Consequently, the overall objective of this communication is to illustrate how appropriate technologies aimed at improving safety, health and wellbeing of the workers leads to higher productivity, which is a need in every country, especially in those fighting for real development. However, the most important goal of this paper is to show that when a certain technique for forest work has been adopted, ergonomics research can help to highlight how much a worker can produce according to the characteristics of the ground, the climate, the stand and the level of physical work load that he should not exceed to avoid fatigue. Examples will be discussed of a proposal to calculate salaries and incentives using tables of standard performance based on this criteria. Finally, a case study which shows how the use of these concepts helps global work organisation, will be analysed.

Material and Methods

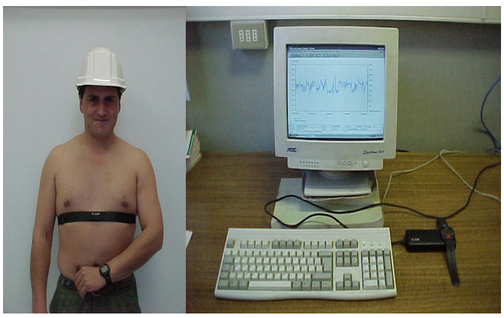
The workers included in the different studies which will be described were selected to be representative of the Chilean forest workers, according to standards already developed in the country by Apud and Valdes (1988), based on aerobic capacity, body composition, body mass and stature. During field studies, evaluations of the climate, ground, stand, physical work load and time distribution were evaluated according to the following procedures:

Physical Work Load

As our purpose was to evaluate the dynamic work load, cardiac frequency was measured, because it is a simple, non invasive and practical method to evaluate the strain imposed by a job without interfering with the activity of the subject. A detailed account of these methods is given in an ILO book entitled "Guidelines on ergonomic study in forestry" (1989). In our studies we used a POLAR VANTAGE monitor which is illustrated in figure 1. As it can be seen, the worker has a sort of “belt” around his chest which has incorporated a transmitter. This sends the signal of cardiac frequency to a receptor, which is used as a watch in the wrist of the worker, where the information is stored. Afterwards the data can be transferred to a computer where it can be analysed.

In Chile, we accept that, as average for an 8 hours shift, the cardiovascular load should not exceed 40 %. This is because, if the work is carried out in a temperate environment, there is a good relationship between cardiac frequency and energy expenditure, so one can assume that workers will perform as average under their anaerobic threshold. In case that the work is done in a hot environment, this limit seems also a reasonable load for the cardiovascular system, in spite that the work is performed with lower pace due to the heat. Cardiovascular load is calculated as follows:

Figure 1. Polar Vantage System for recording cardiac frequency in the field



$$\% \text{ C.C.} = \frac{\text{fC at work - fC at rest}}{\text{fC maximal - fC at rest}} \times 100$$

where:
C.C. = cardiac cost or cardiovascular load
fC = cardiac frequency
fC maximal = 220 - Age

Cardiac frequency corresponding to about 40 % cardiovascular load for different age groups are as follows:

AGE RANGE (years)	CARDIAC FREQUENCY (beats per minute)
20 – 25	115
26 - 30	112
31 - 35	110
36 - 40	108
41 – 45	106
46 - 50	104

Evaluation of the Stand

All our studies have been carried out in plantation forestry of radiata pine. Although, we have worked in forests with only one specie, the characteristics of development of the forests varies according to the area and climate in which they grow. The result is trees with a variety of sizes, forms, growth of the branches, etc. For that reason, in each study, specific measurements of the trees were made. As it will be too long to define all the measurements of trees or branches, those which appeared related to specific tasks will be explained when discussing the results.

Characteristics of the Ground and Climate

The slope of the ground and the roughness index were measured. The roughness index is defined as the quotient between the time taken to cover a distance walking without obstacles and the time to walk the same distance with obstacles. It ranges between 0 and 1. The degree of difficulty for displacement, based on the roughness index, is usually classified as follows:

High: Range between 0.01 and 0.33
Medium: Range between 0.34 and 0.66
Low: Range between 0.67 and 1.00

With regard to the climate, dry, wet and globe temperature were measured every half an hour during the shifts using conventional thermometers

Work Studies

Continuos time recordings were performed as proposed by the ILO (1989). The usual procedure is to establish first the work cycle and afterwards to divide the activities as principal and secondary. Principal activities are specific and they will be explained in detail when analysing different forest tasks. Within the secondary activities are included all those with low or relative periodicity. The following is the classification used in most of our studies:

Material: Time devoted to maintenance and repair of tools and machines.
Personal: Time devoted to personal activities, e.g. physiological needs.
Waiting: Time in which the machine or the worker stops because of the

operation itself, e.g. waiting for one or more members of the crew to complete the job.

Detention: Spontaneous breaks and rest pauses carried out during a normal shift when everything is in order.

General: Unpredictable situations interrupting the normal cycle of work when all the resources are available. Normally they do not last more than 5 to 10 minutes.

Others: Major interruption of the work cycle, e.g., due to rain or break-down of machines. They usually last more than 10 minutes.

To facilitate the collection of the information, each activity, being principal or secondary, was assigned a code. This simplified not only the work of the controller, but also the digitation of the information for posterior analysis.

Results and Discussion.

The results will be presented in such a way that first will be discussed the effects of isolated organisational factors will first be discussed and by the end it will be shown how these can be integrated to improve working conditions and productivity.

Number of Workers Per Activity

Through different studies we have been able to demonstrate the importance of the balance within working groups. For example, studies performed by Apud y Valdés (1995) showed that when power saw operators work with only three axe workers the work load for this last group can be extremely high, so the recommendation was to work with four persons debranching the trees with axes per each power saw worker felling the trees.

During this year, we conducted surveys where it was shown that power saw operators could increase their level of production within reasonable levels of work load if the crews were organised with the correct number of workers. For example, as shown in figure 2, power saw operators increased their production by 36% (from 11.1 to 15.1 cubic meters per hour) when they worked with 4 instead o 3 axe workers. This also allowed a proportional increment in performance of the logging machine employed in this case, which was the most expensive component of the job.

Scheduled Rest Pauses

It is not easy to demonstrate the importance of rest pauses for recovery. However in different studies we have found that rest pauses can help recovery and maintenance of good performance. Although the example that follows was not found in forest production but in pruning which is a silvicultural treatment, the effect was so clear as to help motivate contractors doing final cut activities to introduce scheduled rest pauses. In figure 3, a follow up of trees pruned per hour and cardiovascular load for the equivalent period is shown. As can be observed, the general trend is that work in the first hour in the morning starts with a high level of production and a relatively intense work load. As time goes by, the number of trees pruned per hour tends to decrease but the work load is maintained. In the last hour of the morning, the cardiovascular load increases significantly but the output of the workers decreases. In general terms, an increment of cardiac frequency with a reduction in the level of performance is a signal of fatigue due to the shortness of rest. A very common error is not to schedule the rest in such a way that the workers can take at least a 15 minutes break after two hours work. Depending on the type of work it is even convenient to give ten minutes of rest per hour. As a general rule, short and frequent breaks are more adequate than long and spaced pauses. Of course, the decision has to be evaluated in the field

As an example of the positive effect of rest pauses, a study was conducted in a group of workers debranching with axe in summer time. The workers debranched without any rest during the whole morning. To see the difference, rest pauses of 15 minutes duration were introduced at mid morning and mid afternoon. As it can be seen in figure 4, the output of these workers increased 16 %, from 2.6 to 3.2 cubic meters per hour, while the cardiovascular load diminished from 35 to 33%. In other words, the good recovery allowed the workers to do more work with a lower physical work load.

Job Rotation

Another aspect which has been demonstrated very conveniently, when working conditions allow it, is to introduce job rotation. Changing activities may as reduce the work load for those doing the heavier part of the job and output can be even duplicated.

A clear example was found in a study in which the work of power saw operators felling trees in the forest was compared with that of workers cross-cutting in the logyard. The first activity is far heavier than the second. Therefore, two ways of rotating the job were proposed. The first was according to the simplicity of operation and for that reason it was done at lunch time. The second was a physiological consideration based on the fact that recovery after heavy work is faster the sooner that the rest is taken.

For that reason, essays were carried out in such a way that the workers changed every second hour. They started working at 8 A.M. and they rotated after 10 minutes rest at 10 o'clock. Then they had 1 hour for lunch at 12 noon when they changed again and finally after another 10 minutes rest they rotated at mid afternoon.

