars. Then, staying at fully equipped auto camping sites, they enjoy high-tech displays and audio-visual presentations at the visitor centers in national parks or forest parks. Considering the popularity of such overdeveloped facilities, both state and local governments further develop such facilities in the public forest. This situation is narrowing the spectrum of opportunities as described in the Recreation Opportunity Spectrum (ROS). This vicious cycle further isolates visitors with interest in forest environment from the forest itself. In contrast with oversupply of hardware for forest recreation, software such as interpretation is underdeveloped. Considering the rainy climate and rugged topography, certain amount of development is indispensable. However, current gaps between hardware and software development are wide enough to hinder direct contact with the forest.

Fourth, related to forest recreation facilities, the legal system of protected areas is complicated. Over 31% of forested areas (25 million hectares) in Japan are national forests managed by the Forestry Agency, Ministry of Agriculture, Forestry and Fishery. The agency set aside 63% of national forests (4.8 million hectares) from timber management. The nature park system, including 28 national parks, is often overlapping with the national forests. The Environment Agency in the Prime Minister's Office is in charge of these nature parks. That is, the same forest is often managed by these two agencies. Such dual management was inevitable to establish national parks in the 1930s, but it caused serious inefficiencies in management (Ito 1996).

Fifth, the development of ecotourism is encouraged to revitalize rural communities in protected areas and to promote the understanding of natural environment and rural communities. National surveys revealed strong interest in it, but at the same time lack of leisure time appeared as a major obstacle (Environment Agency and Forestry Agency 1999). Already eco-tour operators are active in several national parks. Rich natural and cultural resources often impress participants. However, once they return home to urban areas, environmental awareness boosted by the ecotour is often forgotten (Naito 1999). Renewing such experiences is recommended. However, domestic ecotourism cannot compete with similar experiences overseas because of higher cost.

Possible Measures to Boost Social Roles of Japan's Forest

Thus, there are both environmental and social issues to promote the non-commodity uses of the forest in Japan. The forest environment cannot change over a short period, but social environment can be improved in a relatively short time. Particularly, Japanese society is rapidly aging due to increasing longevity and decreasing birth rate. Therefore, forest recreation and related services are expected to play important roles in promoting public health

Considering access for the elderly, urban fringe forests should play more important roles in forest recreation. Incidentally, recently more people are paying attention to such forests abandoned in the 1950s. Such interest is attributable to three main reasons: biodiversity, recreation and nostalgia. The urban fringe forest intensively managed for fuels and other commodity resources developed a stable ecosystem, and preserved certain species depending on such human interference. Such intensively managed forests without shrubs are ideal for recreation as well. Furthermore, urbanites recognize management activities like thinning or weeding as new forms of recreation with contribution to the forest environment. That is, traditional demanding work for farmers is being revived as recreation for city dwellers. The third reason, nostalgia for the sustainable life might be an escape from our wasteful modern life. However, Aldo Leopold's successful campaign to promote wilderness preservation reminds us of its importance (Ito 1998a).

Greenways, trails on abandoned railway tracks, have been promoted in the United States. The greenway has multiple roles such as recreation and environmental corridors and future sites for railway restoration. Since railway transportation is still active, development of more extensive greenway networks will be possible in Japan (Ito and Matsushita 1997). Such networks should connect not only between urban fringe forests but also urban fringe forests and the wilderness in national parks supplying biodiversity and diverse recreation opportunities.

The Japanese have been separating the urban fringe forests and wilderness or backcountry forests as *satoyama* and *okuyama* respectively. Accordingly, recreational uses were also distinguished. While *Satoyama* was used for common recreation such as cherry blossom viewing for ordinary people, *okuyama,* recognized as sacred space, was used by mountain priests to practice asceticism (Ito 1998c). Such a distinction enabled the Japanese to preserve wilderness next to a big city such as Nara. Such an old tradition for forest culture can be revived as a factor to give diversity to recreational opportunity as well as ecosystem.

Forest Recreation and Related Services in Malaysia

In 1997, the total forested area was estimated at 20.6 million hectares or 62 % of the total land area. Recognizing this rich endowment, the government has set aside 14.32 million hectares as permanent forest estates (PFEs) throughout the country. The PFEs have four main functions: as protection forest, production forest, amenity forest and research and education forest. According to the National Forestry Policy (1978, 1992), these are managed under sustainable principles to maximize social, economic and environmental benefits for the country. Since the 1900s, the country has been establishing a network of protected areas as part of its conservation efforts. In 1992, the country had 2.14 million hectares of conservation areas in the form of national and state parks, wildlife reserves and sanctuaries, nature parks, bird and turtle sanctuaries. In addition, there are also 120 Virgin Jungle Reserves covering 111,726 hectares serving as nature reserves and natural arboreta of the diverse forest types in the country.[1]

Amenity Resources of Malaysian Forests

Public demand for amenity forests became evident as early as the late 1960s. Rapid urbanization, high economic growth, rising incomes and education levels experienced by the population in the last two decades have heightened that demand for outdoor recreation spaces, particularly natural areas. Aggressive tourism promotion in the international market has also attracted more foreign tourists to visit the country's protected areas. To cater for this ever-expanding demand for recreation in natural areas, a total of 85 forest recreation areas (FRAs) have been established in Peninsular Malaysia (Forestry Department 1997). In addition, there are 39 protected areas in Peninsular Malaysia in the form of national or state parks and wildlife reserves (DWNP et al 1996).

[1] Statistics from various sources by the Ministry of Primary Industries, 1998, Forestry Department, 1997 and Ministry of Science, Technology and Environment (MOSTE), 1998.

The number of people seeking recreation in natural areas is increasing. Approximately 1.35 million locals and foreigners visited State / National Parks, Reserves and other natural areas (including islands) in Malaysia in 1994[2]. In a study of 20 FRAs (Willis *et al*. 1998), a total of 2.57 million visits per annum were estimated. Sites closer to urban areas and with better facilities and natural resources (eg. rivers and waterfalls) received more visitors than those which were more rural, remote and less facilities. Wildlife Department records of visitor numbers to the National Park in Pahang – Terengganu showed an increase from 8,200 visitors in 1984 to 58,157 visitors in 1997 with the development of easier access facilities, better accommodation and recreational facilities. When the Forest Research Institute of Malaysia opened its grounds for public use, with opportunities for hiking along nature trails, jogging, picnicking and enjoying nature; visitor numbers (in terms of organized visits) climbed from under 20,000 in 1990 to close to 60, 000 in 1998 (cited in Noor Azlin 1999).

As forests are often considered as public goods, forest recreation is usually unpriced or under-priced. No entrance fees are charged to FRAs and very low entrance fees are charged for visits to National Parks. Respondents involved in the survey of 20 FRAs indicated a mean willingness to pay RM 1.46[3] for access per visit (Willis et al 1998). Willingness to pay for entrance fees to the National Park were estimated at RM 3 and RM 8 per visitor for existing and improved opportunities respectively. The recreational value of existing opportunities at the Park has been estimated at RM 211,939 per annum and with improved opportunities, this value increased to RM 304,086[4]. Although, at present, there are no FRAs within the North Selangor Peat Swamp Forest (NSPSF), it offers numerous recreation opportunities such as bird watching (migratory birds as the main attraction) and recreational fishing. The potential recreation value of the NSPSF is estimated to be worth RM 142,000 per year (Woon et al. 1999a). Sport fishing

[2] Statistics from National Ecotourism Plan Malaysia, Ministry of Culture, Arts and Tourism, 1996. Cited in Assessment of Biological Diversity in Malaysia, MOSTE, 1997.

[3] Fixed exchange rate of USD 1 = RM 3.80.

[4] Case study cited in Assessment of Biological Diversity in Malaysia, MOSTE 1997.

enthusiasts to the NSPSF were willing to pay an average of RM6 per trip, those with higher education and income levels showing a willingness to pay more (Mohd Shahwahid et al 1999). Development of recreation opportunities at NSPSF will help relieve crowding at nearby popular recreation sites as well as ensure the conservation of this unique ecosystem.

Many of the country's natural areas are being promoted as ecotourism destinations, with loose adherence to ecotourism principles. Some characteristics include "mainstream or casual" visitors to nature-based sites (Lindberg 1991), little or no interpretation programs, activities that are not necessarily nature-dependent, tour operators who market mass tours to natural sites, infrastructure which modify/degrade the natural ecosystem, revenues generated which do not necessarily go back into conservation and benefits enjoyed by only a minority of the local communities.

Some of the common negative impacts occurring as a result of high and frequent use of recreational and protected areas are: the mass clearing of forested areas for tourism-related infrastructure and access roads (including mass clearing of mangroves for coastal reclamation/development), littering and the indiscriminate disposal of solid waste along trails, at camp sites, and on river banks and into rivers, the burning of waste resulting in air pollution or in groundwater pollution when buried, soil erosion and compaction along popular trails, damage to surrounding vegetation at and retreat of wildlife from use areas, and the illegal collection of insects and seedlings. There is an important need to strengthen visitor management to mitigate some of these impacts, achieve conservation objectives while simultaneously ensuring satisfactory recreation experiences.

Socio-economic Benefits from Forests

A large number of local communities living on forest fringes and indigenous groups (some living within forests) depend on the forests for their livelihoods, subsistence and to some extent, their recreation. Several socio-economic studies on peat swamp forest utilization have indicated that many of these communities derive their incomes from other forest resources other than logging activities. Communities rely on the peat swamp for their fishing, hunting, fruit harvesting and medicinal needs. In addition, they rely on the hydrological services provided by the forests for their farming and agricultural activities. The estimated social benefits (covering hydrological, eco-tourism, fish and *assam kelubi* (a forest fruit)) was at RM 113.4 million, contributing about 10% of the total economic value of the North Selangor Peat Swamp Forest (Woon et al. 1999a). Similarly, the social benefits generated from the utilization of the Southeast Pahang Peat Swamp Forest (SEPPSF) amounted to approximately 13% of the total economic value (Woon et al 1999b). In a survey of 236 households living in the vicinity of the SEPPSF revealed that at least two thirds of the households had members engaging in fishing and the harvesting of rattan in the generation of income. More than a quarter depended on the forest for hunting for food and recreation and 17% of the households trapped forest birds for sale. The households also relied on the forest for fruit harvesting, medicinal plants and wood materials for handicraft making. These communities (74%) also preferred the utilization of the peat swamp for agriculture production as the conversion of the forest to oil palm plantations is seen as a good way of generating better incomes. Only 1% supported the use of the forest for ecotourism purposes. Tourism benefits only a minority of people and may in fact restrict the use of forest resources (Lim at al 1999).

Mangroves are equally productive ecosystems in terms of socio-economic benefits. The waters off mangrove forests are rich fishing grounds, providing income and food sources to dwellers near these forests. Today, aquaculture has become a lucrative economic activity located near mangrove forests. The mangroves in Matang and along the northern coast of Perak are pertinent to supporting a coastal fishing industry, which in 1990 generated RM 76.7 million while prawn farming was valued at RM7.6 million (Cheng 1994). Mangroves are also harvested for charcoal production.

Even on the periphery of protected areas there are indigenous communities who rely on forest resources within the park for their livelihood. The residents of Kampung Peta, located on the main access route to Endau-Rompin State Park, collect rattan from the park as their main source of income (for 85% of households surveyed).They also hunt and fish in the forest for their subsistence. Tourism activities only provide an additional source of income to the villagers and cannot be relied on as a steady source. In addition, opportunities to become boatmen, porters and guides are only available to a few villagers (Stecker 1996). The vast socio-economic benefits provided by the forests to communities and the nation have yet to be fully quantified and are often overlooked in the decisions on management and utilization of forests.

Issues and Challenges in the Management of Forest Services

With increasing pressure on forests to produce a multiple variety of goods and services and the need to reconcile differing values of stakeholders, there has been a transition in the traditional role of forest management. Forest management has also moved from ecological and technical concerns towards planning and managing for social and political expectations.

Management of the environment is the joint responsibility of the federal, state and local governments but problems in implementing environmental management often arise from conflicting jurisdictional issues and development objectives. While the federal government has the responsibility to meet conservation objectives, the States often view forests as sources of revenues rather than as a land use option. The economic contribution of non-timber forest benefits (most with poorly developed or no markets) has often been neglected in assessing land-use options. Land conversion for agriculture, urban and industrial development and logging have led to mass clearing of forests (encouraged by competing policies), all of which that yield higher economic rates of return for State finances. Furthermore, land use planning and policies often allocate upland and hilly areas with poor soil and steep terrain (>600m) as protection areas. However, most wildlife habitats are found at lower elevations, of which many are being threatened by deforestation and fragmentation of habitats.

In an Asian-Pacific study on forest conservation, Malaysia was considered to have only a modest protected areas network, scoring a Conservation Index of 0.3 (low). Although East Malaysia has seen a rise in number of protected areas, Peninsular Malaysia is considered to have an inadequate system of reserves (Paine et al 1997). There has been a proposal for a Protected Areas Policy, in which at least 10% of key ecosystems as well as already identified biodiversity hotspots will be placed under protected areas. Currently, there is under-representation of protection of wetlands (including mangroves and peat swamps), lowland habitats below 300m of altitude and lower and upper montane habitats, of which a majority of mammals are dependent (DWNP et al 1996). When a forest is set aside for protection, conservation benefits are not necessarily or immediately tangible (in terms of revenues) to the states. Distribution of revenues generated from nature tourism, in the form of taxes, often benefit Federal finances rather than state. Furthermore, not all protected areas are suited for or should include tourism as a management objective. Market and policy reforms are needed, in particular to better capture the economic values of amenity / ecotourism resources, the option benefits of wild genetic resources, and other non-timber resources such as bamboo, rattan and water.

There are an adequate number of forestry, environment and conservation related policies and legislation in place. Yet, the lack of efficient and effective implementation and enforcement is perceived as the biggest hindrance to natural resource management and protection (MOSTE 1997). Lack of funding and adequately trained staff are among the reasons for poor program implementation and enforcement efforts. In 1991, out of an aggregated national total budget (USD 7.42 million) for agencies in resource protection, a mere 0.2% was allocated for protected areas (Paine *et al.* 1997). The recent economic crisis, which saw operational budget slashed, has also affected the implementation of resource protection programs and enforcement. Capacity building, harmonization of policies, greater Federal-State collaboration and innovative funding mechanisms are needed to overcome some of these institutional weaknesses.

Despite several inadequacies in conservation efforts, the country recognizes the importance of *in-situ* conservation in national policies and planning. This commitment is expressed in the ratification of the Convention on Biological Diversity and in the formulation of a National Policy on Biological Diversity. In addition to conserving habitat, species and genetic diversity, protected areas are also recognized as cultural heritage and for their scientific, educational, recreational and eco-tourism values. One of the thrusts of the Seventh Malaysian Plan (1996 – 2000) is to enhance the level of environmental awareness and commitment among Malaysians. Key progress has been made in the integration of environmental considerations in policies, legislation, market reforms, planning and management of sectoral processes. One of the challenges in this new century is the effective and efficient deployment of the country's financial and skill bases to manage this extremely rich forest resource on a sustainable basis.

Common Trends and Issues

Japan and Malaysia differ in terms of an immense diversity of geography, climate, types of forests and biodiversity, social and economic conditions. Yet, most of the forests in these two countries are surrounded by urban populations or rural communities dependent on forest resources or services. Utilization (whether sustainable or destructive) is very much influenced by both national and international forces and trends. As such, forest management is shifting from conventional forestry concerns to the recognition of a spectrum of uses and integrating these multiple socio-economic uses with conservation and sustainability concerns.

Two trends are obvious, that is, the growing demand for forest recreation areas by urban populations and for nature / ecotourism opportunities in natural forest environments. Asian forests are not abundant enough to supply diverse opportunities to the different demands of users. At present, characteristics of use at easily accessible sites are influenced by over-developed facilities with little interpretation programs to promote awareness of the natural environment. Less developed areas offering wilderness experiences are often difficult to access. To cater for growing demands, urban-fringed forests should be recognized as key amenity resources since access is easy and fuel saving. However, the provision of recreation services should be based on sustainable principles especially in the planning of forest access as well as use. There is considerable growth in the use of private motor vehicles in Asia as it provides freedom and privacy. This tends to lead to further problems such as traffic congestion, accidents and air pollution at sites. For access to wilderness or national parks far from urban areas, public transportation should be encouraged. By introducing disincentives for the use of private vehicles to such areas, it is not only energy saving but also decreases the need to open up more forested areas for parking spaces.

Both countries discussed here have developed policies and legal instruments to ensure the sustainable provision of recreational and social services from forests. However, overlapping or adjacent forests and national parks are often managed by different agencies with different priorities for conservation and development. Conflicting jurisdictional and priority issues need to be resolved through better co-ordination and operational reforms to ensure effective implementation of policies and forest social programs. Nonetheless, the government's role in ensuring longer term conservation and wider social priorities will remain as crucial.

The governments of these countries have also made international commitments through the ratification of several international environment Conventions (Biological Diversity, Wetlands/ Ramsar, World Heritage Areas and Climate Change), taking on obligations to ensure the conservation of forests and provision of environmental and social services. It is foreseen that global environmental issues together with dynamic global economic conditions and social preferences increasingly influenced by global trends will have large impacts on the conservation of forests and the use of forests for recreation, tourism and other social services in both countries as well as Asia.

Abstract

Since the Rio Earth Summit of 1992, sustainability has been widely accepted as a concept for future development. However, rigorous applications of the underlying principles and goals at the level of production and distribution are notably rare. Two paths of developments have emerged. At the political-programmatical level, different sets of criteria and indicators have been developed that mainly address 'best policy' issues. At the technical-operational level, newly evolved environmental management concepts consider primarily the aspects of 'best practices'. These two approaches contain many gaps, and a general framework to guide future thinking and the development of tools is still missing. The goal of this paper is to describe the process for implementing sustainability goals at the operational level. A brief analysis of the sustainability concept has uncovered three major challenges at the levels of technology and operations: 1) environmental soundness of systems requires improved technologies and more efficient technical systems; 2) the careful deployment of technology relies on a more effective institutional framework; and 3) minimizing energy and matter flow per service unit is the main goal of future efficiency improvements. The proposed framework for implementation considered four main aspects: 1) Eco-efficiency is a general principle that makes environmental performance of products and processes measurable, and that is strongly related to the well-established principle of operational efficiency; 2) Environmental management systems provide a set of management, analysis, and assessment tools to achieve ecological goals within overall business processes; 3) New policy tools consider public involvement, independent private inspections, self-responsibility, and communication of environmental performance to consumers and the public; and 4) Life Cycle Assessment (LCA) and Risk Analysis (RA) provide the methods and tools needed to model the flow of matter and energy through a bounded production system, while assessing potential environmental damages and risks. To be able to adapt these options to the "real world" of forestry, planners must rethink the essence of engineering work, and management tools must be modified to meet the special requirements of forestry operations. Engineering is no longer an isolated technical task. It must now integrate technical processes with public involvement, environmental performance assessments, and public choice. A main challenge in future research and development activities will be to integrate Eco-efficiency philosophy with the well-established concept of operational efficiency. Engineering professions should also collaborate actively in the development and improvement of policy tools, as well as in the process of establishing scientifically based environmental standards for forest operations. Emerging tools, such as LCA or RA, must be tailored to foresters' specifications.

Keywords: Development needs, Eco-efficiency, Environmental analysis Environmental performance, Environmental management, Policy tools, Research, Sustainability

Introduction

In 1992, the international community accepted the concept of sustainability as a framework for future development. While many people agree with this general goal, useful ideas and tools are still lacking for implementing the projects and processes that are required for attaining environmental sustainability. Since the Rio World Summit of 1992, a dual-track policy has been adopted. At the political-programmatical level, discussion has been focused on different sets of criteria and indicators that mainly address issues of natural resource management ('best policies' aspect).

At the technical-operational level, environmental management concepts have been evolving. These provide different management, analysis, and assessment tools, and primarily consider issues of industrial metabolism ('best practices' aspect). The continuing problem is how to integrate 'best policies' and 'best practices' into the concept of sustainable development in the forest sector. Farrell (1995) has proposed several possibilities for combining these two aspects, while Galeano (1995) and Heinimann (1996, 1998a) have investigated these issues from a forest-engineering perspective.

The goal of this paper is to provide a framework that can guide future thinking about tools for implementing the general ideas of sustainability at the operational level. Because the primary emphasis here is on environmental management concepts, details of forest policy processes, such as the Montreal or Helsinki processes, will not be discussed. An analysis of the main challenges that derive from economic, social, and environmental sustainability dimensions will be presented first. Secondly, business activities will be linked to sustainability objectives, thus providing a framework of principles and tools for future development.

Sustainable Development – A Technology Perspective

Originally, environmental economists developed sustainability theory by considering the interaction of the economic system with the biosphere (Ayres 1978, Hall 1986). There is broad consensus that achieving sustainability relies on three components: economic, social, and environmental development. The United Nations Conference on Environment and Development (UNCED, held in 1992 in Rio) adopted the concept of sustainable development as a programmatic goal. The main principles and goals were documented in Agenda 21 (UNCED 1992), in which "combating deforestation" (Chapter 11), "sustainable mountain development" (Chapter 13), and "sustainable agriculture and rural development" (Chapter 14) were identified as the core activities of the forest sector. These concepts have intrinsic appeal, especially to people concerned with environmental issues. However, rigorous applications of specific principles and goals at the production and distribution levels are notably rare. To understand the problems that arise from this general model, a short review of the foundation of sustainability provides the key questions to be answered in the near future.

An economic system is intended to supply individuals and society with the necessities of life. Modern societies are based on a division of labor, which has made it possible to increase efficiency tremendously, but which has also resulted in inequalities of well-being and wealth. Environmental economics distinguishes between "natural capital", "manufactured capital", and "human capital" to differentiate the underlying concepts (Farrell 1995). Natural capital comprises the environmental assets that provide flows of ecological goods and services. Manufactured capital is generated by the means of production. Human capital refers to factors that provide knowledge, institutional arrangements, and basic values such as human rights, cultural heritage, etc. The central idea of sustainability theory is that natural and manufactured capital cannot substitute perfectly for one other (Farrell 1995). From an operational point of view, the theory of production is essential. It deals with optimizing the combination of natural, manufactured, and human capital to produce goods and services. Technology is the method by which these factors are combined, based on the state of scientific sophistication. Consequently, technological advancement is an improvement in the combination of those factors that results in greater efficiency. It is usually seen as one of the driving forces of economic and societal change. *Improving technology and controlling its deployment are, therefore, essential issues in the implementation of the concept of sustainability.* Exponents of the Club of Rome (von Weizsaecker *et al.* 1997) proposed an "efficiency revolution" as one approach to future development, because they were convinced that technological advancement offered about half the potential needed to achieve a sustainable state of development.

Sustainability theory relies on equity as a principle for social development. Its aim is to provide just distribution, i.e., a division of resource flows among different peoples, including future generations, that is fair or limited in its inequality (Farrell 1995). After the Rio World Summit in 1992, a subsequent conference focused on the dimension of social development. While planning this World Summit for Social Development of 1995, the United Research Institute for Social Development prepared briefing papers (UNRISD 1994) that identified three important problem areas: poverty, unemployment, and a lack of social integration. Important obstacles were also noted at the operational level, including the observation that the traditional institutional framework continues to lose its effectiveness in controlling human actions. Another problem is that tolerance has declined in day-to-day social relations. From the viewpoint of accomplishing projects and technical processes, human actions should minimize social impacts while maximizing public acceptance. A German expert group (Sachverständigenrat 1994) distinguished the two facets of social impacts: individual and social integrities. Individual integrity tries to guarantee minimal health and safety standards while social integrity consists of several dimensions. Burdge *et al.* (1995) have set up a framework to define these social impacts. Their concept is based on criteria such as use of natural resources, equity of risk exposure, socio-economic conditions, public health and safety, cultural heritage, and aesthetics. It is important to devise new methods for institutional guidance and control of the development and deployment of technology, and to find new procedures for improve public acceptance. The future is promising for the creation of alternative policy instruments and procedures of public involvement.

All human actions are enmeshed with the biosphere. World economies have grown in such a way that they may degrade the environment to the point where serious negative consequences emerge. Three important aspects of the biosphere limit human activities: 1) the capacity to absorb and recycle waste streams created by production and consumption; 2) the limit to which ecological services can be provided; and 3) the change of structures in the biosphere that results in system strain or damage. The publication by Meadows *et al.* (1972) was the first to quantify global environmental impacts and relate them to different scenarios of development. Nearly three decades have passed in which there have been attempts to minimize environmental impacts. At the beginning, a 'cleaning-up' philosophy, also called 'end-of-pipe solution', was used to purify different types of waste, such as sewage.

By the beginning of the 1980s, a more holistic approach was proposed for managing the flow of energy and materials from sources to sinks. This method was intended to operate on a scale that did not erode the carrying capacity of the biosphere. First proposed by ecologists, this philosophy is often called 'begin-of-pipe'. Odum (1989) states that input management requires a major change because the new focus is on waste reduction and recycling, rather than on waste disposal. *The main challenge to implementing this strategy is to integrate 'input management' with the technical and administrative processes of production, distribution, and consumption.* Since the World Summit of 1992, the newly developed environmental management concepts have included several tools and standard procedures to enable enterprises and firms to continuously improve their environmental performance.

Conceptual Framework to Operationalize the Principles of Sustainable Development

Eco-Efficiency

The Business Council for Sustainable Development participated in the preparations for the Rio World Summit in 1992. According to its president, the main outcome of the summit was the principle of 'eco-efficiency' (Schmidheiny 1992). Subsequently, the World Business Council for Sustainable Development (WBCSD). Defined eco-efficiency as creating economic values while reducing ecological impacts and resource use (de Simone and Popoff 1997). This definition covers two basic objectives that have been conceived, for example, by Galeano (1995) or Heinimann (1996). First, the world's consumers must minimize their use of environmental resources (biotic and abiotic raw materials, water, energy, and space). The second goal is to mitigate undesirable impacts on the natural environment, the social environment, and individual human beings. Linking it to economic efficiency has made this concept operational. In economic terms, efficiency is the relationship between input and output factors. Physical units, such as numbers of product or service units, measure output. Economic input factors, however, are measured differently, in units of person-hours (labor), machine-hours (equipment), or volume (fuels, materials). Efficiency measures are widely used as a particular benchmark of economic performance in firms and enterprises. Benchmarking is the study of the top competitor's product or business practices in order to improve the performance of one's own company.

Likewise, the same output measures are used to assess eco-efficiency. The first aspect, resource efficiency, relates the use of environmental resources to the amount of product or service units. Secondly, environmental waste also is related to the number of product or service units. This emerging concept is constantly being refined. The latest developments have been documented by Keffer *et al.* (1999), who provide the following definition of eco-efficiency:

> *Eco-efficiency is reached by the delivery of competitively priced goods and services that satisfy human needs and bring quality of life, while progressively reducing ecological impact and resource intensity throughout the life cycle, to a level at least in line with the earth's estimated carrying capacity.*

They have introduced eco-efficiency metrics by proposing the following core indicators:

Product output: units -- numbers or mass of a specific product or service;

Environmental Input: Energy (GJ), Materials (kg), Water (m^3);

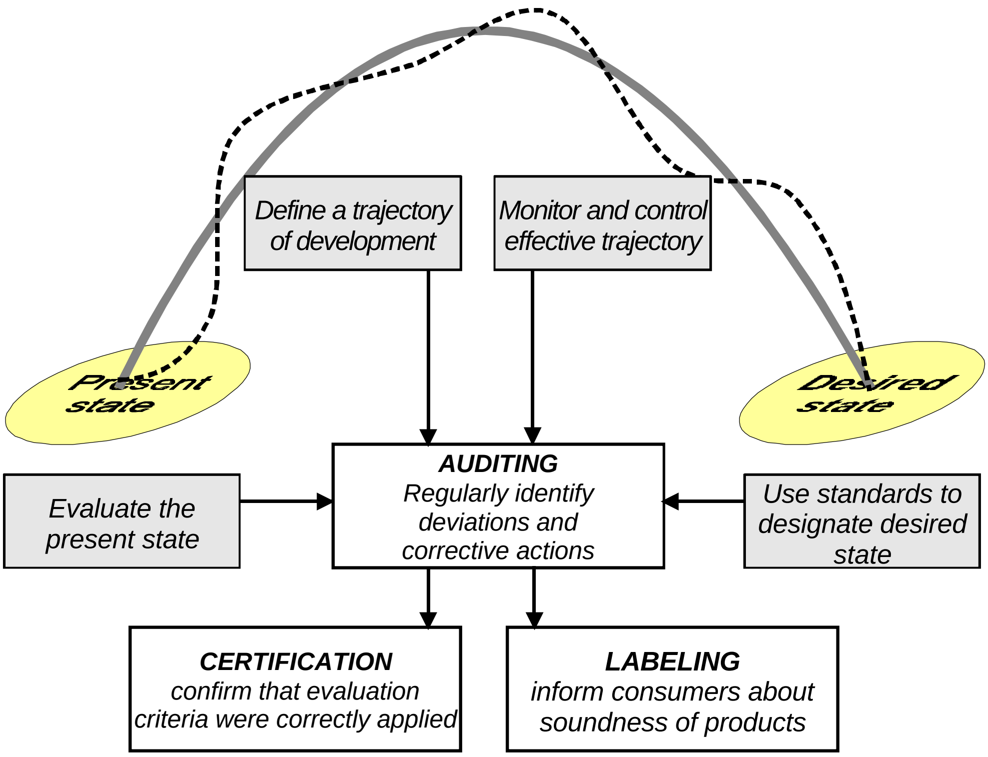
Environmental Outputs: Greenhouse Gas (GHG) Emissions (kg of CO_2 Equivalents), Ozone-Depleting Substance (ODS) Emissions (kg of CFC-11 Equivalents).

The purpose of these metrics is to enable companies to report and communicate the state and development of eco-efficiency in their businesses in a manner similar to how they communicate their financial core data. By following the benchmarking principle, comparisons of environmental performance also are possible.

Environmental Management Systems

The aim of management is to design, control, and develop administrative and technical processes that achieve specific goals while absorbing external disturbances (Fig. 1). Using an integrative management approach, environmental issues represent only one dimension of the overall system of objectives in a firm. A German study by Sachverständigenrat (1994), has followed well-accepted management principles in developing an approach to implementing environmental management. The first phase involves defining principles that will serve as general guidelines for action. Those principles may include: 1) reducing use of materials, 2) lowering energy use, 3) decreasing toxic dispersion, 4) enhancing the recyclability of materials, 5) maximizing sustainable use of renewable resources, 6) extending product durability, and 7) increasing the service intensity of products and services (Keffer *et al.* 1999). The second phase in developing an environmental management plan defines performance standards that can be measured via standard metrics.

Figure 1. Components of environmental management systems. A firm is responsible for designating its own desired state of environmental performance, evaluating its present performance, defining a trajectory of development, and implementing a controlling system. Independent bodies regularly inspect the activities to identify deviations and determine corrective actions (auditing). Communication to customers and to the public uses certificates and product labels.



The third phase deals with designing and implementing a control system that first can recognize deviations between actual environmental performance and environmental standards, and then initiate corrective actions. Making the control system functional seems to be the core problem of environmental management.

Environmental management systems integrate these three phases. They also provide additional instruments to assure quality control and to communicate environmental performance to the consumer and the public. Environmental management is a cybernetic process that continuously compares actual performance with a planned course of action, thus constantly improving production processes. The European Union enacted an Environmental Management and Audit Scheme, EMAS (EMAS 1993), to standardize this management approach. International efforts have led to a series of ISO standards (ISO 14000 series) that address different aspects of environmental management systems (ISO 14001, 1996). The Technical Committee TC 207 has been responsible for coordinating all standardization activities. Six main aspects are emphasized:

Environmental management systems -- ISO 14001 (1996) and ISO 14004 (1995);
Environmental auditing and related environmental investigations -- ISO 14010, 14011, and 14012;
Environmental labeling -- ISO 14020, 14021, and 14024;
Environmental performance evaluation -- ISO 14031;

Life cycle assessment -- ISO 14040 (1997), 14041 (1997), 14042 (1997), and 14043 (1997);
Terms and definitions -- ISO 14050.

The forestry sector has not yet followed the integrative approach of environmental management. Single components (e.g., certification and labeling) have dominated the debate, often overlooking the purpose of the whole system. The main challenge, therefore, will be to integrate principles, standards, controlling systems, and auditing procedures to align the forestry environmental management approach with the mainstream approach of other sectors. To promote this goal of integration, ISO has recently published a standard 14061 'Information to assist forestry organizations in the use of Environmental Management System standards ISO 14001 and ISO 14004'.

Policy Tools

Implementing a concept requires combining 'best policies' and 'best practices' to maximize the probability for success. From a technology standpoint, focusing too much on the 'best practices' aspect can be risky, thereby neglecting policy aspects and institutional feasibility. Therefore, it is important to understand the institutional framework and policy tools, i.e., the formalized rules and procedures for managing affairs among different groups of stakeholders. For a long time, legal compliance was the only requirement considered. The increasing maturity in a profession or scientific community leads to professional rules, such as technical standards and codes of practices, or ethics (Fig. 2). Because professional rules are voluntarily established, they cannot be enforced. Technical standards usually describe the rules for designing engineering structures whereas "state-of-the-art" rules outline the body of proven knowledge.

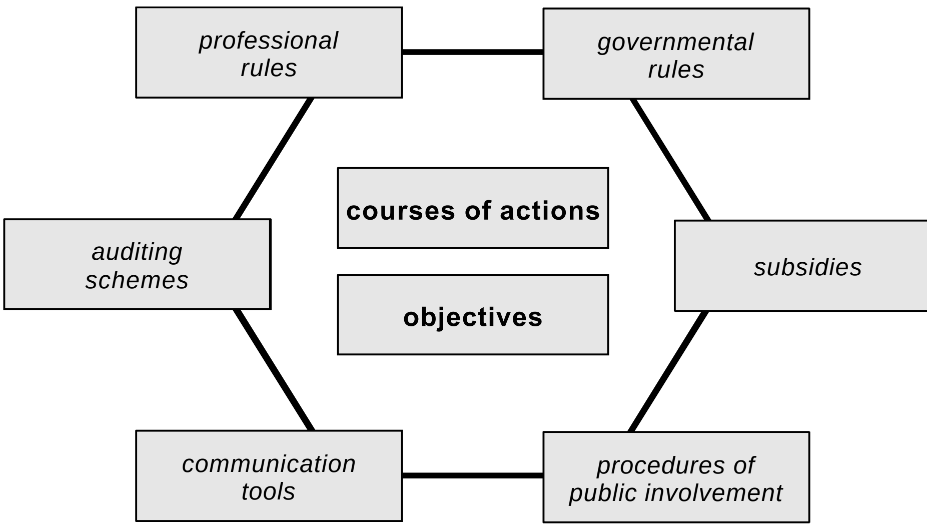


Figure 2. Policy tools building the institutional framework for action. Traditional tools (governmental rules, subsidies) continue to lose their effectiveness in controlling human actions. Novel policy instruments (public involvement, auditing, communication) aim to improve public acceptance.

During the last decade, professional groups have made great efforts to establish a set of international rules, even for the forestry sector.

The FAO model code of forest harvesting practices (Dykstra and Heinrich 1996), and the safety and health code (ILO 1998) are important contributions that should help improve the quality of forest operations and products, while minimizing adverse effects. Several countries and regions also have established their own codes of practices, particularly in Anglo-Saxon countries, and international technical standards are steadily evolving. The most advanced area seems to be in ergonomics, with about 100 technical standards already available or in preparation (Dul *et al.* 1996).

Following the 'carrot and stick' principle, the use of subsidies has been instrumental in promoting the desired courses of actions. However, guaranteeing legal compliance, proposing professional rules, and distributing subsidies do not necessarily result in their public acceptance. Because the traditional institutional framework continues to lose its effectiveness in controlling human actions, a search for new policy instruments has begun. This search considers principles such as self-responsibility, public involvement, continuous improvement, or intelligibility. Three classes of policy instruments have been emerging (Fig. 2):

Procedures of public involvement formalize the process of bargaining with different groups of stakeholders. In Forest Operations, public involvement has become a part of project-planning processes in some countries (e.g., road-network planning), where it is an essential component of environmental impact assessment (EIA) procedures (see Heinimann 1998a).

Auditing schemes are an independent review of a body's activities and operations to ensure that these are being performed or are functioning in accordance with objectives, rules, and standards. The audits identify, at regular intervals, deviations that might require corrective actions. These schemes are an important part of quality-control management that has recently been standardized (e.g., ISO 9000ff, ISO 14010, EMAS). Auditing procedures are an essential component of forestry certification schemes, as stipulated by the Forest Stewardship Council (FSC), the Canadian Sustainable Forest Certification Coalition (CSA SFM), and the Pan European Forest Certification Scheme (PEFC).

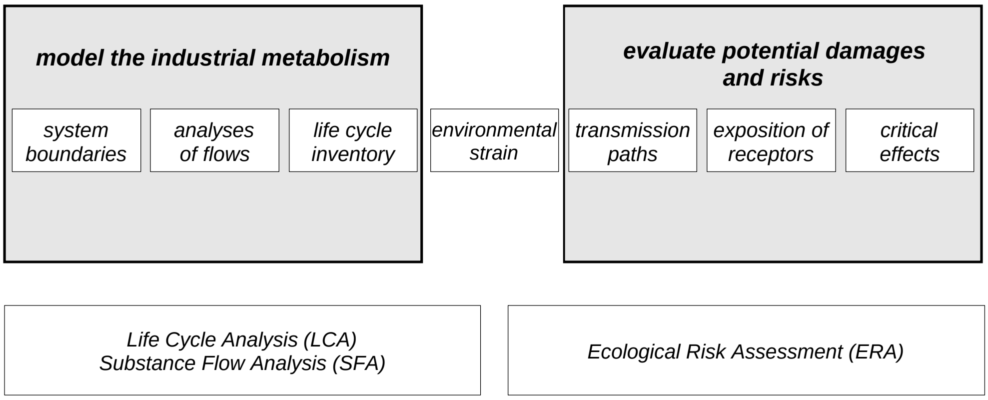
Communication tools allow consumers and the public to discern the environmental soundness of products, services, or processes. *Certifications* are formal statements of the results from a third-party evaluation, confirming that specific evaluation criteria have been correctly applied. Eco-certifications assure that a body is able to manage and continuously improve its environmental performance. *Eco-Labels*, granted by either governments or privately sponsored agencies, aim to typify products, thereby informing consumers that a labeled product has a certified environmental quality, though not necessarily better than that of a non-labeled product of the same category. Some forestry certification schemes provide specific labels (FSC, PEFC), while others do not (CSA SFM).

Traditional policy tools rely mainly on public institutions and on bans and precepts. The latest policy tools are based primarily on private institutions, self-responsibility, and continuous improvement. Adaptation of these novel policy instruments to the forestry sector is on-going; its potential will continue to develop.

Analysis Tools

To evaluate the 'best practices' aspect, analytical tools are needed for quantifying the environmental performance of processes and products. These environmental tools are formalized procedures, based on scientific principles that estimate the biophysical effects of different courses of action. They aim to make evaluations comprehensible and comparable.

Figure 3. Tools for environmental analysis. The tools to model the industrial metabolism have reached maturity while risk-assessment tools still need further improvement.



In this analysis, the industrial metabolism (Fig. 3) is described and modeled along a specific process network, using laws and principles from natural science. According to Bader and Baccini (1996), five types of system boundaries are common: 1) product, 2) process network, 3) region, 4) resource use, and 5) geogene ecosystems. Different methods describe the flow of matter and energy through a bounded system. The simplest approach is the quasi-static input-output analysis (see details in Heijungs *et al.* 1992, Heijungs 1997, Frischknecht 1998, and Hendrickson *et al.* 1998). The so-called Life Cycle Assessment (LCA) approach (ISO 14040, 1997) incorporates this methodology to derive life cycle inventories that quantify system inputs and outputs. Its acceptance has been increasing due to international standardization (ISO 14040, 1997). Bader and Baccini (1996) contend that quasi-static approaches have some major shortcomings in describing industrial metabolism under changing conditions. Therefore, they have developed a more general formalism, called Substance Flow Analysis (SFA), which uses physical laws to model the flows of matter and energy. Their approach can be used on a local to a global scale. Of special interest to forestry is work by Baccini and Bader (1996) in modelling environmental resource flow on a regional scale.

The most difficult part of environmental analysis is relating effects (systems inputs and outputs) to risks and potential damages. These effects must be linked to classes of environmental damage, such as resource depletion, global warming, acidification, etc. (Heijungs *et al.* 1992). Selecting risk categories is a normative process that is heavily influenced by the underlying value system and value preferences. Hofstetter (1998) has introduced a valuesphere model that considers three types of value systems.

Owens (1997) concluded that LCA has shortcomings that affect the appropriate evaluation of risks. He recommended using more detailed assessment approaches, such as risk analysis. Risk Analysis (RA) is a scientific framework to systematically investigate strain-stress relationships and to evaluate them using threshold values for the different dimensions of risk. Judging the tolerability of risks is a difficult process. Relying on public choice results in variable thresholds in space and time. RA was evolved in technical fields, but has recently become common in analyzing and evaluating environmental risk. Conceptual risk models (see Suter 1996) systematically identify 1) sources, 2) transmission paths, 3) exposition of receptors, and 4) critical effects (Fig. 3). Knowledge is still lacking in the understanding of critical effects; even the ISO 14042 standard (1997) was not able to present a conclusive framework. Human toxicology and ecotoxicology are emerging fields that investigate these risk issues (see, e.g., Hansson 1997).

The environmental performance of timber- and lumber-production processes has been extensively investigated (e.g., Sundberg and Svanquist 1987, Richter 1991, Karjalainen and Asikainen 1996, Winkler 1996, Zimmer and Wegener 1996, Heinimann 1998b). Analyses that consider the process network of 'timber production' are static, and rely on sweeping assumptions. Variability in site conditions, silvicultural regimes, and harvesting systems makes comparisons difficult, even impossible. Multinational efforts will help improve the quantification of environmental performance within the forest industry. A European initiative has begun a project „Life Cycle Analysis of Forestry and Forestry Products" (COST E9 program) to coordinate and harmonize LCA methodology. The program started in 1997 and should be finished by 2001. Expected results are documentation of the methodology as well as guidelines for gathering basic data on energy and matter flow.

Prospects for Future Developments

The previous phase of developments in forestry was dominated by environmental and institutional issues. Unfortunately, many people misjudged the significance of technology and engineering sciences, and their roles in sustainable development. Three major challenges arose for defining the necessary levels of technology and operations: 1) Environmental soundness of systems requires improved technologies and more efficient technical systems; 2) Careful deployment of technology relies on a more effective institutional framework; and 3) The main goal in improving future efficiency is to minimize energy and matter flow per service unit. These challenges provide a starting point for engineering disciplines to design and develop sustainable systems. Environmentally Sound Technologies (ESTs) are not just individual technologies, but total systems that include expertise, procedures, goods and services, and equipment as well as organizational and managerial procedures.

A framework is needed for guiding future thinking in transferring the sustainability concept. Eco-efficiency is an emerging principle that will allow environmental performance to be monitored in processes, firms, sectors, and national economies. First, however, the proposed metrics (Keffer *et al.* 1999) must be refined for the forestry sector. Land-use activities often imply adverse effects on watershed processes and site disturbances that should be integrated into eco-efficiency metrics. Environmental Management Systems provide the concept and tools to achieve ecological objectives within the overall business processes. To make such a system effective, a set of environmental standards is needed that goes beyond legal rules. Forest policy incorporates developed criteria and standards that are important for resource and ecosystem management. However, criteria and indicators are still incomplete at the operational level. The traditional institutional framework continues to lose its effectiveness in controlling human actions. New policy tools should help to increase acceptance of technology use via public involvement, independent inspections, and communication of environmental performance to consumers and to the public. The combined efforts of social and engineering sciences are needed to continuously improve and develop our institutional framework. Finally, to transform 'environmental feelings' into facts, we must improve and apply analysis tools. LCA essentially provides an approach to model the flow of energy and matter through a bounded system. However, relevant risks must still be evaluated. RA is a promising approach that could improve the understanding and management of environmental risks.

In bringing these options into the real world of forestry, several issues warrant consideration:

- The understanding of engineering must evolve from being perceived as a technical task to one that integrates technical processes with public involvement, EIAs, and public choice;
- The concept of operational efficiency must be expanded to consider the "eco-efficiency" approach proposed by the World Business Council for Sustainable Development (de Simone and Popoff 1997);

- A set of scientifically based environmental standards must be developed for forest operations, which relies on conceptual models for ecological risk assessment (as proposed by Suter 1996);
- Ecological aspects must be integrated into the design of forest products and processes;
- Emerging management tools must prove their usefulness. These include Enterprise Resource Planning systems (ERP) that currently are being developed by the largest management software providers (e.g., SAP, Oracle); and
- Active collaborations must be encouraged among engineering professions for improving and developing the institutional framework (e.g., adaptation of policy instruments, etc.).

In fact, sustainable development on the planet depends on resource cycling, rather than their extraction and eventual discard. "End-of-pipe" thinking must be substituted with forward-looking approaches to product- and process design. However, we are in the early days of sustainable development, and much more work is necessary in the forestry arena.

Technological Advances - Autonomous Systems as the Basis for Future Wood-Harvesting Operations

by
Antti Peltola,
R&D Mgr, Forestry Applications
Plustech Oy/Timberjack Group
Finland

Abstract

Autonomous systems are broadly defined as functions and chains of functions carried out independently, without direct human control. This narrow definition excludes partly automated systems, e.g., remote-controlled machines, unless they are able to work independently. This presentation concentrates on current wood-harvesting operations that use the most advanced technology. The possibilities for implementing autonomous systems are greater in the silvicultural sector, but the approach and needs are very different. As a rule, an autonomous machine is easily connected with machine movements, and is designed to solve problems associated only with those movements. The dilemma, however, in wood harvesting is larger than that. Wood harvesting is a part of a forest-industry chain of processes. Replacing human supervision and decision-making will be a demanding task. The vision is probably very remote for a present-day forest harvester - forwarder combination chain to act autonomously, especially for silvicultural practices in natural forests. If management trends are toward controlled, cultivated forests, the possibilities for an autonomous system are much better. Progress will be incremental, with partial automation for subfunctions expected to be available soon.

Keywords: Automation, Harvesting operation

Introduction

Forest harvesting has become increasingly mechanized during the past 30 years, with no reason to presume that the overall technical development will not continue. The factors steering this development are costs, quality of the work and the material produced, development of the overall infrastructure, and concern for the environment. Much timber is still harvested with manual tools. In this situation, technologies designed to lighten the work can significantly improve quality and productivity. At the other extreme is the fully mechanized forest-harvesting chain.

Mechanized forest harvesting has been guided both by technical development, which has offered new possibilities for developing machinery, and by changes in the infrastructure and methods of working. The progress in equipment design has been unprecedented during the past 10 years, resulting in machines with properties that cannot be utilized in many markets yet.

An autonomous system is broadly defined as one consisting of functions and chains of functions that are carried out independently, without direct human control. If one closely adheres to this definition, partly automated systems must be excluded from the scope of our discussion. For example, remote-controlled machines would not be included in this autonomous category unless they were able to work independently. In this presentation, therefore, we will concentrate on examining the different technological steps required for developing an autonomous machine or system.

Remote Control – An Intermediate Phase?

Today, the task of the forest machine operator is to control the movements of the machine by making correct choices and optimizing the parameters related to quality. Many of the functions related to controlling the machine have already been automated, and will be further improved. This work has already changed the major role of the operator to one of monitoring the so-called process and related decision-making.

Removing the operator from the machine is, in a way, the first step toward introducing an autonomous machine - i.e., by remotely controlling the machine. In fact, the first remote-controlled machines already presented to the markets have not really increased the autonomy of the machine; a few wires were merely replaced with a radio connection. This modification could have great significance, however, both for machine construction and for the operator. These solutions are significant in a "philosophical sense".

Machine

After the operator is removed from the machine, it is then possible to remove the cab, which is the "problematic" component. Ordinarily, the cab must be positioned to provide the occupant with a good overall view in all directions, and a safe and pleasant working environment. Removal of the cab would create many new possibilities for designing and lowering the cost of the machine.

Operator

Currently, it is possible to move only the operator to the work site. If the operation were to be conducted with cab-less machinery, the operator would have to carry along the machine's control equipment. Significant factors in controlling the machine and making decisions are 1) the operator's ability to see the whole situation (operative decision-making) and 2) his conception of three-dimensional space. A person's ability to perceive these matters deteriorates as the distance from the equipment increases. To be able to control the machine as done currently, the operator would have to work beside the machine, but this would compromise the worker's safety. Therefore, the operator must be moved away from the near vicinity, which means that sensory knowledge and some of the decision-making has to be replaced by other means.

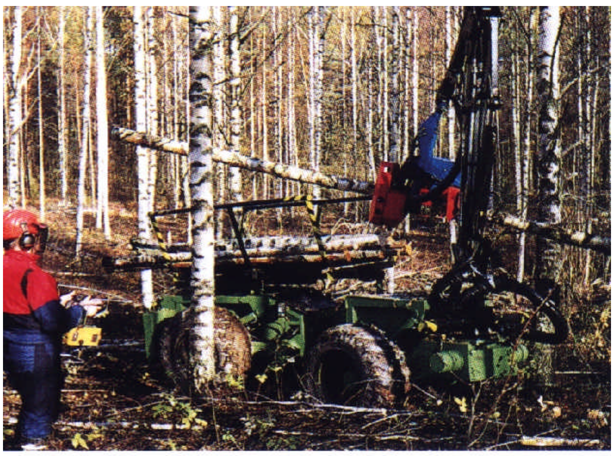
Opportunities and Problems of Autonomy

An essential factor in raising the degree of the machine's autonomy is the possibility for substituting technical solutions for sensory fact-gathering and the decision-making processes of the operator. The facets involved in automation and technological development of forest machines are:

Machine – tree interaction
Machine – terrain interaction
Machine – man interaction
Machine – surrounding information network

Advances in automation and technical development can be found for each facet, but the individual needs vary. Designing autonomous machines also requires more than identifying the interaction between man and machine. Significant innovations and their subsequent development into reliable and cost-effective products also require possible changes in the overall infrastructure and the ways in which organizations operate

Figure 1. Remote-controlled harvester-forwarder (RCM Harvester Ltd.).



Machine – Tree Interaction

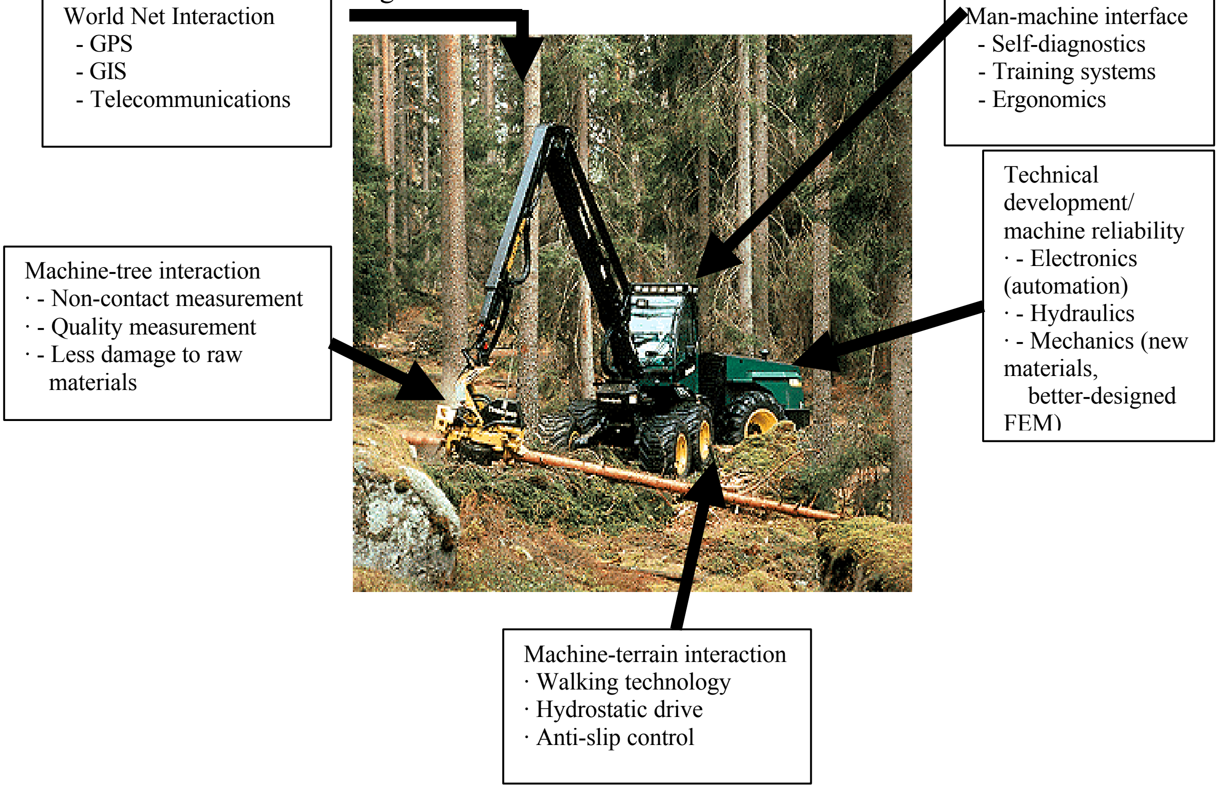
Interaction between the machine and the tree includes all work phases in which timber is moved or handled by the equipment. Increases in the degree of automation are possible, for example, in the automation of trunk feed in harvesters. Current programs can optimize and handle the trunk, based on tree dimensions and without the need for operator intervention. However, the operator is still the eyes of the machine and the decision-maker in matters relating to technical quality. Automation of the feed could be developed much further if trunk quality (straightness, knots, rot, etc.) could be measured, and this information used as a part of the optimization process. An exact method to measure quality is one of the greatest challenges when searching for new breakthroughs.

In crane control, the hydraulic six-lever control has been replaced by an electric two-lever control. Experiments have also been carried out with a single-lever control, but these prototypes have not reached the production stage. The next leap in the progress toward an autonomous machine could be automation of specific movement paths. These could possibly be realized in forwarders.

Machine – Terrain Interaction

The hydrostatic power transmission has improved control of the machine's maneuverability in the terrain, and has enabled development of new features (wheel-slip prevention, etc.). Movement of equipment is probably the technological area with the greatest challenges for developing autonomy. The introduction of GPS technology has lowered the price of applications to a reasonable level, and their accuracy is sufficient for many purposes. "Follow-the-track" or pointing out the drive route on the map is already possible, in principle. The accuracy of maps, which is naturally one of the key issues when developing new modes of operations, is improving very quickly.

Figure 2. Machine interaction with environment.



Machine – Man Interaction

The operator now is the most important component of the machine. Changes in the goals of forest-harvesting methods, as well as in objectives and logistics, have caused significant revisions in the operator's job description. The objective of simplifying the user's interface with the machine is very much in line with that of increasing the level of autonomy. Developing a clearly more sophisticated user interface is very challenging. The worst bottlenecks historically were caused by computer capacity, but current problems lie in designing expertise systems that are sufficiently comprehensive and versatile. At present, the operator has a very significant role in controlling the machine under changing environmental conditions and production requirements. An important intermediate goal is to develop the automation systems that serve this part of the machine, and to make them simpler and more straightforward.

Machine – Surrounding-Data Network Interaction

Today's forest machine is no longer simply equipment, but an integral part of a logistícal timber-supply chain. The future surrounding-data network will have even greater significance, as information relating to the job in question is sent and received through it. So far, the information has mainly been related to desired dimensions and optimization of tree trunks, and to production reporting. New issues include digital maps, geographical information (GIS), and GPS navigation systems. The amount and availability of information will improve, making these technologies much more versatile. The current forest machines mainly utilize ready-made and analyzed information, but one of the most significant future tasks could be the creation of information and correction of errors in that information.

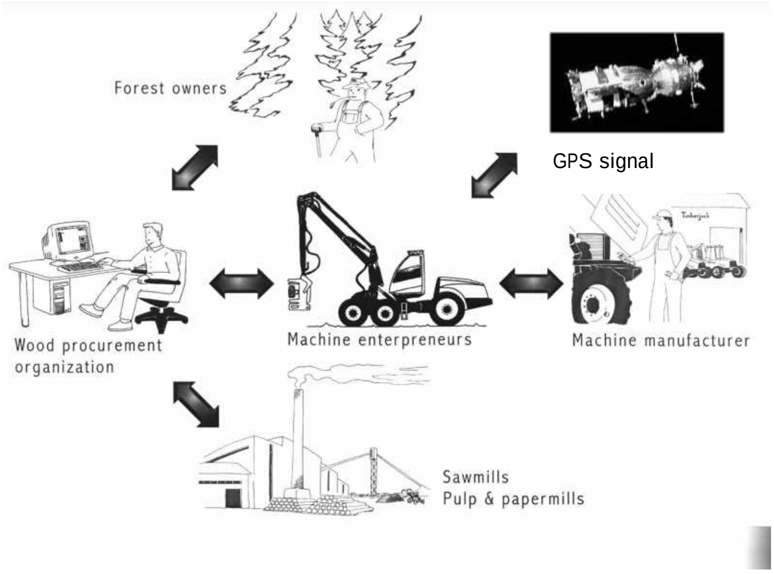
The biggest problem today is the great differences in standards and methods among countries and companies. Data are saved in different formats and with various standards of data communication. Efficient utilization of the already existing features requires harmonization of the concepts.

The increasing speed of data communication will bring entirely new opportunities. In a few years, the transfer of image and sound will probably be an everyday phenomenon. Internet trading will also rapidly become a common practice, bringing new possibilities and challenges. Today's goals and functions were based on the production-control requirements of the forest industry. Another approach, at least with more valuable wood, may be the buying and selling of timber from the seller's point of view. The material produced/yet to be produced would be offered to the market, with trading done in the same way as company shares. This, however, would require changing and developing logistics systems that could control individual logs rather than trade batches.

Maintenance

The machine operator still plays a very important role in its maintenance, being responsible for daily servicing and on-the-spot small repairs. Machine stoppages and waiting times are expensive for the contractor. Fault-finding diagnostic systems in the future may be used to improve preventive maintenance. Servicing, however, is an issue that will have to be significantly developed, in order to raise the degree of autonomy of the machine.

Figure 3. The current information network of a harvester system.



Conclusions

It is a long process to develop an autonomous machine or machine chain. Functions related to human senses and logical decision-making must be replaced by technical solutions. The challenge is great because regulations concerning the quality of timber will most likely be tightened concurrently. The conversion of a present-day forest harvester - forwarder combination chain into one that acts autonomously is probably very far away, especially if silviculture is practiced in natural forests. Moving management practices toward more controlled, cultivated forests will make an autonomous system much more possible.

Another vision often proposed is that of the contractor controlling operations from his home, and following the progress with his own monitor. Whether moving the operator/process controller away from the harvest site is a positive development is more of a question of values. Another possibility is to further improve working conditions so that several processes can be controlled on-the-spot. An intermediate solution would be of the Master - Slave type, where several machines are controlled by one operator. The machines could carry out simple, easily defined tasks but, in more demanding cases, the control and decision-making would continue to be the responsibility of the operator.

Strategies and Methods for Choosing Technology: Perspectives for Development Projects Based on Scandinavian Experiences

Abstract

Sundberg's model, work studies, and cost calculations were compared to select the most appropriate technology for a wood-harvesting project. The main criterion was cost–effectiveness, to be met within the limits of environmental and ergonomic requirements, and within the historical role of Scandinavian logging technology in a forest cluster. Cost-effectiveness appears to be a good basis when choosing technology, but future perspectives also must be contemplated. In an open, global economic system, development is also dictated by new demands placed on the forest cluster. Cost-effectiveness has become an extensive indicator that must now consider the total costs and benefits of logging practices, industrial processing, and marketing. Continued progress in this direction will depend on environmental, societal, social, and cultural sustainability. In many countries with special forested areas, environmental aspects dominate forestry decision-making. There, the impacts of technology on the environment may be the main criteria when choosing a level of technology. The market economy, together with a functioning national innovation system, provides additional creative material for the selection process. Production is still viable at the local level (within suitable areas), but the most significant advances within the forest cluster seem to be made primarily within large global companies. This process is best supported by directing funds toward research and development activities, and by promoting the appropriate circumstances under which companies can compete.

Keywords: Choosing technology; Development project; Timber harvesting.

Introduction

In this paper, we will discuss the general utilization of basic, intermediate, or sophisticated forestry technologies. The level of technology suitable for a particular society usually is predicted through economical calculations. A more detailed analysis is then needed to choose the actual work methods and machinery. Work studies and cost calculations are often used for predicting the cost-effectiveness of different technologies. When sustainability or societal impacts are studied in more detail, however, one must also analyze such elements as enterprise environment, level of organization, infrastructure, social status, culture, and the society's particular traditions. For example, the application of technologies differs at the village-, industrial enterprise-, or government organization level. The same is true if we direct development toward either a 'centralized metropolis culture' or a 'decentralized local production culture' (Sarmela 1982).

To illustrate, the old industrial traditions and underlying ideological factors in Russia make it difficult for managers to accept, at a minimum, an intermediate level of technology, even if this level were certainly more cost-effective than sophisticated technology. This response persists, despite serious problems with unemployment and the promotion of intermediate technology, i.e., the use of chainsaws instead of harvesters.

Development specialists are divided in their opinions on the usefulness of 'grass-roots level' projects. Some say these projects have no influence on societal structure, while others believe that they are the most effective means for alleviating poverty. These two opinions do not seem to exclude one another. Reports by Pehu (1993) and the International Fund for Agricultural Development (IFAD) contend that grass-roots projects must address the very processes that lead to poverty, rather than merely distributing the aid. This influence need not change the structure of society, but only the processes within that structure. The result could be the creation of new economic activity related to production, rotation of money on the local level, and even the creation of a consciousness of their rights among the people. Grass-roots projects may be the only solution in a corrupt society from which capital flows out of the country. The target group, however, must be able to control the prerequisites for production. An innovative atmosphere at all employment levels may promote the successful application of technology and help with the transition to its next level.

Development may be approached in several ways, according to technological, economic, environmental, societal, social, sociological, and/or cultural traditions. The approach is mainly technological, economical, and societal. Case studies have described a society with poor infrastructure and old industrial traditions, where production had collapsed. The educational level was high and this society was trying to move from a centrally planned economy to a market economy. We therefore assumed that:

technological and economical developments are important factors for societal development,

production must be economically profitable and environmentally acceptable, and

social and environmental aspects are important to guarantees of societal peace and fulfill the perception of justice among the people.

The winning strategy must encourage profitable production, the formation of capital for industrial investments and societal needs, and long-term, overall improvements. This strategy must also be acceptable to local authorities and the local people. The objective of the study described here was to compare the conclusions drawn from Sundberg's optimization function (Sundberg and Silversides 1988), work studies, and cost calculations (in the context of historical progress in Finland and other Scandinavian countries), as well as to locate the strategies for development behind their progress.

Materials and Methods

The approach applied in this study was somewhat hermeneutic and historical. The historical progression of logging operations, especially in Scandinavian countries, was analyzed intuitively to identify the strategies behind their development. Recent projects in Russia were used as examples for testing ideas. Sundberg's theory is based on having logging costs at a common level, whereas work studies and cost calculations analyze alternative technologies more thoroughly. Historical analysis may also include global perspectives and environmental, societal, social, and cultural aspects. Some observations were also made on how to make a technological choice that is acceptable to decision-makers.

Results

Application of Sundberg's Model

Sundberg has derived optimization functions to predict the most appropriate level of technology for forestry operations (Sundberg and Silversides 1988). The functions solve for the labor and machine inputs that will generate the lowest unit costs for a logging operation:

$$L = \sqrt{\frac{bd}{e}}$$

$$M = a + \frac{b}{\sqrt{\frac{bd}{e}}}$$

where:
a, b = constants
d = cost per unit input of machines (M)
e = cost per unit input of labor (L).

The basis for deriving the optimization functions is a hyperbolic equation that indicates possible combinations of labor and machinery for implementing a specific logging operation. The following equation was formulated:

$$M = a + \frac{b}{L}$$

The constants *a* and *b* for some logging operations were predicted with a regression analysis that used time-study results. The constants were then placed into the optimization functions to calculate the optimum combinations of *L* and *M* at different labor-cost levels. Finally, the different levels of technologies represented by the various labor and machine combinations were examined, with results shown in Table 1.

This prediction only roughly estimates the most profitable level of technology. Some forest operations that are too heavy for people or animals must be mechanized (e.g., long-distance transport). In the Russian example, application of Sundberg's model resulted in a recommendation that intermediate technology, (e.g., chainsaws) would incur the lowest unit costs.

Application of Work Studies and Cost Calculations

In Finland and many other industrialized countries, the development of logging operations has largely been based on the results of work studies and cost calculations. Therefore, methods and machinery have been chosen according to their cost-effectiveness within the limits set by ergonomic and environmental requirements. Data from "real life" ave confirmed these study results. An evolution toward economically tenable solutions has been considered the only sustainable means of development in the market economy.

Work studies also provide comparisons among different work techniques, methods, equipment, and machines within a level of technology. As with Sundberg's model, comparative studies also suggested that intermediate technology, i.e., chainsaws (motor-manual work) rather than harvesters, was the most cost-effective choice for cutting in Russia (Sikanen *et al*. 1996). Motor-manual cutting can be applied through either CTL or tree-length harvesting; bucking can be done at either upper or lower landings (terminals); etc. Work studies and cost calculations allow comparisons in any of these situations. In one case study in Russia, calculations indicated that the traditional tree-length method was more cost-effective when used with bucking at an upper landing rather than at the traditional terminals. Ultimately, however, the CTL method seemed to be the most cost-effective alternative, especially for selective cuttings, but also for other logging methods (Harstela 1998). The greatest need identified for improvement was in loading for long-distance transport.

Today, the choice of appropriate technology cannot be based solely on logging costs. One must also pay attention to the costs and benefits along the entire production chain, from forest to market via the wood-processing industry. Timber quality and environmental and social factors also require consideration. Work studies and cost calculations are the basis for more comprehensive logistic studies.

Although these studies illustrate only the static situation, the results suggest a direction for development. The work studies in Finland and Sweden were supplemented with prognoses of current trends for labor and machine costs, and the most profitable mechanization level (e.g., Mikkonen *et al*. 1975). Although these prognoses could not precisely forecast the development of mechanization (Harstela 1993), they demonstrated that possibilities for new methods and machines should be investigated. Mechanization itself depends on economical progress and innovation that, for the most part, are still unpredictable. Therefore, one strategy for promoting development is to create an atmosphere for innovation. The question remains how this will be accomplished.

Table 1. The most profitable level of technology, according to daily wages for logging.

Most profitable level of technology	Daily wage of a worker, USD/day
Basic technology	… 20
Intermediate technology	10 … 40
Sophisticated technology	30 …

Development of Finnish Logging Technology as Part of the Forest Cluster

During the last few decades, CTL logging has been intensively developed in Sweden and Finland. These countries have taken a leading role in upgrading both the entire CTL technological environment and the machinery. What was the basis for these efforts that necessitated innovations and organized industrial structures? The societal environments were market economies, which still have some barriers to international trade but have become more receptive to the outside world. An open and extensive exchange of information has also occurred, especially among Scandinavian countries. The strategy of large forest industry corporations is to support institutional research, while maintaining their own research personnel. Governmental assistance is based on providing occupational education at all career levels, funding research institutions, and supporting new enterprises and innovators.

Innovations have come from all levels of occupational organizations. In the 1970s, training for forest workers was organized so that forest work became a respected occupation. In addition, a piece-rate payment system and the creation of an economically independent small-contractor system caused forest work to become relatively free of supervision. Various innovations relating to work techniques, methods, and forest machines originated from the workers, contractors, or other persons involved with the actual work. This has conformed well to innovation theories, which emphasize that identifying a need is a basis for innovation. Many professional foresters, researchers, and small and large manufacturers also assisted in identifying these needs. Consequently, this national innovation system produced material for work studies, which were necessary for selecting the most cost-effective technologies. Because they foresaw the need for continuous development and mechanization, large companies were willing to share in development costs while gaining experience from the running of prototype machines.

The development of a strong forest cluster and strong interactions between forest and wood-product industries, may also explain the development of logging technology in the Scandinavian countries. According to Porter's "diamond model" (Porter 1990) for industrial development (particularly for knowledge-intensive industries), favorable development occurs when "factor conditions" closely interact. These include the firm's strategy, demand conditions, and its supporting industries. The Scandinavian forest industry has developed from rather simple wood-working into a high-tech industry.

In Finland, the actual forest cluster includes traditional forestry; all branches of mechanical wood-working; the pulp and paper industry; as well as related machine-manufacturing, chemical, electronic, information technology, and energy-production industries. The question of why this cluster developed in Finland is not simple. However, Finland is rich in forests and, consequently, its forest industry has long had a strong impact on the national economy. After World War II, the resulting peace treaty imposed heavy war compensation on Finland. This influenced the development of machine manufacturing. The forest industry closely cooperated in this process. A unique form of collaboration among corporations involves sectors from timber procurement to marketing of products. Development has also been furthered by Finnish stockholders and industrial leaders willing to invest in Finnish industry (Kuisma 1993). The strong and growing corporations of the forest industry have opened markets for forest machinery and also enabled new logging technology to develop.

The open market-oriented society also has created wood-working enterprises and technology that are more suitable for small-scale logging operations, mainly by small landowners (e.g., farmers). Government policy now supports new enterprises, especially in under-developed regions. The many-faceted forest sector has included both large industrial companies and small enterprises that operate mainly within local markets. Today, that economic environment has changed. What will the future be like?

Perspectives for the Future

Liberalization, globalization, and technological advancement are the key words for mega trends in an international economy that lead to the "smile-phenomenon". There is only room for either increasingly larger, often global, corporations or for small local enterprises (Miller 1995). The companies in between these extremes will have difficulties. Although small companies are often innovative and make new openings, they lack the resources to support many-sided and high-tech expertise. This kind of development, toward a ‘two-bole system’, has been evident in both the forest industry and forest-machine manufacturing. Mega trends exist at a common level. Elsewhere, however, the future remains highly unpredictable and enterprises must foster an ability to respond quickly to new demands.

The ‘big-me’ scenario, based on material growth and rotation of materials, has faced some setbacks. This rotation of material demands a seemingly excessive amount of energy. The alternative ‘just-do-it’ scenario, sets out to do more with less. Information technology seems to follow this strategy. The forest industry must improve its materials technology. From an environmental point of view, the energy required for transport is a problem for all global production networks (Andersson 1993). This factor leads to a future in which both the large global corporation clusters and the small local production units will be involved in simple, heavy production. In addition, the small innovative enterprises may be able to control new technology in a specific narrow field of expertise as part of the production network.

For the forest cluster to maintain a leading role, it must develop its own high-tech methodology (Kettunen 1998). Research and development (R&D) and the maintenance of a high level of knowledge have now become the main strategies for cluster development. This has also been government policy in Finland. For instance, special funds have been allocated to the forest cluster’s R&D program. According to the diamond theory, a cluster develops only if all its parts are improving. This makes it difficult for some regions to compete against a particular region with a stronger and more complete cluster. In this case, one country may be too small a home base for a forest cluster as companies become globalized. It is then possible for a new region either to become part of a global corporation or production network, or else target its production for only local consumption.

Delphi analyses were used in a continental search for the most prominent areas of technology having the greatest potential. Three sectors were selected as most interesting: information technology, bio-technologies, and material technologies (van Zon 1992). Although ‘the forest cluster’ was not included, one must remember that the Delphi analysis is not a highly reliable forecasting method because it is based on an expert’s opinions and experience under current conditions. Because Finland’s forest cluster incorporates technology from all the areas that were selected, this may well provide synergy for the cluster’s own R&D. Forestry, therefore, has only to find and develop its own technology.

Environmental Aspects as a Basis for the Choice of Technology

In some countries, or in areas of special natural value or with sensitive ecosystems, the environmental impacts of timber harvesting dominate the choice of technology. Schmincke (1993) has argued that we must find balance between conservation, maintenance of biodiversity, and economic development so that the overall benefits are maximized. This may require developing more environmentally conscious logging technology for indigenous forests, although this often increases logging costs. The other alternative may be to stop commercial logging operations in those areas. In North American discussions of CTL versus tree-length logging methods, the main argument for increasing cut-to-length logging has been its favorable environmental impacts (Guimier 1999), although its application may also entail favorable logistic costs.

Environmental sustainability is an appealing concept as a basic requirement for all technologies; public pressure apparently is continuing in this direction. In open markets, however, production costs cannot exceed market prices; therefore, cost comparisons are valid even in situations where environmental aspects might dominate the debate on technological choice. Current environmental restrictions that are based on international agreements enable equal competition for companies in different countries, but this seems to be a slow and ineffective process for effecting competitive balance. Therefore, national and occupational responsibilities for environmental sustainability are required.

Discussion

If the future is to be as illustrated above, the strategy in a country such as Russia may be based on tailoring production to local markets, or embarking on joint ventures with global giants. Enterprises may also try to look for new, innovative openings that apply existing technology to local circumstances. To involve all occupational levels in the innovative development process and to create a good work ethic, occupational education and training should be an essential part of the project. Participatory leadership, open and lean organizations, and innovative teamwork are also ways to build up an innovation system within the enterprise.

Managers in Russia often want the most advanced technology possible for their logging operations. This may mean utilizing harvesters instead of chainsaws, even when cost calculations indicate the latter is more cost-effective. In developing Scandinavian logging technology, cost-effectiveness has been the favored basis for technology selection. The options when preparing for future changes, however, may include further mechanization. In the case of Russia, this would mean applying a more-intermediate level of technology, e.g., large-scale use of chainsaws, along with a few harvesters to gain experience for the future. This application fits a societal situation with serious unemployment. There, local authorities were presented with two alternatives to demonstrate the flow of capital during a timber sale to Japan: if harvesters were purchased, most of the capital would flow to a foreign country. Alternatively, if chainsaws were to be used, a larger portion of the capital would remain with local workers and enterprises as profit, which could then help renew local industries such as sawmilling.

In some autonomous republics in Russia, the strategy has been to contract private enterprises to manage both forestry and logging operations. Other regions have centralized their forestry and logging around government enterprises. There has been some discussion about which is the better way, from silvicultural, environmental, or economic points of view. This is not, however, a simple question in a society that is not free of corruption and which is in economic disorder. Although favorable development in logging technology has occurred within the Scandinavian market economy, forestry legislation also has established restrictions, which have also been enforced. This development was led by educated foresters within large companies and was supported by research. Perhaps one way to unite private entrepreneurship and Russian government responsibility would be through organizations of small logging contractors under the supervision of a government enterprise.

How will logging technology develop in the future as a part of the forest cluster in Finland? Today, three large, increasingly global companies exist along with several small companies. The large corporations are no longer willing to exchange information because they are large enough to maintain their own R&D activities. Knowledge and information have become the means for competition. Universities and research institutes must cooperate directly with companies to maintain their own competence while increasing their synergistic role. Although actual research results are confidential in cooperative projects with companies, the common, updated knowledge benefits the whole cluster. Most large companies no longer own their forest machines – these are both owned and operated by small contractor enterprises. Government policy still enables global enterprises to maintain their operations in Finland under favorable circumstances. Likewise, R&D activities enjoy government support.

New requirements for quality and grading of timber are part of the scenario of doing more with less. In fact, new assortments, even for pulpwood, may soon be a reality. Although this may entail increased costs for logging and transport, total costs may decrease, or the benefits to manufacturing might be sufficient to cover these extra costs. When cost-effectiveness is the criterion for choosing a technology, the analysis must cover all costs and benefits, from the forest to the end-user markets. Logistics will be an important aspect in timber procurement. New international commodities will be made from the hardware and software of information systems that plan and control operations, as well as from the knowledge to operate them.

What happens at the grass-roots level of machinery design? Who will pay the costs of testing prototypes? Large forest-machinery manufacturers currently have enough resources to cover these costs, but how will small, innovative manufacturers be able to succeed? One solution to this problem has been to introduce government funds for R&D programs that develop and study new machinery.

Conclusions

Cost-effectiveness, within certain environmental and ergonomic limits, appears to be a good basis for the choice of technology when future perspectives are being considered. Sundberg's functions provide a starting point in the search for the suitable level of technology that is appropriate for a particular country. However, the actual selection of technology must be based on detailed work studies and cost calculations. In an open, global economic system, new demands have been placed on the forest cluster. Therefore, cost-effectiveness is now an extensive indicator that must also incorporate the total costs and benefits of logging practices, industrial processing, and marketing.

A market economy, together with a well-functioning national innovation system, will drive development and provide innovative material for the selection process. Local production still exists within suitable areas, but the main areas of development for a forest cluster seem to arise from large global corporations. The key strategy in supporting development efforts within a country is to direct funds toward R&D activities, while also making circumstances favorable in which companies must compete. In the end, this is a selfish policy, because it holds market forces responsible for development, and does not guarantee fair distribution of the benefits from natural resources on a global scale.

With large-scale production apparently centered within global enterprises, regional development depends on its attractiveness to these big companies. Unfortunately, some specialists believe that economic liberalization and globalization will lead to extended polarization of countries and their citizens, rich and poor (Korten 1996). However, this mega trend is outside the control of an individual project whose goals are to adapt local development to global trends or else promote small-scale local production.

Abstract

The objective of this research was to evaluate the economic benefits derived from public investments in research and development of a computer system. This system, SISPLAN, is designed to perform simulations on growth and productivity for afforestation and reforestation of *Pinus* in southern Brazil. Criteria can be generated for production planning and reforest management, thereby reducing the uncertainties associated mostly with forest activity planning. This is especially important in cases of technical-scientific knowledge that are not incorporated in production means, because it is generated during field-research activities involved with the ordering, handling, and management of the forest. The methodology consists of identifying the costs and economic benefits derived from the generation, utilization, and maintenance of the SISPLAN technology. The framework of this research is to provide the estimated economic impact, using the cost-benefit technique. Utilization of this system generates information that contributes to improving efficiency in the productive sector and effectiveness in public policies. Economic gains to Brazil were estimated at $77.2 million in 1997 (net present value), with a cost-benefit ratio of 55.7. This indicates that the research is an attractive economic investment.

Key words: Forest management; Information technology; *Pinus* spp.; Research evaluation.

Introduction

Technical change is widely accepted as an important determinant of growth and competitiveness. The pioneering work of Schultz (1954), Griliches (1958), and Mansfield (1968) documented the contribution of research to increased productivity, and provided the first measurement of economic returns from public and private research. Since then, economists have improved the methods for analyzing sources of aggregate productivity growth, as well as the factors responsible for the growth of the different sectors that make up national economies. Within the primary sector, most of these efforts have been toward crop and livestock production (Echeverría 1990). However, considerable interest and intellectual efforts also have been developed for measuring the benefits and returns to forestry research (Herruzo 1997). In general, the empirical results have indicated high economic returns for public and private investments in forestry research (Hyde *et al*. 1992).