In figure 5 it can be clearly seen that with both forms of rotation the physical work load was much lower than when the workers were only felling trees. In the same figure it can also be seen that the output increased both in the number of trees felled per hour and also when expressedin cubic meters. It is necessary to mention that when carrying out research to evaluate real work it is almost impossible to standardise the conditions. In this study, when 3 rotations were evaluated, the trees were smaller and that was why the number of trees was much higher. However, normally when working with smaller diameters the amount of wood in terms of cubic meters is less. As it can be observed in the figure, this was not the case, because even if the conditions were not favourable, when rotating jobs the amount of cubic meters worked increased.

Figure 2. Performance of the power saw operator felling trees when working with 3 or 4 axe workers debranching.

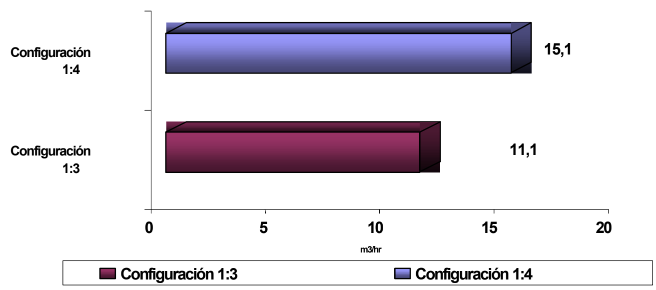


Figure 3. Average number of trees pruned per hour and % cardiovascular load as average of a follow up of 10 workers controlled during the first 4 hours in the morning

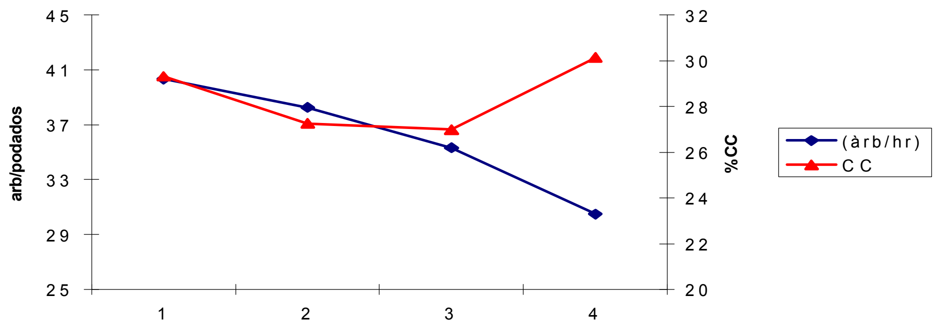

Figure 4. Average output (m^3/hr) and cardiovascular load (%CC) in a group of axe workers debranching with and without schedule rest pauses.

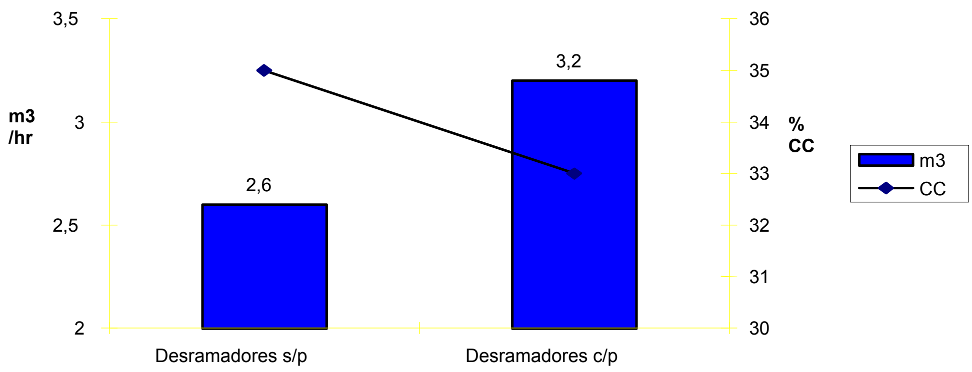

Figure 5. Average output (m^3/hr y trees/hour) and cardiovascular load (%CC) for a group of power saw operators felling trees during the whole shift and rotating job with the power saw operators doing cross-cutting in a logyard. Rotation was done once a day (lunch time) and 3 times per shift (10 A.M., lunch time and 3 P.M.)

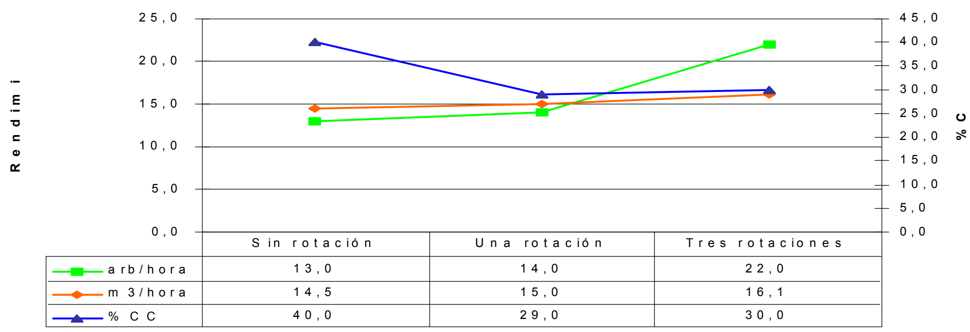


Working Sequences

When the physical work load is evaluated simultaneously in all the workers of a crew, it can be observed, in many cases, that the distribution of work could be changed, increasing output, without an excessive increment in work load. For example, in one of our studies it was possible to demonstrate that the way in which power saw operators felling the trees organised their job, can have an important impact on performance. We had the chance to evaluate this effect by comparing two crews within the same company. In the first alternative, which we called, continuos work method, the power saw operator worked with four axe workers in two felling areas. In such case, when he was felling in one area, the axe workers, at a safe distance were debranching in area. The a second alternative is the so called discontinuous method. The work is performed only in one area in such a way that when the power saw operator is felling, the axe workers remain idle at a safe distance. Afterwards, when the axe workers start debranching, the power saw operator has to stop the dangerous job of felling trees.

As shown in figure 6, the follow up of these two forms of organization, demonstrated that when work is performed in two separate areas, the output of the axe workers increased 35%, because the waiting time is reduced from 42 to 19%. It is important to mention that the 19% waiting time with the continuos system is mainly rest pauses allowing human good recovery.

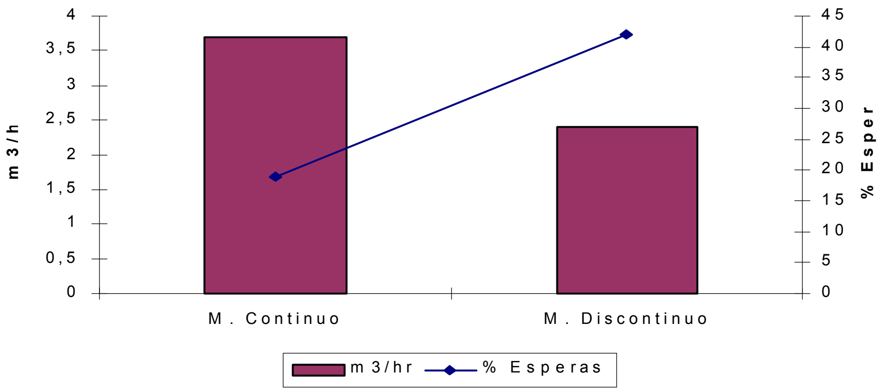
Standard Performance as a Basis for the Calculation of Salaries and Incentives

On most occasions we know that forest work is a heavy task. However, the question is: how much is too much?. To answer this question we have been developing, over many years, a model in which the output depends on the physical work load that a worker can sustain during his working life without fatigue or other risks and on the difficulties he meets in his job. In other words, in forestry there is great difficulty in expecting the same amount of output from a worker all the time. This makes it difficult to calculate incentives and salaries, especially when workers are paid by piece rate. Apud and Valdes(1995) and Apud *et, al*.(1999) have presented several functions to calculate output of different forest activities. We have followed standard procedures for the studies carried out in the field in which we have measured performance as well as physical work load, characteristics of the forests, ground and climate. As it will be too long for the purpose of this text to go into details only a brief example will be given related to power saw operator cross-cutting in a logyard. After a detailed statistical analysis it was found that around 75% of the variation in output of these power saw operators could be explained by the average volume(AV) of the trees they cross-cut, the time devoted to the principal activities(PT) and the effort they expended as judged by the cardiovascular load(%CL), according to the following formulae:

$$\mathrm{OUTPUT}(m^3/\mathrm{hour}) = -7.5 + 0.16*CL + 0.23*PT + 8.1*AV$$

The idea of these tables is to show to the companies and contractors that when salaries are paid according to the amount of work that the workers can do, they should consider carefully how much work can they really expect to be done. In our experience it is mostly the case that the demands imposed on workers will tend to be higher than what they can really achieve. In a practical sense, with these tables a company demanding the service of a contractor and the contractor himself can plan the job considering part of the difficulties that the worker will face in the field. We are promoting a system in which it is recommended. For example, if a previous sampling of the forest shows that the average volume of the trees is 0.9 cubic meters, an average worker with a cardiovascular load of 30%, devoting 70% of the time to principal activities, should produce around 20 cubic meters per hour. To reach this production a fair salary shoud be paid allowing the worker to fulfil his and his family needs. Of course, a motivated worker can still do more work without risks. If as is observed in the table, for the same forest with 0.9 cubic meters average per tree, the labourer devotes 80% to the principal activities with a higher effort at the limit of 40% cardiovascular load, he may produce 24.2 cubic meters per hour, which is nearly 20% more.

Figure 6. Output (m^3/hr) and waiting time (%) for a group of axe workers working with power saw operators using different working parameters.



On this basis a table for easy calculation of performance was prepared as follows:

AV (m^3)	CL 30%		CL 40%	
	PT		PT	
	70 %	80 %	70 %	80 %
0.1	13.9	16.1	15.4	17.7
0.3	15.5	17.8	17.1	19.3
0.5	17.1	19.4	18.7	21.0
0.7	18.7	21.0	20.3	22.6
0.9	20.3	22.6	21.9	24.2
1.1	22.0	24.2	23.5	25.8
1.3	23.6	25.9	25.2	27.4
1.5	25.2	27.5	26.8	29.1

So to motivate the labourer incentives should be paid. Although to work at that level is still safe, we are talking of the higher limits of physical performance and that is not possible to obtain if the worker does not feel that his effort is recognised.

It has to be warned that incentives should be discontinued beyond the higher levels proposed in the tables since there are serious risks of fatigue, accidents and work of poor quality at thesefore. On the other hand, the main limitation of the system is that we are talking of an average worker and not every human being is alike. The tables cannot therefore used in a rigid way. However, our experience indicates that forest workers doing heavy manual work tend to have a good physical fitness irrespective of age. For the reader interested in this topic, Apud *et. al.* (1999) published a book in which standard performance tables are presented for most of silvicultural treatments and harvesting activities.

An Integrated Study

Until now, examples have been presented on how simple considerations in the organisation of work can help to improve performance. On the other hand, we have discussed how to use tables for the estimation of the expected output in isolated activities. However, what it is fundamental is to demonstrate that the integration of this knowledge can help to balance good working conditions with productivity. The study which is described below was precisely carried out for this purpose.

The work evaluated was final cut. Labour was organised in such a way that a power saw operator felled the trees and 3 axe workers did the debranching work. Afterwards a choker setter fixed the logs to a cable crane for aerial transport. This work was done over two days. Afterwards, the same workers went to the logyard where the trees, previously moved with the help of oxen, were cross-cut by the same power saw operator and piled by the axe workers. The work in the logyard lasted one to one and a half days.

After field studies, a new work organisation was proposed because there was a clear imbalance and in some cases the work load was too high and risky. The problem started with the power saw operator felling trees who devoted too short a time to principal activities. However, it was not possible to increase his performance if the bottle-neck caused by the high work load of the 3 axe workers was not solved. As a consequence it was proposed that an additional axe worker was added to the team. At the same time, considering the expected increment in production, it was also recommended to include a second choker setter.

With respect of manual piling of logs, this task has to be eradicated from the forest. The illustration of the back of the worker in figure 7 is self explanatory . Therefore, the work of piling and ox skidding was taken over by a machine (triloader). Furthermore to ensure a possible increment in production it was necessary to consider using 2 choker setters to handle the increased workload.

With the addition of two assistants needed in the log yard, the crew grew from 7 to 12 workers, showing that with this kind of technology mechanisation does not necessarily means reduction in the number of workers. It has to be pointed out that with this new organisation the work in the forest was simultaneous to that in the log yard and not done on different days by the same workers as in the original organisation.

The new organisation included 15 minutes rest pauses at mid morning and mid afternoon. During this scheduled rest, the workers were provided with a soft drink and fresh fruit. Both the rest and the snack were very much appreciated by the workers.

Figure 7. The workers pick the logs from the floor and load them on the shoulder. As can be seen the shoulder on which they load is about 10 cm lower than the other shoulder.

Information provided by the contractor and by the large company for which he was providing services confirmed that production increased from 700 m^3 to 1.500 m^3 per month with the new form of work. Of course there was more investment and expenses but the economic analysis which will be discussed also showed good benefits. Although a detailed economic analysis was made, for the purpose of this paper only some briefs comments of the most important points will be made. The fact that with the new organisation the number of workers increased and a machine was introduced to the system, there were new incremental costs. These were considered in the economic evaluation of both systems.

As a summary although the contractor had to pay the rent of the triloader, he had a real increment in earnings of 60%. The workers increased their salaries as follows:

Machine operators (tower and triloader)	47 %
Choker setter	26 %
Power saw operators	19 %
Axe workers	1.5 %

The situation analysed was calculated for a forest surface of 55.6 ha and a density of 398 cubic meters per hectare. This means that about 22.000 cubic meters of wood more harvested. Projecting these figures, it would have take the original crew 32 months to complete the task whereas with the modified organisation, it would have taken only 15 months. From this summarised analysis the following benefits can be seen:

The work was more balanced so the work load was more evenly spread

The dangerous activity of manual piling was eliminated

The was an increment in employment

Most of the actors had better earnings

Time was left available to start a new job

The company obtained the product required in a shorter time.

As a conclusion two important facts should be highlighted:

It is possible to innovate successfully without big investments

To keep the positive changes for the long run, salaries have to be improved. After the study everybody was satisfied with the new system, except the axe workers doing the demanding job of debranching the trees. Their salaries remained about the same during the whole process. Therefore the recommendation to the contractor was to increase the salaries of the axe workers.

Final Remarks

In this paper an attempt was made to show how performance could be improved with simple organisational changes. However, although examples always show good results, it is very important to mention that to get improvements in productivity there are a number of other factors such as hygiene and facilities for workers living in forest camps, food according to nutrient and energy needs, safety equipment and training not only in technical aspects but also in safe behaviour. The study we have described in this paper shows that should be given serious consideration the application of the broad concept of ergonomics can help in the development of a society.

Abstract

Resource managers worldwide face challenges in responding to expanding urbanization and its effects on forest resources. These challenges can be met head on if managers work toward: (1) comprehensive management of forest resources in urban and urbanizing areas, and (2) connection of urban people with forests and their management. Opportunities exist for accomplishing both of these goals through involvement of a broad spectrum of urban residents and organizations in collaborative management of forest resources in urban and urbanizing areas. Comprehensive and adaptive management of forests in urban and urbanizing areas is outlined, and efforts to involve individuals and groups in that management are discussed with examples from the Chicago, Illinois, area. Involving urban citizens in resource management can have implications for forest resource management across the urban to wilderness landscape.

Keywords: Urban residents, Forests, Collaboration, Involvement, Partnerships.

Introduction

Urbanization is having increasing implications for forest resource management around the globe. Urban expansion is displacing or transforming significant forest resources and changing the interactions between residents and forest resource management. In the process of urbanization, conflicting demands for resources emerge, as do different perspectives on resource management. Diverse values -- including functional, economic, recreational, wildlife, esthetic, and symbolic values -- must be considered in resource management decisionmaking. Land ownership across the urban to wilderness landscape is becoming more complex and fragmented. The decisions on resources management near a community are now influenced not only by the people who live there, but also perhaps by seasonal and part-time residents, casual visitors, and others whose only involvement with the forest may be reading about it.

Experiences to date suggest that while there is substantial public support for the protection, restoration, and management of urban forest resources, there can be controversy over particular management practices such as removal of trees and brush, use of herbicides, burning, and control of deer populations. Controversy can revolve around the appearance of an area. "Good forest management" is not always pretty. Research has found that native landscaping may look messy and overgrown to certain segments of the population, signaling an area is being neglected rather than managed (Nassauer 1995). In addition, controversy may involve how and where specific management practices are planned and carried out, how much and what type of information is made available to the public, how the public is involved in decisionmaking and planning for management activities, and how or if they are informed of proposed changes to the landscape (Gobster 1997). Implementing comprehensive and adaptive management of forests in urban and urbanizing areas, as well as connecting urban people with forests and their management will help address these challenges.