The scientific literature deals principally with cases involving forestry research in physics, chemistry, and biology. However, a virtual methodological and empirical vacuum exists in areas of evaluation analysis for research in forest resource economics, forest management, and other disciplines that focus on improving the organization and planning of forest activities. (See Smith and Pardey's 1997) discussion of this in comparison with agricultural research.) This lack of evaluation studies has at least two negative outcomes. First, it is difficult to determine whether current expenditures in forestry economic research are adequate. Second, the lack of studies precludes comparing the social gains from forest economics research with the social gains derived from other research activities for which quantitative estimations may be available. The latter situation could place forestry economic research at a disadvantage when personnel are competing for scarce research funds.

One of the main problems in trying to compute the economic benefits of research activities is to determine the vehicle by which a particular type of research contributes to increasing social welfare. Results of forestry research activities performed in experimental sciences often materialize in the knowledge embodied in new processes and products, whose impact can be easily identified. On the other hand, forest economics and management research produces disembodied technical knowledge, in the form of new information, which may allow decision-makers to enhance productivity and economic welfare. In the latter case, however, the steps necessary for manifesting these benefits are less tangible and more difficult to measure directly. This could be one reason why empirical information on returns for this type of research activities is relatively scarce. Fortunately, the new information technologies, i.e., innovations oriented toward rapid and automated processing of information, are broadening the chances for transmitting "organizative" knowledge of the type generated by forest management research. We are presenting our results within this new context.

The objective of this analysis was to assess the economic benefits of a new silvicultural management tool, the production simulation system SISPLAN. This computerized projection system was developed in 1988 by the National Center for Forestry Research of the Brazilian Agricultural Research Corporation (*Embrapa Florestas*). It was designed to spawn new criteria for improving the planning and organization of *Pinus* plantations in southern Brazil.

The SISPLAN Technology

The origin of SISPLAN is better understood within the context of the recent Brazilian reforestation process. As part of its reforestation policy, the Brazilian Government implemented a broad program of fiscal incentives from 1966 to 1987 to induce reforestation with exotic species *Pinus* and *Eucalyptus*. The objectives of this fiscal-incentive scheme were two-fold: satisfying a growing internal demand for forest products while also slowing the increasing environmental costs of deforestation of native species. As a result of this program, the area reforested with the above-mentioned species increased from 600,000 ha in 1967 to more than 6.5 million ha in 1992. About 89% of this activity was realized through a fiscal-incentives program. The newly reforested area of *Pinus* was 1.06 million ha in southern Brazil alone (Bacha 1993, Antonangelo 1997). Program beneficiaries were required to follow a set of pre-established guidelines with respect to silvicultural practices, such as rotation age and the number and timing of thinnings. These management guidelines were based on limited information gathered from different sources available at the time. The use of forest management was justified by the increase in newly planted *Pinus* forests, together with diversification of potential uses for wood that resulted from changes in product prices.

Information technologies play an increasingly important role in the technical and economic administration of production processes, both at the management level and at the level of the decision-making centers. However, more-effective procedures are lacking to facilitate the knowledge diffusion on available silvicultural practices. Ultimately, this knowledge would facilitate the adoption of new technologies more adapted to increments in forest productivity, improvements in wood quality, and evaluations of the beneficial impacts to foresters and wood-based industries (Oliveira 1995, 1997).

The SISPLAN technology combines a production simulation model with financial economics methods (Oliveira 1995). This computerized system makes growth and yield projections based on the age of populations for specific location and management variables. Ultimately, it should facilitate organization of the newly available information about silvicultural practices and transmit it to foresters in a way that could be easily incorporated into their decision-making processes. Since 1989, the SISPLAN software has been used as a decision-making tool in managing more than 500,000 ha of *Pinus* plantations in southern Brazil (de Alencar 1999). To a lesser extent, SISPLAN is also being used in other areas of Brazil as well as in other Latin American countries. It has contributed to the adoption of more efficient management regimes, thereby increasing the profitability of forestry activities in those regions.

This technology consists of three modules: 1) SISPINUS software that simulates the thinning, annual growth, and distribution of wood for multiple uses as a function of log-diameter classes; 2) PLANIN software that calculates parameters of economic and financial evaluation, and analyzes sensibility of the profitability at different discount rates; and 3) REPLAN software that generates a database of the profitability for different systems of management in forest populations, as a function of, among other variables, clear-cut, site index, and discount rates. Integrating the three modules allows us to obtain a combined vision of the biological and economic factors. It also allows for the simulation of different scenarios in production planning as a function of different destinations for the wood, changes in the prices, costs, and discount rates (see Oliveira 1995, 1997).

Methodology

The evaluation approach used in this paper for estimating benefits and returns to research from SISPLAN is based on Marshallian welfare theory. It follows the evaluation approaches to forestry research assessment adopted by Huang and Teeter (1990) and McKenney *et al.* (1991, 1993, 1996), among others.

Private benefits of research are determined by the extra production due to new silvicultural methods induced by the new technology (the production projection system SISPLAN). Total net benefits (economic benefits) of research are obtained by subtracting the cost of research from the total private benefits. A new technology derived from research is considered profitable if it generates positive net benefits. Given the long time span of forestry investments, a large part of the research benefits have not been realized yet, even though the SISPLAN has been available since 1989. For this reason, the analysis has a double nature *ex ante* and *ex post*.

The changes in Marshallian economic surpluses that are induced by research depend on market conditions (demand and supply-price elasticity), and on the nature of the supply and demand shifts. In many research assessment projects, particularly in agriculture, demand and supply conditions are explicitly modeled. In forestry, however, obtaining information about these conditions is difficult, and a long span exists between the time of research and when production is changed. Therefore, evaluation approaches less sensitive to market conditions usually are employed (McKenney *et al.* 1996). We have adopted this strategy in order to assess the economic gains of research and development of SISPLAN technology for this paper**.** The extra production attributed to research is valued at a single market price (current price). It assumes that the supply curve is vertical and shifts against a horizontal demand curve. Total private-research benefits are then measured by the change in the expected value of the extra productivity. (Thus, although economic surplus changes may not be explicitly measured, economic surplus calculations are still implicitly being made when net present values are calculated to place a value on the extra output attributed to research; see Alston *et al.* 1995.)

The model developed below assumes that the availability of the SISPLAN technology provides foresters with information conducive to adopting more-profitable silvicultural methods. This increase in profitability may be caused by one or more of the following circumstances: 1) selection of the optimum rotation age; 2) selection of optimal thinning regimes; and 3) increased timber value when production is better targeted to industrial uses.

Private benefits (on a per-hectare basis) derived from adoption of the technology are obtained by subtracting the net present value (NPV) of the traditional management regime from the NPV of the most profitable management regime (simulated with the SISPLAN). The optimal forest rotation age for commercial harvest is given by Faustmann-Pressler-Ohlin's well-known formula (hereafter referred to as FPO), which maximizes the NPV of timber harvest by considering infinite plantation cycles (see Samuelson 1976, Hyde 1980, and Johansson and Löfgren 1985). The simplest expression of the FPO formula is:

$$NPV = [I(t)\ \ e^{it}\ \ \ K]\,(1\ \ \ e^{it})^{1} \qquad [1]$$

where NPV = net present value of timber harvested at time t ($/ha); I(t) = timber revenues; t = rotation period; i = discount rate; K = cost of production.

Following Romero *et al.* (1998), Formula [1] can be extended to a more general forestry context as follows:

$$NPV = \ I(t)\ \ e^{it} + \ \ {}_{h} R_{h}\ e^{ih}\ \ \ K\ \ \ G\ {}_{0}^{t} e^{it}dt\ \ \ T\ {}_{0}^{t} e^{it}dt\ \ \ \ {}_{s} M_{s}\ e^{is}\ \ \ E\ \ e^{it}$$

$$(1\ \ \ e^{it})^{1} \qquad [2]$$

$$h = h_1, h_2, \ldots$$

$$s = s_1, s_2, \ldots$$

The symbols and variables from [2] are defined as: I (t) = sales revenue derived from final felling; t = rotation period; i = discount rate; R = cash flow associated with the thinning operations; these operations take place in subperiods h_1 , h_2 ,...... ; K = planting costs; G = general annual management payments; T = annual technology payments; M = payments associated with cultural operations; these operations take place in subperiods s = s_1 , s_2 ,..... ; E = harvest costs. It is assumed that annual expenditures are distributed evenly throughout the year.

By performing simple algebraic operations on [2], the following general expression for NPV is obtained:

$$NPV = \ I\ \ e^{it} + \ \ {}_{h} R_{h}\ e^{ih}\ \ \ K\ \ \ G\ \ i^{1}\ (1\ \ \ e^{it})\ \ T\ \ i^{1}\ (1\ \ \ e^{it})\ \ \ \ {}_{s} M_{s}\ e^{is}\ \ \ E\ \ e^{it}$$

$$(1\ \ \ e^{it})^{1} \qquad (3)$$

Sales revenues derived from final felling and thinning operations are obtained by multiplying timber volumes (according to final use, i.e., fuelwood, pulpwood, sawnwood, and veneer) by their corresponding prices.

Annual Private Benefits

Assuming the forester uses this technology to manage a new plantation in year 'r', the increase in benefits due to the technology is obtained by subtracting the NPV of the traditional management regime from the NPV (on a per-hectare basis) of the adopted management regime. The difference in both NPV for each year 'r', multiplied by the forested area over which the technology is adopted in each year 'r', determines the potential regional NPV of the technology. Therefore, from expressions [1] and [3], the NPV due to the additional revenues that are generated by adopting the technology is obtained as follows:

$$PB_r = A_r \ \{ [\ I \ e^{it} + \underset{h}{\ } R_h \ e^{ih} \quad K \quad G \ i^{1} \ (1 \quad e^{it}) \ \ T \ i^{1} \ (1 \quad e^{it}) \quad \underset{s}{\ } M_s \ e^{is}$$
$$E \ e^{it} \ ]_2 \quad [\ I \ e^{it} + \underset{h}{\ } R_h \ e^{ih} \quad K \quad G \ i^{1} \ (1 \quad e^{it}) \ \ T \ i^{1} \ (1 \quad e^{it}) \quad \underset{s}{\ } M_s \ e^{is}$$
$$E \ e^{it} \ ]_1 \ \} \ (1 \quad e^{it})^{1} \qquad (4)$$

where PB_r = private benefits of the area planted in year r and harvested in year t; A_r = area in which the technology is adopted in year r (ha); r = year in which plantation was initiated.

The area of land over which the technology is adopted is obtained by multiplying the area planted each year with *Pinus* by a coefficient Ta_r, which represents the adoption rate in that same year. That is:

$$A_r = AT_r Ta_r$$

where AT_r = total area with new plantations in year 'r'.

Total Private Benefits

Total private benefits of the technology referred to in the base year are expressed as:

$$TPB_a = PB_r \int_m^n e^{i(a \ r)} dt \qquad [5]$$

where TPB_a = Total private benefits; PB_r = Annual private benefits; a= base year (1997); *m*, *n* = first and last year of the study period. Expression [5] assumes that data corresponding to year 'r' are used. If only base-year data are available, the total private benefits will be obtained by adding annual private benefits.

Total Net Benefits

Total net benefits of the technology are obtained by subtracting the total costs of research from the private total benefits obtained in [5]. These research costs may include the resources assigned to research as well as any additional expenses required for developing and maintaining the technology.

$$TNB_a = TPB_a \quad C_r \int_x^z e^{i(a \ r)} dt \qquad [6]$$

where TNB_a = Total net benefits of the research; C_r = Annual costs of research; *x, z* = first and last year of the research program, respectively.

Benefit-Cost Ratio

Any forestry research program with a positive total net benefit is profitable. However, computing the total net benefit, per se (NPV of investment), does not provide a convenient ranking of alternatives for public investments. A substitute is to express the total net benefit per unit of research investment (benefit-cost ratio), then rank the programs accordingly. In the context of the model, the benefit-cost ratio can be express as:

$$B / C = TNB / CI \qquad [7]$$

where TNB = Total net benefits; CI = Total costs of research

Analysis of Sensibility

The Analysis of Sensibility is used to determine how the results of the pattern may be influenced by possible variations in the values for different economic and technological parameters that define the investment (e.g., price of the wood, discount appraisals, or site index).

Parameters and Data

Data required for the analysis include: 1) forested area involved in adopting the technology; 2) commercial volume retrieved from alternative management regimes; 3) roundwood prices; 4) production costs; 5) costs of research and development; and 6) discount rates.

In this analysis, the time interval is 1981 to 2005. Year 1981 was selected as the starting point because only trees planted in that year and after could be fully managed with SISPLAN. This is because the first thinning is usually performed eight years after planting; SISPLAN was not available until 1989. Likewise, the year 2005 was chosen because estimates are lacking for *Pinus* plantations in southern Brazil beyond that year. Based on the amount of land managed by the foresters and firms who acquired the SISPLAN, the area adopting the technology during this time interval was estimated at 546,000 ha. This amounts to an adoption rate of 84.5% (de Alencar 1999). Roundwood timber values were determined according to their final destination (i.e., fuelwood, pulpwood, sawnwood, or veneer). Table 1 indicates the roundwood prices for *Pinus*, expressed in 1997 US\$ m^{-3}. To evaluate the potential benefits of SISPLAN, 25 management regimes (MR) were simulated (Appendix 1). The selection of each management regime was based on available studies of silvicultural practices in southern Brazil (Ahrens 1992, Oliveira 1995). *Pinus taeda* was chosen because it accounts for more than 50% of the area planted to *Pinus* in southern Brazil. This species is highly productive, and provides good-quality long-fiber wood that is well-suited for lumber and white pulp and paper products. MR14 corresponded to the silvicultural guidelines established by the program for fiscal incentives to reforest, implemented by the Brazilian government in 1966. For our analysis, this management regime is considered representative of the old technology. MR14 has a rotation age of 20 years, with thinnings at Years 8, 12, and 16. The other 24 management regimes are considered new technologies, i.e., new management alternatives derived from research.

Appendix 2 summarizes commercial volumes according to various industrial uses in each simulated management regime. Commercial volumes were estimated by assuming that conditions were similar for genetic content, original stand density, and site quality. The largest total volume was harvested under MR25 (776.5 m^3 ha^{-1}). The rotation age here was 30 years. The maximum clear-cut volumes for each industrial use were obtained by MR19 for veneer (289.0 m^3 ha^{-1}); MR6 for sawnwood (425.1 m^3 ha^{-1}); and MR1 for both pulpwood (132.5 m^3 ha^{-1}) and fuelwood (21.1 m^3 ha^{-1}).

Besides the information on commercial volumes and roundwood prices, computing the cash flows for the 25 management regimes requires additional information on production costs. Table 2 contains the estimated average costs (referred to 1997) for silvicultural operations on a *Pinus* plantation in southern Brazil. These estimates include costs for planting, operating, thinning and felling, and management. The yearly research and development costs of SISPLAN (in the form of personnel costs and supporting operational expenses) are shown in Table 3. Research expenditures for SISPLAN began in 1988. A first version of the system was obtained in 1989, and extensions and modifications to the system were later performed. Maintenance research costs are assumed to last until 2005. Throughout the study interval, the estimated total cost for investing in the technology is 1997 US\$1.39 million (de Alencar 1999).

The discount rate also has a significant effect on profitability because investments in forestry plantations take a long time to realize benefits. In this study, a real discount rate (6%) was needed because all monetary calculations were performed in constant 1997 US\$. In the sensitivity analysis, discounts of 4% and 8% were used. (For an example of the magnitude of the discount rate, see Kula 1994).

Table 1. Average roundwood prices for *Pinus*, by industrial use.

Industrial uses	Diameter (cm)	Average price* (US\$ m^{-3})
Fuelwood	<8	9.38
Pulpwood	8 – 15	12.49
Sawnwood	15 – 25	19.2
Veneer	> 25	27.86

Results

The economic model used in this analysis generated the following economic results: private benefits per ha, total private benefits, total net benefits, and a benefit-cost ratio. Appendix 3 presents the present net values of the 25 simulated management regimes, with net private benefits per ha expressed in 1997 US$. The net present values (NPV) ranged from $1.708 (MR19) to $2.160 (MR1) per ha. To compute the potential benefits of SISPLAN, three situations were considered (Table 4). *Case 1* compared MR14, established by the Brazilian government program of fiscal incentives for reforestation (old technology), with MR1, the most profitable management regime. *Case 2* compared MR14 with MR9. Rotation age was the same for both, but their thinning plans differed. The objective with this comparison was to see how profitability was affected by thinning regimes different from the one established by the fiscal incentive program. Finally, *Case 3* compared the most profitable management regime, MR1, with the least profitable, MR19. This comparison was intended to show the maximum potential benefit that could be derived from the SISPLAN technology. Column 2 in Table 4 indicates the private benefit per ha based on the NPV obtained for each management regime (Appendix 3). The total net benefits were derived after subtracting public expenditures involved with the development of SISPLAN (Table 4).

he comparison of MR1 and MR14 (*Case 1*) in Table 4 indicates that the total net benefit of investments for research and development, using SISPLAN, was US $77.2 million, with a benefit-cost ratio of 55.7. MR1 had a rotation age of 16 years, with no thinning operations (Appendix 1). This regime was especially suited for the production of pulpwood and fuelwood. The longer rotation age for MR14 (20 years) provided for greater output, and was better suited for producing veneer logs. MR14´s lower profitability was due, in part, to the cost involved in the three thinning operations not used in MR1. The comparison of MR9 and MR14 (*Case 2*) showed total net benefits of $37.9 million and a benefit-cost ratio of 27.3. Finally, when MR1 (most profitable) and MR19 (least profitable) were compared, the total net benefits were $245.5 million, with a benefit-cost ratio of 176. These three cases demonstrate high public returns to investments in research and development, based on SISPLAN. Similar results were found in analyses of forestry research by Huang and Teeter (1990, and McKenney *et al.* (1993).

Some additional comments are required. First, MR1, shown to be most profitable, is used by the Brazilian pulp and paper industry, which demands *Pinus* roundwood with small diameters. In general, these industries both produce and process wood. In contrast, the regime showing the lowest profitability (MR19; 30-year rotation), is preferred by mechanical-processing firms (i.e., sawnwood and veneer) in Brazil. These firms require roundwood with better technological properties and larger diameters for use in construction, furniture making, and plywood. Therefore, in the current context of southern Brazil, it is more profitable to produce roundwood for pulp and paper-making than for other industrial uses, if one considers only the profitability of wood production (the first part of the production chain). This latter conclusion is also made in a recent report of the ”Banco Nacional de Desenvolvimento Econômico e Social” of Brazil (BNDES 1995). This report signals the economic disadvantage of long rotations in Brazil, although they may be short when compared with the rotations of more than 80 years that characterize temperate forests.

Second, management regimes that are less profitable, but which have longer time spans (e.g., MR19), could provide a substitute for the use of native woods and, in turn, ameliorate the increasing exploitation of these valuable ecological resources. Thus, there appears to be a trade-off between financial and environmental gains. To reduce this trade-off, public policies should be implemented that provide the necessary technical and institutional means for increasing the profitability of management regimes with longer rotation ages, such as RM19, thus providing optimal or at least near-optimal solutions.

Potential benefits of SISPLAN (as shown in Table 4) are affected by the assumptions used in the initial simulation of the model. Sensibility analyses were performed on wood prices, discount rate, and site index. First, when roundwood prices were increased, the profitability of shorter rotation regimes also increased. Alternatively, when roundwood prices were reduced, longer rotation regimes were more beneficial. The change in timber prices also affected the profitability of public investment in the research and development of SISPLAN. In this sense, higher wood prices were also identified with a higher benefit-cost ratio of research. Second, model results were also sensible to the choice of a particular discount rate. As was also demonstrated by Samuelson (1976), the empirical results indicated a tendency toward reduced rotations as the discount rate increased, because returns to forestry investments diminish more rapidly with time. Although the choice of alternative discount rates affected the estimations of SISPLAN research benefits, the relative advantage of the new technology over the old was unaltered. Finally, our results were not significantly affected when the site index was altered.

Conclusions

Information technologies present great possibilities for transmitting technical knowledge and, ultimately, analyzing the impact of research activities. This is true mainly for scientific technical knowledge, which is not incorporated as much into the productive process as that generated by forest-planning research.

The economic evaluation of the computerized projection system SISPLAN showed that the potential benefits were derived from research investments on management technologies that contribute to improved planning and organization activities in forestry. Estimates for our base case (the government-recommended policy at that time) suggested economic gains to Brazil of $77.2 million (net present value referred to 1997), with a cost-benefit ratio of 55.7. The research, therefore, was an attractive economic investment.

Our results also show how countries like Brazil, with intermediate forestry research systems, can reap important gains from more-developed systems through the transfer of technical knowledge. The analysis of the development of SISPLAN illustrates how, with limited personnel and financial resources, a country can capture a large volume of technical knowledge and channel it to improve its silviculture. Of course, for this type of technological ”spill-in” effects to materialize, some previous local scientific and technological research is required, as has been the case analyzed in Brazil.

Finally, the SISPLAN projection system has also generated ”spill-out” technological effects. This technology is now used in other Brazilian regions and in other countries that were not contemplated in this analysis. However, a complete evaluation of the SISPLAN technology should consider, in addition to these spillover effects, the potential environmental externalities derived from the adoption of this technology.

Table 4. Benefits of SISPLAN.

Management regimes	Private benefits/ha (US$)*	Total private benefits (US$$10^6$)*	Total net benefits (US$$10^6$)*	Benefit/Cost Ratio

Abstract

This overview presents some assessment methods for communicating environmental performance in forestry. Perspectives are also offered for the development of Life Cycle Assessment, LCA, in forestry. Several methods, such as Substance Flow Analysis, Risk Analysis, and LCA use static models and predominantly quantitative elements to assess environmental performance. Certification and an Environmental Impact Assessment, EIA, also include qualitative elements and public involvement. Examples of LCA-related studies in forest operations and two possible developments for LCA will be presented here. Although LCA comprises more qualitative elements, difficulties arise when it is linked to dynamic models for biological processes. An important issue is whether to include land use in this method of forestry modeling. Other methods might be preferable, e.g., when handling topics with qualitative values or political priorities. The alternative is to restrict the use of LCA in forestry to principally a technosphere, and use other means, e.g., EIA or certification, for analysing issues that affect qualitative values. Regardless of the direction chosen, the basic concerns when developing LCA are the quality of the data, the building of models, and the development of tools that are sufficiently simple, relevant, and robust to provide support in the decision-making process.

Keywords: Environmental management; Energy use; Forest management; Forest operations; LCA.

Environmental Issues Go Global

After World War 2, the world experienced strong economic development, but the negative aspects of industrialism became clear. Many people feared that the impact on nature, regarded earlier as an acceptable sacrifice for economic progress, would put the very existence of human life at risk. A well-known alarm clock was Rachel Carson's *Silent Spring* (1962). Environmental issues thus gained more importance in the industrial world during the 1970s. They reached global recognition in connection with the 1987 United Nations conference on environment and development, UNCED (WCED 1987, Humphreys 1996). UNCED established the term Sustainable Performance, a political goal to serve the present generation without putting future generations at risk. Sustainability includes three general principles (Upton and Bass 1995):

> Environmental sustainability requires that the ecosystem be able to support healthy organisms, while simultaneously maintaining its productivity, adaptability, and capability for renewal.
>
> Social sustainability reflects the relationship between development and social norms. An activity is considered socially sustainable if it conforms with social norms or does not stretch them beyond a community's tolerance for change.
>
> Economic sustainability requires that the benefits for the parties involved exceed the costs incurred and that the capital is handed down from one generation to the next.

UNCED was followed-up by the Earth Summit 1992 in Rio. This meeting reflected the controversies between industrialized nations and the less developed world. In spite of these differences, Earth Summit resulted in Agenda 21, concerning global cooperation in social, economic and environmental development, as well as the Convention on Biological Diversity (Upton and Bass 1995, Humphreys 1996). The latter represents an agreement about the conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of benefits arising from the use of genetic resources. The Commission on Sustainable Development (CSD) was created in December 1992 (Humphreys 1996) to ensure effective follow-up of UNCED, and to report on implementation of the Earth

Summit. In Rio, forests were among the most controversial issues being considered. The North-South polarization concerning forests did not permit agreements beyond the text of a non-legally binding authoritative statement of “Forest Principles”. After the Earth Summit, the CSD established the Intergovernmental Panel on Forests (United Nations 1999), to continue the forest policy dialogue. IFF, the Intergovernmental Forum on Forests, later followed up the IPF; it will cease its activities in 2000.

Goal and Scope

This paper presents an overview of some methods for assessing the impacts of forest operations on the environment. The scope comprises the chain of operations in forest management, from the creation of the stand until timber is delivered to the gate of the timber yard or at the mill. This presentation will concentrate on LCA (Life Cycle Assessment) and will investigate 1) whether methodology must be adapted to forestry, 2) and what the requirements are for improvement. This paper is written against a background of the author’s experience in European forest operations.

Standards Replace Legislation

Today, environmental issues concern so many that they represent hard facts in eco-sensitive markets. The process behind UNCED encouraged the International Organization for Standardization (ISO; Upton and Bass 1995, STG 1996) to establish environmental standards. Following the success of the ISO 9000 standards for quality management, ISO introduced the 14000 series for use in environmental management by an organization. Five areas are addressed in this family of standards:

- Environmental Management Systems
- Environmental Performance Evaluations
- Environmental Auditing
- Life Cycle Assessment
- Environmental Labelling

Through standardization, complicated international legislation can be avoided in the area of environmental management. The ISO 14000 series of standards for Environmental Management Systems (EMS) are standards of procedures, whose level of attainment is set by the organization itself. A third independent party, with no vested interest in the organization, must perform the audit for the certification process.

Forest legislation in many countries that export forest industry products have not satisfied consumers in some export markets. Hence, the exporting countries and Environmental Non-Governmental Organizations took the initiative to create standards for forest management. Groups that endorse forest management standards, e.g., Forest Stewardship Council (FSC), International Tropical Timber Organization (ITTO), and Pan European Forest Certification Scheme (PEFC), prescribe a certain performance or level of management that the company must reach. In Canada, parties involved in sustainable forestry have developed the CSA Sustainable Forest Management System Standard together with Canadian Standards Association (CSA). This is compatible with the ISO 14001Standard for Environmental Management Systems.

Means of Environmental Management

Because of prevailing pressures from markets and governments, several decision-support methods for studying environmental mechanisms were developed prior to the ISO process (Hofstetter 1998). These were drawn up differently, depending on whether they focused on product/organization/site or on society/environment/economy. Environmental performance can be followed in several ways (Figure 1). Substance Flow Analysis (SFA), Risk Analysis and LCA are analytical, and aim to quantify consequences for the environment with the aid of principles of natural sciences. LCA, Environmental Impact Assessment (EIA), and Certification all contain qualitative elements that tackle economic or social issues.

SFA (CIT Ekologik 1996), or Material Flow Accounting (MFA; CML 1998), is a method for tracing the flow of a substance in a defined area or organization. This involves identifying the substance, its flow, and the organizational or geographical entity. The flows are quantified and their effects then evaluated.

Risk Analysis, Assessment or Management (McCallum and Fredericks 1996, Anon. 1997) is a technique to analyze, evaluate, and control risks; its dimension also includes society. The entity for Risk Management is an organization, site, area, or project. The ISO 14001 requires that environmental risk management must be undertaken (STG 1996).

The EIA is an instrument for evaluation and decision-making, with public involvement. In many situations, legislation requires EIA when land development is impending or when new methods of agriculture or forestry, for example, are to be introduced (Westling 1995,Environmental Protection Authority 1999). EIA is a means of comparing the effects of change on natural resources in a natural environment. As such, an EIA describes and evaluates environmental effects, identifies any lack of knowledge, and prescribes actions. It is a part of a transparent democratic process and can deal with quantitative or qualitative estimates at the level of area or site.

Certification is a market-based instrument for raising awareness or providing incentives for producers, retailers, and consumers toward a certain quality of product. This quality may be derived from aspects of the manufacturing process, patterns of trade, social consequences, or environmental impacts. The goal of certification is to follow a standard of procedures, e.g., ISO 14001, or to reach a certain level, such as with the FSC. Certification is always voluntary. The achievements of the organization are assessed by an audit; the highest level of credibility is gained when the assessment is done by an accredited third party.

LCA is a method for assessing the environmental impacts of a product or service during its lifetime (Nordic Council of Ministers 1992, STG 1998, Heinimann 1999). This method is related to SFA or MFA (Klöpffer 1998), but has a product perspective rather than a site perspective (Hofstetter, 1998). LCA is intended as a comparative assessment that can be used in:

assisting in decision-making for improving products or processes,

marketing purposes (for an environmental profile), and

advising the public or politicians in the process of public decision-making.

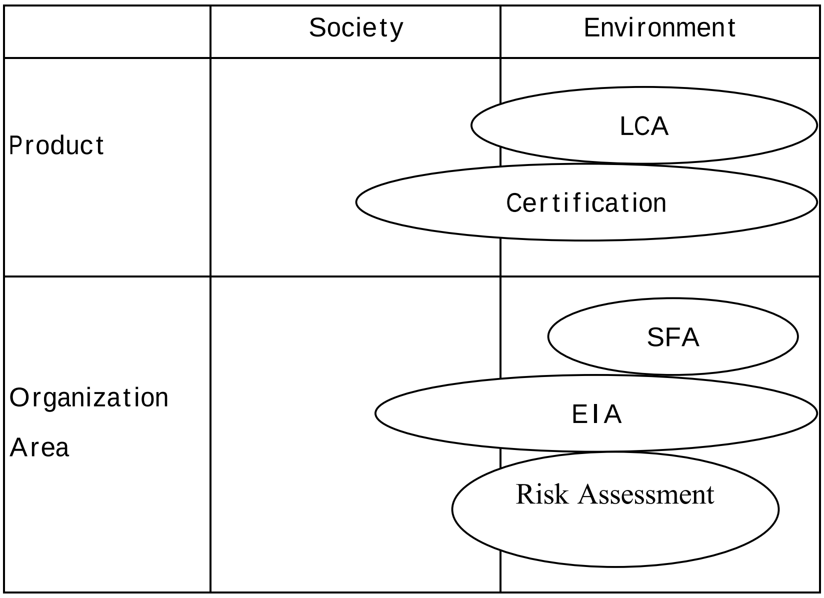
ISO14040 characterizes the four steps in a complete LCA 1) defining the Goal and Scope; 2) Inventorying data as a Life Cycle Inventory (LCI); 3) Impact Assessment, and 4) Interpretation. The Impact Assessment has three stages. Data from the inventory are assigned to impact categories (classification), and the influence of each compound is valued according to a quantitative weighting system (characterization). These characterized values are normalized to a common reference impact (Wenzel et al. 1997). Impact categories are determined according to an agreed value on safeguard subjects, e.g., Global Warming Potential (GWP) or Acidification Potential (Nordic Council of Ministers 1992). The interpretation is the weighting of end-effects across impact categories.

LCA under Development

Life Cycle Assessment is one of many tools for studying the environmental dimension in sustainability. This fairly new approach has possibilities for improvement (Ecomed 2000). LCA should be regarded as support for a decision-making process, rather than as a single indicator for good and bad. It comprises comparisons between alternatives and the results are compared from a product perspective. In that sense, LCA provides a global assessment as it follows the product from beginning to end, regardless of where it is used. Input data reflect average processes and average ecological conditions. Presently, LCA models are static, with no consideration given to time and space. Their results are only descriptive.

LCA is dominated by the inventory analysis of a product system (Hofstetter 1998). Its interpretation is influenced by the environmental implication of single compounds. This is called a bottom-up approach. With enhanced knowledge of a system, this approach leads to extensive protocols of inventory data. It is difficult to determine the important criteria for evaluating the environmental impact of the whole system.

Figure 1. Position of some decision-support tools according to the level of analysis (product-organization-area) and concerned party (society-environment).



Another approach is top-down modelling, in which modelling is influenced by relevant, identifiable impacts on the environment. This approach must be supported by values, which means that the modeller has to consider which safeguard subjects (e.g., human or ecological health) are relevant in the context. Data collection is adjusted to satisfy the evaluation of those subjects.

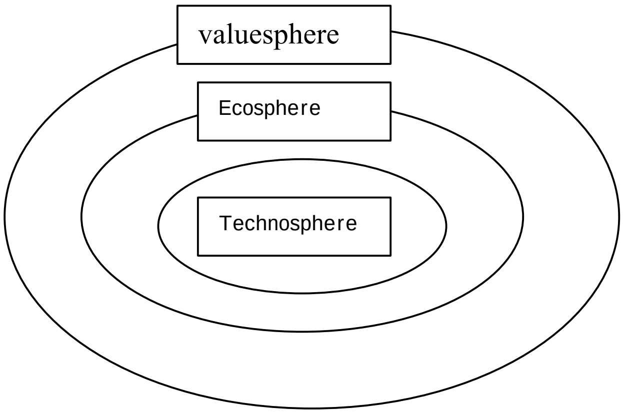
Hofstetter (1998) describes an extended look at LCA as modeling in three spheres (Fig. 2), i.e., a fundamental "Technosphere", an "Ecosphere", and a "Valuesphere". He anticipates the LCA tool should address all three spheres, with e.g., sociological and psychological models for Valuesphere, and models based on natural sciences to describe the Technosphere and Ecosphere.

LCA Approaches in Forestry

LCA-related techniques can address environmental issues in forestry operations, as shown in several recent studies. These followed a bottom-up approach and were basic Life Cycle Inventories of the use of fossil fuels. To avoid the obvious variation that results from using different conversion factors from input sources to emissions, results were compared in terms of the input energy of fossil fuel.

Schweinle (1996) provided a thoroughly technical and biological analysis of forest production in Germany, from an LCA perspective. The forest production system was considered a theoretical high forest. All measures, from reforestation to timber transport, were accounted for in a number of forest types classified by the dominant species. The results were characterized according to some impact categories. GWP was analyzed as a net effect by the forests. The total energy inputs in the chain of actions from stand establishment of Norway spruce to its harvesting, in terms of fossil fuels, were around 801 and 315 MJ per t atro m. R. (ton completely dried wood over bark) for pulpwood and sawn timber, respectively. The energy expenditure for transporting timber 50 km to the wood yard or mill constituted an additional 303 and 215 MJ per t atro m. R., respectively. These results were compared with work by Wegener *et al*. (1994), who had calculated a smaller total for energy used in production and transport.

Figure 2. Three spheres linked by LCA, according to Hofstetter (1998).



In the Nordic countries, Berg (1998) inventoried energy use for forest operations ranging from stand establishment to timber transport to industry. Rates of energy use in northern and central Sweden were 193 and 183 MJ/m^3 of wood, respectively. Within this total, timber transport accounted for 104 and 93 MJ, respectively. In a study from Central Europe, Knechtle (1997) examined the system from the view point of machine history during its lifetime, rather than from an operations perspective. This meant that energy input in machine manufacturing and end-of-life were also incorporated. Resources (for harvesting and timber transport) that were allocated to the processed-timber volume consumed 114 and 91 MJ/m^3 of wood for motor-manual and mechanized logging, respectively. Of this amount, the energy used for attaining raw materials and manufacturing varied between the systems. In the motor-manual operation, 2.2% of the energy used for power saws could be accounted for by raw materials and manufacturing; for forwarders and skidders, the corresponding amount was 16 to 18%, and for harvesters, 12 to 20%. Results from these and other studies are presented in Table 1. Although these cited papers present fair descriptions of the methods, the results are hardly directly comparable because of different or unclear systems boundaries.

The variation among results might be explained by shifting conditions such as terrain, infrastructure, type of machinery, forest management regime, type of cutting (felling-thinning), and tree size. This presentation illustrates the problems associated with data origin and its quality when forestry inventory data are collected for an LCA. The consequences of these dynamic effects, not explicitly shown in the table, include situations where:

data originate from thinning (small trees) or final felling (big trees), or

harvesting and necessary regeneration work results in a new forest with production goals that differ from those of the stand just harvested.

Carriers, i.e., fossil fuels as diesel oil or petrol, provide the energy for these operations. Their inputs can be re-categorized as emissions to the air, water, or ground via emission factors. These factors are compiled or deducted according to the present state of available information, true or not. Operations with similar levels of energy use may produce varying emissions depending on fuel quality.

Table 1. Studies on energy use: MJ/m^3 of solid wood over bark.

	Forest operations	Transport to industry	Sum
Schweinle (1996) sawn timber[1]	135	92	227

.

These would be expressed in terms of emission factors, e.g., the amount of carbon dioxide per MJ. A study of engine emissions from agricultural tractors and forestry machines (Hansson *et al.* 1998) demonstrated that using one single emission factor (for one fuel) for all types of driving operations could result in very high levels of error. In fact, they conclude that the emission factors hitherto used in LCI - LCA studies were not applicable to agricultural tractors. A further evaluation of impact categories could be misleading unless the emission factors and boundaries are relevant to the comparison.

Nevertheless, despite these difficulties, several LCA of forest products are made with data that use forest production as a base. Because paper products are refined products, made from worked-up timber, analyses show that forestry processes represent only a small part of the total environmental load that can be quantified (Anon. 1998a). The importance of forestry is palpable when less-processed goods, such as sawmill products, are analyzed. EMPA (Künninger and Richter 1998) conducted an LCA of railway sleepers, comparing those made of wood (beech), steel, and concrete. The aim was to investigate the impact on the environment due to all the steps connected with the manufacturing, use, and disposal of the sleepers. These analyses revealed that most environmental impacts are caused by the rail-construction work, the use of the rails, and the maintenance. Procuring the raw material had smaller significance. Concrete sleepers were environmentally less disturbing than those made of other materials. The problem with the beech sleepers was not caused by the heavy load during forest production, but because impregnation and more maintenance work were required during the shorter lifetime of those sleepers. This analysis helped identify the hot spots or the environmental problem area associated with each sleeper type, thus enabling improvements in reducing environmental impacts.

Different stages in the process of timber transport from forest to industry have been identified as major sources of energy use and as contributors to GWP (Wegener 1994, Karjalainen and Asikainen 1996, Schweinle 1996, Winkler 1997, Heinimann 1998, Berg 1999). In addition, Karjalainen and Asikainen (1996) have studied forestry operations throughout Finland, from the perspective of carbon storage and GWP. The amount of carbon stored in timber (in Finland) exceeded emissions from fossil fuels.

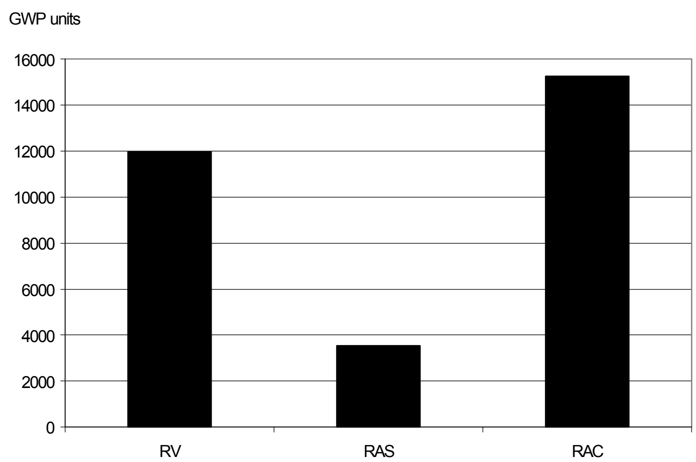
The effects of timber transport to a mill in northern Sweden were compared according to the impact caused by using rail versus road vehicles (Berg 1999). The infrastructure is such that timber can be transported by road vehicles only, or with road vehicles and electrified railway. Both solutions carry the same cost, but the railway is considered better because, although its transport distance is longer, rail has, inter alia, a lower environmental load. The main providers of electricity in Sweden are nuclear power plants and hydropower dams. In these studies, the emissions from the railway system were compared with the use of a hypothetical source of electricity, namely, a coal-condensing plant. The survey of the environmental impact on GWP (Fig. 3) showed that the railway solution contributed far less per m^3 to GWP than did timber transport by road vehicles alone, despite the longer distance. However, if electricity were to be supplied from a coal-condensing plant, the order would be reversed. This case shows that the energy carrier is vitally important when choosing among transport solutions. A supposedly environment-friendly investment in railway transportation can become less desirable if the conditions for energy supply are changed.