Urbanization transforms lands uses, ownership patterns, distributions of people and settlements over the landscape, and changes the social/political environment of the affected areas. The people who move to these new developments largely come from urban areas. Compared to those who already lived in the affected area, these new residents may have different values and preferences for the management of forest and associated resources. Previously rural communities may experience substantial growth in population, businesses, and industry. Smaller tract sizes and higher population densities may reduce availability of timber and increase the costs of harvesting it. Important recreation areas on private and public lands may be lost or rendered inaccessible by developments. The altered landscape is likely to bring changes in ecological processes. Development brings new challenges to managers such as increased risk of introduction of exotic weeds and pests, heightened conflicts between people and wildlife, increased threat of fire, and altered movement and control strategies for pest populations. An increased number of landowners, including a significant portion of absentee landowners, will complicate the management of landscapes to provide opportunities for outdoor recreation and esthetics, wildlife and wildlife habitat, and water and flood control. Planners and developers face new challenges, as do existing communities and businesses in the affected area (e.g., farms surrounded by homes).

Defining the boundaries of the urban forest is becoming increasingly complex in a country where the population continues to sprawl across the landscape. In the past the definition has depended on a relationship between the geographic location of the forest and its proximity to a large population center. As the United States increases in population, the boundaries of populated areas are rapidly expanding and constantly changing. It is difficult to determine where the rural forest ends and the urban forest begins, but even more difficult to designate resource management practices as being more appropriate in an urban forest rather than a rural forest. Given this integration, comprehensive and adaptive management at the regional scale is critical

Comprehensive and Adaptive Management

Several implications for the planning and management process begin to emerge, given that U.S. urban forests are substantial and growing; are complex ecosystems with diverse resources that are owned and influenced by a number of important groups; are connected to other urban and natural systems; and undergo significant change over time.

The diversity of urban forest resources and their extension across land uses, property lines, and political boundaries calls for management programs that bridge jurisdictions and employ multiple disciplines. Among the fields that may be involved in urban forest planning and management are forestry and arboriculture, ecology and wildlife management, entomology and pathology, hydrology and soils, meteorology and atmospheric science, landscape architecture and recreation management, psychology and sociology, planning and economics, and political science.

Given the unique character of urban forests found in particular settings, effective management also requires different forest management strategies within an urban environment (for example, by land use, land ownership, degree of development, and population density) and among urban areas (with different ecoregions, populations, and other attributes). Because of the complexity of land uses, ownership, and resources, a “one-size fits all" urban forest management scheme is not appropriate.

A key element in managing urban forests in a regional context is the coordination of activities among different owners and managers across jurisdictions, as well as the acceptance of different management goals. The participation of multiple stakeholders in urban forest management requires a forum to help link forest structures and their management throughout and beyond the urban system. Such collaborative stewardship should include not only owners, users, and managers of natural resources; but also individuals and groups involved in the management of other urban components (for example, commercial developers, city planners, utilities, and residents). Collaboration among a wide range of decisionmakers who affect urban forest resources provides opportunities for those involved to identify common interests, resolve potential problems, and coordinate efforts to meet multiple objectives. Our subsequent discussion of the Urban Resources Partnership, Chicago Wilderness, Volunteer Stewardship Network, and TreeKeepers illustrates such collaboration.

The diversity and connectedness of urban forest resources demand comprehensive approaches to their planning and management (Dwyer et al. in press). The complex interrelationships between urban forest components and air and water quality, wildlife habitat, utilities and other infrastructure, and the overall aesthetic character of the community point to the need for an ecosystem-based approach to policy, planning, and management.

Because urban forests are dynamic systems, their management must also accommodate rapid changes in the extent, health, and use of resources over time. Implicit in adaptive management of urban forests is the ability to monitor progress and evaluate the effectiveness of management decisions. By monitoring the effects of program activities on the extent, health, and use of the resource, by identifying areas for improvement, and by modifying management plans to address problems, adaptive management provides the flexibility necessary to sustain and enhance important forest resources in changing urban environments.

The advantages of comprehensive and adaptive planning and management are clear; however, implementing this approach to planning and management poses difficult challenges to urban forest managers (Dwyer and Nowak in press, Dwyer et al. in press). Specific emphasis areas for the future that will facilitate the implementation of comprehensive and adaptive management include improving: comprehensive health of urban vegetation; ecological restoration techniques; inventory and monitoring of the urban forest resource; dialogue among urban forest owners, users, and managers; collaboration among agencies and groups; understanding of how forest configuration influences forest use and benefits; knowledge about urban forest health; and the dissemination of information about urban forests, their benefits, and their management.

Involving Individuals and Groups in Resource Management

Urban populations in the United States have diverse incomes, education, racial/ethnic backgrounds, lifestyles, and associations with and views of resource management. It is important to recognize and embrace this diversity when dealing with urban populations. It is also important to recognize that many urban residents, as individuals or members of groups, have existing or potential ties to urban natural resources and their management. Efforts to connect urban residents to resource management should take advantage of the existing infrastructure for linking people and natural resources in urban areas.

Urban residents may obtain natural resource experiences in settings different from what a natural resource manager is accustomed to. Their involvement in natural resource issues may not be active -- they may not purposely feel, touch, and explore nature. However, they may be involved in less direct ways. Urban residents may behold nature (view it from a window) or derive pleasure from just knowing it is there. They may read about it, vote on issues related to it, write letters to the editor, join organizations that impart a philosophy in tune with their own, donate time or money to a cause, protest an activity, attend city council meetings and public hearings, etc. Urban residents experience nature not only by vacations to faraway forests but also by walks in a neighborhood park or by visits to zoos, museums, libraries, web sites, and nature centers. This diversity of experiences with nature shapes how urban people value the forest and view forest management.

Overall, the effectiveness of forest resource management in urban and urbanizing areas in the years ahead is likely to hinge on collaborative partnerships among a wide range of public, private, and not-for-profit groups; the expertise from a large number of scientific disciplines; and perhaps most important of all -- the involvement of citizens in planning for, implementing, and monitoring the results of resource management.

The results of comprehensive management of urban forest resources, including collaborative approaches and the dialogue with citizens about forest resources and their management, are likely to have influence across the urban to wilderness landscape as urban residents purchase, use, and care about forest and associated resources. The success of the extension of the urban experience to rural areas is likely to hinge on the extent to which urban natural resource management issues are linked to their rural counterparts, the involvement of urban people in planning and carrying out management, and the ties made among resource management, resource use, and environmental education.

In the subsequent discussion we will examine two forms of involvement in natural resources management: (1) citizen participation, and (2) urban coalitions or partnerships.

Citizen Participation

A key to enhancing the management of forests in urban and urbanizing areas and connecting urban people with forests and their management is the involvement of urban residents in comprehensive and adaptive forest resource management. To illustrate this involvement, we have drawn examples from the urban forestry and ecological restoration movements in the Chicago area. These efforts provide useful models for more effective connections between urban people and forest ecosystems in the 21st century.

Both the urban forestry and ecological restoration movements have developed in response to loss of valuable urban natural resources. Each has evolved into a strong movement that significantly influences resource management in urban areas and beyond, but each has developed a different strategy for involving people in natural resources management. There are important similarities, differences, and opportunities for synergism between these two movements (Dwyer and Childs 1997, 1998). Both contain important elements of comprehensive and adaptive management in urban and urbanizing areas. Our subsequent discussion focuses on the Chicago area and draws heavily on USDA Forest Service work with the Openlands Project's TreeKeepers urban forestry program, as well as with the ecological restoration efforts of the Illinois Nature Conservancy's Volunteer Stewardship Network (Ross 1994, Westphal 1993, Westphal and Childs 1994).

Urban forestry in Chicago has grown and gained strength partly in response to the catastrophic loss of trees, including the loss of elms to disease, and the loss of trees, forests, and greenspace to urban development. Given significant past losses and a high level of interest in trees by citizens and public officials, urban forestry has received significant attention in the Chicago area. Early urban forestry efforts focused on maintaining the trees along streets and in parks and forest preserves, but the scope has broadened over time to include comprehensive management of trees, forests, and associated greenspace across the urban environment and adjacent areas. Many urban forestry organizations such as city forestry departments and not-for-profit organizations spend most of their effort caring for trees in areas where the native ecosystems have been significantly modified.

Ecological restoration focuses on rehabilitating and maintaining biologically significant natural systems. There are many such systems in the Chicago area, including some that are unique and highly valuable, which have generated significant attention. The effort developed partly in response to the continuing loss of plant and animal diversity in prairies, but subsequently expanded to savanna, woodland, and forest ecosystems. In Chicago, the loss of diversity includes the incremental loss of natural areas to development, erosion of the quality of protected natural areas due to the lack of fires and other natural disturbances, as well as the introduction of exotic species. Traditionally, restoration activities are planned with reference to landscapes as they appeared before European settlement, but also consider current conditions, problems, and resources. Interest in ecological restoration is now extending beyond individual species and sites to the broader regional landscape. This landscape-level approach has accelerated under the Chicago Region Biodiversity Council (i.e., Chicago Wilderness) (Chicago Wilderness 1999b, Ross 1997).