LCA is mainly a method for quantitative estimates. An evaluation of land-use aspects would also be desirable (Blonk *et al.* 1997). This concern is also expressed in an on-going Cost E9 project "LCA of Forestry and Forest Products". The report from an environmental project by Axel Springer Verlag AG, Stora, and Canfor (Anon. 1998b) includes a proposal for a new forestry assessment method in LCA. Their report contains examples of land use on government holdings in British Columbia, government and private holdings in Germany, and company and private holdings in Sweden. It can be difficult to incorporate such a qualitative aspect as land use in a quantitative assessment method, and interpreting biological indicators can differ among sites. As far as I am aware the report was the first attempt to address the practicalities of the problem. This approach reached no solution, but illustrated the difficulties of reflecting the complicated interaction between different land qualities and on-going or historical land use.

Future Perspectives

Environmental concern has developed from green dreams over survival issues on the political agenda to a money-making business. The public fears a limit of resources. It is always good to economize the consumption of raw materials and energy use, but in some markets, greater sales can result from suggestions that a company practices good environmental management.

Figure 3. Global warming potential expressed as GWP units per m^3 solid i. b. By road vehicles only (RV), by road vehicles and railway with electricity of Swedish average (RAS), and by road vehicles and railway with electricity from a coal-condensing plant (RAC).



A number of tools have been developed by concerned parties to support their own functions. The perspective clearly changes, depending on whether the observer is a consumer, producer, or a state. The design of the tool also depends on whether the entity for evaluation is a forest product, forest area, or organization.

LCA methodology can be used for assessing operations to provide inventory data for the forest industry. Complex analyses can also be performed when the technical and biological aspects of technical management and ecosystem reaction are considered. In this paper, a number of reports were analyzed, but few were comparable because of shifting scope, data quality, and boundaries. LCA is powerful when used with quantitative input data, but qualitative inputs can also be handled. LCA's strength lies in maintaining a life-cycle perspective through a complicated chain of events. Problem areas, "hot spots", can then be identified.

From my perspective, two basic developments are possible for LCA in forestry. This method might be developed to comprise a Technosphere, Ecosphere, and Valuesphere, according to the paradigm described by Hofstetter (1998). However, difficulties arise with this. Forest operations in the "Technosphere" are described by inventories of data according to static models. These static models must be linked with models of dynamic processes for forest growth and sequestration of compounds that have environmental impacts. There is also room for a dynamic approach in forest operations -- "the Technosphere", which is well motivated because forest operations also are dynamic. Variability in results is caused by the type of forest management system, stand conditions, and tree properties. Complexity increases if a "Valuesphere" is added. A central issue is whether to include land use in the LCA of forestry. This is a challenge to model builders because of the lack of both models and apparent data. The issue here is whether other methods are preferable, e.g., when handling topics with qualitative values or political priorities. Many problems concerning ecosystem state and stability fall into this category, and our knowledge is often limited.

Another direction is to restrict the use of LCA in forestry to predominantly the "Technosphere". Other means, such as the Environment Impact Assessment or Certification, would be used for addressing issues that affect environment or society. In such a process, LCA would have a strong role in providing basic data for the evaluation.

Environmental management is one very vital aspect of forestry today. Efficient tools are needed. Regardless of the direction chosen, the basic need in developing LCA concerns data and its quality, the building of models, and the development of tools that are sufficiently simple, relevant and robust to provide support in the decision-making process.

Abstract

Finland has been active in promoting sustainable forest management (SFM) at both the international and national levels. National criteria and indicators for SFM have been developed and reported on to describe and monitor society needs. The nature conservation and forestry legislation has been completely rewritten during the past few years in order to safeguard the key biotopes in Finnish forests, which are mainly owned by families and other non-industrial small-scale woodlot owners. Forest management guidelines have been improved to comprehensively include management of valuable biotopes, and protection of biodiversity trees, soil and water, as well as issues related to recreation, game management, and other socio-cultural values. A National Forestry Program (NFP) was developed as a transparent and open-ended process, and has recently been approved by the Government. The NFP incorporates economical, ecological, social and cultural aspects, and related actions as well as establishing the mechanisms to continue the process. In addition, Forest Certification issues have been investigated in an open manner. To support these activities at a company level, the forest industry has been active in developing environmental and quality management systems (EMS and QMS, respectively). These have been not only for the manufacturing side but also for wood procurement. The three main companies, Stora Enso Metsä, UPM-Kymmene Forest, and Metsäliitto, which together procure 80% of the domestic timber in Finland, all have certified QMS and EMS for wood procurement. Furthermore, based on the long-term work carried out by the Trade Association of Finnish Forestry and Earth Constructing Contractors, forest machine contractors are increasingly establishing their own QMS and EMS. Because of the small scale of the contracting companies, certification of these systems may not be economically viable. However, auditing mechanisms by either the forest industry or an independent party are being developed and, to some extent, are already in use. Both QMS and EMS, as addressed in the international standards ISO 9000 and ISO 14000 series, respectively, concentrate on management issues such as procedures, organization, responsibilities, competence, information flow, records, etc. The principle of continual improvement is clearly stated in ISO 14000, and will probably be included in the upcoming, revised version of ISO 9000. The main purpose of QMS and EMS is to help companies improve their own practices. The existence of such systems, however, especially the certified ones, also generally improves the public image of the company and is definitively an asset in business relations. Practically all nationally important issues related to ecological, social, and cultural aspects have been included or referred to in the QMS and EMS of forest industry. Environmental issues must be considered at all levels of the organizations. Thus, the systems have an important role in bringing theory and ideas into practice at the local level.

Keywords: Contractors, Environmental management systems, Forest industry, Quality management systems; Sustainable forest management, Wood procurement

Introduction

Forestry and Forest Industry in Finland

In Finland, forested land accounts for 23 million ha, or 70% of total land area. Finland is a family-forestry country; small non-industrial private woodlot owners hold 59% of the forested area. Another 28% of the forests are state-owned (40% of which is in nature conservation areas), while 8% are owned by forest industry companies. The remaining 5% is owned by municipalities, parishes, and other collective parties (Sevola 1999). The annual growth of the forests is about 75 million m^3, with a total drain (removals and mortality) of approximately 64 million m^3. In 1998, the industry used about 57 million m^3 of domestic roundwood. Some 80% of that roundwood came from family forests. Roundwood imports were 10 million m^3 (Sevola 1999).

Three major forest industry companies - Stora Enso Metsä, UPM-Kymmene Forest, and Metsäliitto Group - dominate the markets, buying 80% of the domestic roundwood. Their main products are sawn timber, pulp, paper, and paperboard. The majority of the sawn timber, paper, and paperboard are exported (Table 1), and account for 29% of the total value of Finnish exports.

Sustainable Forest Management

Since the 1992 UN Convention on Environment and Development (UNCED) in Rio de Janeiro, sustainable forest management (SFM) has become a hot topic. In Finland, wood production-related sustainability has been carefully monitored for some 80 years, since the pioneering work in national forest inventories of the 1920s. The ecological and socio-cultural aspects of SFM have also been appreciated for decades; the first national parks were established in the 1930s, and the unique everyman's right now grants everyone free access to the forest for recreation as well as for gathering berries and edible mushrooms.

Based on UNCED, the work related to Criteria and Indicators (C&I) of SFM has been carried out nationally and in international forums. The national report on C&I (Ministry of Agriculture and Forestry 1997) is currently being updated. Finland, like many other countries, has recently redesigned forestry-related legislation and forest management guidelines to better reflect the ideas of SFM.

Ecological sustainability is secured via protection measures. In Finland, 1.7 million ha of forests are strictly protected. An additional 0.7 million ha are limited in their wood production. Furthermore, under the Nature Conservation and Forestry Acts, certain valuable biotopes are strictly protected. The Nature Conservation Act also requires all forest species needing strict protection to be carefully considered.

To protect biodiversity in production forests, the Forestry Act lists certain valuable biotopes, e.g., the immediate surroundings of springs, brooks, and small lakes; specific herb-rich forests and swamps; as well as forests around gorges and gullies. These biotopes are to be managed so that their special values are not threatened. In many cases, these areas are fully excluded from harvesting and other forest management operations. In addition, certain key tree species (e.g., aspen, goat willow, alder, and rowan), snags and other decaying wood, as well as groups of old trees are retained in harvesting operations. Special measures are also taken to increase the amount of burnt wood in the forests for dependent flora and fauna.

Table 1. 1998 wood consumption, production, and the proportion of exports in the Finnish forest industry (Sevola 1999).

Type of product	Wood consumption (mill. m^3)	Production (mill. m^3)	Exports (%)
Sawn goods	27	11.3	73
Other wood products	5	1.6	58
Mechanical pulp	13*	4.6**	0
Chemical pulp	35*	6.7**	25
Paper and paperboard	-	12.7**	89

* including sawmill chips (2.8 mill. m^3 for mechanical pulp, 9.5 for chemical)
** mill. metric tonnes

Finnish Forest Certification Scheme

Voluntary Certification, as defined for this paper, is a documented procedure in which an accredited, independent body establishes the extent to which an organization or product meets the requirements of an applicable standard or set of regulations. Conformance with these requirements is assessed through document review and auditing. Certificates typically are valid for a limited period, e.g., three to five years, and require annual or semi-annual surveillance.

In this paper, forest certification refers to endorsement of the management and use of forests. The Finnish Forest Certification Scheme has been in development since 1996 (Finnish Forest Association 2000), as a response to increasing interest in SMF when marketing forest products. The elements of the Finnish scheme are specified in eight draft standards:

1) vocabulary of forest certification,
2) application of group certification,
3) forest certification criteria,
4) Audit guidelines for certification at the regional Forest Centre level,
5) Audit guidelines for certification at the Forest Management Association (FMA) level,
6) verification of chain-of-custody – material flows accounting method,
7) verification of chain-of-custody – physical segregation method, and
8) requirements for auditors and certification bodies.

A Forest Certification Council has been established to implement the scheme and further develop the standards. The Council is assisted by a secretariat and a working group for development work, as well as by an independent appeals panel (Forest Certification Council 1999, Finnish Forest Association 2000).

Based on the scheme, certification can take place at three different levels:

group certification at the Forestry Centre level (37 criteria)

group certification at the Forest Management Association level (13 Forestry Centre level and 24 FMA level criteria)

forest owner level (23 required and 12 compensatory criteria)

The criteria were formulated openly, and were completed in 1997. Twenty-nine organizations participated in the work, representing economic, social, and ecological interests. Nine organizations with economic interests were the forest industry companies, forest owners' organizations, and the Finnish Forest and Park Service. The 11 social organizations included trade unions, organizations for hunting, skiing, and other recreational activities, the Sámi Parliament (organization for indigenous people in North Finland), and the Finnish 4H Federation.

In practice, forest certification has been carried out at the regional (Forestry Centre) level. The system is voluntary for forest owners and requires an audit by a third party. This includes both forest certification and wood chain-of-custody certification, but excludes its own product labelling. Links will be made to the Pan-European Forest Certification Scheme (PEFC) and, possibly, to other international certification and labelling schemes for product labelling (Forest Certification Council 1999, Finnish Forest Association 2000).

By 1999, 7 of the 13 Forestry Centre areas in Finland had been certified, thereby covering the management and use of over 13 million ha of forests. More than 180,000 forest owners have chosen to participate in the certification. By the end of 2000, all 13 Forestry Centre areas will be certified (Finnish Forest Association 2000).

Members of the Trade Association of Finnish Forestry and Earth Constructing Contractors have already committed themselves to the national certification criteria. The complete list of the criteria, with explanations, can be found at the FFCS website (http://www.smy.fi/certification/eng/). For example, nine of the group certification criteria are directly related to forest harvesting:

- increase biological control of spruce root rot and spongy sap rot of pine in high-risk areas during summer harvesting;
- retain all typical features during forest operations in key biotypes;
- maintain existing monitoring systems for harvest damage, stores of unpeeled soft-wood, and root rot control;
- provide at least 20% of the clerical staff, forest workers, and harvester/forwarder operators with annual, supplemental training, including topics on biodiversity and occupational safety;
- in forest organizations, engage only entrepreneurs who have paid their legal dues and taxes, and who adhere to the employment legislation and collective agreements in force;
- leave intact the existing snags, hollow and other decaying trees, single windfalls, trees of previous generation, natural oaks, maples, ashes, elms, lindens, goat willows, and large aspens;
- in regeneration areas, leave at least five storm-resistant trees per ha;
- during harvesting, ditch cleaning and supplemental ditching, forest fertilization, site preparation, and prescribed burning, leave a buffer zone along waterways and minor water bodies;
- during forest harvesting, avoid damage to residual crop trees and the terrain.

Basic Features of Quality and Environmental Management Systems

A Certified Quality Management System (QMS) provides a framework for managing the quality of products and services in an organization. Customers are reassured that the goods and services supplied will meet their quality expectations. In certain cases, a certified QMS is a prerequisite for inclusion in tender lists. A QMS not only improves the product or service, but also increases staff effectiveness and enhances customer satisfaction. It may also improve in-house communication, decrease the number of employee accidents, and reduce material and energy waste. A certified QMS based on an internationally recognized standard makes it easier to do business around the world.

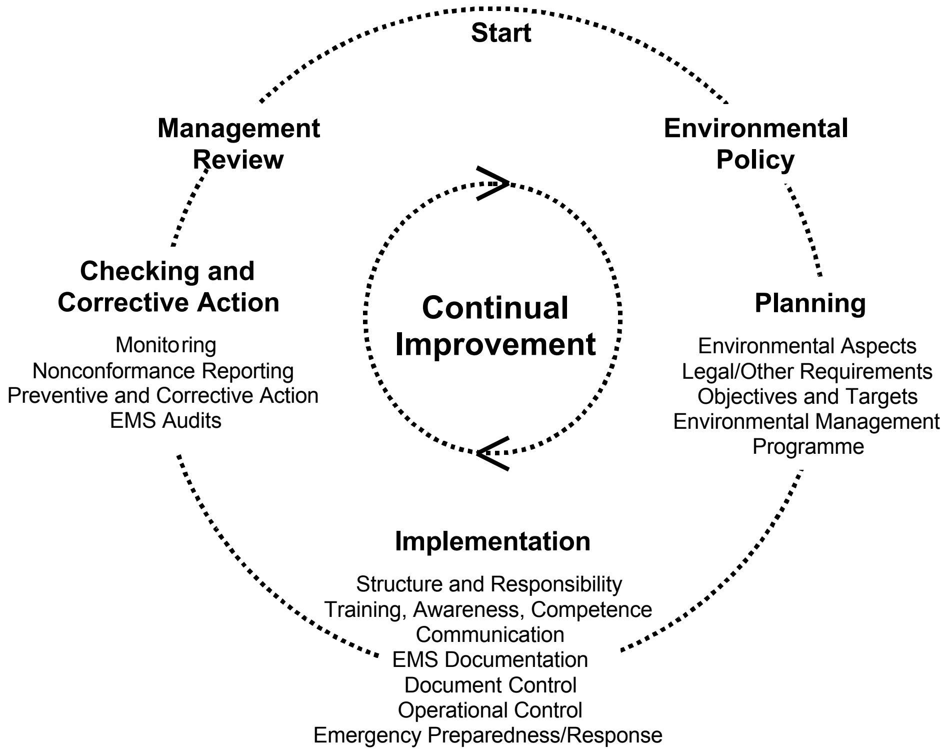
The ISO 9000 series contains international standards for QMS. The standards describe the elements to be included in QMS. Although the series does not contain any technical specifications regarding the actual manufacturing process or the final product, these can be included on a voluntary basis.

QMS elements in the ISO 9000 series standards include:

- management responsibility
- quality manual and system procedures
- contract review
- design control
- purchasing
- process control
- handling, storage, packaging, preservation, and delivery
- product identification and traceability
- inspection and testing
- control of inspection, measuring, and testing equipment
- corrective and preventive action
- control of documents, data, and quality records
- internal quality audits
- training
- servicing
- statistical techniques

An Environmental Management System (EMS) is a continual cycle of planning, implementing, reviewing, and improving the actions that an organization takes to set and meet its environmental policy and objectives (Fig. 1). It provides a proactive systematic approach to meet both business and environmental goals, and to satisfy environment-related stakeholder expectations in an increasingly transparent society.

Figure 1. Environmental Management System.



The numerous potential benefits from a certified EMS standard certification include:

Operating-Cost Savings

- improved efficiency of resource and energy utilization
- reduction of waste disposal costs through minimization of waste
- savings in emission fees or equivalent
- reduction in employee accidents

Environmental Compliance

- compliance with both internal and external environmental requirements
- minimal environmental impacts
- environmental statistics made available

Public Relations and Promotion of a Responsible Corporate Image

- improved external relations and corporate image among customers, suppliers, sub-contractors, regulatory bodies, investors, stockholders, insurance companies, environmental groups, and the public
- useful basis for identifying improved regulatory approaches
- increased shareholder value through EMS excellence

Creation of Marketing Opportunities

- good environmental performance gives a competitive advantage and is likely to attract potential customers and open wider markets
- "Better sooner than later"

The ISO 14000 series describes structures, procedures, and documentation related to EMS. It is applicable to manufacturers of all size, as well as service and public-sector organizations. The key element of the EMS is the organization's written *environmental policy* of commitment to continual improvement of its environmental performance. Environmental objectives and targets are derived from the environmental policy and implemented through clearly defined structures and responsibilities. Important elements of the EMS include:

- training, awareness, and competence
- communication
- operational and document control
- emergency preparedness and response
- monitoring and measurement
- non-conformance reporting as well as corrective and preventive action
- internal environmental auditing
- management review

As a standard, ISO 14000 does not establish any absolute requirements for environmental performance beyond the commitment in the policy, except for existing laws. The standard recognizes that an organization may have occasional regulatory non-compliances and still meet the requirements of the standard. Two organizations with similar functions may have different levels of environmental performance, yet both would be in conformance with the standard. The key ISO 9000 standards are currently being completely revised. For instance, new requirements will likely include a commitment to continual improvement (currently in ISO 14000 but not in ISO 9000) and arrangements for communication with customers. The revised ISO 9000 should be available by the end of 2000.

In many cases, QMS and EMS are incorporated into a single system. Companies with certified QMS/EMS may use the respective label in marketing (advertisement, letterheads, etc.). However, these are not eco-labels and cannot be attached to the final product. Certification of QMS/EMS ensures that the system is working and continues to conform to the standard. Deficiencies can be identified, thereby ensuring that the necessary corrective and preventive measures are taken. These systems provide independent verification and recognition, and reinforce the environmental commitment of an organization in the eyes of customers, employees, and the public. The initial cost of setting up QMS and EMS can be relatively high because the process requires much time and effort. Procedures must be written down and personnel trained. Certification with external initial and surveillance auditing may prove relatively expensive, especially for small companies. Depending on the market situation, this can often be an unavoidable investment for the future, however.

The European Eco-Management and Audit Scheme (EMAS) was introduced by the Council of the European Union (EU), and has been implemented on a voluntary basis in EU-member states since 1995. Because it is an EU Regulation, it has the status of law for countries within the EU. In addition to ISO 14000 requirements, the participating organizations are required to prepare an annual *environmental statement* and have it validated by accredited, independent environmental verifiers. The environmental statement must be registered nationally and made available to the public. Furthermore, the EMAS contains requirements for identifying ”environmental impacts”, which can be more complicated than the ”environmental aspects” found in the ISO 14000.

When compiling the environmental statement, the organization should consider the information needs of the public and other interested parties. The report should include a description of the organization, its environmental policy, the significant environmental impacts, related environmental objectives and targets, and a summary of its environmental performance. The verifier checks the compliance of the organization’s EMS with the respective EU Regulation, and the reliability of the information in the environmental statement and other related documents.

EMAS is currently available for industrial enterprises only. An amendment to the regulation is under preparation, and will enable all organizations to participate, with the aim of improving the efficiency of their environmental operations.

QMS and EMS in Wood Procurement

Because most of the major forest industry companies already have certified QMS and EMS for their industrial operations, the pressure is increasing for the certification of wood procurement as well as forest management.

In Finland, the major wood-procurement companies — Stora Enso Metsä, UPM-Kymmene Forest, and Metsäliitto — have developed QMS and EMS (ISO 9000/14000) for their operations. Metsäliitto was certified in June 1997, Stora Enso Metsä in June 1998, and UPM-Kymmene Forest in September 1998. The Finnish Forest and Park Service received their ISO 14000 certificate in April 1998. FFPS also has a QMS, but has not yet applied for certification. Stora Enso Metsä and UPM-Kymmene Forest have also participated in EMAS since 1999, and have prepared environmental statements (e.g., Stora Enso Metsä 1999).

All organizations emphasize that the task of developing the systems has been more difficult than was foreseen. The processes have included extensive training components, for both the systems themselves and the upgraded environmental and forestry legislation of the late 1990s. Training for staff, as well as for harvesting contractors and machine operators, has been done accordingly. The latter has been necessary because nearly all forest harvesting is carried out by private contractors who, typically, own one to three pieces of harvesting machinery each.

QMS and EMS have been developed mostly because of their high potential as marketing and management tools, as well as being tools for improving operations. Other important benefits include:

- staff motivation
- increased profitability
- external recognition
- increased competitiveness
- building up company spirit after mergers
- staff development

QMS and EMS typically are available in electronic formats (Lotus Notes or equivalent), which improves their availability and makes upgrading more efficient. Future developments may include an upgrade of the revised ISO 9000, and improved user-friendliness in the systems. Occupational Health and Safety Management Systems, as outlined in the British standard BS 8800, also are likely to be incorporated.

The new environmental and forestry legislation, management guidelines, and the criteria applied in the national certification scheme for forest management are incorporated in the QMS/EMS. The key areas to be monitored and documented include:

- log dimensions and quality
- thinning quality (spacing, damage)
- worker safety
- biodiversity in production forests (key biotopes, key tree species, decaying and burnt wood, trees left standing)
- protection of soil and water (protective zones, erosion control, avoidance of rutting and soil compaction, guidelines for operations in groundwater areas)
- landscape architecture
- forest health (level of pollutants, defoliation, damage, nutrient balance)
- protection of pre-historical and other cultural sites
- recreational infrastructure
- integrated management plans
- other environmental aspects (energy efficiency, emissions into the air, noise, amount and treatment of waste)

Much attention is paid to securing communication channels between purchasing agents, harvesters, contractors, and operators. Contractors and operators require detailed instructions with site maps and all machines must be equipped with cellular phones. In addition, because of full-scale training, the level of environmental and quality consciousness as well as emergency preparedness among supervisors and contractors has increased.

Communication with public authorities and other stakeholders is an essential part of the current ISO 14000 and the upcoming revised version of ISO 9000. The companies have implemented procedures for receiving and documenting information provided by stakeholders and for responding to their requests. This facilitates a dialogue with the stakeholders and helps the organizations improve their policies.

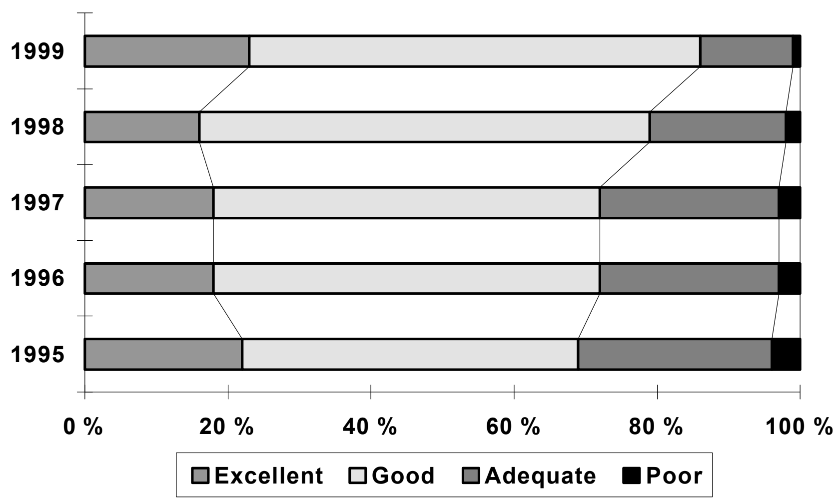
The Forestry Development Centre, Tapio, has been monitoring nature-care aspects in forest harvesting operations since 1995. The areas of interest are management of key biotopes, ”biodiverse” trees that are not cut during regeneration felling, and protection of water during harvesting and site preparation. In 1999, the Centre investigated 1729 harvested stands, which represented 2% of the regeneration felling and 0.4% of the thinned stands. The overall results show a clear improvement in nature-care aspects (Fig, 2). In 1999, 91% of the valuable biotopes were entirely or almost entirely preserved, compared with 73% in 1995. The share of stands with an excellent or good rating for biodiversity trees left standing also increased during that period, from 66 to 81%. Protection of water bodies was excellent or good in 92% of the cases in 1999 vs. 83% in 1995.

These improvements are the net effect of updated forestry-related legislation and guidelines, on-going inventory of valuable biotopes, the forest certification process, and the development of QMS/EMS for wood procurement. However, no matter how well staff and contractors are trained, non-conformances do occur occasionally. Nevertheless, the EMS/QMS contain procedures for managing these non-conformances and learning from them.

QMS and EMS in Forest-Harvesting Contracts

QMS and EMS are also gaining popularity among harvesting contractors. The Trade Association of Finnish Forestry and Earth Constructing Contractors has been very active in assisting contractors in its QMS/EMS development work. This activity began in earth construction during 1993 and spread into forest harvesting one year later. Currently, over 300 of the 1200 forest-harvesting members of the association have or are developing an integrated QMS/EMS for their companies. A 20-page model system has been developed by the association. In addition, six-day training courses are provided and individual consultations are arranged. These training programs have received some funding from the European Union.

Figure 2. Overall rating for nature care in forest harvesting operations.



The model EMS and QMS consist of the following components:

- quality policy
- flow of internal and external information
- responsibilities of the contractor and the operators
- staff training and competence
- equipment maintenance and repair
- work quality-assessment procedures
- working instructions for harvester and forwarder
- environmental aspects and waste disposal
- occupational safety
- list of supplemental guidelines
- contract review
- data collection
  - scaling certificates
  - calibration sheets
  - stand-specific instructions from client (notes and verification by operator, significant changes verified by client representative)
  - worker time card
  - feedback from operators, clients, and forest owners
  - training records
- special communication requirements when working in dangerous conditions (on-site repairs, operation close to power lines, etc.)
- feedback to clients

Among the Finnish forest industry companies, Stora Enso Metsä has been the most active in promoting QMS/EMS for forest-harvesting contractors. More than half of their Finnish contractors already have or are building QMS/EMS for their companies. Because the systems are a prerequisite for contract renewal, all contractors should have their systems ready within a few years. The Finnish Forest and Park Service also requires its contractors to build respective systems. The other two major players in wood procurement, UPM-Kymmene Forest and Metsäliitto, also strongly support QMS/EMS for contractors, but do not currently require their contractors to have such systems. By 2010, 80% of the forest-harvesting contractors will have established QMS/EMS for their companies.

Of the 1000 log truck contractors in Finland, 700 are members of the Association of Forest Industry Road Carriers, one of the branch organizations of the Finnish Trucking Association. These contractors handle nearly all roundwood transport by road. Some 200 log truck contractors have QMS for their companies. As with their forest harvesting systems, Stora Enso Metsä requires all truck contractors to have QMS within a certain time frame, while the other companies are recommending and supporting that such systems be built.

In the terminology of the Finnish Trucking Association, the EMS Level 2 is equivalent to the ISO 14000. Few such systems now exist in the roundwood transport sector. Level 1 requires a half-day course on economical driving and another half-day course on general environmental issues. In addition, the companies must complete and submit annual contractor's Environmental Workbooks, individually summarizing the major environmental issues in trucking. So far, a couple dozen companies in the roundwood transport sector have received the Level 1 certificate from the Association, after having completed the requirements. The Association is also developing a model system that incorporates quality, environmental, and safety issues for trucking contractors.

Because the contracting companies for both forest harvesting and trucking are usually small, the independent certification of their systems may not be economically feasible for them. Instead, second-party auditing by representatives of forest industry companies is applied. The contractors are assessed for their conformance with requirements; those who pass receive quality certificates.

Conclusions

The Finnish economy is highly dependent on forestry and forest industries. Finland has been active in promoting sustainable forest management both nationally and internationally.

A growing interest in the market, especially in Europe, has been a driving force in establishing a national certification scheme for the management and use of forests. The scheme, FFCS, will be linked to the Pan-European Forest Certification Scheme (PEFC) and, possibly, to other international certification and labelling schemes for product labelling.

Finnish forest industries have been active in developing QMS/EMS, not only for themselves, but also for wood procurement. Despite the high workload, the companies consider QMS and EMS valuable tools in improving management practices. Furthermore, QMS/EMS improves stakeholder relations through dialogue and increased availability of relevant environmental and quality-related information. For certified systems, an independent third party verifies this information along with the functioning of the entire system. This may also include systematic analysis of stakeholder expectations.

Some forest industry companies also require their contractors to develop QMS and EMS. Even where this is not the case, interest in developing management systems is increasing among forest-harvesting contractors.

The main purpose of QMS/EMS is to help companies improve their own practices. However, the existence of such systems, especially certified ones, also generally improves the public image of the company and is definitively regarded as an asset in marketing and other business relations. Practically all nationally important issues related to ecological, social, and cultural aspects have been included or referred to in the QMS/EMS of the forest industry. Dialogue with stakeholders continues to introduce new issues for consideration in the continual improvement of company policy. Environmental and other issues must be considered at all levels of the organizations; these usually involve a major training component. Thus, the QMS and EMS play major roles in bringing theory and ideas of sustainable forest management into practice at the local level.

Abstract

Throughout the world, approximately 1 to 2% of the tropical forests (about 1.700 million ha) are cleared each year for wood and non-wood products, and to give way to agricultural activities, infrastructure, and settlements. The increasing number of forest users and pressure groups on this environment has forced timber-harvesting companies in several countries to adopt harvesting systems that attempt to guarantee sustainability. Forests and forest product industries provide employment to the local population and habitats for various animal and plant species, but only a small proportion of the forests are under proper management. Many factors contribute to the lack of economically, environmentally, and socially acceptable harvesting systems, including the unavailability of trained manpower, an absence of laws and regulations governing forest operations, and a lack of capital for undertaking proper forest operations. Mechanization has reduced the use of manual labour in developed countries, but most of the forest operations in developing countries depend on human power. Because much of that labour is untrained, the result is usually low productivity, rapid turnover rates for employees, and high accident rates among forest workers. Likewise, the inherent differences in body size and physical working environment means that some tools and machines designed for forest workers in developed countries do not properly fit workers in developing countries. This may cause both physical and mental stress, accidents, and injuries. Therefore, data must be gathered on anthropometric parameters, as well as on workplace conditions and workers' physical capacity in these developing countries. Appropriate employee training also should precede the transfer of technology, and must accommodate the existing infrastructure and socio-economic conditions of a particular area. As the forest industry becomes globalized, developing countries are faced with challenges in training forest workers in how best to operate and maintain equipment, and in providing them with protective gear to reduce accident risks and injuries. Rural living and working conditions also must be improved in order to attract and retain a young and educated labor force. This paper presents an analysis of forest working conditions and harvesting problems in developing countries, and the ergonomic and technological interventions required for improving productivity. These measures may also ensure that forests meet the needs of the present without compromising the ability of future generations to continue fulfilling these objectives.

Keywords: Appropriate logging technology, Ergonomic intervention; Manual versus mechanized logging methods, Logging in tropics, Tropical forest workers

Introduction

Tropical forests cover about 1.7 billion ha, mostly in developing countries. Despite global efforts to conserve these forests, approximately 1.5 to 2 million ha (about 1 to 2%) of the total forests are cleared annually to provide for agricultural land, infrastructure, and urbanization (Heinrich 1994, EU 1997). About 3.4 billion m^3 of roundwood are removed from these forests each year for industrial uses as well as for fuel wood (Heinrich 1997). Because of this alarming shrinkage in forestland and increasing pressures from society or the community in general, many logging companies lately have found it necessary to change their practices so that harvesting is carried out in a manner that guarantees sustainability of the forest resource base.

In the past, forests were mainly associated with timber harvesting but, today, a multitude of non-wood products also beneficial to the local population are harvested. These other products include plants for ornamental and medicinal use, honey, resins, tannin, fruits, mushrooms, and wildlife (Dykstra and Heinrich 1994). Currently, a number of countries from the developing world earn a significant amount of foreign currency from the export of non-timber products. For example, of the US $5.4 million derived from the export of forest products by Tanzania in 1998/99, timber and timber products accounted for only 50% of that total. The balance came from the export of honey and beeswax (23%), or tree seeds and carvings (27%; GoT 1999). In other countries, e.g., Indonesia, non-wood products account for 10% of the total exports from their forests (Dykstra and Heinrich 1994). Forest harvesting clearly is no longer synonymous with logging. These additional activities result in a variety of forest outputs beneficial to the local population in terms of service, employment, and income generated.

Because of their complexity and diversity, tropical forests require well-planned and controlled forest operations to make full use of the potential timber and non-timber products. To achieve this, trained manpower must be in place to take responsibility for pre-harvest planning, execution of operations, and monitoring and evaluating of post-harvest operations (Heinrich 1994). With such trained manpower, productivity may be increased without compromising the regeneration capacity of the forest. Unfortunately, many developing countries lack or have inadequate, trained manpower for adopting new logging technologies and optimizing both timber and non-timber production.

This paper analyzes the current forest working conditions and harvesting problems in developing countries. Here we determine the ergonomic and technological interventions required for improving productivity and ensuring that forests meet the needs of the present as well as future generations.

Forest Operations in Developing Countries

Forests and Forest Workers

Forests and forest products in many developing countries contribute about 2 to 4% of the national GDP, in addition to providing jobs for a good portion of the population (ILO 1981, Fenner 1996, Abeli and Nsolomo 1998, Fue *et al*. 1999). In some countries, such as Malaysia, forest products account for 15% of the total exports, while that sector employs up to 12.5% of the total labour force (Dykstra and Heinrich 1994). Despite their contributions to the socio-economic development in these countries, the majority of these forests are ill-equipped in terms of personnel, equipment, and funds (FAO 1993). Only a small fraction of these forests could be considered properly managed; many of them are managed only to facilitate the collection of revenues from timber products, wildlife- or game-viewing, and non-wood products.

Studies of tropical forests show that only a few tree species are logged intensively because of restrictive market demands and a poor knowledge of the physical and mechanical wood properties of the many other available tree species (EU 1997). Intensive exploitation of these few, valuable tree species has led to reduced seed production and regeneration capacity of the productive forests. Because only a small volume of timber per unit area is harvested, logging in such forests is also relatively more expensive.

Population increases have created more demand for agricultural land, housing, and domestic fuel wood (EU 1997). With population growth of about 2.8 to 3%, more people are finding refuge in the forests in order to earn a living or look for basic necessities, legally or illegally. This has been the main cause of deforestation or forest degradation, especially near settlements or towns (Abeli and Nsolomo 1998).

Although improper logging, especially in steep areas, may cause land degradation, logging *per se* does not cause deforestation (Dykstra and Heinrich 1994). By using appropriate logging and forest-management practices, only a few, selected tree species are harvested or thinned while the majority of the trees remain for future use. To encourage sustainable forest management, more efforts are being directed toward training of forest workers and users, stronger legal and institutional frameworks, and the involvement of the nearby population (EU 1997).

Although every forest manager aims to adopt economically, environmentally, and socially acceptable harvesting operations, attaining this goal can be limited by such factors as forest type, physical workplace conditions, accessibility, requirements of industry or market, availability of trained manpower, proper tools and equipment, laws and regulations governing forest operations, and available financial resources. In most developing countries, financial resources to invest in forest operations are limited while a trained and skilled work force also is scarce. Worse still, laws and regulations to promote sustainable use of forests are not in place or, if formulated, are not adequately enforced.

Forestry Work

Compared with other occupations, forestry work is strenuous, dangerous, and energy-demanding, especially where performed manually (Abeli 1979, Ayaz 1986). Unlike other occupations, this work is normally performed under conditions where mankind has little influence or control over the terrain and ground- or weather conditions. Therefore, productivity is low, the physical workload or stress high, and the rate of labour turnover relatively high (Lipo-glavsek 1998, Fue *et al.* 1999). Creating a safe and good working environment is a way to improve workers' morale and reduce labor turnover.

Most of the forest operations in developing countries utilize manual and semi-mechanized methods, which demand high expenditures of energy (Ole Meiludie *et al*. 1988). The crew usually works under hot and humid weather conditions, and travels long distances to their workplaces. This long-distance travel causes stress, reduces the effective working time, and may cause accidents. At some sites, forest laborers work in isolation, with no appropriate safety gear and inadequate contingency plans. These factors, combined with poor supervision, contribute to low productivity and high accident rates in the forests (Abeli 1979, Fenner 1996).

Studies of forest operations in developing countries have revealed that some forest hand tools, equipment, and machines are not designed appropriately to fit the workers and the working environment. Ergonomic studies, including anthropometric surveys, have not been done so that manufacturers can produce optimally designed tools and equipment. For example, differences in body dimensions, weight, and weather conditions have presumably resulted in some forestry tools and equipment causing stress, injuries, and accidents in Chile, India, Sudan, and Brazil (ILO 1982, Apud 1989). It is possible, however, that employee training, work organization, and tool maintenance could also have contributed to stress and accidents in these cases.

Technology Transfer

Physical, social, and mental differences are fundamental between the populations of the developed and the developing countries (Shahnavaz 1992). Technology designed for the former is not necessarily ideal for the latter population. Where this technology has been transferred without adjustments or modifications to fit the local conditions, stress, injuries, and poor quality of work have sometimes been the result. When technology is to be transferred from the developed world to developing countries, Shahnavaz (1992) proposes that the following ergonomic principles be observed or considered:

> Anthropometry: Because body sizes and dimensions differ, some of the imported logging tools and equipment designed for the developed world might not fit the users in developing countries, without modifications.
>
> Physical working capacity: The capacity of the human body to perform prolonged physical work is related to individual health, age, weight, sex, level of nutrition, as well as the working environment. These factors must be considered when designing tools and equipment for use in developing countries.
>
> Workplace conditions: High temperatures and humidity, and poor ventilation make tractor cabins (meant for winter logging) uncomfortable for tropical work. Likewise, discomfort can prompt workers to hardly wear or put on protective gear. Because human comfort depends on relative humidity, temperature, and wind velocity,

these factors must be considered when planning and designing optimal workplaces and organization in the tropics.

Mechanization in forestry is meant to render the work less labourious, minimize energy requirements, increase worker output, and reduce drudgery. However, inappropriately used mechanization has increased mental workload and has caused accidents and injuries to workers (ILO 1982). Accidents have been caused mostly because of a lack of experienced and skilled workers for using these machines and a disregard for the basic principles of work physiology. Again, accidents also occur because logging machines and hand tools are not being appropriately designed to fit the local conditions or population. Despite these few negative instances, however, overall mechanization has eliminated much of the physical effort and minimized wood waste. It is now possible to undertake tasks that once were difficult, uneconomical, and almost unthinkable.

The science of ergonomics has been used in the design and introduction of appropriate new technologies to workplaces, thereby ensuring efficient use of the labour force. This science has also been used in designing jobs that fit and give satisfaction to workers, besides being a tool for evaluating the choice of technology to be adopted in new areas (Shahnavaz 1992). In transferring this technology, ergonomic factors such as working techniques, physical workload, energy requirements, occupational safety, health, and working conditions must be taken into account at the planning and design stages (Apud 1989, Shahnavaz 1992, Dykstra and Heinrich 1994).