These two movements in Chicago are similar in many ways. Both share a large amount of citizen involvement, including a high level of activism. Not-for-profit groups organize and train volunteers and build strong volunteer organizations that in themselves become important advocates for urban natural resources and their management. Studies show strong commitment by volunteers and similar motivations for the two movements (Westphal 1993, Schroeder 1998). Charismatic leadership among volunteers and in not-for-profit groups has been a driving force in shaping both movements. Efforts of both movements have brought increased public attention to trees and other natural resources in the urban environment.

Urban forestry volunteers participate in site design, site preparation, tree planting, mulching, and follow-up care of young trees such as watering and pruning. Ecological restoration volunteers participate in site mapping, location of significant species of plants and animals, prescribed burning, seed harvesting, and removal of non-native species. These tasks are sometimes organized as social events that may include potluck dinners or picnics in addition to the work activity. While both movements stress on-the-ground action, some volunteers participate in other ways, including writing newsletters, scheduling and coordinating events, and so forth. Increased attention is being given to volunteer training so that they can work more effectively with natural resources, as well as with the people who manage and use them. Training materials are sophisticated, well developed, and updated regularly. Both movements have strong environmental education programs aimed at children and adults.

Both movements capitalize on "active" participation as a means for citizen involvement, but neither has fully embraced or mastered widespread public involvement. There is a belief among both movements that if people can see and participate in management activities they will support these activities. Both movements are working hard to make urban residents and public officials more aware of urban vegetation, its management, and its significance to the urban environment and quality of life.

A comprehensive and adaptive approach to management of vegetation throughout the urban ecosystem would encourage linking of urban forestry and ecological restoration efforts, as well as collaboration among them (Dwyer and Childs 1997, 1998). From the standpoint of citizen involvement with natural resources, combined training and environmental education programs for individuals and groups involved in urban forestry and ecological restoration would provide a wider range of skills and experiences for volunteers, enhancing their experiences and the contributions that they will be able to make to resource management across the urban environment and beyond. The movement in this direction is encouraging. Some of the TreeKeepers effort is being focused on the restoration and management of specific sites. Volunteers from TreeKeepers and the Volunteer Stewardship Network have received training and are working to survey for the Asian longhorned beetle, an exotic invasive pest that was recently discovered in three Chicago-area neighborhoods.

Discussions with homeowners in the areas where trees were lost to the Asian longhorned beetle made it clear that they wanted to be kept well informed about the beetle, control options, and decisionmaking concerning management of the pest and its damage. This response reaffirms the interest of urban citizens in learning about and becoming involved in natural resource management. Such interest is a cornerstone of citizen involvement in collaborative management of urban forests.

Urban Coalitions and Partnerships

Collaborative stewardship requires a wide range of organizations working together to manage natural resources. To illustrate how this can take place, we will discuss two initiatives in the Chicago Area: (1) the Urban Resources Partnership, and (2) Chicago Wilderness. Both of these efforts bring public agencies, not-for-profit groups, communities, and citizens together into new working relationships to do a more effective job of natural resource management in the Chicago area. Each effort seeks improvement in the management of urban natural resources, but has different origins, emphases, and goals.

Both efforts encourage citizen involvement and have included volunteers from the urban forestry and ecological restoration movements. Although the efforts involve some of the same organizations, they remain separate in their mission and goals.

The Urban Resources Partnership

The Urban Resources Partnership (URP) is administered by the U.S. Department of Agriculture and co-sponsored by the Forest Service and the Natural Resource Conservation Service in 13 cities around the United States. Agencies with missions related to the urban environment have joined the partnership. In Chicago these partners include the U.S. Fish and Wildlife Service, National Park Service, U.S. Environmental Protection Agency, U.S. Department of Housing and Urban Development, and Cooperative Extension Service; as well as the State of Illinois (Department of Natural Resources) and City of Chicago (Department of Environment). The program advocates and assists community-based action through local partnerships to enhance, restore, and sustain urban ecosystems. These actions contribute to the improvement of the social, economic, and physical well-being of the people and their natural environment. The partnership provides technical assistance and partial funding to community-driven environmental restoration, enhancement, and educational projects. The program stresses projects that have physical (on the ground) components. URP strives to link community residents and the environment. The URP philosophy hinges on the belief that through education and participation, project participants build lasting ties to the natural environment, their communities, the government agencies that serve them, and most importantly, each other.

Chicago URP projects range from community gardens to large-scale ecosystem restorations. Chicago URP resource goals include: open space enhancement; water quality improvement; urban habitat creation, enhancement, and management; environmental education and stewardship; and the implementation of ecosystem management techniques.

The partnership supports natural resource conservation projects throughout the Chicago Metropolitan Area. Many individual projects involve Federal partners, not-for-profit groups, and community organizations. Projects target underserved inner city areas. Efforts are made to support projects where there is substantial community involvement and to encourage the involvement of urban residents in the actual management efforts. URP does not try to organize community groups, but rather approaches groups that already have community consensus for a project. URP targets urban conservation projects through a unique network of community groups such as boys and girls clubs, block clubs, public housing resident associations, and youth service organizations.

The URP experience in cities around the U.S. demonstrates a wide range of useful approaches for enhancing the management of urban natural resources by spawning partnerships that involve many different actors, organizational structures, and group missions in each city. Variation in the types of groups, resources, and resource issues involved in the different URP cities suggests that the most effective mix of partners, working relationships, and leadership structures in collaborative urban natural resource management may be different for each city.

What has been learned from the Chicago URP experience?

1. There are a wide range of important conservation needs in urban areas, and while local residents and community groups are interested in addressing these needs, they are often unfamiliar with the public agencies and not-for-profit groups that can assist them.
2. Urban residents see conservation efforts as a way to derive a range of important benefits for their community such as improving appearance, increasing recreational possibilities, creating jobs and opportunities for youth involvement, and building the capability to tackle other issues.
3. Community-led projects can be difficult to manage for a natural resources professional. In some cases,

the community may have different priorities for resource management than the professional.

4. Local support and involvement are critical to getting urban conservation projects started, and absolutely essential for sustaining them.
5. In getting urban conservation work done, technical assistance is often as much of a limitation as funding is. The demand for technical assistance for natural resources management exceeds current capacity of natural resource agencies.
6. Natural resource management issues in urban areas may be more complex than rural resource issues, and may require a level of sophistication and expertise beyond what one agency can provide. Agencies problem-solving together may be a solution.
7. There are substantial differences in the way that federal, state, and local agencies, even within the same urban area, approach resource management issues in urban areas. Thus, there is much to share and to learn through collaboration, and that sharing enhances the resulting projects.

Chicago Wilderness

The 100 + members of the Chicago Region Biodiversity Council (or “Chicago Wilderness") work to protect the natural communities of the Chicago region and to restore them to long-term viability to enrich the quality of life of citizens and to contribute to the preservation of global biodiversity. Chicago Wilderness has brought significant attention to the management of more than 200,000 acres of public and private land in northeastern Illinois, southeastern Wisconsin, and northwestern Indiana; and brought new collaboration among diverse groups. The areas that make up Chicago Wilderness are seen as a globally significant concentration of rare natural communities -- woodlands, forests, grasslands, streams, and wetlands.

Chicago Wilderness originated in local efforts to protect, restore, and enhance biodiversity. Those efforts drew support from the existence of significant remnants of pre-settlement vegetation in the Chicago Metropolitan Area and the desire to prevent their loss to development or exotic invasive plants. As this work expanded in scope, scale, and significance and began to take a landscape perspective, Chicago Wilderness was born.

The scope of the work of Chicago Wilderness is captured in the titles of the teams responsible for work that is carried out: science, land management, education and communications, and policy and strategy. There are strong efforts to integrate the work of these teams. The science and land management teams often meet jointly to be certain that there is a science input into land management. Policy and strategy works to implement initiatives developed by the other teams. Education and communications are tightly interwoven into developments in science and land management, and there are designated demonstration areas for restoration activity.

The partnership expanded rapidly and includes members from land management agencies; environmental groups; educational institutions; and federal, state, and local natural resource agencies. Chicago Wilderness provides funding for a wide range of projects that further its mission. A substantial amount of the initial funding has come from Federal agencies, but there has been some funding from state, foundation, and private sources.

Chicago Wilderness took a multi-pronged approach to engaging the public in restoration activities. The partnership attracts public interest by creating museum displays, zoo exhibits, and demonstration areas in forest preserves, organizing volunteer days at forest preserves, parks and nature centers, and by publishing and distributing Chicago Wilderness magazine throughout the metropolitan region. In addition, the partnership has produced a series of educational materials, including: an *Atlas of Biodiversity* (Chicago Wilderness 1999a), and *12 Natural Wonders of the Chicago Wilderness* (Chicago Wilderness 1998). The *Atlas of Biodiversity* has been distributed to every 8th grade teacher and every library within Cook County. Chicago Wilderness has also produced the *Biodiversity Recovery Plan* *for Northeastern Illinois* (Chicago Wilderness 1999b) that outlines the steps necessary to achieve the overall goal of Chicago Wilderness. The plan was adopted by the Northeastern Illinois Planning Commission (NIPC) in December 1999, the first major metropolitan planning agency in the nation to adopt a biodiversity plan for its region. Not only do these documents broadcast the importance of biodiversity to urban residents, they serve as a means of instilling public pride in the uniqueness of the prairie landscape.

What has been learned from the Chicago Wilderness experience?

1. The coalition can accomplish much in terms of public awareness and environmental policy that individual member organizations cannot do alone.
2. Preservation and enhancement of biodiversity can be a useful integrating theme for a group of diverse organizations with missions that focus on land management, research, and education.
3. There are numerous linkages among the Chicago Wilderness partners, with many opportunities for productive partnerships.
4. Public relations are important for the effort, and it can be a challenge given the large number of diverse organizations involved.
5. Coordinating a large coalition with a wide-ranging mission is a challenge that requires a significant amount of time and effort. Coordination across political and institutional boundaries is difficult. Even though most Chicago Wilderness partners agree on the mission, and the mission reflects that of their own institution, each institution has prior commitments of time, resources, and personnel that complicate its participation in Chicago Wilderness.
6. Even with the commitment to public relations and public outreach, Chicago Wilderness is hardly a household name with the metropolitan public.

Summary and Conclusions

Urbanization poses important challenges to resource managers. These challenges can be met by implementing comprehensive and adaptive management of forest resources in urban and urbanizing areas, and by connecting people with forests and their management. Comprehensive and adaptive management involves a wide range of disciplines, government organizations, citizen groups, etc. In this process, a widening spectrum of people become involved in forest resource management, including the establishment of policies and plans, generating support for those efforts, and actually carrying out resource management activities. These efforts are enhanced by coalitions and partnerships of public agencies, not-for-profit groups, community organizations, and others. Examples of successful collaborations include the Urban Resources Partnership and Chicago Wilderness. Direct involvement of citizens in resource management through groups such as TreeKeepers and the Volunteer Stewardship Network is also helping to implement collaborative stewardship and to connect citizens to natural resources and their management. As urban forestry becomes more comprehensive and more people are involved, the ties between it and forestry in rural areas become stronger, and the urban experience is more likely to influence what happens in rural areas. Comprehensive urban forest management can become a demonstration or reference for management of forests in rural areas. Citizen involvement and collaboration among groups is not only improving the management and use of urban forests, but also helping to establish critical links between people and resources that will help enhance resource management across the urban to rural spectrum of lands in the 21st century. Individuals and groups interested in involving urban residents in resource management decisionmaking might find it productive to work in conjunction with urban forestry programs and associated collaborative and citizen involvement efforts in urban areas.

Abstract

Urban values have become increasingly dominant in today's society. The share of the world's population living in urban areas has now bypassed that of those living in rural settings. Moreover, the socio-economic, cultural and ecological footprint of urban areas extends far beyond their physical boundaries. The world's rural and nature areas have become 'backyards' for the world's cities, primarily aimed at delivering goods and services to them. Forests and forestry are among those areas affected by the process of urbanisation. Forestry has typically been characterised as a rural profession. However, forestry today, to an increasing extend, has to deal with the dynamics of urban society. This paper features city and forest as both the Romeo and Juliet, and Cain and Abel. It describes how forests can be used in the continuous effort to create liveable cities, where the bad sides of urban life are minimised, while the positive aspects are optimised. As a recent study on urban woodland policy-making, planning and management in major European cities has shown, forests do in fact have potential to contribute to better cities through a wide range of social, economic and environmental values. Most importantly, they are crucial tools for keeping urbanites in contact with nature and natural processes. Some of the values of urban woodlands within an urban context will be elaborated, following an elaboration of the dichotomy of the city as being both 'good' and 'bad'.

Keywords: Forests, Cities, Urbanisation, Social values, Urban forestry

The Urban Boom

Most of us are urban people, even if we still have some green blood of the countryside in our veins. Internet, McDonald's, supermarket, cinema, traffic jam: urban phenomena that are part of our daily lives. But mostly we have to go only one or two generations back to find a farmer in our immediate family. Much has changed within the short period of one century. The Industrial Revolution may have been the incentive, but it is the 20^{th} century has really made the difference. According to United Nations figures, only 14 % of the world's human inhabitants lived in cities around 1900. In late as 1960, 2/3 of the people still lived in rural areas. At the start of this new millennium, the world hosts more urban than rural dwellers for the first time in history. By 2025, the UN estimate, only 1/3 of the people will still reside in rural areas. This development, jointly with the population explosion from 1.7 to over 6 billion within the past 100 years, had led to a boom in the number of urbanites. In 1950, there were only 2 megacities with over 8 million inhabitants. In 2015, there will be 33, and an additional 500 cities with over 1 million people. (Ponting 1991, EEA 1995, National Geographic 1998)

Even more rapid has been the physical growth of urban areas. Jack Ward Thomas (1999), former chief of the US Forest Service, has elaborated on the phenomenon of urban sprawl in the USA. He mentioned, among others, that while the city of Atlanta doubled its population during the past decades, its urban area increased by 400 %. Cities have gradually been 'eating away' at the countryside, not only through direct building activities, but also via the extension of railroads, roads and communication infrastructures. Through the latter, the dominance of urban values and norms has increased. Even in the most rural areas of Europe, children dress up in LA-style street gear, wear Manchester United football shirts, and people watch the Bold and the Beautiful and ER. In the process, we humans are steadily losing our direct contact with the earth. The dirt under our fingernails is gone.

Europe, of course, was the first continent to become truly urbanised. At this moment, over 2/3 of the Europeans can be classified as urban. Even though some large cities have actually lost inhabitants, urban agglomerations are steadily expandeding. Countries such as the Germany, Netherlands and the United Kingdom are approaching the 90 % urbanisation rate (e.g. EEA 1995, World Resources Institute 1996). My own life, for example, has also been urbanised. I started off in two small villages with just over 1000 people, before I moved to Wageningen, a Dutch university town with 35,000 people. Via Joensuu, Finland (55,000) I have now reached very urban Frederiksberg, a town of almost 100,000 absorbed within Greater Copenhagen with its 1.2 million people. The home computer entered my life when I was 13, the Internet when I was 20. Still, my great grandparents were farmers and fishermen.

The City Calls

Why do so many of us prefer to live in cities? People are social animals, like ants, but why do we seemingly prefer ant heaps of concrete, steel and tarmac over the rolling hills of the countryside? In his book 'The Gaia Atlas of Cities', Herbert Girardet (1992) mentioned the Industrial Revolution as major catalyst of urbanisation. Economic development became increasingly concentrated in cities and pulled people from the countryside. This process is still ongoing, particularly in developing countries. Cities have been windows of opportunity, offering prospects to dramatically change people's life. As Frank Sinatra sang about New York: "if you can make it there, you can make it anywhere"…

Spiro Kostof, in his book 'The City Shaped' (1991, p. 37-41), mentioned that cities are places "where a certain energised crowding of people takes place". Simply by putting a lot of people together on a small surface, a high level of activity and creativity is generated. People are pushed, one could say, towards and beyond the limits of their capacities. City life requires continuous learning, communicating, understanding, and adapting. Thus it is not surprising that Kostof said that in order to understand a city, one has to understand its cultural dimension.

Exactly what constitutes a city is, one has to say, a very difficult question to answer. In Iceland, settlements of over 50 people are already classified as urban (Benedikz and Skarphéðinsdóttir 1999). This is not really in line with the image most of us have of cities. Scholars have tried to grasp the concept of a city. The well-known urban designer Kevin Lynch (cited by Kostof 1991, p. 40) stated: "City forms, their actual function, and the ideas and values that people attach to them make up a single phenomenon". Kostof (1991, p. 37-41) provided a range of characteristics. Cities, he said, are places made up of buildings and people. But cities are also distinguished by some kind of monumental definition, that is, where the fabric is more than a blanket of residences. Cities have some physical circumscription, whether material or symbolic, to separate those who belong in the urban order from those who don't. In the old days, these were the city walls. But cities are no independent entities. They are "intimately engaged with their countryside, a territory that feeds them and which they protect and provide services for". Kostof concluded his work on city design by expressing his admiration for the city as human phenomenon: "the city is one of the most remarkable, one of the most enduring of human artefacts and human institutions."