Technology transfer is the utilization of a technique in a place or situation where it was not previously found. After its introduction, the technology is either accepted and used as it is, or modified to suit local conditions. The new technology may again be transferred to a different physical environment, to be used by workers who vary either in their physical dimensions and capacities or in their attitudes toward their jobs because of their socio-economic background. Thus, appropriate studies and training must precede the transfer of technology and should, as far as possible, fit into the infrastructure, physical working environment, and social economic conditions of the recipient country. The aim of technology should always be to improve the standard of living of the recipient population and provide good working conditions, while offering possibilities for future improvement.

Accidents and Their Impact in Forestry

The number of accidents in developing countries is higher than in developed countries, although the degree of severity is much less (Mbowe 1995). Fortunately, where technology transfer has been adopted correctly, productivity has improved and occupational accidents, injuries, and diseases have been greatly reduced. In contrast, where workers have not been trained on the proper use and adoption of new technologies, the result has been high rates of absenteeism and sick leave among forest workers due to accidents and injuries. For example, a study of logging in Brazil showed that the number of accidents per month was 49, while the risk of incidence for forest workers was 42% (Fenner 1996). This study also revealed that the average number of days lost per accident was 18.

In a study of a logging crew of 160 in Tanzania, about 33% of the workers had experienced accidents varying from minor (65%) to severe (35%; Mbowe 1995). Accidents were classified as severe if a worker was kept out of work for at least one day; here, the number of days lost per accident averaged 3.7.

In Nigeria, where 802 ha of plantation forest were established between 1990 and 1994, accidents and ailments caused a financial loss of $17,400, in 435 cases reported over the five-year period. Losses incurred from accidents accounted for about 7 to 9% of the total budget, while the average number of days lost per accident was four.

Despite there being some published reports of accidents in forest operations, accident records are not very reliable. For example, a study in Tanzania showed that between 1980 and 1990, only 34 accidents were reported at SUA Training Forest (Fue *et al.* 1996). These accidents were estimated to have cost only $240, while the number of lost days due to accidents for the entire 10-year period was apparently only 173. The recommendations in this study were to 1) educate forest workers on the importance of reporting accidents whenever they occur, and 2) train the managers to keep proper records of accidents and the actual cost of treating and compensating accident victims.

Challenges for the Future

In many developing countries, a number of challenges face the logging industry and the forest sector in general. While there seems to be very little internal pressure in these countries to adopt sustainable forest-management systems, globally the pressure is mounting and intensifying. For instance, the introduction of Timber Certification will force developing countries to follow or adopt internationally accepted forest-harvesting practices if they are to sell their forest products on the world market. On the other hand, in order for these countries to adopt environmentally sound and sustainable harvest practices, they must learn from and share experiences with managers in other countries.

Improvement of Working/Living Conditions

Where forests have been or are being converted to other uses, a significant portion of the nearby population that once depended on these lands loses a source of employment. As a result, some inhabitants resort to subsistence agriculture while the young people migrate to urban areas to look for other and better opportunities. In developing countries, the labour force engaged in forest operations is old and unskilled because the younger and better-educated ones tend to move to big towns and cities. To stop this migration, deliberate efforts are needed for improving the living conditions in the rural areas. For example, forest workers must be offered good incentives and attractive wages. Currently, even though forestry work is difficult and hazardous, it is a lowly paid job.

In addition to improving the working and living conditions of forest workers in rural areas, logging companies must ensure that forest workers are provided with the right tools, protective gear, shelter, and training on safe working methods. Companies must also provide social services like schools, health services, a good water supply, and reliable communications within or near working areas (Strehlke 1987). When these are lacking, logging companies must work closely with the local communities to make these services available because productivity depends on the workers' health and living conditions.

When forest workers live at their job sites or in nearby villages, the workers and their family members should be encouraged to cultivate small farms or gardens to supplement incomes from forestry activities. Cultivation of food crops will not only subsidize incomes but will also improve the nutritional status of the workers, thereby increasing their physical working capacity and leading to a higher work output (Strehlke 1987). However, where cultivation is not possible, employers need to provide food and other items to workers at subsidized cost.

Because heat stress hinders higher productivity in the tropics, a sufficient supply of drinking water, with adequate replacement of electrolytes, is essential. Heat stress can also be reduced by wearing loose-fitting clothes and broad hats, and by implementing adequate rest periods and job rotation at workplaces to avoid working continuously at one point or directly under the sun (Chandra 1987, Strehlke 1987).

Training

Both supervisors and forest workers must undergo in-service training to increase job satisfaction and self-confidence. Employers have to realize that a trained and stable work force is more efficient and more productive than untrained and temporary laborers. Although the use of untrained workers appears to be economical, these employees are expensive in the long run when they cause accidents, equipment damage, and unnecessary wood waste (Ayaz 1986, Fue et al. 1999). Trained supervisors will also assign tasks that are fair and reasonable, and will serve as a good link between workers and management.

Training programs for forest workers should be very thorough and well-planned to convey the knowledge that is essential to the tasks being assigned. Specifically, training must be concentrated on safe operation and maintenance of logging equipment, improvement of workplace conditions, development and promotion of local tools and auxiliaries, as well as on safety and hygiene matters. Such topics could be offered as part of 'on-the-job training' or organized into short courses at vocational training centers.

Technology Intervention

Lack of technological know-how in many developing countries has hindered the process of innovation. This has resulted in these countries being perpetual importers of technologies from the developed countries. Because of a lack of trained personnel, these "acquiring" countries also have had little opportunity to develop technologies that best fit their workers and the working environment. Importation of working tools to these countries will continue, so it is important that, when introducing new technologies, the following should be observed or considered:

- Investigations of occupational safety, health, and working conditions of the forest workers
- Consultations with recipient countries during the planning and design stages for tools
- Proper selection of equipment to match the required level of technology in the recipient countries.

Shahnavaz (1992) defined an appropriate technology as a technology in line with the prevailing conditions of a particular population and the environment in which it is used. Because countries differ in culture, race, political systems, and socio-economic well-being, it is difficult to have a technology that is appropriate for all. The lack of a uniform prescription or single system that is relevant or appropriate for all countries simultaneously means that each country must define and develop a technology appropriate to the needs and in line with the resources available. For instance, work, equipment, and tools have to be designed and adapted to the anthropometrics of workers to provide comfort and protection against stress and accidents.

Although the main objective of technology transfer is to improve the economic situation and the general standard of living for the working population, this technology has to be transferred appropriately. Historically, technology has sometimes been inappropriately transferred in one of three ways: 1) Incomplete transfer - not all aspects of technology transferred, with some omitted or neglected; 2) Imperfect transfer - end-users not considered (e.g., operating manuals not in local language); or 3) Inadequate transfer - environmental working conditions not considered.

No matter how efficient the new technology was at its origin, before it can be transferred, the existing technology in the recipient country must be thoroughly studied. Where possible, the new technology must be modified to fit existing conditions or the existing technology will have to be improved to match the new technology (Heinrich 1994). It is also important to identify the right technology to fit the local population or working environment, as well as seeking the best method or approach for transfer to the end users. For example, in the case of new machines, basic principles and instructions on how to operate and maintain them should be available in local languages to achieve optimal output.

Labour- Versus Capital-Intensive Methods

Although the notion exists that developing countries have an abundance of labour, in the real-field situation, a skilled, reliable, and permanent labour force that is wholly devoted to forestry is in short supply. Most of those engaged in forestry operations are farmers or villagers living near the forests. Forestry jobs are usually taken as a supplemental activity during the agricultural off-season. Therefore, it is difficult for forest enterprises to invest (in terms of training) in such seasonal, part-time workers. When logging takes place far from the villages, problems arise in recruiting enough forest workers and transporting them to the work sites. To solve the problem of daily transport, these workers are sometimes forced to stay in logging camps with deplorable living conditions. If resources were sufficient, the use of capital-intensive methods would definitely reduce the number of workers to be transported to and from the forest every day.

Most of the research studies done in the developed world have aimed at making logging and forestry technology more labour-saving or with less demand for labour because of the high cost. However, in developing countries where labour is still cheap, the objective in research studies is to improve the existing labor-intensive methods by introducing efficient tools and energy-saving techniques. Because labour-intensive methods also create employment for the rural population, this method has always received government support. When deciding which logging method to adopt or recommend in a given area, a number of factors are considered, including the availability of labour and capital, and the terrain conditions. Both the capital-intensive (mechanized) and the labour-intensive logging methods have advantages and disadvantages (Table 1).

While labour-intensive logging methods seem to be more accepted in developing countries, some logging companies still prefer to work with a small labour force to avoid the overhead costs associated with accident compensation, subsidies on transport, housing, annual leave, and legal conflicts. In some areas, labour-intensive methods have occasionally met with some resistance from forest workers, especially those already used to capital-intensive methods. Such workers normally view manual methods as outdated technology with low status in the society. To avoid employee conflicts if labour-intensive methods are to be introduced in such areas, it is better to recruit new working crews rather than forcing already trained and experienced machine operators to change to manual methods (ILO 1981).

Personal-Protection Equipment

Human beings at work are liable to make mistakes that sometimes lead to accidents or injury to themselves and others workers, or damage to tools or equipment (Zander 1979, Pettersson 1983). These human errors can be reduced if the tools and machines are matched to the working conditions and, above all, to the capabilities and limitations of individual workers

Unlike other branches of industry, the nature of the logging industry makes it impossible to create a working environment that is completely free from accidents or hazards. Therefore, besides matching tools to environment, other additional measures have to be taken or introduced at workplaces to minimize or reduce accident risks. These include:

- Provision of personal protective clothing and equipment
- Use of properly designed and maintained equipment or tools
- Training of forest workers on proper operation and handling of logging tools and machines
- Improving workplace and living conditions of forest workers
- Increasing awareness of the importance of safety measures to both workers and supervisors

Experience has shown that most logging companies will not improve the working environment for its workers if the workers are willing to work in such an environment. To protect these employees, labour laws, regulations, and safety rules must be formulated and enacted for all forest operations to ensure that forest workers are protected and compensated by employers in case of accidents. These regulations should require that employers provide protective gear to their crews, that crews wear the protective gear during work, and that accidents be reported and analyzed by the relevant bodies.

Table 1. Advantages and disadvantages of mechanized and labour intensive methods in developing countries.

Method	Advantages	Disadvantages
Mechanized method	Demands less human energy	Requires skilled and trained manpower
	Productivity per unit time is high	Although few, when accidents occur they are severe and sometimes cause or lead to death
	Low number of accidents per working session	Causes more environmental damage
	Inaccessible and difficult areas made accessible	Requires heavy investment and foreign currency to purchase equipment.
	Able to harvest big and heavy logs from difficult terrain	Creates unemployment, especially in rural areas
Labour-intensive method	Employs large number of people, especially in rural areas	Not economical in large-scale operations
	Uses locally available resources such as manpower	Results in high physical work loads or high energy consumption
	Doesn't require foreign currency to purchase and run logging equipment	Improperly designed tools cause stress and sometimes accidents or injuries
	Causes minimum soil and tree damage	Doesn't attract young and trained labor force
	Requires no heavy investments on capital or training of workers	Cannot handle or harvest big and heavy logs from the forests

Conclusions

Most logging in developing countries is done manually by an untrained and unskilled labour force. Productivity is low, while the number of accidents and labour turnover is relatively high. Inadequate techniques, use of poorly maintained tools, high physical workloads, and overall poor working and living conditions are the main factors contributing to low productivity.

Body sizes and dimensions differ between workers in the developed world and those in the developing world. Therefore, tools and equipment should be studied to identify specific areas needing improvements or modifications. Modified tools would reduce not only stress or workloads, but also the number of accidents and injuries in these developing countries.

Collecting anthropometrical data is essential for facilitating the design of appropriate tools and machines. This should precede other initiatives aimed at improving working conditions. Other measures should include training of forest workers on correct working techniques, proper operation and maintenance of tools, implementation of safety measures on the job, and the importance of improving the working environment.

To improve productivity and reduce workloads for forest workers, research studies must also be conducted to 1) improve working methods as well as the health and nutritional status of forest workers, 2) plan optimal work organizations, and 3) encourage the use of appropriate protective gear.

Abstract

A revolutionary development in forest management took place in India in the late 1980s, when participation of local, forest-dependent communities was sought for the management and protection of State forests under the umbrella of the Joint Forest Management (JFM) program. This new approach has now been adopted by 21 of the 25 Indian States. Approximately 3.5 million ha of forestland have been regenerated by more than 35,000 forest protection groups in different parts of the country. This has been accomplished through indigenous and innovative methods and approaches. The Latest Report on the State of Indian Forests (in 1997) shows that, although the amount of new forest cover is small in regions where JFM has been implemented, there have been marked increases in biodiversity, biomass productivity, tree basal area, and other ecological parameters in these areas.

As the phenomenon of JFM has strongly taken root, managers have realized that classical silvicultural systems and operations are not adequately equipped to address the newly emerging needs and demands of the society. The JFM program considers the dependence of local, forest-dwelling communities as well as those living on the forest fringes. Thus, intermittent yields of locally valuable, multiple forest products become critical to the sustainability of this co-management concept. This also conforms to the emerging global consensus regarding the vital role of forests in facilitating the anti-poverty crusade, which is high on national agendas around the world.

Forest management is now recognized as being more than just protection. The local community should be involved in the manipulation of trees and other forest vegetation if total and effective co-management is to be achieved. Thus has evolved the practice of <u>Participatory Silviculture</u>, which is the new thrust area in the JFM-practicing States of India. The techniques and operations implemented under Participatory Silviculture incorporate local knowledge and use perceptions, temporal and spatial dimensions of local needs, and institutional setup. Additional factors include aspects of a wider socio-economic environment apart from forest types, the history of forest management, and other vegetation-related characters. Beginning with species selection and through to silvicultural operations, local needs and aspirations are considered supreme. These silvicultural methods, though simpler, are evolved jointly and continuously by the technically skilled foresters and the forest-dependent community. Local communities now conduct their own operations, such as lopping for fodder and fuelwood, rotational blocking for NTFP collection, multiple shoot (MS) cutting, stump dressing, pruning, etc.

This poster attempts to answer the following questions regarding the potential role of Participatory Silviculture in the sustainable management of community forests:

1) Are community forests being managed effectively to respond to the needs of the user groups?
2) What kind of silvicultural manipulations are being carried out by the forest user groups, and how do both scientific and local knowledge come into play in determining such practices?
3) Is there any need and/or scope for further strengthening and improvement of these silvicultural interventions to address both social and environmental needs?

The poster highlights and analyzes the results obtained from field studies in Central India (Harda Forest Division), Bihar (Singhbhum Forest Division), West Bengal (Bankura Forest Division), and Nepal (Kavre Forest District). Ecological factors have been re-examined that limit natural forest recovery on degraded areas under co-management. The studies also

evaluated various management options and the socio-economic and policy issues that influence silvicultural decisions for restoring and rehabilitating degraded natural forests.

Abstract

A dramatic economic transition in Russia has caused difficulties for Russian forest industries. Annual cuts have been drastically decreased, and numerous sawmills and pulp mills are experiencing hardships because of a shortage of raw material. At the same time, exports of roundwood make up the core of forestry income. Reliance on earlier timber-harvesting systems has been very difficult, because Russia's own machine production is also struggling in the transition. Therefore, redesigning the harvesting systems is proposed as a solution. Western machine manufacturers consider Russia a potentially strong market, but the lack of capital hinders transactions. In addition, unemployment is a serious problem among forest workers.

A Taiga Model Forest (TMF) project was launched to establish a model forest area for demonstration and experimental purposes. One objective of this project was to find profitable and cost-effective technological applications for forest operations in northwestern Russia. Technology transfer within the project itself was mainly an exchange of scientific knowledge among scientists. Nevertheless, one purpose of the project was to demonstrate Scandinavian timber harvesting and to compare it with local Russian methods in a large thinning experiment. Shortcomings of this approach included the Russian counterparts' lack of knowledge in the actual planning of forest operations, as well as the unstable situation in Russian society. Both of these situations have caused serious problems with the realization of the TMF project's goals. In this paper, the TMF project was analyzed in a Samli's framework of technology transfer. One aim was to examine international transfer of forest technology by observing an on-going case. The Samli's model used in this study was improved upon by attaching outside motives to the framework. These outside motives (from non-governmental environmental organizations) had been one of the driving forces when the TMF project was established.

Comparative studies based on unit-cost calculations indicate that, economically, an intermediate technology would be the most profitable method in this case. This is because of a low level of salary in relation to the price of advanced technology. An intermediate timber-harvesting technology would also be more profitable for the economics of northwestern Russia because of its positive influence on employment and its smaller demand for foreign currency when procuring harvesting equipment.

The best results from the TMF were obtained in the training and advising of forest workers, who quickly adopted the principles of the new methods. In the TMF, Scandinavian forest road-construction methods also were demonstrated in cooperation with Russian road-construction companies. The local machinery labor was suitable for forest-road construction when the Scandinavian methods were used.

Intermediate technology practices in timber harvesting seem to be the most promising way to help northwestern Russian forestry in this difficult situation. However, because the current need for forest worker education is so great, the transition to more cost-effective Scandinavian systems may be slow.

Keywords : Timber harvesting, Taiga model forest project, Northwestern Rusia.

Using the Delphi Method to Forecast Priorities in Forest – Engineering Technology

Abstract

Forest engineering technology must be promoted as a pivotal component in sound management of Japan's forests. Using the Delphi method, we conducted a technology-forecast survey to gain a long-term perspective on the future of forest engineering. Survey results were consolidated through two questionnaires. We selected respondents who were experts with extensive knowledge of forest engineering: 20% from the forestry sector, 19% in machine manufacturing, 26% university-related, 29% in public research institutes, and 6% in other areas. For the first part of the survey, we sent questionnaires to 79 respondents, of whom 50 were then sent the second questionnaire. We excluded those who withdrew from the survey after the first questionnaire. The rate of response was 63% for the first part and 90% for the second.

The preliminary questionnaire was used to determine the forecast topics. We divided forest-engineering technology into four categories: machinery, operations, ergonomics, and roads. Within each category, the respondents were asked to state topics of concern that could be addressed, or ”realized”, in Japan by 2030. Predictions for the technological stage of fulfillment for each topic were made with one of three phrases: ‘in development’, ‘in practical use’, or ‘in widespread use’. The respondents proposed more than 100 topics. After all topics were prioritized according to importance and generality, 37 were selected for special consideration (14 in machinery, 13 in operations, 5 in ergonomics, and 5 in roads).

The respondents forecast the time for realization of half the topics by 2010, 90% by 2015. The earliest two topics forecasted (in 2007) were ”Widespread use of the instruction manual of forest operations for voluntary workers” and ”Widespread use of non-clear cutting operations using mobile tower yarders”. The topic ”Development of unmanned harvesting machines” was forecasted for realization after 2020.

Based on results from the second survey, an importance index was calculated for each topic; the overall average was 59.7. The topics with the three highest indexes (all >80) were related to environmentally aware technology: ”Widespread use of the evaluation and management methods of environmental conservation in forestry”, ”Widespread use of near-natural road construction methods”, and ”Widespread use of the accurate predicting methods of environmental impact through forest operations”. We also asked for ‘Effective measures the government should adopt for realization’ of each topic. Among the choices, ”Increase in government funding for research” was most frequent (average 50.5%). ”Personal exchange between the industrial, academic and government sectors” was chosen in 39.9% of the replies.

The forecasted realization time for each topic will be referred to during development of technology strategies in the forestry sector. Environmental concerns should be emphasized more in the future as R&D is promoted in the field of forest engineering technology. In particular, financial support for R&D and collaboration between industry, university, and government are expected to be considered when forest technology policies are proposed.

Abstract

Various approaches have been proposed for prioritizing forestry research programs. Evaluating the merits and demerits of each approach may provide a means for ranking individual programs. Unfortunately, all of the current methods are rooted in agricultural environments, with the primary focus only on prioritizing particular species in annual crops. In contrast, the man-made models that are designed for studying natural systems in forestry consider species to be but one of many components in the system. Therefore, a practical approach is needed, which is applicable to the unique requirements of forestry. Our proposed method comprises two phases: Phase I -- prioritization of forestry projects; and Phase II --prioritization of research programs. This approach reduces subjectivity by introducing objective questions whenever judgments must be made.

The process of Phase I begins by identifying the relevant issues in forest management, viz., Geographical Cover of forests; Conservation of Bio-diversity; Protection of forest resources from all kinds of destabilizing factors; Restoration of the degraded forests; Production of material goods; and Extension of forestry for practice by the public. These are the primary objectives in tropical forest management. Forests are categorized, based on both biotic and abiotic characteristics, by the amount of ground they cover. At this stage, judgments are made according to the relevance or importance of each objective in various forest categories. Grades are assigned as Absent, Poor, Low, High, and Highest.
The subjectivity inherent with making judgments can be reduced by using objective questions. The graded judgments carry scalar values of 0, 1, 3, 6, or 10. Direct or inverse weights are introduced that account for the extent to which a forest is impacted by each objective. The total scores earned by the various combinations of forests and objectives are ranked in descending order. Rankings are improved by introducing the level of impact that each objective has on Economic, Environmental, Political, and Sociological aspects. The final ranking, which includes the improved, combined scores, provides the priority for forestry projects.

Phase II commences with identifying the chief components involved in technological activities. These components are ranked according to their contributions toward fulfilling forestry objectives. The technological activities are assigned to one of five levels: 0, 1, 2, 3, or 4, with 'Level 0' referring to rudimentary or absent, meaningful technology; and 'Level 4' indicating the highest level of technology that is feasible for a particular component. Technological Levels are scored as 0, 10, 30, 60, or 100%, respectively.

The goal of all research programs is to progress from some lower level to higher technological levels. Each upgrade is a gain toward fulfillment of the objectives. The gains from technological upgrade are estimated for all the components of Prioritized Forestry Programs. This is followed by an estimate of the final score, which is the product of both the expected gains from the technological upgrade and the score of the Prioritized Forestry Programs that was estimated under Phase I. Using this method results in the identification of Prioritized Forestry Research Programs, with final scores listed in descending order.

Impacts of Forest Harvesting Operations on Soil Properties

by
Sun Molong, Associate Professor
Center for Forest Operations and Environment
Northeast Forestry University

People's Republic of China
Fax: +86-451-2110146

Abstract

Forest operations in northeastern China include planning for harvest systems, logging, transport, road-network design and construction, slash disposal, and planting after harvesting. These activities are significantly correlated with soil disturbance, which can be measured in terms of the degree of break and compaction as well as the loss of soil nutrients. Four sub-projects were conducted to study the effects of forest operations on physical and chemical soil properties at the operation sites. The study variables included such factors as cutting system, skidding traffic, layout and construction of forest-road networks, and slash disposal. In general, the degree to which soil physical properties were affected was closely related to the level of energy input, i.e., how much timber was removed from the forest, during operations at the harvest site.

Three cutting systems were employed: selective cutting, thinning, and small-area clear-cutting. Of these, selective cutting has been the most commonly used system over the past 10 years, and will probably be the best harvesting method in the near future. However, soil physical properties were affected most significantly by this method, as measured by the degree of disturbance associated with the volume of timber removed per ha. This is because more movements and greater energy inputs were required for executing the operations on each tree. Clear-cutting and thinning were ranked second and third, respectively. In terms of disturbance per unit area, however, the clear-cutting system had the most significant impact on both physical and chemical properties of soil, accounting for approximately 15% of the variation. This was because of the more-concentrated operations involved with this system.

Timber was moved from the site by tracked crawler, wheeled skidder, cable-yarding, or animal skidding. During the winter, ground-skidding traffic did not significantly influence soil physical properties, even after six to eight passes by the machinery. However, the opposite was true when the ground was not frozen. The wheeled skidder then had a greater impact than did any other means of log transport. Field investigations showed good natural regeneration in the areas disturbed by crawlers, but not at the landings or in the main skidding-track ruts. Animal skidding was an environmentally sound technique, with moderate operating costs. Because no soil damage is inflicted during winter operations and only slight amounts during the other seasons, the use of animals has increased to about 90% of all the skidding done in the last 5 years.

Three slash-disposal methods -- burning, piling, and spreading -- have been employed during the last 10 years of harvesting. Although the burning method has impacted the soil more because of nutrient losses, it has been beneficial in improving soil acidification. The other two slash methods have had moderate influences.

A well-planned forest-road network can reduce soil erosion. To lessen the impact of forest-road construction on soil properties, we are presenting a new mathematical model for optimal layout of forest roads. Both economical and ecological benefits are considered in this plan.

The Historical Development of Forest Operations in China and a Look Ahead 10 Years

by
Wang Lihai, Professor
Department of Forest Operations

Wangqing Forestry Bureau,
Jilin Province, China

Abstract

The history of forest operations in China since ancient times (more than 2000 years ago) has included developments in operation technology, equipment, organization, and professional education. We used the Entropy Growing Analysis method for studying the dynamics of these developments, particularly with regard to the interaction between human society and forest ecosystems in a given region. In China, the deforestation rate is highly correlated with an increasing population rate i.e., each era of great population explosion has resulted in large-scale deforestation.

Forestry activities have changed greatly in the last century because of the fast development of science and new technology, unbelievable population growth, and rapidly changing social structures and market systems. In the first half of the 20th century, large forests were destroyed during continuous wars, mad land-grabbing by invaders, and unanticipated establishment of farms by immigrants. The main goal of forest operations during that period was to extract as much timber and farmland from the forest as possible. Machinery, such as a forest railway transportation system powered by steam engines, significantly improved operational efficiency. Unfortunately, this new trend toward mechanization increased the capacity for human interference in the forest. However, the rest of the work was done manually, and contracted teams were a popular means for organizing forest operations.

Since 1949, and particularly in the past 20 years, forest operations in China have been greatly modified. Not only have the science and technology of forest operations been developed significantly; the environmental aspects, profitability, and economic efficiency have also been emphasized. Forests are now recognized as important suppliers of non-wood forest products such as water and soil protection, climate adjustment, and an assortment of flora and wildlife. These factors are considered when decisions are made about harvesting, timber extraction, and civil engineering in forests. In integrated forestry, planning is done from the viewpoint of sustainability for both timber and non-timber forest products. All activities, e.g., forest resource surveying and harvesting planning, road planning and construction, harvesting, post-harvest site disposal, and planting and protection must now serve these key purposes. As well, forest-operations technology and techniques have been converted from manual- to machine-driven, and are now part of an environmentally sound complex. Planning and organization has been changed from that of small, manual working groups to large-machinery operations. The working system now involves many contracted groups at different levels.

"The Natural Forest Conservation Project", begun in 1998, identified the challenges and opportunities in Chinese forest operations. The market for small- and mid-sized machines, with multi-functions, will be the most dominant in the near future, depending on the forest resources available in China. Environmentally sound, low-cost, and highly efficient forestry technology and techniques will be in the spotlight of both research and practice in the next 10 years. Forest operations will also play quite an important role in the management of sustainable forestry.

Abstract

In this paper we describe why carbon is an issue in forestry: forests and forestry have an important role in the global *and regional* carbon cycle and therefore provides connection to the global climate and climate change. The role of forests in carbon cycle has been emphasised in the United Nations Framework Convention on Climate Change (UNFCCC) in 1992 and more recently in conferences of the parties to the UNFCCC in Kyoto and Buenos Aires.

The first part of this paper deals with commercial forestry: what are the specifics of intensive versus extensive forestry in relation to carbon sequestration. This includes comparisons between natural forests and plantations, previous land-use, forest management (available mechanisms for optimising production and C storage), and to what extent management for maximum C competes with / complements other management objectives (for example timber supply, biodiversity, aesthetic). The contribution of forest products as a temporary reservoir, but with human control, in the carbon cycle is also included. Finally, the role of wood in products that avoid energy emission in their manufacture and as a source of energy to replace fossil fuels is addressed.

The second part deals with these issues at the regional/biome level - in boreal, temperate and tropical forests – examining differences in carbon stocks and fluxes, as well as differences in timescales. This section consider the unique properties in each biome, i.e. forest fires in boreal regions, intensive forest management in temperate forests, land use change in tropical regions. Several case examples are described, including a discussion of the relative role of wood products/bioenergy and the future role for forest sector carbon offsets.

As a conclusion, potential environmental and economic changes with environment and new values associated with carbon are discussed. Past changes, present fluxes and future possibilities (risk and opportunities), scientific challenges, gaps in data and understanding, as well as recommendations for research and development are highlighted.

Abstract

Forests are a critical element in the global carbon cycle. While forests are currently a small net carbon sink worldwide, there is the risk that this trend will change, significantly increasing the accumulation of greenhouse gases in the atmosphere. The forest sector must become engaged in the process of using forests as a key instrument in addressing climate change. There is a need for large scale reforestation and the protection of remaining primary forests as part of the global efforts to achieve a safe level of atmospheric carbon dioxide. The design of large scale reforestation programs should consider social and economic factors and should incorporate other environmental benefits related to watershed management and biodiversity enhancement. A system of environmental credits could be used to stimulate such a new approach to forest management.

Keywords: Carbon sequestration, Kyoto protocol, Watershed management, Environmental credits

Introduction

Climate Change is now recognized by the global scientific community as the greatest environmental threat facing the world today (UNEP 1999). The negotiation of the Kyoto Protocol to the Framework Convention on Climate Change in December of 1997 (UNEP 1998, UN 1992) has included a recognition of the role of forests as a significant terrestrial storehouse of carbon and a potential tool in removing carbon dioxide from the atmosphere. In fact the loss or degradation of forest cover worldwide has been a significant contributing factor to past increases in carbon dioxide in the atmosphere. The emphasis on forests as a key element in global efforts to address climate change may provide the forestry community with a new impetus to expand forest cover and strengthen the commercial foundation for forest conservation and management. However, the size of this challenge means that care must be taken to ensure that climate change related actions are integrated with forest management, and not overwhelming it.

Forests serve three principal roles in global efforts to address climate change (IPCC 1996). The first is as a major storehouse of carbon in terrestrial vegetation and forest soils and, where the area of forests is extended or biomass increased, as a sink of carbon dioxide from the atmosphere. Secondly, wood products can serve as a low embodied energy building material, replacing those materials with higher embodied energy or emissions associated with their production. Finally, forests can contribute many forms of renewable energy for society, including biomass energy, charcoal and liquid fuels such as ethanol (Lugar and Woolsey 1999). Together, these three roles may generate both an increased emphasis on the establishment or re-establishment of forests and on their use in substitution for fossil fuel based energy and production systems (Brand 1998).

The Kyoto Protocol left the details of many issues related to accounting for forest-based carbon sequestration and storage for ongoing negotiation. At the fifth Conference of the Parties to the Framework Convention on Climate Change (COP5), held in Bonn, Germany in November 1999, it was decided that negotiations related to forest sinks should be intensified, with the aim of concluding agreement on key outstanding issues by COP 6, in November 2000. These negotiations encompass issues that are technical, commercial and political in nature. The rules that emerge will have an effect on the patterns of investment in forest management, the objectives of forest management and the size and nature of markets for forest products. It is important therefore, that the forestry community be actively engaged in supporting and providing input to these negotiations.

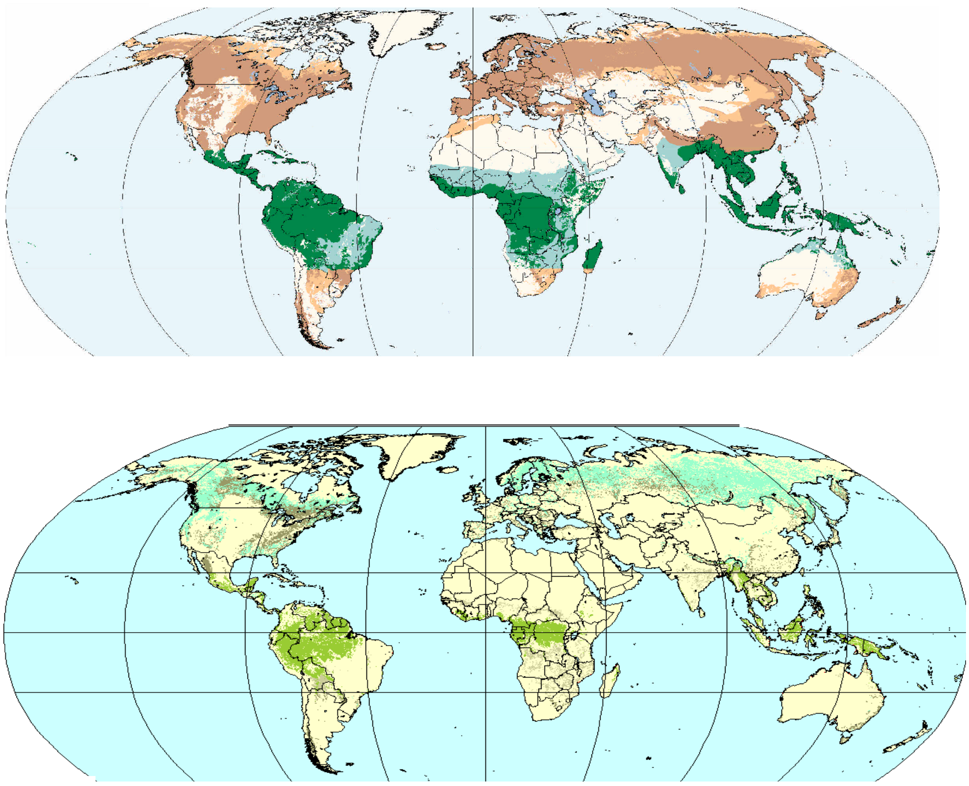
This paper will review technical issues related to carbon sequestration and storage in forests and the potential ramifications to forestry of the Kyoto Protocol being ratified and entering into force. It will be important that the forestry community takes a pro-active stance on the role that may be played by forests in addressing the global threat of climate change.

The Role of Forests in the Global Carbon Cycle

At a macro-scale, forests are currently considered globally to be a carbon dioxide sink from the atmosphere (IPCC 2000). Over the past two centuries, it is estimated that approximately 265 Gt C has been emitted as carbon dioxide from fossil fuels and cement product, while a further 140 Gt has been emitted from land based change, primarily related to forest clearing. Of this total, it is further estimated that about 225 Gt have been re-sequestered in oceans and in the biosphere. At present the terrestrial ecosystems are estimated to be a small net sink, of about 0.2 Gt per year, meaning that vegetation growth across the globe slightly exceeds emissions from forest clearing or harvesting. It has been suggested, however, that this sequestration cannot continue indefinitely and, if it stops or reverses, will lead to substantial increases in the rate of annual atmospheric greenhouse gas accumulation (Anon. 1999).

Protection of remaining primary forests and the re-establishment of forests, therefore, is a key challenge for the international community (Figure 1). A sole focus on the reduction of emissions from fossil fuels will not address the fundamental objective of the Climate Change Convention to achieve a safe level of greenhouse gas concentration in the atmosphere (FCCC 1992). It is for this reason that both the Framework Convention and the Kyoto Protocol made arrangements for accounting for land use, land use change and forestry as part of the national level management of greenhouse gas emissions.

Figure 1. Extent of primary forests 8,000 years ago and today. Protection and regeneration of forest cover is a significant element in addressing the global greenhouse gas accounts (Source: World Commission on Forests and Sustainable Development).



Forests are managed at a regional or management unit scale, rather than at a national scale. For this reason, the forest-related aspects of the Kyoto Protocol must be translated down to a project scale for meaningful actions to be taken. If the Protocol comes into force with agreed modalities for the flexibility mechanisms (Emissions Trading, Joint Implementation and the Clean Development Mechanism) and for the use of carbon sinks, there is the potential for a direct reward system for increases in terrestrial carbon sequestration.

Carbon Accounting at a Project Scale

The growth of a forest established on previously cleared land follows a logistic growth curve—initially slow as the forest occupies the site, then rapid as canopy cover occurs, then declining as the forest matures and respiration rates approach photosynthesis rates. Forest management has long relied on the ability to measure and forecast the volume of timber in tree stems. In many jurisdictions there has also been significant effort in measuring total above-ground biomass of the tree. Carbon accounting, however, requires a complete measurement and forecasting of the carbon content in the forest, including the stem, crown, root systems and soils. For this reason, the development of improved tools for forest carbon measurement and accounting has been an active area of research in recent years (eg Woomer and Palm 1998, Hruska et al 1999).

Forests can be managed for both conservation and production purposes. Where conservation is the primary objective and the forests are intended to be maintained without harvest in perpetuity, the initial growth period, up to maturity will represent carbon sequestration. In forests being managed through a harvesting cycle, the carbon accounts will include periods of sequestration and periods of emissions related to harvesting. Current guidelines issued by the Inter-governmental Panel on Climate Change require that any harvesting of forest products be treated as an immediate emission back to the atmosphere (IPCC 1996). Combining a series of forest stands into a carbon pool can smooth the overall carbon stocks over time. For example, a forest management unit established over a rotation period with balanced age classes will sequester carbon throughout the first rotation and then stabilize (Figure 2)

From a commercial point of view, a market for carbon sequestration credits would potentially stimulate the establishment of new forests. Conservation forests would be able to earn revenue from 'carbon credits' if the Kyoto Protocol mechanisms are finalized and endorsed. Production forests would benefit from a cash flow during the early stages of forest growth, where long time periods without revenue have often acted as an impediment to forestry investment. Creating a forestry system that manages the dual incomes from carbon sequestration and timber or energy production will be a new challenge for foresters. In particular, the carbon sequestration must occur on a long term basis, or else any credits sold would need to be re-purchased if the forest is cleared and reverts to pasture or other non-forest land use.

New South Wales, Australia, has pioneered the development of some of these businesses. The government introduced legal carbon rights that can be registered on land ownership titles. State Forests of NSW has used that legislation to design investment packages that blend together the management of forests for carbon sequestration and timber production. In February of 2000, the Tokyo Electric Power Company, which is the world's largest privately owned electricity company, signed a contract with State Forests to provide up to 40,000 ha of new forests in the next decade. This contract may be a harbinger of a new class of investor in the forest sector and a new partnership between the forestry and energy sectors.

Landscape or Management Unit Scale Issues in Management of Carbon Sequestration

At the landscape or management unit scale foresters must contend with the intersection of socio-economic and environmental or ecological systems. Building up the carbon sequestration capacity on a regional basis will involve land use change and may cause shifts in social and economic conditions. The value of carbon sequestration in an international emissions trading regime may be enough to stimulate significant reforestation in areas of degraded land, but may also compete with traditional agriculture and grazing economies. Where traditional agriculture is declining, however, the carbon sequestration credits can provide an economic boost, encouraging reforestation and associated employment opportunities.

Figure 2. A series of age classes of forests, can be managed both for timber production and as a carbon sequestration pool.

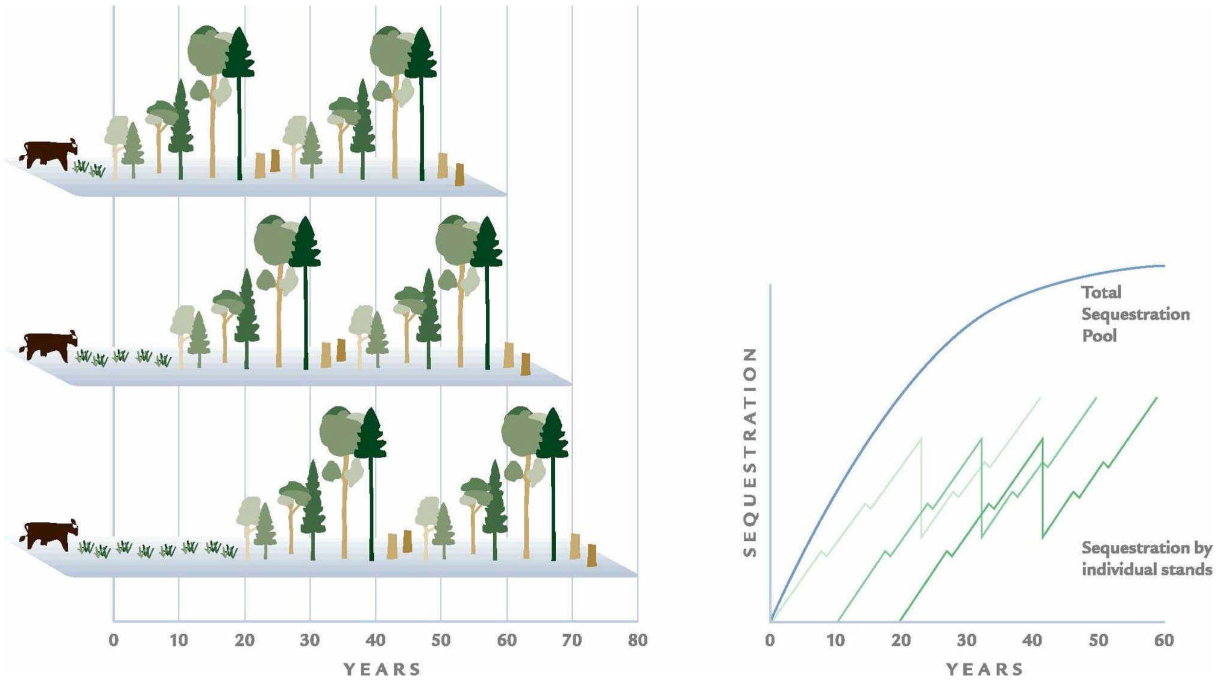


Figure 3. Past clearing of forests and woodlands has led to rising saline water tables and threatens water quality in the Murray Darling Basin. A large scale reforestation program will need to be part of the solution to this problem.

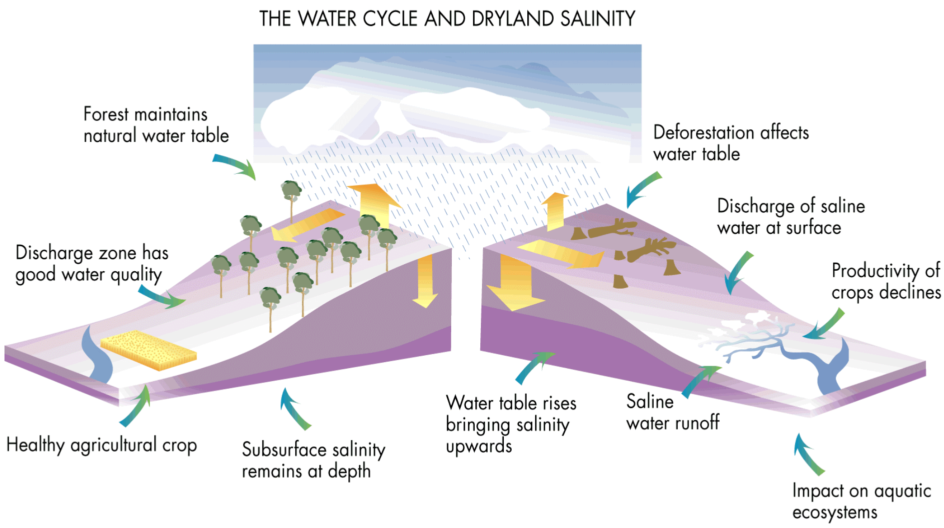

In many areas of the world reforestation is a critical need for rehabilitation of degraded areas, improvement of water quality, prevention of soil erosion or landslides, management of soil water tables or soil chemistry or any of a variety of other values. In Australia, for example, long term clearing of forests and woodlands for agriculture has led to a growing recharge of soil water, elevating saline water tables and leading to a saline discharge into the river systems (MDBC 1999) (Figure 3). This threatens community water supplies, downstream irrigation-based agriculture, and critical wetland ecosystems.

Without large scale reforestation in this region, there will be a decline in both socio-economic and environmental systems across the key agricultural region of Australia.

Much of the Murray Darling basin has precipitation levels below 700 mm, which has been the traditional limit for commercial forestry. This salinity crisis, however, has led to the piloting of a salinity control credit scheme, based on downstream water users paying a fee per Megalitre of transpiration from new planted forests. Combining the potential for carbon sequestration payments with these salinity control credits will be a major impetus for the reforestation programs needing to be undertaken. This will require that the community determine the level of salinity that they are prepared to live with and then letting a market evolve for these salinity credits.

The new forests being established for carbon sequestration and other benefits can also contribute to the expansion of renewable energy systems. While biomass energy has been one of the most widespread energy sources for subsistence energy and home heating, it has not been seen as an alternative to fossil fuel based electricity generation. A carbon tax or emissions trading regime would narrow or remove the cost advantage of fossil fuel based energy systems. Forest biomass can also be used as a reductant in metal smelting and as a basis for liquid or gaseous fuels.

Past attempts have been made to introduce the concept of energy farming, but again, the cost of biomass has not been able to compete with fossil fuels. With carbon sequestration credits and a commercial boost to biomass energy systems through emissions trading, it is now becoming apparent that we need to develop highly efficient systems for growing forest biomass, almost like a solar harvesting system. Recent work in Australia points to a current delivered price for biomass of $25.00 per tonne, but a growing, harvest and delivery cost of $30.00 per tonne. If carbon credits and emissions trading systems can bridge that gap, forests can be used to support smaller, regional power plants. Current estimates are that a 5 MegaWatt electricity plant would utilize about 3,700 ha of forest on a continuous rotation basis (Figure 4)

Bringing together the carbon sequestration, salinity control credits, new energy farming systems and the enhancement of biodiversity is a concept with widespread support in Australia. These packages of environmental goods and services may actually expand regional economies and create new jobs. Similar approaches could be developed in every region of the world.

Conclusion

Forest management faces a period of opportunity, but also of challenge, as we witness the emergence of one or more envrironmental markets. In some ways carbon sequestration is the perfect global commodity, as the world has only one continuous atmosphere. The absorption of carbon dioxide from the atmosphere in Australia, paid for by a greenhouse gas emitter in Japan, will be an ever more common scenario. But following now behind the market for carbon sequestration credits are other environmental credit markets for watersheds and biodiversity enhancement. Markets create incentives and rewards to those who can successfully respond, and these new forces will shift the objectives of forest management. If the global challenge of managing atmospheric carbon dioxide spurs a large scale reforestation in many regions of the world, it should be undertaken in a way that is also contributing to rural social and economic systems. Focussing reforestation in areas of marginal agriculture or regions with soil degradation may create significant benefits for the environment and for rural economies.

Figure 4. Energy farming may become a reality if the value of carbon sequestration and fossil fuel emissions offsets are factored into the price.

Abstract

At CATIE, long-term research has focused on development of technologies for sustainable management of natural tropical forests and their biodiversity. Forests cut using sustainable practices can have higher seedling regeneration, and also higher understory biodiversity than forests cut using conventional methods. Post-harvest silvicultural treatments increase the diameter growth of potential crop trees though the consequences for sustainability of their effects on forest composition, through the elimination of non-commercial competitors, remain to be evaluated. Different management operations affect plant diversity in different ways, over different time scales, but there is no evidence for drastic changes of diversity during the first felling cycle even in stands whose structure is radically altered by refinement/liberation treatments. Patterns of seed dispersal and germination can also be affected as a result of defaunation and changes in the forest microenvironment.

CATIE researchers are also involved in the design of systems of diversified forest management, involving studies on the ecology and management of non-timber forest species. Many forest management practices are best suited to small farmers, farmer cooperatives, or to community forest users. Some farmers'cooperatives in Costa Rica manage the forests for eco-tourism and non-timber forests products, while they cultivate other portions of their land, and reforest degraded land with native species, often in mixed-species designs. Tropical plantations can supply wood products, contribute to carbon accumulation, land reclamation and acceleration of natural regeneration. Domestication of promising species for plantation forestry involves selection of outstanding trees, evaluation of genetic variability, trials of seed germination and storage, evaluation of the performance of species under different silvicultural systems, and the development of seed orchards for the production of genetically improved seeds.

Abstract

Forestry may play an important if not critical role in the ability of the U.S. to meet its greenhouse gas emissions target under the terms of the Kyoto Protocol. Given the low rate of change in the U.S. forest land area, the major anthropogenic influences on the current net forest carbon flux are forest management and protection activities that have resulted in continuing increases in forest carbon storage. Natural disturbances such as fire, insects, and diseases are locally important factors, but when all U.S. forests are considered, they are small relative to the effects of harvesting and growth. Carbon in U.S. forest ecosystems, wood products, and landfill wood was estimated to account for an annual net sequestration of about 300 TgC/yr during the 1980's, and are projected to comprise at least 200 TgC/yr over the next several decades. Proposed accounting rules under the Kyoto Protocol article 3.3 may render most of this C sequestration unaccountable towards the U.S. emission reduction target unless additional activities are accepted under article 3.4. Forestry practices that are likely to result in a positive C sequestration in the U.S. include afforestation of marginal cropland and pasture, improved forest management, adjustments in harvest timing, establishment of short-rotation biomass plantations, improved utilization of harvested biomass, and tree planting in urban and suburban areas.

Keywords: Kyoto Protocol, forestry, carbon sequestration

Introduction

The United States signed the Kyoto Protocol[1] on November 12, 1998, reaffirming America's commitment to meeting our most profound environmental challenge -- global climate change. Under the terms of the Protocol, the U.S. must reduce net emissions 7 percent below 1990 levels by the first reporting period, 2008-2012. This reduction is substantial given that emissions are expected to rise during this period due to population growth and economic expansion.

The role of forestry and land use change has been controversial throughout the international negotiation process. There are differing opinions around the world on whether forestry activities should be counted. A country's position depends on factors such as whether its forests are currently or prospectively a net source or sink for carbon dioxide (CO_2), whether carbon (C) stock changes in forests can be measured and verified, and the relative emphasis that should be placed on reducing emissions versus increasing sequestration. Some countries express concern that forest responses to "natural" factors such as increased atmospheric CO_2 (which may increase growth) would allow a country to claim credit for greenhouse gas reductions that are not associated with specific activities.

The Kyoto Protocol attempted to reconcile the diversity of viewpoints on land use change and forestry. According to Article 3.3 of the Protocol, land-use change and forestry activities that can be counted toward the emissions reduction target include afforestation, reforestation, and deforestation since 1990 if the changes in stocks can be verified. Some interpretations of the definitions of terms under article 3.3 exclude managed forests with harvest and regeneration cycles from counting toward the emissions reduction target. However, article 3.4 provides an opportunity for nations to propose including additional activities such as forest management, and the agreement does include sustainable forest management as part of a general statement supporting sustainable

[1] http://www.unfccc.de/resource/protintr.html for the full text of the Protocol.

development and protection and enhancement of sinks.

The language, terminology, and accounting methods contained in the agreement are somewhat vague, and can be interpreted in different ways. Definitions of key terms such as reforestation are not stated, which becomes a problem for implementation of the Protocol because there are many different definitions in use throughout the world (Lund 1999). The proposed accounting system is vague. For example, it is not clear whether harvested timber should be counted as a forest sink and if so, under which circumstances it could be counted.

To address these issues, the United Nations Framework Convention on Climate Change (UNFCCC) asked the Intergovermental Panel on Climate Change (IPCC) to establish an expert panel to develop a special report on the land use change and forestry provisions of the Kyoto Protocol. The panel is reviewing definitions, accounting issues, and activities that could potentially be included within the terms of the Protocol, and will document the various options for eventual reconciliation during the ongoing Conferences of Parties. This paper reviews the status and trends in U.S. forests as revealed by long-term monitoring, and explores the potential to increase carbon storage in forests as a contribution to the emissions reduction requirements of the Kyoto Protocol.

Trends in U.S. Forest Resource Statistics

The area of forest land in the U.S. has not changed significantly since the early 1900's. The area of forest land in 1907 is estimated as 307 million hectares, and in 1997 the area of forest land is estimated as 302 million hectares (*from preliminary statistics of the 1997 Resources Planning Act Assessment*). However, changes for the whole U.S. mask divergent regional trends. For historic and physiographic reasons, we speak of four regions in the U.S.: the North, South, Rocky Mountains, and Pacific Coast (Fig. 1). Since the 1900's, the North has been gaining forest land area, with the other three regions each losing forest land area (Fig 2). There have been significant shifts between land use categories, such that gains in forest land area from afforestation of agricultural land approximately offset losses of forest land area to development. There has also been a significant shift from natural forests to planted forests. The area of plantations in 1997, mostly in the South, is approximately 33 million hectares, or 11 percent of the total forest land area.

Figure 1. Regions used in the analysis

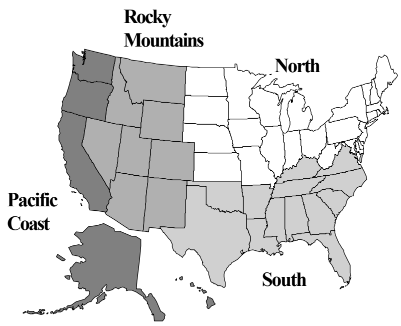

Figure 2. Forest land area in the U.S. by region, 1907-1997 (from Review Draft, 1997 RPA Assessment of the Nation's Forests)

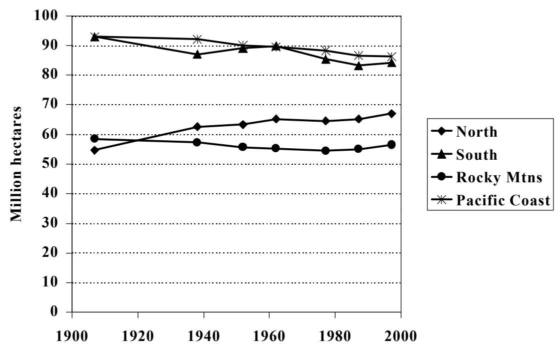
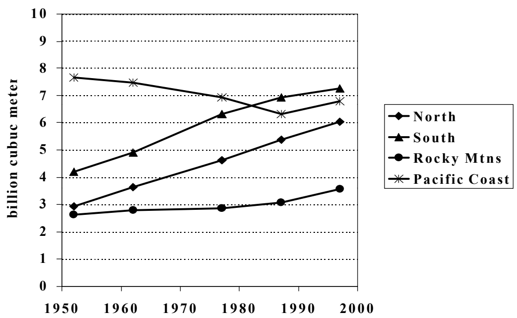


The net volume of softwood growing stock increased by 12 percent between 1952 and 1997 to a total of 14 billion cubic meters. During the same period, the net volume of hardwood growing stock increased by 90 percent to 10 billion cubic meters. As is the case with forest land area, these changes differ by regions. The North, South, and Rocky Mountains each gained growing stock volume, while the Pacific Coast lost growing stock volume (Fig. 3).

Figure 3. Volume of growing stock in the U.S. by region, 1952-1997 (from Review Draft, 1997 RPA Assessment of Nation's Forests).



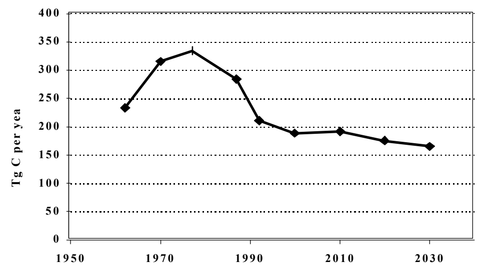
Differences in forest land area and growing stock volume trends reflect long-term changes in land use and harvesting. Millions of hectares of forests in the North, particularly in the Northeast, have regrown on agricultural land that was abandoned to forest land prior to 1900, causing a long-term increase in growing stock volume. These regrowing forests are now maturing, and therefore the rate of increase in growing stock volume is expected to slow substantially. The historical pattern is similar in the South, but the intensive utilization of southern forests for wood products over the last few decades has effectively halted regional gains in growing stock volume, as growth and removals have come into rough balance. Forest land area has not changed much in the Rocky Mountain region, where removals have been low relative to growth. Fire suppression and low removals have caused a substantial buildup of growing stock volume, and a corresponding increase in the potential for catastrophic wildfire in the region. In the Pacific Coast, growing stock volume has declined as old-growth forests have been harvested and converted to young regrowth. Growing stock volume is expected to continue the recent increase as more area of forest land has been reserved from timber harvesting operations.

Trends in Carbon Storage of U.S. Forests And Wood Products Under

A Comprehensive Accounting System

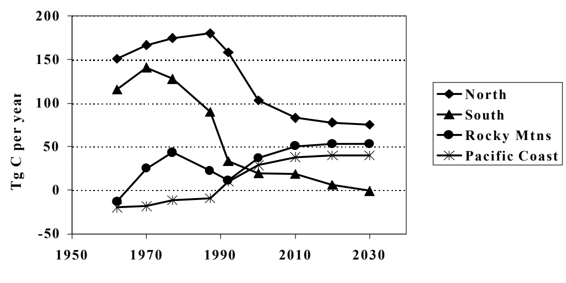
Forest inventory statistics can be converted to estimates of ecosystem C using known relationships between volume and mass for different species and regions. Ecosystem C pools are usually separated into several components: above- and below-ground live biomass, coarse woody debris, litter, and soil organic matter. Estimates of ecosystem C show that increases in biomass and organic matter in U.S. forests from 1952 to 1992 added 281 Teragrams of carbon per year (TgC/yr) to forest ecosystems, enough to offset 25 percent of U.S. emissions of CO_2 for the period (Birdsey and Heath 1995). Baseline projections using the U.S. carbon budget model FORCARB show additional increases of approximately 177 TgC/yr in forest ecosystems through 2040 (Fig. 4). This "baseline" carbon budget refers to long-term trends in forest carbon storage using economic assumptions from the 1993 RPA Assessment (Haynes et al. 1995), in the absence of major forestry policy changes or changes in forest productivity or species distributions as a consequence of climate change. The projected baseline includes forest policies in effect at the time the projections were made; in particular, reduced harvest levels on National Forest lands, decreases in clearcutting and increases in partial cutting practices, and continuation of federal cost-share programs at recent historical levels.

Figure 4. Past and projected carbon sequestration in U.S. forest (from Birdsey and Heath 1995)



There are significant regional differences in historical estimates and projected C storage in forest ecosystems (Fig. 5). These differences reflect the influence of many factors including variations in species composition and natural growth rates, and long-term changes in land use, management intensity, and harvesting practices as described earlier. A negative number indicates more carbon is being emitted to the atmosphere than being sequestered into forests.

Figure 5. Past and projected carbon sequestration in U.S. forests by region (from Birdsey and Heath 1995)



The amount of carbon in forests that are harvested and re-grown underestimates the total carbon sequestered in the forest sector. The amount of carbon sequestered in wood products and landfills is in long-term storage, and continues to increase because removals are projected to increase. Heath et al. (1996) estimated that by 1990, about 3,600 Tg of the 10,700 TgC removed from U.S. forests since 1900 remained sequestered in products and landfills. The quantity of C sequestered in wood products and landfills is increasing at about 37 TgC/yr, equivalent to 40 percent of the annual increase in forest biomass.

Possible Trends in Carbon Storage of U.S. Forests Under Article 3.3

Article 3.3 of the Kyoto Protocol states that only verifiable C changes due to afforestation, reforestation, and deforestation activities since 1990 may be credited or debited as part of a country's emissions reduction target. The trends in C storage will depend greatly on the adopted definitions of these activities. For example, under a narrow interpretation of the definition of reforestation, the only land on which carbon changes would count is land that changed use between forest and nonforest categories. This is projected to be a very small quantity of C in the first reporting period (2008-2012) based on area change data. Table 1 displays an estimate of gains and losses in forest land, calculated on an average annual basis (personal communication, Bryan C. Murray, and U.S. Department of Agriculture, Natural Resources Conservation Service 1996).

The estimated total non-Federal forestland area in 1982 was 162,296,000 ha. Thus, the annual gain in forest area is approximately 0.37% of the total forest area base, and the annual loss in forest area is even smaller. If these trends continue, approximately 10,890 hectares will be considered area increases in forest use by 2008, which is about 6% of the total forest area in 1990. Although the losses and gains are fairly close in absolute magnitude, the changes in C storage will be quite different because much of the area loss is to the land use categories of developed and miscellaneous uses. Land use changes to development are often more of a reclassification based on use rather than loss of tree cover. The net result of reclassification generally has very little effect on terrestrial C storage.

It is also unclear how deforestation will be counted in the future (Heath and Smith, 2000).

Carbon will be emitted as forest becomes cropland, but after a number of years, the farmer may switch to "no-till" practices that sequester C as compared to traditional tillage practices, or perhaps the land may revert to forest use again. In other words, the deforestation may be afforested. Keeping track of these possibilities may be confusing.

Under a different interpretation of article 3.3 definitions, changes in carbon stocks on a much greater area of forest land would be counted during the period 2008-2012. A common definition of reforestation includes land areas that were previously classified as forest, but were disturbed or harvested and are being re-grown as forest. Forests in the U.S., particularly the South, are actively managed, and this interpretation would therefore result in a much greater area on which carbon changes would be counted during the first reporting period. However, even this area would be substantially less than the total forest land area of the U.S. because only part of the forest land area would be disturbed or harvested between 1990 and the first reporting period.

Management Practices to Increase Carbon Sequestration

Article 3.4 of the Kyoto Protocol allows countries to propose additional activities that could be credited toward emissions reduction targets. Several categories of management practices that could have a positive carbon sequestration benefit in the U.S. are reviewed below. Not all have been studied thoroughly, but where possible, estimates of the gains in C storage are presented (summarized from Birdsey et al. 2000).

Afforestation of Marginal Cropland and Pasture

Many studies have estimated potential gains in C storage from afforestation in the U.S. A few examples are reviewed here. Moulton and Richards (1990) estimated that offsetting U.S. emissions by 10 percent (about 160 TgC/yr) would require about 29 million ha at an average cost of $12 million per TgC or $1.7 billion per year. Parks and Hardie (1995) estimated that converting 9 million ha of land to forest would increase C accumulation by 44 TgC/yr and cost $21 million per TgC. These two studies did not include effects of increased supply of timber on the forest sector, which may partially offset C gains by reducing prices and increasing demand. Parks and Hardie (1992) used FORCARB and forest sector models to develop two reforestation scenarios and compared the results with a base run (Heath and Birdsey 1993; U.S. Environmental Protection Agency 1995).

The average annual increase in C flux (including C in wood products and landfills) over a 50-yr period is projected to be 14.3 TgC for a 0.5 million ha/yr program costing $220 million/yr, or approximately $15 million per TgC. These costs include only the direct costs associated with tree planting and payment of subsidies.

Table 1. Estimates of changes in forest land use between 1982 and 1992 (1000 ha/yr). Federal ownership is not included.

Type of forest change:	Cropland	Pastureland	Rangeland	Developed and miscellaneous	Water	Total
Loss to--	59.9	116.9	46.5	281.6	19.1	524.0
Gain from--	129.5	337.6	62.8	67.8	7.5	605.2

Projections using a forest/agriculture sector model (FASOM) suggest that efforts to expand forest C flux should have a rather different geographic and species focus than that proposed in past studies (Adams et al. 1999). In contrast to both Moulton and Richards (1990) and Parks and Hardie (1995), FASOM projections suggest a greater emphasis on hardwood species in minimum cost strategies. FASOM simulations indicate that the bulk of the projected afforestation and management changes should occur in the North, mostly in the Lake States region. This is an area of large concentrations of hardwood forests in which hardwood stands can yield significant rates of C uptake. Although the FASOM model recognizes the rapid growth potential of afforested stands in the South just as in previous studies, broader measures of costs and inclusion of welfare trade-offs across markets and regions act to shift the minimum cost solution away from the customary prescription of pine plantations on marginal Southern agricultural lands. In reality, all of the land considered in these studies that could support trees may not be available. Even if the land were available, the infrastructure may not be in place to provide seedlings and assure regeneration for all available land. Additional technical assistance must also be provided to landowners for the planting programs to be effective.

Improved Forest Management

Timberland in the United States amounts to 198 million hectares (66% of the total forest land area) and includes a diversity of ownership objectives, forest types, site productivities, and stand conditions (Powell and others 1994). There are opportunities to sequester additional C on some portions of this large area of forest. Of particular interest are opportunities to increase the density of trees on non-stocked or poorly stocked forestland, and to apply silvicultural treatments to stocked forestland so as to increase the average biomass per unit area. Forest management practices in the U.S. to increase C accumulation may include: (1) restoration of poorly stocked forestland by clearing and regenerating if current productivity is well below average, (2) application of intermediate stand treatments (thinning or timber stand improvement) if the current stand is overstocked, and (3) management for longer rotation lengths (Birdsey 1992b). Including the value of C along with the value of timber increases the optimal economic rotation (Plantinga and Birdsey 1994; van Kooten et al. 1995).

Many silvicultural practices are designed to increase the production of growing-stock volume in desirable species. Gains in C storage are not necessarily proportional to gains in growing-stock volume because: (1) unmerchantable trees will also accumulate C, (2) stocking will increase naturally in poorly stocked stands, and (3) some management practices may remove biomass or disturb the site, resulting in loss of stored C. Studies have shown that thinning, for example, reduces total C storage compared with unthinned plantations (Dewar and Cannell 1992). Nevertheless, intensive forest management can increase total C accumulation over time relative to unmanaged forests, especially if the additions to wood product and landfill pools are counted. Row (1996) presented several case studies illustrating the potential gains from intensive forest management. Loblolly pine (*Pinus taeda*) plantations that are 30 years old contain on average 87 percent more C than natural stands on comparable sites. Gains of more than 100 percent over natural stands are possible with intensive management and genetically improved planting stock. Similar gains were found from converting natural aspen-birch forests in the Lake States to red pine (*Pinus resinosa*) plantations. Vasievich and Alig (1996) estimated that implementing economic opportunities on 82 million hectares of timberland could yield gains in C storage of approximately 140 Tg C/yr in vegetation, wood products, and offset fossil fuel C.

Conversion of mature or old-growth forest to young forest, which may have a faster growth rate, will reduce C storage until the harvested C remaining in products and landfills, plus additional C in the forest ecosystem from renewed growth, reaches the pre-harvest level. This may take 200 years or more in the case of old growth forest (Harmon et al. 1990), depending on site productivity and on how wood burned for energy is accounted for. Marland and others (1997) analyzed the effects of forest management on C in forest ecosystems, wood products, energy substitution, and product substitution. Results of their model (GORCAM) suggest that over long time periods, sustainable management for forest products on highly productive sites will yield a larger C offset than simply protecting the forests intact. They note the difficulty of estimating the magnitude of the substitution effects, and of attributing the C offset to particular projects because the indirect effects of any given project are spread widely and are likely to be partly claimed as a credit elsewhere.

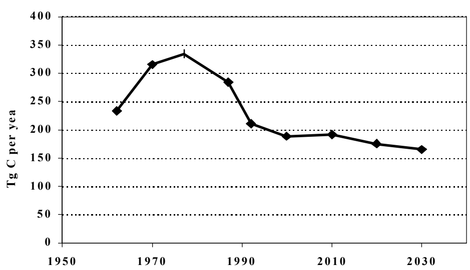
Adjustments in Harvest Timing

Reducing the area harvested can cause an immediate short-term increase in the amount of C stored in forests because losses of C to the atmosphere during the removal of biomass and processing are avoided. On average, only about half of the live biomass is removed from the site, while logging debris (leaves, twigs, branches), stumps, roots, and unmerchantable biomass is left behind to decompose, transfer to another C pool (e.g. litter or soil), or become part of the new stand of trees (Birdsey 1992a). Of the biomass that is removed, about 35 percent ends up in durable products or landfills (based on removals since 1900 and historical patterns of utilization and disposal), while the remainder is burned for energy or emitted to the atmosphere (Heath and others 1996, Skog and Nicholson 1998). Combining the estimates of on-site and off-site losses, only about 20 percent of the forest biomass ends up in long-term storage after harvest, and the remainder may be emitted to the atmosphere. Avoiding this loss by reducing harvest can be a short-term strategy to sequester additional C; however, over the long term, a continuous cycle of harvest, efficient utilization of biomass, and regrowth can sequester more C than not harvesting since the accumulation of C in the forest will eventually slow or stop, while it is possible to accumulate C in wood product and landfill pools for a very long time (Row 1996).

The effects of reduced harvest on C storage are evident in the estimated past and prospective C flux for National Forest lands (Fig. 6, Birdsey and Heath 1995). High rates of harvesting in the 1970-1990 period caused emissions of 50 Tg C/yr or more, while the significantly reduced harvest of the 1990's, if sustained, will cause a prolonged addition of C to National Forest lands, more than 80 Tg C/yr. In the unlikely event that all harvesting were stopped in the U.S., public and private timberlands could sequester an additional 328 Tg C/yr over a 50-year projection (Heath and others 1993).

Reduced harvest in one ownership category or region may be offset by increased harvest elsewhere, by substitution of energy-intensive non-wood products for wood products, or by changes in wood processing technology. Depending on the exact response, apparent gains in overall C storage may be lessened. The U.S. Environmental Protection Agency (1995) concluded that reducing National Forest harvest by 21 percent would be fully offset by increased harvest from private timberlands and increased imports. Adams and others (1996) concluded that reduced harvest on public lands in the West could be largely offset by substantial private forest investment and increased harvest on private lands in the South. Martin and Darr (1997) found evidence for increased imports from Canada as a consequence of reduced National Forest harvest but inconclusive evidence for substitution of nonwood products or increased harvest on private lands.

Figure 6. Past and projected carbon sequestration in U.S. National Forests (from Birdsey and Heath 1995)



Short-Rotation Biomass Plantations

Short-rotation woody crops could be established specifically for biomass production on marginal cropland and pasture. Current average dry biomass yields for short-rotation crops (rotations less than 10 years) are approximately 12 t/ha/yr, with higher rates attainable (Wright and Hughes 1993). Very high rates of C sequestration are possible over longer periods in forests that are managed for biomass production. For example, the average C storage in biomass (including cut and dead trees) for 40-year old hardwoods in the Lake States under different management intensities was 331 Mg/ha (Strong 1995). This is equivalent to an average annual C accumulation of 8.3 t/ha/yr over the entire 40-year period.

Conversion of productive forestland to short rotation biomass crops may result in a decrease in ecosystem C storage that would have to be offset over several rotations by counting the substitution of wood biomass for fossil fuel energy. Cropper and Ewel (1987) compared C accumulation under existing forestry practices for slash pine (*Pinus elliottii*) and found that annual C storage decreased by more than half in some cases, due to reduced tree biomass and soil C.

The U.S. Congress, Office of Technology Assessment (1991) estimated that a program to plant about 1.25 million hectares of biomass plantations per year for 20 years would eventually produce 30 TgC/yr of harvestable biomass. The study estimated that about half of the harvested C would offset fossil fuel C.

Improved Utilization of Harvested Biomass

Heath and others (1996) estimated that of the 10,700 TgC harvested in the U.S. since 1900, 35 percent remained in products and landfills, 35 percent was burned for energy, and 30 percent emitted to the atmosphere without producing energy for consumption. Improved utilization of removed biomass could reduce losses of C to the atmosphere. For example, if the percentage of C in wood products were increased by 50 percent the annual C storage in products would increase by about 10 TgC/yr, while the other disposition categories (landfills, wood burned for energy, and emissions) would each be reduced by about 3.5 TgC/yr (Heath and others 1996). Also, retention in landfills could be increased as documented by Micales and Skog (1997).

Increased recycling of wood products may have two effects: keeping the C sequestered in usable products longer, and reducing the timber harvest. The U.S. EPA sponsored an analysis of recycling that concluded that each ton of recycled paper increased forest C sequestration by 0.73 tons (U.S. Environmental Protection Agency 1997). This estimate was derived from a cluster of U.S. Forest Service models including FORCARB and associated economic models of the pulp and paper industry. Another study estimated that rapidly increasing paper recycling to 45 percent of total fiber used would sequester an average of 10 TgC/yr (Heath and Birdsey 1993).

Plant Trees in Urban and Suburban Areas

Urban and suburban trees store C and can reduce energy use in buildings if the correct species are properly placed. Rowntree and Nowak (1991) estimated that urban areas in the U.S. have an average tree cover of 28 percent, and store an average of 27 t/ha. McPherson and Rowntree (1993) estimated that a single 7.6 meters tall tree could reduce annual heating and cooling costs of a typical residence by 8 to 12 percent, which both saves money and avoids the use of energy generated with fossil fuels.

Nowak (1993) concluded that planting an additional 100 million urban trees and maintaining them for 50 years would cumulatively store approximately 75 TgC in biomass and offset 275 TgC due to energy conservation. This is an annual average of 7 TgC/yr over the 50-yr period. The rate of sequestration would be very low for the first 2 decades, and higher toward the end of the period as the trees reach maturity (more than 10 TgC/yr). Assuming a cost of planting and initial tree maintenance of $5-25/tree, such a program would cost from $50 to $250 per ton of C after several decades (McPherson 1994).

Summary and Conclusions

If the U.S. is to meet the emission target, forestry could play an important, if not critical role, in this reduction. Globally, the most important activity that affects carbon fluxes is deforestation. However, in the U.S. the amount of forest land has remained fairly constant during the last several decades at approximately 298 million hectares or 33 percent of the total land area. Given the low rate of change in the area of forest land of the U.S., the major anthropogenic influences on the current net carbon flux are forest management and protection, forest product processing, urban tree planting, and research and transfer of environmentally sound policies and practices. Natural disturbances such as fire, insects, and diseases are locally important factors that affect forests and C storage.

The Kyoto Protocol establishes an accounting system that includes only part of the carbon attributable to forestry and land use change. The forestry baseline as described under article 3.3 would account only for forest lands that have been or will be affected by reforestation, afforestation, and deforestation since 1990. The exact definitions of these activities are not given in the Protocol. Additional activities such as forest management would not likely be counted unless accepted as additional activities under article 3.4 of the Protocol.

The net sequestration of C in U.S. forest ecosystems and wood products (including disposal in landfills) from all activities during the 1980's was about 300 TgC/yr, and is projected to be at least 200 TgC/yr for the next few decades. The causes of continued net sequestration in forests are varied. Forest management practices that may increase carbon storage include regeneration of harvested natural pine and oak-pine in the South to fast-growing plantations, increasing use of genetically improved planting stock, and maintenance of optimal stocking density for growth. Some areas of maturing forest in the North and some areas in the West are unlikely to be harvested, allowing stored carbon to reach higher levels than recent decades as long as natural disturbance rates are low. Increased use of partial harvesting methods that minimize impacts on stored soil carbon will increase retention of carbon on forest sites. Improved efficiency in converting roundwood to products, and increasing product's useful lifetime, will also contribute to net forest carbon sequestration in the U.S.

Regardless of how the Kyoto Protocol or any other international agreement to limit greenhouse gases may be implemented, forestry in the U.S. offsets a significant percentage of CO_2 emissions, and will continue to do so for a very long time. The value of forests for C sequestration should be widely recognized, and efforts to manage and protect this and other values of healthy forests continued.

Abstract

The forestry sector, public forest policy and forest administration in many countries are currently involved in a process of change. Public budget crises, inefficient and obsolete administrative structures, changes in social requirements with respect to forests and low timber prices have all given rise to persistent requests for fundamental administrative reform in the forestry sector. New Public Management (NPM) has been gaining acceptance as the most common concept in this context. Originally developed in New Zealand, this concept has been the inspiration behind widespread reform in all kinds of countries in East Asia, North America and Europe. We would like to present reforms implemented by forest authorities in Germany and Switzerland as examples of such authorities which have already gained experience with elements of New Public Management. By doing this, we will show that the concept of NPM can cover a wide range of proposals and that the projects in Germany and Switzerland are examples of how different aspects of this approach have been implemented. With respect to the outcome of these reforms, at this point in time, it is only possible to put forward hypotheses on their efficacy and efficiency as the evaluation of effects will be the subject of further research.

Keywords: New public management, Reorganisation, Administrative reform, Forest administration

Pressure for Reform of the Forest Sector

The pressure for reform of the forest sector has increased in recent years for a number of reasons. Some of these reasons can be identified in areas associated with the sector itself, for example, financial crises and public budget deficits in OECD states, which in many countries have resulted in the implementation of widespread cost-saving measures, from which the forest authorities have not been spared. Other reasons include timber prices and increasing global competition. The demands of citizens with respect to the state and the administration have also changed. In many of the old democracies, there is a negative attitude to over-regulated and bureaucratised administrative structures and decentralised, efficient and effective administrative action - the very values promoted by New Public Management - are now in demand. The need for “de-bureaucratisation” is particularly obvious in the case of younger democracies which are in the process of completely dismantling former centrally-planned economies (Krott 1999).

In addition to these general and non-forest-specific causes, specific administrative problems can be identified within the forestry sector which are also behind the attempts at reform. These include, for example, the outdated and strongly hierarchical administrative structures in this sector. In Switzerland, for example, the political authorities were responsible for decisions concerning the implementation and organisation of the forest administrations. Administrative structure - right down to the level of the forest rangers - was defined by the federal legislator. Although the tasks assigned to the state have changed over time, it is still possible to find administrative structures in the forest sector which were established over one hundred years ago. The administration can be described as an authoritative police organisation firmly based on the principles of hierarchy and territory. Most jobs are still filled by uniformly trained specialists. The original tasks, which were mainly authoritative, were complemented with social and economic tasks. The extension of forest tasks resulted in overlaps and hence double-tracking with other policy areas which, of course, gives rise to inefficiency. Moreover, an analysis of forest legislation in Switzerland also shows that although there has been a significant increase in regulations, clear objectives are still lacking. Thus, the suspicion that the control is directed at the input and ignores criteria such as efficiency and efficacy is gathering credence. Distant and obsolete administrative structures, ossified decision-making processes, the absence of success monitoring and the more or less non-existent evaluation of forest transfer practices all underline the absolute necessity for the modernisation of the administration in this sector.

The Central Elements of New Public Management

New Public Management is something of a buzzword for which no clear definition exists and a wide variety of versions and interpretations can be found throughout the world. As a starting point, we would like to select one definition which identifies the salient characteristics of NPM and distinguishes it from other models: "New public management can be understood as a comprehensive management approach which replaces those elements of the political-administrative system which hinder performance and motivation with modern management systems, structures and instruments. The basic element is the shifting of control from the instruments (input) to the performance (output) and effects (outcome, impact). This creates an improved basis for decision-making by the political and administrative leadership" (Schedler 1995a, 17).

On the basis of the above definition, it is possible to identify the main objective of NPM as the reorganisation and transformation of the administration into an effect-oriented administration. NPM is in a better position to fulfil this objective than any new or old reform efforts because it tailors familiar management modules to each other and directs them towards a new general target (Reichard 1995, 66). (Reichard 1995, 65) summarises the general direction of this approach as follows: "In contrast to the rationalistic planning concepts of the '60s and '70s, which were aimed at the optimisation of the planning capacities of state actors, NPM-related reforms have a wider scope in that they strive to complement the improvement of state management patterns with economic (strengthening of the "market") and social (strengthening of "self-help forces and third sector") regulative forms".

Two observations of the above observations are particularly relevant in this context: firstly, NPM should not be understood as simple deregulation to the point of privatisation as practised in the 1980s by the neo-liberal governments of the UK and USA. On the contrary, the state and the administration continue to play an important role under NPM. Secondly, reform approaches which incorporate the principles of NPM are not limited to actual administrative structures, as was sometimes the case in earlier processes; they include and affect the entire political system.

Based on this albeit very general perspective, within the theoretical discussion it is possible to identify central elements of NPM which affect the political process (final control and division of tasks), which are based on economic factors such as the market and potential customers (creation of markets and effect control) or which directly relate to the internal organisation and structure of the administration (organisation/management/culture).