A Tale of Two Cities

The development of the city, however, has always been put into the perspective of its good and bad sides. Or, as Charles Dickens wrote in his Tale of Two Cities (1859, 1992 edition): "It was the best of times, it was the worst of times, it was the age of wisdom, it was the age of foolishness, it was the epoch of belief, it was the epoch of incredulity, it was the season of Light, it was the season of Darkness…"

The Bad City is, as the American philosopher and writer Henry David Thoreau stated, the place where "millions of people are feeling lonely together" (cited by Ponting 1991, p. 312). American president Thomas Jefferson called the city a "sore on the body politic" (cited by Kostof 1991, p. 39). Jefferson favoured development via agriculture, so his view was perhaps rather biased. A more objective view has been expressed by the sociologist Redfield (1956, cited by Mak 1995), who described how cities obtain more power and wealth in their development, but have to pay a high price for this in terms of alienation, absence of norms and personal isolation. Ultimately, this would lead to the collapse of many cities. Human history, indeed, is full of cities that where once great but then declined, and in some cases - like Rome - became great again.

Cities are often overcrowded and evoke feeling of stress. This feeling is enhanced by the continuous information overload, the noise, fast moving traffic, the rapid pace of city life and the difficulty to escape from it. It is never completely dark in a city and senses are over-activated. Social conflicts emerge, for example due to increasing income inequality and immigration. Urbanisation has led to the break with traditional social ties towards individualisation. The German sociologist Bahrdt (in Zijderveld 1983) mentioned the transition from a Gemeinschaft build upon traditional social ties (the family, the neighbourhood), to a Gesellschaft where impersonal arrangement and institutions have to be created for maintaining law and order.

Cities are often seen as irresponsibly draining scarce natural resources. The price paid for development is high, for example in terms of environmental pollution and degradation. Girardet (1992, p. 67) cited Lewis Mumford, who wrote: “The more complete the urbanisation, the more definite is the release from natural limitations; the more highly the city seems developed as an independent entity, the more fatal are the consequences for the territory it dominates.”

Urbanisation has drastically changed the relationship between people and nature. People have become supermarket hunter-gatherers, as Girardet called them. They are primarily spending time in sealed, climate-regulated buildings. Encounters with nature are restricted to the *Ficus benjamini* in the hallway and the Grand Canyon screen saver on their computer. The European Environment Agency, in its 1998 ‘State of the European environment’ report, signals a large number of environmental threats in Europe’s cities. Car traffic is further expanding across the continent, primarily due to a steep rise in leisure traffic. In spite of better air quality in EU cities, problems still exist with winter smog, ozone and other pollutants, particularly (also) in Eastern Europe. Noise levels are too high and clean water resources are under pressure. As remarked, urban problems are not confined to the cities themselves. Growing areas of land are needed to provide city populations with all the resources they need and to absorb the emissions and wastes they produce. The urban footprint has long reached Big Foot dimensions.

It is not fair, however, to simply classify the city as a source of evil. Cities have taken a central place in the development of humankind. They have been centres of innovation, of culture - the winds of intellectual advance blow strong (American Behavioral Scientist 1978) - and the arts, economics and politics. The citizens were those who first challenged feudal relations and called for democracy. Even today, this call especially is uttered on city squares, the true theatres of politics. Wenceslaw Square in Prague, Tiananmen Square in Bejing, Plaza del Mayo in Buenos Aires; indeed, as the Dutch cultural-sociologist Zijderveld (1983) has claimed, democracy is in the city’s heart.

Cities are centres of learning, transmitting accumulated knowledge on which future achievements can be built (Girardet 1992). In the bible, in Genesis 11, 3-5, it is written: “Come let us make bricks and bake them hard. Come, let us build ourselves a city and a tower with its top in the heavens, and make a name for ourselves; or we shall be dispersed all over the world.” (see Girardet 1992, p. 39). Cities also play a critical role of acculturating refugees from many countrysides.

The Forested City

This ‘Tale of Two Cities’ may support the notion that, for developing liveable cities, the good sides of the city have to be maintained and enhanced, while negative aspects are minimised. Liveable cities need liveable environments, where pollution levels are not too high and where there are enough opportunities to occasionally escape from hectic city life, from overcrowding. Where there are enough places, particularly in people’s everyday living environments, where they can get in contact with nature, see the change of the seasons, get dirty fingers - and not just from eating junk food.

It is my strong believe, based upon a four-year study of urban forestry in Europe (Konijnendijk 1999), that the forest can be a major partner in this quest for liveable cities. Forests and cities, they seem so different and even contradictory. But history has shown that forests and cities can in fact make a pact, a symbiosis to create very special places. This is not to say that cities and forests have not been at war. When cities developed, forests were often among their first victims, when land was needed for feeding urban mouths. Later, forest land was - and in some cases still is - directly used for urban expansion. Mostly there was not much protest against this development. The relationship between forests and people has been very much two-sided. The Dark and Dangerous Forest has often had the upper hand over the Cathedral and Refuge (e.g. Schama 1995). Even today, forests and woods are often associated with unwanted activities and danger, in the form of murder, sexual abuse, robbery, but also rabies and Lyme's disease. As Simson (1998) mentioned: whenever the English press reports on a murder, they make clear that it happened in, near or on the way to a wood, or perhaps on a place where there once was a woodland.

In spite of the negative feelings woodlands sometimes evoke, history shows that cities and forests can go together very well. What would Paris be, for example, without its Bois de Boulognes or Bois de Vincennes? Or Vienna without its Wienerwald and Berlin without its Grunewald? The benefits of having forests nearby were recognised by city governments centuries ago, who tried as a result to expand their forest ownership. Woodlands could be used by the local population for gathering food and fodder, as well as construction and fuelwood.

Later, forests became appreciated as recreation environments. First of all by the noble and the rich, and then by all social strata. Woodland parks became stages for plays of social order. Different social classes had their own way and time of using the forests, thus reconfirming their place in society (Konijnendijk 1997). When the railroad network reached the Fontainebleau, 60 kilometres from Paris, the forest was turned into a 'promenade parisienne' and mass recreation commenced (Kalaora 1981). The annual Dunlop Fair in the Epping Forest near London attracted crowds of over 100,000 Londoners as early as the mid-1850s (Green 1996).

During the 19th century, another role of forests and green spaces became apparent. Scientists and planners started to promote the image of the 'organic city'. Cities, like plants and animals, were subject to sickness and decay. The Industrial Revolution was regarded as the villain, threatening the life of the city and its inhabitants (Kostof 1991, Ponting 1991). Parks and other green areas were the lungs of the city. Ample green spaces were needed for maintaining a healthy working class. Industrialists and city governments favoured labourers spending their free Sundays in the open air with their family, instead of embarking on bouts of socially harmful behaviour.

Both the recreation and 'sanitary' use of urban green and woodlands became more important over time. Urban dwellers also founded the nature conservation movement and urban woodlands such as Fontainebleau and Zonienwoud near Brussels, Belgium were among the first of such areas (Konijnendijk 1999).

The Urban Woodland under Pressure

Nature conservation, recreation environments nearby, providers of cleaner air and water: urban woodlands were seen as providers of myriad goods and services to urban society. City governments had also started to realise that woodlands could assist with creating attractive cities. Attractive for rich taxpayers and for businesses, that is. Woodlands and parks were bought specifically for this purpose. Some cities wanted to rapidly cash in on the presence of woodlands, and they converted them to areas of upper-class housing.

Threats to urban woodlands, for example from urban development pressure, are still manifold. The intensive recreational use of the limited forest resource is another major concern for ecosystem conservation. Many of Europe's urban woodlands have annual rates of 2,000 visits per hectare per year or more, rising to over 5,000 in Amsterdamse Bos and Bois de Vincennes (Paris) (Konijnendijk 1999), i.e. 1 visitor per 2 m^2 of forest each year.