With respect to the political process, the NPM concept proposes the clear separation and differentiation of executive and administrative tasks. The effect-oriented administration tries to distribute the roles and **tasks between the actors of the political-administrative system** in a new way. The objective is to reinforce strategic management at political level and, thus, create a clearer distinction from operative responsibility. Thus, in its role as legislator, parliament should define the basic features of policy by means of final programs or framework laws and fix the relevant allocation of funds to policy areas by means of global budgets covering several years. In concrete terms this means that the legislature defines the product groups to be produced by the administration and guarantees their funding. The government in turn decides which offices and departments shall be commissioned to provide the relevant services. As a result of this differentiation, the administration has significant scope for action in the operative implementation of tasks. End control and the corresponding differentiation of tasks between the administration and political control authority is necessary for the implementation of the above-described ideas. At instrumental level this means an integrated service and financial planning, extensive organisational competence for the executive, global budgets and contracts between the executive and the relevant administrative units (Schedler 1996, 160ff).

The central elements of **internal control of the administration** include organisational proposals which are aimed at the decentralisation and simplification of structures and, where possible, perhaps even privatisation (agency) and improved implementation through possible administrative self-organisation. At the level of the management concept, the aim is a leaner administration which is mainly based on quality assurance. Moreover, the new and modified administrative culture should increasingly concentrate on the requirements of potential customers and employees. Furthermore, all administrative action must be directed at effect control. Hence, controlling and periodical evaluation are also necessary to establish whether targets are being achieved. Correspondingly, extensive scope will only be provided in the area of operation if the administration has a global budget at its disposal and is free to decide on the mode of production while being under contract for a range of services.

The concept of New Public Management also includes an economic perspective in that the target groups of a policy are increasingly perceived by the administration as **customers** and the services provided are increasingly tailored to their requirements (cf Schedler 1996, 158f). The idea is also to create markets, and hence competitive pressure, both within and outside the administration. The aim is to achieve a cost-effective provision of services based on a defined range of products with the corresponding product budgets. This can be achieved through competition within the administration, the awarding of contracts to private external suppliers (outsourcing) or through the generation of competition between service providers. A distinction should be made between those who finance a service, buyers and service providers. Customer surveys can be used to ensure that production is tailored to the actual needs of customers.

With respect to the economic calculations, effective and efficient state action requires the implementation of instruments to **control** it. Important activities in this context include: controlling, the corresponding quality assurance and cost calculation and the periodic monitoring of efficacy and efficiency.

This list of management elements shows how the initiatives to modernise the public sector make it possible to introduce new trends. From an international perspective, the modernisation of the public sector is not a homogenous and linear process. It is possible to identify a range of regulative regimes here which also make it impossible to make a precise statement about the optimum direction or corresponding assumptions with regard to efficiency.Table 1 contains a summary of the central elements of NPM linked with its objectives.

Examples of the Reform of Forest Administrations in Germany and Switzerland

As an illustration of reform efforts in forest administrations, we shall present two modernisation projects in Germany and Switzerland. These projects specifically involve structural reform in the Federal German *Laender* of Rhineland-Palatinate and Lower Saxony and the federal Swiss administration's EFFOR 2 and VAFOR projects.

Table 1: Central Elements of NPM

Element	*Content*	*Objectives*
End control	Replaces conditional control	Elimination of excessive control
Division of tasks	Separation of strategic and operative levels	Elimination of excessive control Degree of freedom in implementation of tasks
Organisation	Decentralisation Privatisation Self-organisation	More efficient and flexible administration
Management	Lean administration, Quality assurance	Service-oriented service companies
Administrative structure	Customer and employee orientation	More service orientation, willingness to take decisions
External/internal markets	Competition between service providers	Efficiency
Effect control	Testing of effects, evaluation	Increased efficiency, efficacy

Source: Schedler 1995b, 18-21

The forest administrations in most of the German *Laender* were reformed during the 1990s and a variety of trends were set which reflected the extensive competence at *Land* or regional level in the forest sector. The pressure to reduce costs can be identified as the main motive behind all of the reform measures. In general terms, the scope and nature of task fulfilment was examined and this resulted in the reform of the organisation and function of the administration (Schmithüsen 1998).

In Switzerland, the cantons also have generous scope for action in the area of forest management. As modernisation efforts at federal level are more advanced than the cantonal administrative reforms, we shall present the pilot project on forest subsidy policy (EFFOR 2) and a federal project which is directly aimed at the owners of forests and has set out to promote a stronger customer-oriented focus in forestry operations and the marketing of forest services (VAFOR).

The Rhineland-Palatinate Control Model

Elements of a "New Control Model" are being introduced over the period from 1996 to the year 2000 in the West German *Land* of *Rhineland-Palatinate,*. In this case, the action taken was strongly influenced by administrative reform in the Dutch town of Tilburg, a European NPM Mecca for administrative reformers. The regional forest administration will implement the administrative reform as part of a pilot project for further reforms in the Rhineland-Palatinate administration and is being supported in this task by a commission for the modernisation of the administration, which reports directly to the regional government, and by external business experts. The most important elements of this administrative reform project in Rhineland-Palatinate are:

> Forest policy targets were defined and hence important strategic issues were clarified (Martini 1997, 285). The main objective was defined as "the maximum possible total social utility of forest services for today's society and future generations". In addition to this emphasis on the welfare functions of the state and sustainable use, partial commercial targets were also defined for the so-called "profit area" of the timber industry (Leonhardt *et al*. 1997, 289). In general terms, the

definition of targets and development of a model meant that the focal points for action by the forest administration could be redefined and extended in the direction of forest maintenance, environmental protection and nature conservation. This also enables the separation of the strategic and operative levels and the delegation of operative implementation to the forest authorities.

Similarly, conditional control is replaced by end control due to the definition of new service-oriented and target-oriented budget specifications. Administrative action is no longer controlled via the input (existing resources to be implemented) but via the output (the expected services and targets). Finances are managed by the director of the forest authority who is also responsible for keeping within the allocated budget. Incentives for the economic use of resources were created by a system whereby part of any excess earnings or savings are injected into the budget for the following year (Härtel 1997, 286).

Controlling is of central importance. The budget can be agreed by the ministries and directors of the forest authorities during planning on the basis of the comprehensive data available from all of the forest authorities. Controlling also serves in helping to verify that targets are being fulfilled (Nick 1997, 294). As budget control and controlling can only function if the individual activities and their costs are recorded in detail, both instruments give rise to the increased cost transparency of services (Temme 1997, 298).

With respect to organisational change, the 106 forest authorities in Rhineland-Palatinate were amalgamated to form 88 authorities. This mean an average rise in the area managed by each authority from 7,500 ha to 9,100 ha.

In addition to the clearer definition of targets and the use of end control, incentives for efficient production and customer orientation, the reform in Rhineland-Palatinate also involves the restructuring of the forest authorities.

Structural Reform in Lower Saxony

Reform in *Lower Saxony* was initiated in 1994. As in Rhineland-Palatinate, reform of the forest administration was part of a regional administrative reform programme, although in this instance more impulses came from directly within the forest administration (Janssen 1997, 1116). The main elements of the reform programme in Lower Saxony included the streamlining of the administration and the introduction of a leaner administration through the decentralisation of tasks:

Previously, the organisational structure was divided into three levels and as part of the reform measures the central “district” level (or *Bezirksebene*) was completely abolished. Some competencies were transferred to the lower level, for example matters concerning operative forest management tasks. In contrast, specialised tasks, such as consultancy, surveying, personnel management and marketing, were transferred to the relevant ministry at regional or *Land* level. This meant that the distance between the forest authorities and the ministry was increased, making co-ordination with other instances which were still organised at district level more difficult. However, the advantages of the new system included savings with respect to basic administration, a reduction in the number of official channels and the elimination of bureaucracy. Specialist activity was intensified as a result of the centralised concentration of resources. In terms of personnel, this resulted in more specialists in environmental protection and nature conservation being employed in the ministry (Rijpken 1997a, 1997b).

The increase in the size of the forest authorities heralded even greater change. Of the existing 80 forest authorities, 70 were abolished and 40 new authorities created. The forest territories were also reduced in number and increased in area. The purpose of these changes was to reduce expenditure (Schmithüsen 1998, 3).

Another feature of reform in Lower Saxony was the alteration of the system for the payment of forest workers. In contradiction to what might be expected under the heading of service-oriented administrative form, the service-related component of the forest workers' wages and piecework payments were replaced by a fixed monthly salary. The rationale behind this reform was that it allowed greater flexibility in assigning forest workers to new tasks which are less focused on timber production and also reduced the administrative cost involved in the calculation of the piecework payments. This may have also reduced productivity incentive but another positive by-product of this reform was a reduction in the number of work accidents caused by overmanning (Behrndt 1997).

The services and authoritative functions provided by the regional forest administration were also examined. This reflects the increased target orientation of administrative action and serves in the analysis of unnecessary routines and the improved differentiation of tasks. The instruments of budget control and controlling were not implemented, as was the case in Rhineland-Palatinate.

New Forestry Subsidy Policy in Switzerland

In Switzerland, approximately 200 million Swiss francs are paid by the state to forest owners as forest indemnities and financial aid each year. And the cantons contribute the same amount of public money again (Poffet 1998). As part of an assessment of financial compensation mechanisms between the state and the cantons, in the mid-1990s a group of financial experts were commissioned to examine the efficiency and efficacy of the use of public finances (Frey *et al.* 1996). The following factors emerged as sources of inefficiency, particularly in the forest sector:

Very high indemnities: the payments are so high that they give recipients the impression that the service is cheaper than actually assumed. The perception of the actual costs of a project is, therefore, distorted (fiscal illusion) and which restricts the possibilities for the more efficient use of resources. An average 80% of costs are covered by the state and canton.

Excessive differentiation and detail in regulations: approximately twelve subsidy categories with provisions for different measures exist for the forest sector. This level of differentiation gives rise to complex administration and high transaction costs. Moreover, the distribution of finance is regulated in the Forests Act, the forests decree and more than a dozen *Kreisschreiben* (circulars from the Swiss Forest Agency to the individual offices). In some cases, the cost of administration and monitoring bears no relation to the actual level of contributions.

Unclear targets: the myriad facts relating to subsidies and detailed regulations cause the targets of forest policy to be pushed to the background. There is no clear target formulation for the individual measures which would enable their evaluation.

The Swiss Forest Agency is fully aware of these deficiencies and is hence participating in a pilot project which is aimed at the differentiation of federal tasks and increasing the efficiency of subsidies. EFFOR 2 is a forestry pilot programme for the new regulation of financial federalism. Unlike the old subsidy policy, which financed individual projects on the basis of applications from the cantons, as part of this new financial equalisation, subsidy allocation shall be decentralised, the strategic and operative levels separated and incentives set to achieve more economic use of resources. The keywords for this programme are, therefore, subsidiarity, efficacy and efficiency. The old system of providing subsidies shall be replaced by a system involving contractual agreements or partnership-based relationships. Fulfilment of contracts, and hence the achievement of the target-efficacy of measures, is crucial for the flow of finance. In addition, the costs of individual projects will no longer be reimbursed but the political willingness of the executive to pay for specific projects or forest policy aims shall be established and incentives created for the rational use of resources. The targets, services to be defined, the level of finance and evaluation criteria shall be defined by means of a service agreement between the state and canton. The pilot programme "Nature

Conservation in the Forest" which is being implemented in the canton of Aargau and aims to restore 650 ha of forest area by the year 2001 is an example of such an agreement. A further service agreement exists between the forest authority and the canton of Valais in the area of the "Protection against Natural Hazards".

The advantage of such package solutions is that the canton must provide certain services as part of the fulfilment of targets but it can also decide which projects it finances and how the money is used (Effor2 1997f).

VAFOR

The VAFOR (*valorisation des forêts* = valuation of the forests) project was launched by the Swiss in 1994. The main aim of this project is to provide help and support to forest owners in the marketing of forest products and services. This has been deemed necessary as subsidies and income from timber sales are no longer sufficient to cover the cost of forestry operations. Taking into account the legal and economic framework conditions, VAFOR aims to establish the marketing potential of forest goods and services and to encourage the development of an innovative approach by the owners. The aim of this pilot project is to increase the income of forestry operations from the sale of non-timber products to 25-40% by the year 2010 (Kocher 1997, 192).

In ideal terms, VAFOR is based on the idea that in the past most of the non-market-benefits of the forests were barely remunerated and additional sources of money could be obtained in forestry operations through the marketing of external effects and the redesign and alteration of the characteristics of goods, e.g. the creation of club goods or the use of eco-sponsoring (Kissling-Näf 1999). VAFOR services encompass, therefore, the overall forest service offered by a forestry operation, but not including raw timber production. VAFOR has not only drawn up long lists of potential products and studied the legal and economic environment for the marketing of such products, as part of 15 test operations, it has analysed whether innovative managers can succeed in operating in a service-oriented manner and develop new competitive and cost-effective products. The profitable and marketable VAFOR services exist, however many companies lack the expertise required to market such services (Buwal 1998).

Initial experiences indicate that the direct marketing of private goods is difficult because most of these profitable products are public products and services, e.g. road maintenance etc., which are required by public corporations. Existing use and property rights in Switzerland have emerged as a further restriction (Kissling-Näf 1999). The Swiss Forestry Management Association (*Schweizerische Waldwirtschaftsverband*) was commissioned to continue this pilot project in 1996. The intention is to support the managers of forestry operations and owners of forests by means of further training courses and teach them to respond more actively to users and inquirers and help them gain the necessary expertise in the area of marketing and cost calculation.

Discussion

The most conspicuous feature of the German modernisation projects is the amalgamation of forest areas and the resulting reduction in jobs. In contrast to Germany, forestry in Switzerland has not jet been affected by amalgamations and large-scale job cuts, despite the fact that the small size of forestry operations lies at the root of the inefficiency.

As the two German examples show, the verification of the fulfilment of tasks by the state is linked with organisational reform. End control, differentiation of tasks, leaner administration, decentralisation and increasing economic incentives are also planned. The reform in Rhineland-Palatinate seems to be particularly strongly based on the NPM model and to incorporate the ideal central elements of NPM. The reform processes described in Switzerland are, in contrast, less comprehensive and relate to specific sub-areas in the effect-oriented public management. VAFOR is trying to bring about a stronger emphasis on customer wishes and target groups in local forest operations. EFFOR 2 is concerned with political decision-making processes and allocation of public funding. The efficiency and target orientation of state funding will be improved through end control by means of service contracts. The fact that the full potential for reform of the forest sector in

Switzerland is not covered by these initiatives is obvious. There is further need for reform at the level of company structures, the division of tasks between the different political levels, the differentiation of tasks and control of effects (Kissling-Näf and Zimmermann 1996). The extent to which these issues have already been tackled as part of the cantonal administrative reform initiatives must remain open.

Conclusions

It is not yet possible to ascertain whether the desired effects are actually being achieved by these reforms. It will be necessary to carry out the relevant evaluations in order to establish this. It is, however, possible to formulate the following hypotheses with respect to the effects of NPM:

> For a range of reasons, mentioned at the beginning of this paper, forest authorities in many countries are being forced to implement savings, which in some instances could be described as drastic. As the example in Germany shows, in many cases this results in restructuring and extensive job losses, the social costs of which are very high. The elements of New Public Managements offer the possibility of implementing at least some of the cost-cutting measures without job losses while simultaneously increasing the operational scope for action of the forest administrations (Krott and Sohns 1999).
>
> The clear division of tasks between the actors of the political-administrative system will prompt the forest administrations to describe many of their services as products. By showing what they do, the forest administrations can improve their legitimation with respect to the public and policy in the long term.
>
> The definition of the products and product groups will result in greater transparency with respect to costs. This will make it possible to establish, for example, whether timber production by public companies is cost efficient and how much other services, e.g. nature and landscape protection, tourism and sport, cost. As public services can no longer be cross-subsidised by timber production, the forest administrations must seek new sources of income, for example through increased consultancy activities or joint political lobbying with groups from the nature and environmental protection sectors.
>
> This shift in focus will result in the forest administration working more closely with groups from nature and landscape protection and the leisure and tourism sectors. This will also change the composition of the forest administrations with respect to personnel. The highly specialised staff trained in the forest schools and universities currently found in forest administrations will be replaced by persons with more general qualifications in the areas of biology, the environment and economics.

The Dynmic of International Forests Regime by the Example of the Intergovernmental Forum on Forests

by
Dave Humphreys
United Kingdom
E-mail: d.r.humphreys@open.ac.uk

Abstract

Despite the failure of the United Nations Conference on Environment and Development and the Intergovernmental Panel on Forests to reach a consensus for a global forests convention, by the start of the twenty-first century a global forests regime is in place. The paper uses regime theory as a tool to explain the formation of the regime. It is argued that the formation of the regime can be traced to 1994 when actors involved in intergovernmental negotiations sought to engage in integrative bargaining rather then the distributive bargaining that characterised forest negotiations in the early 1990s.

The forest regime does not however embrace solely governments and intergovrnmental actors. The normative framework of the regime, which is best seen as a mix of hard provisions (namely international legal instruments with a forest-related mandate) and soft provisions (namely non-legally binding options) both shapes and is shaped by non-governmental organisations and business actors.

Abstract

Confirming the integrity of large forest ecosystems and ensuring their ability to provide for a sustained and integrated set of goods and services is of increasing concern to managers and users of forests. Troublesome, however, is the reality that public programs focused on forest ecosystems are often fragmented among many levels of government and among many agencies within any one level of government. To appreciate the nature and extent of this fragmentation, one needs only look at the large number of government agencies (state and federal level) in the United States that have influence over the use and management of forests. Needed is research that will enable the diverse landscape of government agencies to better connect in a holistic sense with the forests they are attempting to sustain and the services they seek to provide.

Keywords: Forests, Organization, Government, Agency, Coordination

Ecosystem and Institutional Consistency

Confirming the integrity of large forest ecosystems and ensuring their ability to provide for a sustained and integrated set of goods and services is of increasing concern to managers and users of forests. Troublesome, however, is the reality that public programs focused on forest ecosystems are often fragmented among many levels of government and among many agencies within a particular level of government. To appreciate the nature and extent of this fragmentation, one needs only look at the large number of government agencies in the United States that have influence over forests (for example, pollution control agencies, departments of commerce, environmental quality boards, departments of agriculture, economic development agencies, departments of health); the differences in agencies' authority to influence forest use, management and protection (for example, protection of endangered species, management of air pollutants, regulation of forest practices, certification of pesticide use); the variation in agency capacity to exercise authority over forest conditions and to serve various clienteles (for example, size of budgets, type of program authority); and the diverse sets of interests that struggle to secure, often for individual gain, an agency's programmatic attention (for example, timber, wildlife, water, recreation).

A major theme in the literature of public administration is that government agencies should be organized and coordinated in manners that enable them to function effectively (Denhardt 1991, Dresang and Gosling 1999, Galbraith 1973, Garnett 1980, Gibson *et al*. 1994, Reitz 1987). Over the years, however, public environmental and natural resource agencies have become fragmented in their missions and organization, often looking at forests and the opportunities they represent as ecosystems that are easily divisible and readily amenable to a large number of often unrelated programmatic activities (Haskell and Price 1973, General Accounting Office 1996, Jenks and Wright 1993, Rabe 1986). This fragmentation is not the result of any master plan. Rather it occurs incrementally as new agencies are created and reorganized, new policies and programs are established, and additional levels of government (federal, state and local) focus attention on the use and management of forests. Although compelling cases have been made for more integrated approaches to safeguarding the integrity of forest ecosystems, forceful and conceptually sound arguments have yet to be articulated for a more integrated institutional setting – a setting that would complement the holistic approaches being suggested for sustaining the physical attributes of forest ecosystems (Cortner *et al.* 1996, General Accounting Office 1994a, Rabe 1986). Useful research actions in this direction would be to secure an understanding of the existing institutional landscape and then to suggest a modest but meaningful research agenda.

Government Organizational Patterns

State Government Agency Landscape

States have a long tradition of establishing government entities (variously identified as agencies, bureaus, offices, departments, commissions and councils) through which public programs are focused on forest resources. Fostered initially by federal-level forest resource laws in the 1920s (notably the Clarke-McNary Act of 1924), and subsequently augmented by a variety of state and federal forest and environmental laws in the 1970s, states have generated an especially rich assortment of government organizations that are responsible for programs involving forests. Consider *state government organizations* in the *executive branch of government* whose policies and programs have potential for *statewide influence* (however large or small) over the use, management and protection of forests

<u>Frequency and Type of Entities</u>. Cabinet level entities are generally the highest organizational level in state government and are variously labeled as agencies, commissions, departments or offices. In 2000, states had seen fit to create nearly 320 cabinet-level entities that are responsible in some manner for influencing the use and condition of forest resources (Table 1). The average number of cabinet-level entities per state is approximately six, with states in the West having, on average, the most per state, namely 7.4. The most common name assigned to cabinet-level entities is "department."

Cabinet-level entities have been divided into at least two organizational tiers through which cabinet level legal mandates and missions are accomplished. At the first tier sub-cabinet level, states have created nearly 591 entities that implement programs affecting the use, management and protection of forests (Table 1). Official names assigned these entities are diverse and include "division," "office," "bureau," "department," and "program." The most commonly used name is "division," followed by "bureau." The second tier organizational level involves more than 200 government entities, most of which have been assigned names that duplicate labels assigned to first-tier entities.

State governments have also seen fit to establish governing or advisory entities. Responsibilities assigned to such bodies can range from providing advice on program development and implementation, to being legally responsible for directing and managing a particular unit of government. Often, but not always, they are composed of interested citizens appointed by a state's governor or by the chief administrator of the entity to which the body is to provide advice or exercise governance. In 2000, states had created 204 governing or advisory bodies, variously labeled as boards, councils, committees or commissions (Table 1).

<u>Functional Orientation of Entities</u>. Executive branch units of state government that implement polices and programs affecting forests can do so in a number of ways depending on their functional orientation. Some are responsible for long-standing policies and programs that have a very direct focus and impact on forests. An example is a state's Division of Forestry within a Department of Natural Resources. Others entities have broader functional responsibilities that can directly as well as indirectly involve forests. For example, the water quality division of a state's pollution control agency may exercise authority over forest practices to the extent that the division directly affects water quality, while the strategic planning division of a state's department of economic development may only indirectly influence expansion of wood-based enterprises through broad planning processes that affect business development statewide.

Table 1. Governing or Advisory Bodies to Executive Branch Units (all levels) of State Government Affecting the Use, Management or Protection of Forests in the United States, by Region, Name and Number of Units. Year 2000.

	103	36	65	

For purposes of furthering understanding of the primary functional orientation of state government entities having influence over forests, functions can be categorized as involving resource use and management; service, assistance and enforcement; promotion and development; health and safety; and environmental and resource protection (Table 2) Within any one of these broad categories there may exist a host of more specific functions.

Of 341 cabinet-level entities identified, 44 percent engaged in functions involving resource use and management, while 21 percent (next most frequent) involved promotion and development activities (Table 2). Within the former, agriculture (45 entities so involved) and conservation and natural resource cabinet level units (35 entities) are most common. In the promotion and development major category, tourism units (11 units) and business promotion and economic development units (51 entities) dominate. At the first-tier sub-cabinet level, resource use and management functions also dominate (42 percent of 635 entities), with environmental and resource protection functions (25 percent of entities) being the second most common functional orientation. Within all major functional categories, the most common orientation of entities at the sub-cabinet level (first tier) is (in descending order) fish and wildlife (71 entities), business and economic development (46 entities), parks and recreation (43 entities), water quality and pollution prevention (41 entities), recycling and waste management (35 entities) and information, information management and public affairs (35 entities).

Governing and advisory bodies are heavily oriented toward functions involving resource use and management (61 percent of 204 such bodies) (Table 2). For all functional orientations, most common were boards, councils or commissions that focus on soil conservation (27 bodies), with the next most frequent orientations being fish and wildlife (17 bodies), business and economic development (17 bodies), environmental protection (16 bodies) and forests and forestry (14 bodies).

The crosscutting nature of state government agencies focused on forests can be further highlighted by the diversity of entities implementing programs to monitor landowner and timber harvester compliance with state required or suggested (voluntary) forestry practices. Of 54 state government organizations involved in compliance monitoring in 1997(in 34 states with compliance monitoring programs), 43 percent (23 agencies) were other than a state's lead public forestry agency – most commonly a state's environmental or pollution control agency. In the North and West regions of the United States, the category of "other organizations" actually exceeded the number of lead state forestry entities engaged in compliance monitoring. In only 20 states was the state's lead forestry entity identified as the only entity involved in the monitoring of compliance with recommended forest practices (Ellefson *et al.* 2000).

Gathering and management of information also suggests diverse entity (public and private) involvement in some aspect of managing and protecting forests. In 1999, nearly 400 public and private entities at the state level were engaged in gathering, managing or distributing information about forests (National Association of State Foresters 1999). An average of eight organizations per state were so engaged, with some states identifying 18 or more different entities exercising an information role pertaining to forest resource use or management. Commonly focused on by these many entities was information about protected lands, insects and diseases, timber harvest rates, types and size of forestry programs, educational activities, enforcement actions, legal requirements (laws), and forest practice applications. The various entities were most consistent in their information gathering activities when they focused on basic forest resource information (area and forest type) and on agency implemented forestry programs (budgets, personnel). Least consistent across agencies were information gathering efforts associated with social, economic, legal, and institutional conditions involving forests.

Federal Government Agency Landscape

The federal government also has a varied organizational landscape that expresses the national interest in the use, management and protection of forests. As occurs at the state level, the organizational landscape of the federal government is also composed of many departments, bureaus, divisions and commissions that are large in number and have varying degrees of influence over forests (Government Printing Office 1999, National Research Council 1998). To date, a careful and holistic examination of this landscape has yet to be completed. However, informative examples depicting important parts of the federal organizational landscape involve wetland programs, federal land management, strategic and program planning, and rural development initiatives.

Forest and Related Wetland Management. At least 36 federal agencies implemented wetland management and protection programs from 1990 through 1997 (General Accounting Office 1998). In many cases, these programs involve forested wetlands or mitigation activities involving forests. Specific program activities involved acquiring, regulating, restoring, enhancing, mapping, inventorying, delineating and conducting research related to wetlands. Annual average total funding (1990 through 1997) of the 36 programs ranged from a low of $508 million to a high of $787 million (in constant 1997 dollars), while each year's staffing ranged from 3,300 full-time equivalents to more than 4,300 full-time equivalents. Six of the 36 agencies accounted for 70 percent of the funding and 65 percent of the staffing.

Federal Land Management. Federal agencies are responsible for management and protection of 262 million hectares of land (82 million hectares forested) or about 30 percent of the total land area in the United States. Six federal sub-cabinet level entities are responsible for most of this federal land, namely the USDA-Forest Service, DOD-Corps of Engineers, USDI-Bureau of Land Management, USDI-Bureau of Reclamation, USDI-Fish and Wildlife Service, and USDI-National Park Service.

The laws directing these entities require them to implement quite different land management strategies. In specific agency cases examined in 1995, 31 different land management and related programs were being implemented (with little commonality), even though the entities were responsible for fundamentally similar federal interests in natural resource management, habitat conservation, and rangeland management (General Accounting Office 1997). Examples of similar resource and management issues often receiving quite different program approaches were ecosystem planning and monitoring, wild fire management, fish and wildlife habitat management, watershed improvement, environmental education, riparian area management and protection of threatened and endangered species.

Strategic USDA-Forest Service Plan. The extent of federal multi-agency responsibilities involving forests is also highlighted by the USDA-Forest Service's Strategic Plan 2000 (draft) and the agency's intent to coordinate (at an appropriate level) with 31 other federal entities that have crosscutting responsibilities important to the Plan's successful implementation (USDA-Forest Service 1999) (Table 3). Coordination at the cabinet level will involve five departments, at the Office of the President level two entities, at the bureau level 17 entities, and seven independent agencies. These departments, offices, bureaus and independent agencies are identified by the USDA-Forest Service as important entities with which to coordinate because of their programs' capacity (however large or small) to influence the use, management and protection of forests. The complex organizational landscape facing plan implementation is obvious, and becomes even more so given that entities may be engaged in more than one functional area. For example, implementation of the agency's Clean Water Action Plan will involve coordination (at the appropriate level) with 15 different entities, namely three departments, 10 bureaus, and two independent agencies. The forest health aspect of the Plan's implementation will involve 14 entities, namely one department, 10 bureaus, and three independent agencies.

Rural Development Programs. Rural forested regions of the United States are frequently of concern because of their need for economic development. The entities and programs established to address the latter provide an additional example of the organizational diversity influencing the condition and use of forests. Between 1983 and 1992, rural forested and agriculture areas in the United States received rural development assistance from about 800 different programs administered by five different cabinet-level departments, and the Small Business Administration and the Appalachian Regional Commission (General Accounting Office 1994b). The intent of these programs was to influence economic well-being by focusing on issues involving agriculture, natural resources, human resources and infrastructure development (e.g., roads, communication). Of the approximately 800 programs, 109 focused directly on natural resources and agriculture and involved an investment of $288 billion over the 10-year period.

Potential Avenues for Future Research

The organizational landscape affecting forests is at times a confusing array of agencies and programs that have been fostered by overlapping legal mandates which often do not holistically connect government agencies with broad interests in the ensuring integrity of forest ecosystems. Needed is further understanding, through research, of the organizational patterns involved in the delivery of forest resource policies and programs. Such research should be designed to foster organizational structures that are less fragmented and more capable of effectively interfacing with societal interests in the sustainability of forest ecosystems at both large and small scales. Potential strategic directions for such research include:

Catalyst for Establishment of Organizations. What factors stimulate interest in establishing a government entity which has potential to influence the condition and use of forests (for example, state response to citizen demands, organized interests, or federal initiatives) (Hanf and Scharpf 1978)?

Rationale for Establishment of Specific Organizational Designs. What processes and criteria determine the specific structure of an entity (for example, overarching department versus a landscape of many fragmented entities) that potentially can affect the condition and use of forests(Zumeta and Ellefson 1999)?

Linkages Between Various Levels of Government. What organizational mechanisms (involving, for example, finances, regulations, technical assistance) might better link organizations at various levels of government so as to improve program efficiency and yet accomplish local, state, regional and national interests in forests (Wright 1982)?

Mechanisms for Coordinating Same or Similar-Level Entities of Government. What structures or processes (for example, formal boards and commissions, comprehensive planning processes, memorandums of agreement) are most effective in focusing the forestry activities of disparate entities operating at a specified level of government (Bardach 1998, Kilgore and Ellefson 1992)?

Conditions Fostering Innovation in Organizational Structure. What conditions (for example, presence of leaders-innovators in government, access to new research-generated information) foster the establishment of especially creative and effective organizational entities focused on forests (Galbraith 1973)?

Organizational Development over Extended Periods. What learning experiences result from long-term actions (many decades) involving the design, establishment, implementation and possibly abandonment of various organizational structures used to delivery certain programs to forests and those that depend on them (for example, forest protection, forest planning)?

Abstract

Forest policy development is presently caught between two contradictory tendencies. On the one hand forest issues are increasingly becomiong globalised with concomitant calls for global governance through international conventions, regulations and programmes. At the other hand there is put much emphasis on the need to enhance local participation in the management of forest resources and to formulate location-specific forest management plans on the basis of negotiated consensus of the various stakeholders concerned.. At a first glance these tendencies seem to be inconsistent. In this paper it can be argued that the two tendencies can be reconciled. The paper summarizes the major developments concerning global forest policies and indicates how these incorporate the principle of local community involvement. Such involvement is predicated on the creation and empowerment of local institutions for governance and control over forest resources. Forest policy makers often assume that the implementation of the global policies proceeds in a linear process, but forest policy researchers increasingly consider that in transferring policy decisions to local levels interface situations occur. Such interfaces are often of a conflicting nature with policies being reshaped into new meaning by the local actors. In order to understand the nature and outcome of such interface situations, forest policy researchers should focus on empirical reality rather than define normative principles as well as develop new theories for better understanding of the processes involved.

Keywords: Global forest policies, Decentralisation, Institutional change, Policy interfaces

Introduction

Forest policy development is presently caught between two contradictory tendencies. On the one hand we are witnessing a globalisation of issues, and a call for concomitant global governance through international conventions, regulations and programmes. On the other hand there is put much emphasis on the need to enhance local participation in the management of forest resources and to formulate location-specific forest management plans on the basis of negotiated consensus of the various stakeholders concerned. Such participation is predicated on the creation and empowerment of local institutions for governance and control over forest resources.

At a first glance these tendencies may seem to be inconsistent. However, it can be argued that the two tendencies are not necessarily inconsistent, but that they can be reconciled provided that they are applied in a mutually consistent manner. The aim of this paper is to summarise the major developments concerning global forest policies and to indicate how these incorporate the principle of local community involvement. Also interfaces between such global policies and local action will be indicated. Finally it will be discussed how the increased interest in stimulating both globalisation and localisation processes poses new challenges to forest policy research.

Trends Towards Globalisation of Forestry Issues

In the past the formulation and implementation of forest policies were mostly considered to be national tasks. Since the last two decades, however, many international initiatives to stimulate effective forest conservation and development have been undertaken (Grayson 1995; Humphreys 1996; Mayers & Bass 1999). For instance in 1983 the International Tropical Timber Agreement was negotiated which resulted in the establishment of the International Tropical Timber Organisation (ITTO). And in 1985 the Tropical Forests Action Programme was launched. A major event crystallising international concerns on forestry was the 1992 UN Conference on Environment and Development (UNCED). During this conference serious consideration was given to the need to formulate an International Convention on Forests. No agreement on such a convention was reached, but instead a (legally) Non-binding Statement of Forest Principles was formulated. Furthermore, two conventions (the UN Convention on Biological Diversity and the UN Framework Convention on Climate Change) were adopted at the UNCED; both of these conventions include elements on forest conservation and management. After the UNCED many international meetings have been held to further elaborate the UNCED agreements and to review their implementation, e.g. by the Intergovernmental Panel on Forests (IPF) and the World Commission on Forests and Sustainable Development (WCFSD 1999).

This growing international concern about forests is predicated on three major global concerns:

- Concerns about global environmental problems and need for environmental and biodiversity conservation;
- Concerns about just international economic relations and international trade;
- Ethical concerns as reflected in the principles of human rights, fulfilment of basic human needs, international development assistance and good governance.

Each of these concerns impacts on thinking on forestry and together have resulted in the formulation of international norms for forest management (Table 1). For instance, the environmental concerns resulted in increased international attention to the need for forest conservation and their sustainable management. The concerns about a just regulation on international trade resulted in the formulation of the International Tropical Timber Agreement, the first international trade agreement explicitly incorporating the notion that the production of internationally traded goods should be done in an ecologically sustainable way. As a result of this Agreement the idea of the need of certification of internationally traded timber having been produced in a sustainable way became accepted. The implementation of this idea was strongly stimulated when in 1993 an international NGO coalition formed the Forest Stewardship Council as an independent organisation to accredit timber certification programmes.

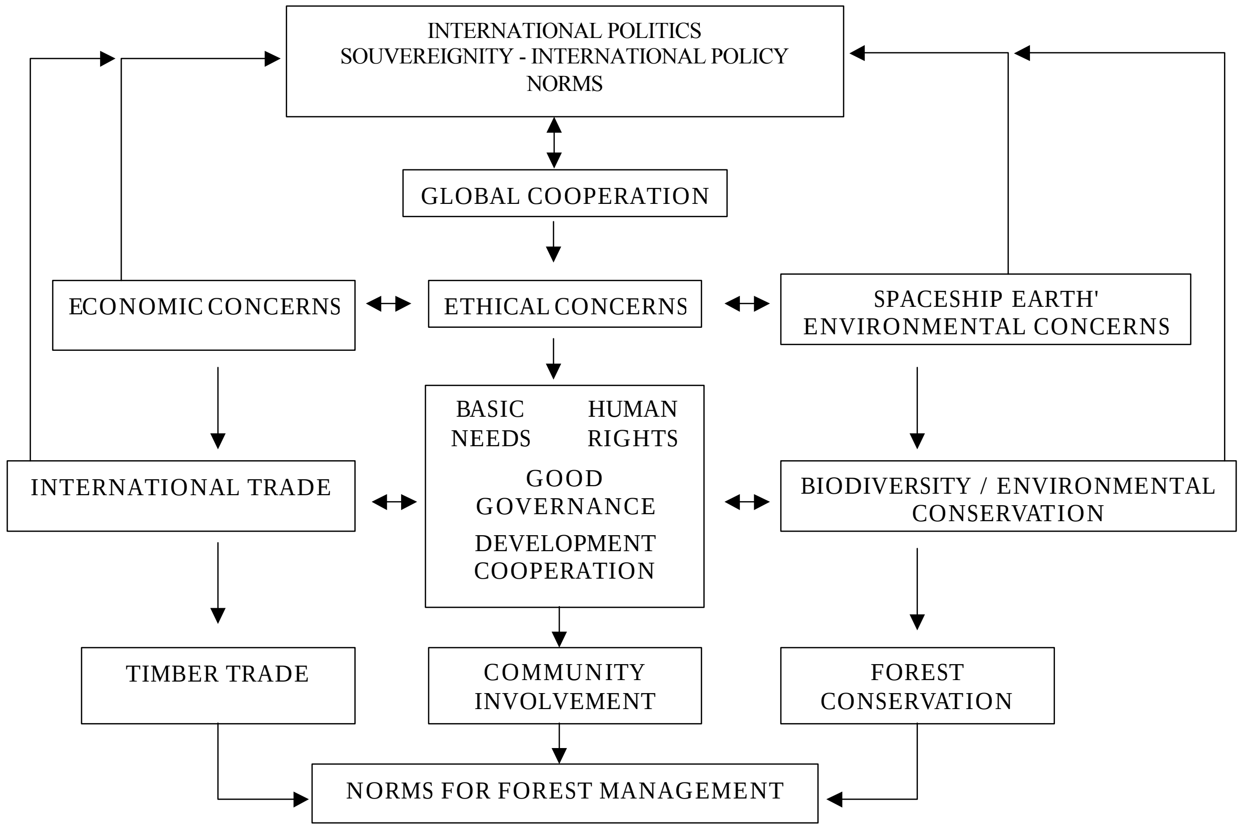
In addition to these global concerns regarding the state of forests, forest policy is also confronted with other trends towards globalisation. In this respect, the trend towards globalisation of markets is a major issue. The discussions within the World Trade Organisation (WTO) on trade liberalisation illustrate this trend as well as the many questions about how to balance environmental concerns with the principle of free trade.

Trend Towards Localisation of Forestry Issues

In addition to this trend at globalisation of forestry issues also a trend towards localisation of forestry issues can be discerned. In fact, the need to adjust forest management to local conditions is an explicit issue in many of the global discourses regarding forestry development. This trend towards localisation is predicated on global ethical concerns regarding fulfilment of basic needs, human rights and good governance. These concerns resulted in increasing attention being given to the need for community development and participation of local people in forest management. As a result, most global forest policies recognise that

- Forest management should maintain or enhance the flow of benefits from forest resources, with access generally perceived as just by all stakeholders;
- The voice of all stakeholders must inform forest management with all stakeholders having an acknowledged right and means to participate in equitable forest management (Pierce Colfer *et al*., 1995).

Table 1 Concerns resulting in the formulation of global principles for forest management



These perspectives are demonstrated by the following examples of principles incorporated in international agreements on forestry:

> "Indigenous people and their communities, and other local communities, have a vital role in environmental management and development because of their knowledge and traditional practices. States should recognise and duly support their identity, culture and interest and enable their effective participation in the achievement of sustainable development" (Principle 22 of the Rio Declaration on Environment and Development).

> "The legal and customary rights of indigenous peoples to own, use and manage their lands, territories, and resources shall be recognised and respected". (Principle 3 of Forest Stewardship Council principles for sustainable forest management)

These perspectives are not only based on normative commitments, but also on the understanding that sustainable forest management is only feasible in where all concerned stakeholders are involved. For instance, in a recent policy review seven desirable processes to achieve good forest policy, were identified (Mayers & Bass 1999). These policy processes included:

> A forum and participation process aimed at understanding multiple perspectives and needs, negotiating 'deals' between the needs of wider society and local actors, and initiating partnerships.

> Devolution of decision-making power to where potential contributions for sustainability is greatest, because decisions are best made and implemented at the level where the trade-offs are well-understood and there is capacity to act and monitor.

It is important to recognize that the formulation of such global principles take place in an international political arena. In this arena the parties are often concerned with questions about international relations, e.g. how to balance the setting of international norms with the principle of national sovereignty. The agreements which are reached are mostly primarily based on international political considerations (e.g. see Kolk 1996) rather than on operational considerations. Consequently, the agreed principles are often of a general nature and they need to be further elaborated before they can be applied in practice.

Decentralisation of Forest Management Control

As a result of the global agreement on the need of forestry becoming more responsive to the forest-related needs of local communities and at enlisting active community involvement in forest management, these ideas have by now been incorporated in many forestry development programmes. These developments have been most pronounced in tropical countries (Mayers & Bass 1999; Wiersum 1999), where they have been stimulated by both national governments and international funding agencies for development co-operation. A basic consideration in many development programmes focusing on the stimulation of community participation in forest management is often that such local involvement can only become accomplished by decentralisation of forest management control. This reflects the general view of considering decentralisation as an essential means to achieve sustainable development. This view was described as follows in the Brundtland Report (World Commission on Environment and Development):

> "The pursuit of sustainable development requires a political system that secures effective participation in decision-making... This is best secured by decentralising the management of resources upon which local communities depend, and giving these communities an effective say over the use of these resources. It will also require promoting citizen's initiatives, empowering peoples' organisations, and strengthening local democracy “(WCED, in Hobley 1995).

Various common policy assumptions support the view that decentralisation is a major prerequisite to improve sustainable forest management:

- Governments often lack the personnel and financial means to effectively control and manage all forests areas, and therefore they should enlist the assistance of local communities for doing so.
- Considering the great variety in ecological and socio-economic conditions, forest conditions are nowhere exactly the same; local people can best take account of such specific local conditions.
- Local communities who are directly dependent upon forests products and services; therefore they can be expected to have a greater interest to carefully manage these forest resources than government officials who do not have such relations of direct dependency on forest resources.
- Community control of forest resources and their accountability in managing these resources will increase in the case that local communities have the rights to use and manage the forest for their own purposes.
- A more equitable distribution of the benefits of forests can best be assured by involving the people who are most dependent on forest resources directly in the process of decision-making on and implementation of forest management plans.

In general these assumptions reinforce each other, although they are not necessarily based on similar normative perspectives. For instance, in the first assumption local involvement is mainly considered as a pragmatic instrument to fulfil management decisions which have already been made by the government. In contrast in the last assumptions local involvement is not considered as a tool for more effective forest management, but rather as a basic objective for community development.

In addition to such different perspectives on the reasons to stimulate decentralisation, there also exist different interpretations on what decentralisation precisely involves. The concept of decentralisation may be interpreted in the following ways (Mayers pers.com.):

Deconcentration:	transfer of decision-making powers within the administrative structure, i.e. downwards extension of authority to the "grass roots".
Delegation:	transfer of authority from an administrative service to a semi-public, non-governmental organisation (NGO) or private company.
Deregulation:	(partial) lifting of regulations imposed by a public authority on a sector or activity.
Devolution:	transfer of power from a larger to a smaller jurisdiction, e.g. transfer to local communities of decision-making over forest resources on their lands.
Privatisation:t	ransfer of ownership or management of resources from public to private entities, either directly or through parastatal institutions.

From these different interpretations of the meaning of decentralisation, it can be concluded that decentralisation involves two major institutional dimensions. In the first place it involves Deconcentration or organisational change by extending the governmental structure downwards. Such Deconcentration should enable the officials to be more responsive and more adaptable to community needs than is the case with a concentration of administrative power and responsibility in a central government. However, the downward extension of state bureaucracy does not automatically bring with it such adjustment to local realities. Instead, it may lead to the consolidation of state power over local communities (Hobley 1995). Consequently, in order to involve local communities better in the process of decision-making on forest management, not only a deconcentration of government bureaucracy is needed, but also a bureaucratic reorientation regarding the tasks, roles, attitudes and behaviour patterns of the government officials. Such reorientation will involve a (partial) devolution of government power of decision-making on forest management to local communities, as well as the deregulation of government regulations regarding forestry. It may also involve a certain amount of delegation of authority from the forest service to other organisation such as non-governmental organisations (NGOs).

Interfaces between Global Policies and Local Action

As discussed above, internationally the idea is gaining ground that local communities must participate more actively in the process of decision-making on community forestry development. In order to implement this idea, it will be necessary to decentralise state government control over forest management. However, the globally agreed principles do not indicate what form of decentralisation should take place and it is left to individual governments and/or forestry development programmes to decide how to implement the process of localisation.

In trying to operationalize the global principles into local action, an important factor to be considered is how one envisages the relation between policy formulation and implementation. In the circuit of international forest policy and development often there is the view that there exists a linear process in policy formulation and implementation. According to this view policy decisions are formulated at (inter)national level and transferred through some stages of geographic-administrative echelons to the local 'target groups' or 'beneficiaries'. Policy researchers increasingly question whether this view regarding policy implementation does justice to reality. Increasingly they consider that in transferring policy decisions interface situations do occur. Such interfaces are "critical points of intersection or linkage between different social systems, fields of social order where structural discontinuities, based upon differences of normative value and social interest" (Long 1989). This arena of interactions is often of a conflictive nature: the interfaces reflect differing and often conflicting life worlds. At such interfaces the international or state development policies are reshaped into new social meanings by the interpretation and strategies of local actors (Long 1989). In this view, local actors are not perceived as mere 'beneficiaries' of development policies, but people having their own values, interests and frames of reference, a world endowed with a diversity of interests and differential responses to external influences. These worldviews are unlikely to fundamentally coincide with the world of the international organisations or government bureaucracies. Consequently, policy interventions may take a very different shape to those which might be expected from linear translations of policy to. And instead of focusing on linear continuities one should rather focus on the discontinuities resulting from the interactions of the different parties involved and the need to effectively reshape global policies into local practices based on social values of local actors. implementation (Long & Van der Ploeg 1989).

When considering the process from global policies to local action at least two major interfaces can be identified: (i) national policies, (ii) field level government staff.

As demonstrated by the discussion on decentralisation, a first critical point between global principles and local action occurs at the level of national states. It is at the level of national policy that major decisions have to be taken which local groups should be involved in the implementation of community forest management and how to implement such schemes through a process of decentralisation. For instance, it needs to be decided whether the process of decentralisation should primarily involve a deconcentration within government administration, a delegation of government power to other organisations, or a devolution of power to community groups. It also needs to be considered to which groups in society control over forest utilisation and management should be transferred, and whether the process of devolution of power needs to be accompanied by a process of deregulation. This all means that for the implementation of global principles they have to be elaborated and incorporated into national policies (Mayers & Bass , 1999).

The elaboration of a proper national policy system indicating which groups of people should be entitled to participate in the process of forest management decision-making and control is of special importance, because effective forest management requires that not only clear objectives are set for forest management, but also that proper control is exercised over the utilisation of forest resources and their management. In order to be able to exercise such control, decisions must not only to be taken on how many forest products can be collected and on which management practices should be implemented, but also on who is entitled to the forest products and who is responsible for carrying out the management practices. The basic assumption for stimulating community involvement in forest management is that proper forest management can best be assured by effective linking of entitlements to forest with responsibilities to maintain these forests (Borrini-Feyerabend, 1996). A major prerequisite for this assumption to come true is that it must also be identified who holds no entitlements to forest utilisation and what means can be used to effectively control these (groups of) people from (mis)using forests. Local communities are often not in a position to realistically address such issues, and it remains a major government task to tackle them.

The second major critical point between global principles and local action concerns the position of the field level staff of the forest service (Wiersum & Lekanne dit Deprez, 1995). When considering the process from policy making to implementation as a linear one, the local forestry agent is normally perceived as the link between the service and the local population. His task it is to strengthen community participation in forest management by 'educating' villagers to carry out the management practices as deemed needed by the professional staff of the forest service. In this linear model local communities are considered as a "target group" whose awareness about the need for forest conservation and management needs to be raised through extension. The conceptualisation of relations between government officials and local communities in such unilinear terms brings with it that the concept of decentralisation being interpreted in terms of downward extension of the state bureaucracy. And the tasks of the forestry agent are therefore to act as a technical implementator of government policies.

A quite different view on the role of the forestry agent emerges from the notion of the process of policy formulation to implementation being characterised by interfaces. This view put less emphasis on the forestry agent in his capacity as implementor of the policies of the forestry service - including the donor-sponsored projects - and more on his role to negotiate conflicts which arise of the different values and interests between the state officials and local communities (Wiersum & Lekanne dit Deprez, 1995). In this view the task of the forestry agent is essentially related to the assumption that the development of community forest management involving a process of democratisation and the recognition of customary rights. The local population is perceived is that having a world of its own, with its own values, interests and frames of reference, which do not necessarily coincide with those of the government bureaucracies. Consequently, the role of the forest agent should not be one of 'educating' local communities, but rather to facilitate local decision-making on who should be involved in forest utilisation and management. In this case, the role and tasks of the forestry agent are defined by the notion of the decentralisation process incorporating the aspect of devolution of power rather than only Deconcentration of state authority.

Conclusion

Forest policy development is presently caught within two seemingly contradictory tendencies. On the one hand we are witnessing a globalisation of issues, and a call for concomitant global governance through international conventions, regulations and programmes. On the other hand there is put much emphasis on the need to enhance local participation in the management of forest resources and to formulate location-specific forest management plans on the basis of negotiated consensus of the various stakeholders concerned. Such participation is predicated on the creation and empowerment of local institutions for governance and control over forest resources.

Although, at a first glance, these tendencies may seem to be inconsistent, a closer assessment of both trends indicate that they can be reconciled. To allow for such reconciliation, it is essential that the process of implementation of global policies is not conceived of as a linear process, but as an interface process. In this process the role of national governments is of utmost importance with better adjusted national policies being essential to to establish proper links between global policies and local action. The principles embedded in the global policies require the creation of a new policy environment which enables community involvement in forest management and the reorganisation of state forestry organisations as facilitators for community management. For this purpose the following national policy actions are needed:

- Formulation of flexible forestry legislation
- Adjustment of forestry organisations including reformulation of roles of field level personnel
- Selection and empowerment of relevant stakeholder groups for using and (co)managing forests
- Creation of credible power relations, which allow the control of forest (mis)use by non-entitled outsiders.

The increased interest in stimulating both globalisation and localisation processes as a means to stimulate sustainable forestry development poses new challenges to forestry policy research. In the past, much of this research was of a normative nature. It was primarily based on the idea of scientist developing the most appropriate forestry strategies on the basis of their academic knowledge (Glück, 1995). Much of these efforts were based on the idea that the implementation of such scientifically-designed policies would proceed along a linear process. However, when it is accepted that the road of policy formulation to implementation is characterised by interface situations, the task of forest policy researchers cannot be any longer be viewed in such a normative way. Rather, their task becomes one of analysing where and why such interfaces do occur, and how they could be dealt with under specific conditions. As a consequence, in forest policy science new approaches towards understanding the nature and working of the policy process are being developed. For instance, increased attention is given to the concept of policy networks, and to the question how multi-level governance may assist to mediate interests of stakeholders from global to local level (e.g. Hogl, 1999).

These developments also imply, that forest policy scientists should look at the underlying processes of forest policy formulation and implementation rather than restrict themselves to the development of norms to be applied in forestry policies. This means that they should increase efforts to bring enlightenment about the nature of normative pluriformity concerning forest resource management and to identify the relative values of the various tools such as state regulation, market regulation or social negotiation to overcome conflicting demands on those resources (Wiersum, 1999).

Abstract

The mechanization of agriculture during the 1950s resulted in rural depopulation and a subsequent shortage of human labour and work horses in forestry. It therefore became necessary to develop working methods in the forest. The introduction of chainsaws was poorly controlled and resulted in occupational diseases and accidents. Ergonomic research, the development of better equipment and work methods, and mechanization eased these problems.

The fully mechanized cut-to-length system is today the globally known trade mark of Nordic forest technology. Independent highly-motivated entrepreneurs, typically owning a harvester and a forwarder, or one or two heavy trucks, have become responsible for the implementation of timber procurement to the industries. Consequently, the number of wage earners has diminished radically, but the remaining work force enjoys a greatly improved working environment, and the rate of accidents is only a fraction of the former level. As capital-intensive technology has replaced labor-intensive technology, the physical strain on workers has decreased but the mental strain on machine owners and operators has increased.

The efficiency and cost of logging and trucking has been reduced substantially, and work methods have also been developed successfully with respect to the demands of environmentally sustainable forestry and good management practices. However, Nordic forestry has not fully met the requirements of social sustainability with respect to job opportunities in rural communities.

Keywords: Forest work, Harvesting, mechanization, Productivity, Forest energy, Nordic countries

Background

Of the five Nordic countries, Iceland does not have any commercial forests. Denmark, Finland, Norway and Sweden possess a total area of productive forests of 50 million ha and the annual cut is almost 150 million m^3 (Table 1).

The last decades of the 20th century witnessed fundamental changes in forest work in the Nordic countries. As the infrastructures developed and the societies changed, the concepts of forest work and forest operations broadened accordingly.

The definition of the discipline by Sundberg (1988) portrays the Nordic approach: "The discipline of Forest Operations and Techniques is the study of the interaction of labour and machines with the forest. It involves an understanding of the relationships between labour, technology, the forest resource, forest industries, people and the environment. It becomes an approach to other, traditional subjects and disciplines rather than a subject itself. Yet, it is an academic discipline and a subject in forest science conducted with scientific rigour, and the approach has important practical applications"

During the second half of the 20th Century the Nordic countries were consistently in the forefront of the research, development and commercialization of improved techniques for forest work. It is not surprising that they also played an active role in the development and implementation of IUFRO's research program within the frame work of Division 3 and its predecessor Section 32.

Table 1. The area of productive forests and the annual cut of timber in the Nordic countries.

	Productive forest area, mill. ha	Annual cut million m³/annum
Denmark (Miljöminist. 1993)	0,4	2
Finland (Finnish… 1999)	20,1	61
Norway (Statisk… 1996)	7,4	8
Sweden (Skogstyrelsen 1998)	22,6	73
Nordic countries, total	50,5	144

Among the great Nordic forest technologists with an outstanding career in the service of IUFRO are IUFRO President Ivar Samset from Norway, Division 3 Coordinators Ulf Sundberg (Section 32), Bengt Ager and P.O. Nilsson from Sweden, and Deputy Coordinator Kalle Putkisto from Finland. Their active involvement in IUFRO's work, combined with the strong interaction between science and practical forestry, is undoubtedly one of the key factors behind the global success of Nordic forest technology

The Nordic Cut-To-Length System

Up to World War II, timber harvesting all over the world relied on simple hand tools, human labour and draught animals. In the Nordic countries, farm work in the summer time and forest work in the winter time balanced the seasonal fluctuation of rural employment. The mechanization of agriculture led to rural depopulation which resulted in a shortage of loggers, horses and horse drivers. In the 1950s it became necessary to start mechanizing forest operations as well.

The appropriateness of a procurement system is highly dependent on the environment and infrastructure in which the timber is produced. Although the tree-length system was found economical in North America, it was not satisfactory in the Nordic countries, where logging was performed not only for the exploitation but also for the management of small, non-industrial private forest holdings.

To meet the concern over the forest environment and sustainability of wood production, it became necessary to develop a completely new technology for these specific conditions. The key characteristics of the technology which evolved are the bucking of stems to assortments at the stump and subsequent transportation to the road side in load-carrying tractors, i.e. forwarders, completely off the ground. This technology was first called the shortwood system, but as the length of pulpwood logs gradually increased, forest engineers started to call it the product-length system, log-length system and finally the cut-to-length system. The reasons northern Europe developed its own technology include:

- In the boreal forests trees seldom reach large dimensions. The productivity of skidders is low when trees are small, whereas the forwarders are less sensitive to tree diameter.
- Thinnings are a central tool in the Nordic forest management system. Less tree damage occurs with the cut-to-length system.
- Soil compaction reduces the growth potential of forests. The forwarders have a larger number of wheels and more balanced load distribution, apply lower tractive forces, travel less, and are able to travel on a protective bed of logging slash so as to reduce the disturbance of soil.
- The vibration-induced health problems are less serious with forwarders due to a better load balance, larger number of wheels, and slower traveling speed.
- Small private forest holdings are short of landing space. Forwarders stack the logs at the road side into 3—4 m high piles, thus saving space.

- The forwarders sort the timber in conjunction with unloading. The value utilization of timber is improved and criss-cross transportation is reduced.
- Road side piles facilitate truck loading and free the trucks from a hot operation schedule.
- Load-carrying forwarders help to keep the timber clean.

With the introduction of the cut-to-length system, the North American and Nordic technologies diverged. The two systems evolved apart, until they as a result of the globalization process, began to converge in the 1980s. At present, of all wood raw material used globally in the forest industries, about a quarter or 400 million m^3/annum is harvested using the cut-to-length system. Finland and Sweden together are the world leaders in this ergonomically and environmentally advanced technology.

The Chainsaw Period

Logging is typically carried out in isolated places far from home. In the Nordic countries, most of the timber is harvested during the harsh winter season. Work sites are changed frequently, and the employment fluctuates seasonally.

Logging has always been a strenuous and hazardous task which has lacked the respect of “modern” society. The great Finnish philosopher and statesman, J.W. Snellman, otherwise known for his far-sightedness, stated in the mid-19th century: “It is doubtful whether the cutting and hauling of timber can hardly support anybody for a single day a year. It is work that requires no mental exertion and only ignorance and brutality are its consequences”.

The shift from traditional hand tools to chainsaw raised the status of logging, but the uncontrolled introduction of new technology in the 1960s resulted in unexpected health problems. Workers were seriously affected by damaged hearing, vibration-induced white finger disease, and injuries caused by muscular-sceletar strain from unsuitable working positions. The exposure to deep snow and cold accelerated the consequences.

Comprehensive programs were launched to fight these problems. In the 1970s, systematic ergonomic research probably played its strongest role ever in the field of forest operations. The occurrence of occupational diseases was reduced, and the frequency and severity of accidents was brought down. Among the means used were:

- The ergonomic properties of chainsaws were improved. Safety chain, automatic chain brake and isolation of handles from saw vibration were introduced. The performance of the saw was improved while the total weight was reduced radically.
- Protective equipment and clothing were developed and made more comfortable for the users. New safety regulations were brought into force.
- Machines and work methods, such as techniques for manual bunching of heavy logs, were adjusted in accordance with the capabilities of forest workers.
- In Sweden particularly, the piece rate system was replaced by time-based salary.
- Workers training, including refresher training, was intensified.
- Finally, the transition from motor-manual to fully mechanized technology moved the man from the ground to a protected harvester cabin.

Figure 1 shows an example from Finland of the development of the accident rate in all forest work from 1983 to 1996. Although the harvest increased, the amount of accidents was reduced by 73 %. Proportional to the amount of timber produced the reduction was 77 %. However, proportioned to the total work time, the reduction was less, 42 %.

Mechanization of Cutting

Few people could have anticipated the rapid increase in the productivity of harvesting. In addition to the mechanization and introduction of the modern logging machines, the work was also rationalized, changed and reduced by several other means, including:

- Work, for example debarking, was moved from the forest to the mill.
- Forest roads were built. In Finland alone, almost 130 000 km of permanent forest roads, i.e. 6,5 m/ha of forest land, were constructed in half a century.
- Future conditions of logging were improved through precommercial thinnings and the increased role of regeneration cuttings.
- The skills and motivation of the chainsaw operators, machine operators and foremen were developed through intensified training.
- Work organization and logistics were improved throughout the timber procurement schedule.

During the first half of the 20th Century, one of the hardest jobs in the forest was the manual debarking of timber. Debarking was the first phase of logging which was moved from man to machine. The next step was the mechanization of off-road transport through the development of the forwarder (Figure 2).

The mechanization of cutting was begun in the late 1960s using processors. They were followed by harvesters, which initially were used in clear-cuttings only. As the technology developed, mechanized logging became possible in thinning cuttings as well. Within two decades the cutting work was almost fully mechanized. In 1998, 82 % of thinnings and 95 % of regeneration cuttings were performed with harvesters in Finland (Figure 3). In Sweden the percentages were even higher.

Today, the harvester operator selects the trees, fells and delimbs them, bucks the stems to optimum logs, and measures the volume of timber with great accuracy. He can also protect the stumps against the root rot fungus, as well as pile the residual biomass from tree tops and crowns for subsequent recovery for energy. The operator of a modern forest tractor works in much improved and controlled environment in a comfortable cabin which is effectively isolated from noise and vibration, working temperature is convenient year around, and the visibility through panoramic curved windows is good. The man in the cabin is not only a machine operator but also responsible for the silvicultural management of the stand.

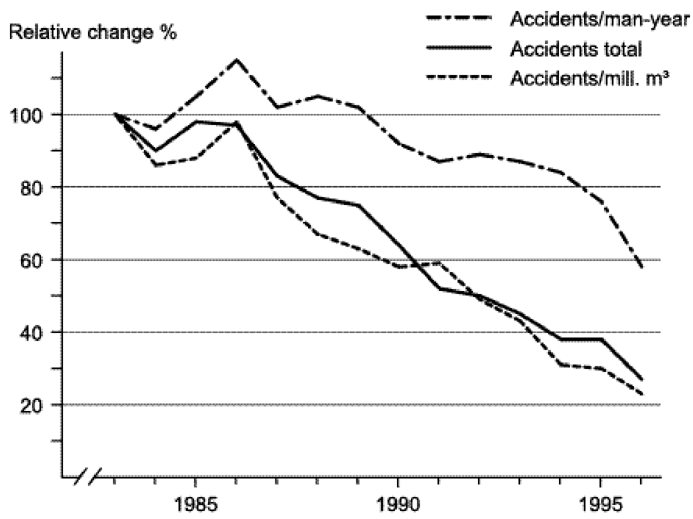

Figure 2. The development of timber harvesting technology in the Finnish forest industry companies since 1940.

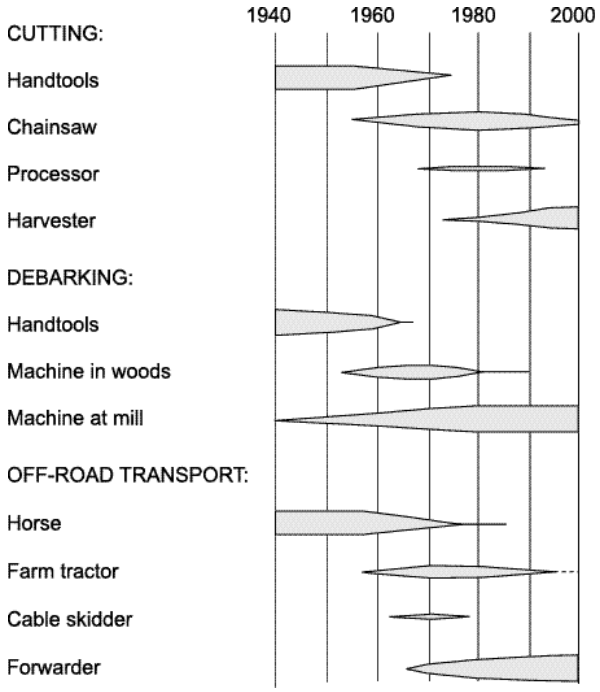

Figure 3. The share of mechanized cutting in the logging operations of the forest industries and Forest and Park Service in Finland (data *Sateri et al.*).

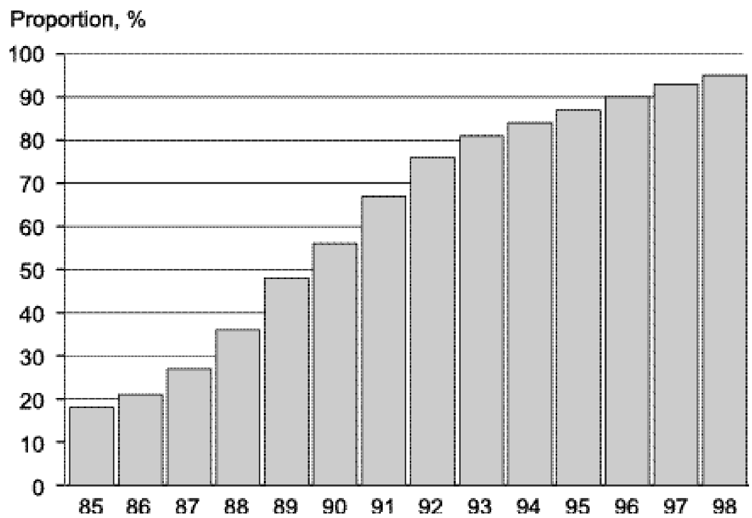

The following quotation from Tom Burch gets to the very heart of recent development of forest work in the industrialized world (Drushka and Konttinen 1997): "We don't know what hard work is since mechanization is like it is now. --- Logging's just not that kind of work any more. But it takes a lot smarter man to be able to run the kind of equipment we run today. Especially on the cut-to-length machine. On something like that, you gotta have a man that's really up on what he's doing, well trained, to be able to run cut-to-length machines. --- A man's hand never touches the timber. There's no manual labor, when I think of mechanization. A man, he sits up here running the machine, punching buttons. He gets that tree on the truck and hauled to the mill without any sweat. I call that mechanization."

However, the machine operators are exposed to a multi-stress situation. Rapid selection of trees, optimizing the timber value, protection of the remaining trees and environment, maintenance of an expensive machine, and responsibility for the profitability of the operation, all serve to create a great mental work load. At the same time, the static work load and long work days tend to cause stress and injuries to neck, shoulders, arms and cervical spine. There is still need to improve machine design, working techniques and work organization.

In the XXth IUFRO World Congress, Staudt (1995) summarized the ongoing changes in the working environment. His conclusions describe aptly the state of forest work also in the Nordic countries at the turn of the millennium:

- The modern worker is no longer a subordinate object, but a grown-up partner in the organization;
- The modern worker is increasingly his/her own supervisor;
- Transfer towards horizontal organizations is taking place, with fewer management levels, fewer supervisors, and workers with a wider range of tasks;
- Forest workers are becoming contractors and owners of the machinery;
- Mechanization and automatization is replacing heavy physical work;
- The operators have to meet higher demands of knowledge regarding the silvicultural, environmental and working conditional consequences;
- Higher demands for knowledge are often combined with an increase in mental work load;
- The need for continued training and education is increasing;
- The need for certification and qualification of the worker is increasing.

Development of Truck Transport

In the Nordic countries, distances from forest to mill are long and the cost of transport high. Land transport was originally only complementary to water transport. As the rail and road networks and equipment developed, the shift from water to land took place only gradually. Public funds were used to promote forest road construction on private lands. Because of the Nordic public right of access, these roads can be used free of charge for recreational activities as well. On the other hand, the high road density has been criticized for the disturbance of nature.

In the 1950s, trucks were still loaded by hand, and the driver had one or several assistants. When the hydraulic cranes appeared in the 1960s and became standard equipment in timber trucks in the 1970s, the use of assistants was abandoned. Improvements of the road network made it possible to use heavier trucks throughout the year. In half a century, the vehicle length was doubled, the engine power was increased fivefold, the total weight was increased sixfold and the load capacity was increased tenfold (Table 1, Figure 4).

Truck transport became feasible over longer and longer distances. In Finland, the average trucking distance of timber in the 1940s was less than 20 km, but at the end of the 1990s it was 100 km. The productivity increased and is now 33 000 m^3 per annum per truck.

The cabin of a modern Nordic timber truck is like a small office equipped with air conditioning, refrigerator, phone, microcomputer and communications with the timber procurement organization, customer mills and the truck services. Satellite navigation technology enables the procurement organization to send the truck information on the location of timber inventories on digital road maps, and instructions concerning the daily timber orders to different mills by assortments. The application of information technology and efficient logistics speeds up the flow of timber from stump to mill, promotes the value utilization of the raw material, and improves the productivity of trucking.

Table 1. Development of the timber trucks in Finland. Typical truck properties at the end of each decade during the second half of the 20th century (adapted from Köhler 1998 and Karhu 1999).

Property	1940s	1950s	1960s	1970s	1980s	1990s
Engine power, hp	100	150	250	350	400	500+
Number of axles	2	3	3—5	4—5	5—6	6—7
Max. vehicle length, m	..	14	18	22	22	25
Maximum weight, t	10	24	32	42	48	60
Load capacity, t	3	6	11	16	31	41
Load/total weight, %	30	25	34	38	65	68
Productivity, m^3/a	..	..	10 000	15 000	21 000	33 000
Loading	Manual or Winch	Manual or Mech. crane	Mech. or Hydr. crane	Hydr. crane	Hydr. crane	Hydr. crane

Loss of Job Opportunities

The economically active population consists of three main sectors: agriculture including forestry, industry including construction, and the services. While the productivity of labour increases continuously, the possibilities to expand the production of agriculture and the consumption of agricultural products are limited. Consequently, jobs move from the agricultural sector to industry and, as the society develops, to the services. In 1950, Sweden lagged 30 years behind the USA and Finland 30 years behind Sweden in this development. In the mid 1980s, Sweden lagged only 10 years behind the USA and Finland 20 years behind Sweden. Today the differences are small (Figure 5). The industrialized world is becoming ever more similar.

Although the demand for labour has reduced and the work environment has improved, the shortage of forest labour is becoming a serious threat in post-industrial societies. Despite forestry's great importance for the national economics of Finland and Sweden, only a small proportion of the jobs in the agricultural sector are in forestry. Within forestry the number of wage earners and self-employed farm owners harvesting timber in their own forests has been steadily declining (Figure 6).

The number of chainsaw operators particularly has decreased radically, while the reduction in the salaried permanent staff, such as office personal and forest technicians has decreased more moderately. Work has been moved from wage earners to independent machine entrepreneurs and their drivers. In Finland, about 1 % of all employed people work in forestry, but in the other Nordic countries the percentage is still smaller. The social sustainability of forestry has suffered.

Renewable Energy - A New Challenge

Climatic change caused by the greenhouse gases from fossil fuels is considered to be the most serious global environmental threat. The industrialized countries have agreed under the Kyoto Protocol to reduce emissions of greenhouse gases by an average of 5.4 % from 1990 levels during the period of 2008—2012. In the Nordic countries, the reduction obligation is 21 % for Denmark, whereas for Finland it is sufficient to maintain the 1990 level. An increase of 1 % is allowed for Norway and of 5 % for Sweden. Since the greenhouse gas emissions presently exceed the level of 1990 in all countries, the task is in reality greater than the percentages above show.

One way to reduce the emissions is to substitute renewable energy for fossil fuels. Biomass from agriculture, forestry and municipalities accounts for a large proportion of the potential of renewable energy. In countries with large forest resources and well developed forest sectors small-sized trees and logging residues from conventional forestry form a major source of biomass. This is particularly the case in Sweden and Finland, but even Denmark with its much smaller forest area places great importance on biofuels.

Figure 5. The proportion of labour force employed by the agricultural sector in the USA, Sweden and Finland (data from Heikinheimo 1987 and Finnish Statistical…1999).

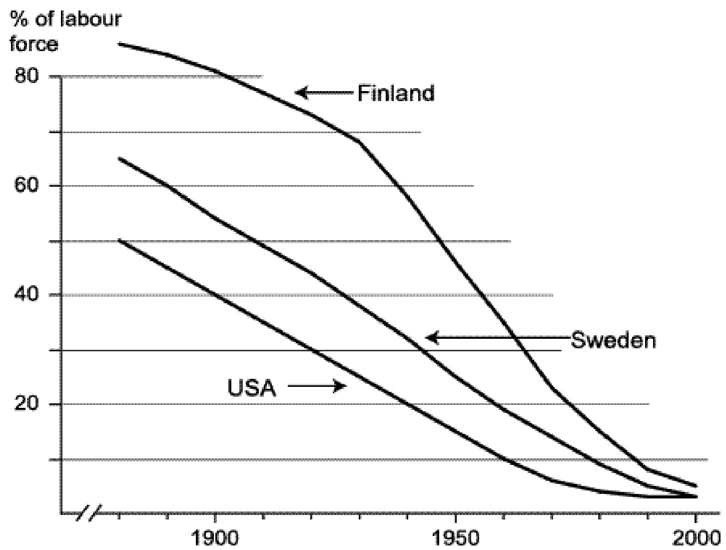

Figure 6. Labour force in the Finnish Forestry (data from Finnish Statistical... 1999).

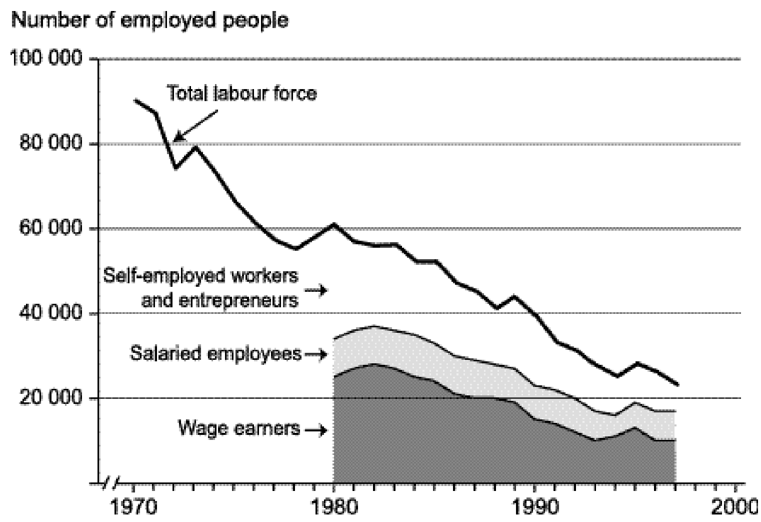

The appearance of modern energy harvesting on an industrial scale adds a new dimension to forestry operations(Björheden 1999). Erratic variations of quality, low energy intensity, distant location, and poor distribution systems have been the drawbacks of forest fuels which must be overcome. The sustainability of the forest ecosystem must be maintained while the recovery of biomass is intensified.

The increased use of forest energy enjoys the support of the green movement, nature conservation organizations and most of the society. But forest fuels must be economically competitive, and the customers require comfort, convenience and automation. The Nordic solution is to reduce the biomass into chips, to build district heating systems in areas of dense settlement, and to combine the production of heat and electricity from chips.

The demand for stemwood as an industrial raw material is good in the Nordic countries. On the other hand, of all above-ground biomass more than one fourth is crown mass for which there is no commercial demand. It follows that the harvesting of energy from conventional forestry often means the recovery of crown. Logging technology must be adapted accordingly.

It was earlier thought that the main source of forest energy in the Nordic countries will be whole-tree chips from early thinnings, and this is still true in Denmark. In Sweden and Finland, logging slash from regeneration areas has become a more important source of forest energy. This shift reduces the effectiveness of forest energy as a silvicultural tool, and the number of new job opportunities remains smaller than originally expected.

Forest biomass has a high priority in the energy policies of Nordic countries, while the forest industries see in it an opportunity to improve their environmental image. The production of clean renewable energy will make a considerable impact on the social and environmental position of the Nordic forestry. In the year 2000, the production of forest chips for fuel will be over 5 million m^3 in Sweden, almost 1 million m^3 in Finland and 0.4 million m^3 in Denmark. In Norway, which is a large producer of hydroelectric power and fossil fuels, the role of forest energy is less important.

Effect of Mechanization on Management Practices

In the early 20th century, the marking of trees for selective cutting was made by a team often led by a university-trained forester. When the cost of manual labour increased, the job was "downgraded" first to forest technicians, then to on-the-job-trained tree markers, then to chainsaw workers, and finally to the harvester operators with a machine technical background. Since the harvesters frequently work in two shifts and during the night, the operator has sometimes to select trees in conditions where the tree crown cannot be seen properly. The silvicultural result may then suffer.

Forests cannot be managed on the terms of logging alone. Compromises between the needs of silviculture and logging technology are necessary. Because the reach of the harvester crane is seldom more than 10 m, the distance between the strip roads in thinning cuttings has been reduced to 20 m. The strip roads cover up to 20 % of the forest area. However, due to the edge effect, the growth loss is only a fraction of the ground area loss. Nevertheless, the loss of increment adds in the Nordic countries up to millions of cubic meters annually. On the other hand, many studies show that the cut-to-length system results in less tree and ground damage than the tree-length system (Sirén 1998).

Mechanization made year-around logging not only possible but also economically necessary. Job opportunities were distributed more evenly over the year. This improved the living conditions of the loggers who remained, but summer-time logging created environmental problems such as the increased risk of the root rot fungus.

Abstract

This paper is part of a research carried out by a team which also includes Manuel Gutiérrez, Silvia Lagos, Fabiola Maureira, Felipe Meyer and Jorge Espinoza. The purpose of this communication is to illustrate how appropriate technologies aimed at improving safety, health and wellbeing of the workers lead to higher productivity and to show that when a certain technique for forest work is adopted, ergonomics research can help to highlight how much a worker can produce according to the characteristics of the ground, the climate, the stand and the level of physical work load that he should not exceed to avoid fatigue. Examples are discussed of a proposal to calculate salaries and incentives using tables of standard performance based on this criteria. Finally, a case study is presented in which it is shown how the use of these concepts helps global work organisation with beneficial effects for contractors and workers

Keywords: Ergonomics, Productivity, Physical work load, Rest pauses, Job rotation, Working sequences, Organization of labour.

Introduction

Increasing productivity without harmful effects on the working population is one of the most important goals of ergonomic research. This is the way in which ergonomics contributes to development of labour. However, the approach centred only in tools, machines, work places and work organisation seems not to be the right model for developing countries. The final aim should be not only to make forest work safe and more profitable but also to find strategies for making the social environment of the workers and their families of better quality.

In other words, the small communities living around the large forest companies, should have access to good housing, health and education. Although these changes in communal organisation requires a global approach through governmental policies, one way to help these changes is through increments in salaries allowing the workers to satisfy their family needs. However, the efforts that they should do to get fair salaries should be without fatigue or other risks for their physical and mental health. In this respect, ergonomics research may help to demonstrate that better work design and organisation leads to more profits and that all the actors involved should be benefited from the increments in efficiency.

One urgent need in developing countries is to analyse the convenience or not to change traditional working methods for sophisticated technologies. There are experiences showing that machines can sometimes bring more harm than wealth to populations who earn their daily living from forest work. Furthermore, in not few cases, well organised methods using manual tools and simple machines can lead to higher productivity than capital intensive methods. However, high productivity in the forest sector, specially when the work is performed using labour intensive methods, can only be achieved if the whole working system is designed to be compatible with human capabilities and limitations. It is important to highlight that a job cannot be safe and efficient when carried out by people physically and/or mentally overloaded due to excess work.

Although knowledge and common sense to face manual and mechanised work should lead to well-designed jobs, to get into practice is a difficult task. Planners, managers and engineers are not easy to convince. Their aim is to keep production at the highest possible rate with the lowest cost and with the means they have available. Normally, because human beings are very flexible and in developing countries labour is cheap and easily available, they do not pay much attention to the workers. The consequence is low productivity, high accident rate, work related diseases and low salaries, which in the end contributes to the circle of poverty increasing the social problems.

One of the aims of this paper is to communicate simple examples on how to improve performance in some forest operations carried out with basic techniques, through the application of simple ergonomics research methods. The idea is to show how this approach can be used for the selection of tools, machines and also for work organisation.