Threats also occur through air pollution, abuse (a nearby woodland comes in handy when you have to get rid of some rubbish), and the risk of conversion to more financially profitable land use. In more unstable times, and times of war in particular, urban woodlands are an easy victim. In the 16th century, the Dutch Count William of Orange wanted to cut his Haagse Bos, an urban woodland, so that he could pay his soldiers fighting against the Spanish. The people of The Hague went as far as melting the church bells to generate enough silver in compensation, so that the forest was saved (Buis 1985). Town forest successfully competing with religion, perhaps incredible but true. Wars continue to threaten urban forests, even in Europe. The forests around Sarajevo were stripped of fuelwood during the Bosnian War. Before the war, they were popular recreation environments for the local people. As soon as the war was over, young people took to the forests again, in spite of the risk of mines. Some of these people were killed (Pettenella, pers. comm.). A dramatic and deadly close relationship between urbanites and woodlands…

The word 'urban forest', of course, holds intrinsic tension. Urban pressures, be it not typically in the form of a siege, are an everyday reality. As reasoned in my dissertation, a clear need exists for a sustainable urban forest resource, large and healthy enough to meet the manifold current and future demands of Europe's urban populations. This can only be realised by means of a strategic approach, bolstered by a widely supported and enforced framework of concepts, policies, plans, laws and regulations. In this way, existing urban woodland resources can be conserved and managed to optimally fulfil their roles. Moreover, new woodlands can be created to relieve the pressure on existing woodlands and to meet new social demands. There are still many forest-poor cities across Europe, and especially in the Western and Southern countries. For example, Dutch, Belgian, British, Danish and Italian cities seldom make it to the 5 % woodland cover mark. On the other hand, the European municipal forest cover average is pushed to over 15 % by forest-rich cities in Scandinavia, Eastern Europe and parts of Central Europe. It is a big contrast: less than 1 % forests within the municipal area of Amsterdam versus 42 % in Freiburg, Germany (Konijnendijk 1999).

Towards an Urban Forestry Approach

Strategic planning and management of urban woodlands, old and new, can only find sufficient public and political support when woodland benefits are unambiguous. No false expectations should be raised. The Bad City will not become Good just by pouring a sauce of urban woodlands over it. On the other hand, not every Good City is characterised by a high share of urban woodlands. But, as has been discussed here, urban woods do deliver many goods - going for an evening stroll away from the city noise, bringing the rhythms of nature into the city, perhaps improving mental and physical health, and reducing air pollution. Even raising real estate prices, as demonstrated in a doctoral study carried out by Tyrväinen (1999).

It is right to focus on benefits, if done in an honest way by not ignoring the attendant difficulties and problems. Urban woodlands do have negative sides to them, as we have seen. But if the true values become recognised within their proper context, a political case can be made for the need to conserve and manage forests, and for the expansion of urban woodland cover.

As a next step, people are needed who are ready for the tremendous task of uniting city and forest. Luckily we can build on a vast human resource base of planners, designers, managers, researchers, educators, and volunteers. In Europe, we are lucky to have a strong tradition of town forestry, at least in many cities. It would be silly to ignore the existing expertise and to reinvent the wheel. Private financing to support public funds? Generating public support for forest conservation? Many lessons can be learnt, just by studying urban forestry history.

But times have changed, of course. Urban pressures and demands are higher than ever before. Traditional expertise and knowledge are no longer sufficient and innovations are needed. I have argued, for example, that traditional forestry is not ready for the job. We foresters are no experts, in most cases, in communication, conflict management, public participation and education. All of these are crucial skills in urban forestry, and suggest a multi-disciplinary approach to the discipline, such an approach being defined as encompassing "*the art, science and technology of managing trees and forest resources in and around urban community ecosystems for the physiological, sociological, economic and aesthetic benefits trees provide*" (Helms 1998). Thus urban forestry does not only incorporate the planning and management of urban woodlands, but is an integrated approach towards all urban tree resources. Many of the innovations in forestry, such as multipurpose management, public participation, and forest certification have been built on experiences from 'tests' in woodlands closest to urban centres. German founding fathers of forestry science such as Pfeil and Hartig had urban forests as their experimental areas. Tree species from abroad were often first introduced to urban forests and woodlands parks. Today, forestry faculties and departments often use the forests in or near the cities where they are based as testing grounds, for research as well as education (Konijnendijk 1999).

Who should take the lead in future urban woodland planning and management? Who should ideally own and manage the forests? Most important, as history has shown, are committed and knowledgeable owners and managers, with public support and sufficient power and means. This often can be a city. Over 2/3 of all woodlands within municipal boundaries are in fact owned by cities (Konijnendijk 1999). But in other cases the best owners may be private owners. Urban forestry may be 'social forestry' in optima forma, but private urban woodland ownership is not a dirty phrase. Thanks to private owners and their efforts, be it based upon egocentric motives, some urban woodland jewels have survived the ages.

Whoever own**s**, plan**s** for or manage**s** urban woodlands, their actions have to be based upon a sound knowledge base. Urban forest managers across Europe complain about the lack of research specifically dealing with woodlands in urban areas. It has become recognised, for example within the European research network COST Action E12 'Urban Forests and Trees' and the IUFRO-supported European Forum on Urban Forestry, that traditional, sectoral research is not enough in high-pressure, urban environments (e.g. Krott and Nilsson 1998, Forrest al. 1999). Urban forestry research has to draw upon and integrate perspectives and methods from various disciplines, including forestry, horticulture, planning sciences, landscape ecology and the social sciences. This is promoted within the urban forestry approach. Apart from looking beyond disciplinary boundaries, other walls have to be brought down, for example between different types of green areas. Urban woodlands, parks and street trees have often been dealt with separately. Urban forestry, on the other hand, looks at the green structure as a whole. It also favours a close link between green and overall town planning. More recently, an integrated approach to the urban-rural interface has become favoured as well. Most city walls have long gone, and the traditional differentiation between city and countryside is outdated. The city is everywhere. Perhaps it is about time that the countryside, particularly in the form of forests, was everywhere as well.

Urban forest, the forest at people's doorstep. Woods can be a mighty means for keeping urbanites in touch with natural values, processes and realities. When school children in Berlin start to think that cows are purple (thanks to a popular milk chocolate commercial), nature is far away. The forest is needed as a school. Not only for children, but increasingly also for their parents. It should become a logical, integral part of the city, just like the theatre, the railway station, or the local football club. Like the last, forests may help cities that are loosing their distinct identities. The forest should be seen as a social stage, as nature nearby, as green lung, as attractive environment for economic and other activities.

In spite of his rather negative look upon today's cities, Girardet (1992, p. 181) concludes by acknowledging the immense potential of the Good City: "Cities should be places where we can all feel as some of our ancestors did: that we are making cities to be proud of and where future generations will be proud of to take our place." Well-planned, managed and protected woodlands can significantly contribute to recreating these Good Cities. By identifying the specific, often European-wide characteristics, challenges and opportunities of urban forestry, and by calling for a structured and integrated approach to urban woodlands, research may contribute to the further establishment of urban forestry as a multidisciplinary field. Moreover, by operating on the cutting edge of the urbanisation of forests and forestry, it can act as a testing ground for forestry and other disciplines for better meeting the changing demands of society.

Abstract

The underlying concept of urban social forestry (USF) is active public participation in urban forest resources management. Community participation can enhance the quality of community life through a strong partnership among government officials, non-governmental/voluntary organizations, foresters and local people. Public involvement is strongly encouraged, with community members viewed as the most reliable motivation force for implementing USF programme. As a developing concept of public participation in urban ecosystem management, this program needs exploration of its principles, setting, development of strategy, and application. Sensitization of the community people toward tree resources is important and their attitude toward the USF programme can be measured. Public agencies, neighborhood groups, academic institutions, business establishments, PVOs/NGOs are brought to make a coalition of an effective organization for USF implementation. The strategy of developing an USF programme includes organizing community assembly/group meetings to determine local priorities, identifying viable options to address its prospects and aspiration, developing action plans and schedules, and mobilizing members, non-members and local resources. People feel encouraged with the empowerment of working side by side with government/municipal agency. Community understanding and realization about the importance of tree resources in urban area and their active participation in tree resources management can strengthen and materialize USF programme.

Keywords: Urban social forestry, Community participation, Neighborhood groups, Sensitization, Resource mobilization

Introduction

Urban afforestation as a means of environmental and aesthetic improvement has been a long practice by the foresters/arboriculturists in the city administration. Despite a growing awareness of the importance of trees in the physical welfare of urban communities, limited consideration has been given to their social and psychological functions (Johnston 1985). Involving community in urban forest development and management is a new concept in modern day practice. Social forestry is of recent interest in ecosystem management and urban forest management. It can perform multiple objectives of natural resources management and extension. Public education and awareness creation about nature and natural resources, sense of stewardship or ownership development among the citizens, and above all, satisfaction to transfer a habitable environment to next generation are some of the prime outcomes of community participation in urban forest management. Study by Sommer et al. (1994) revealed that city residents who planted their front/backyards by them or paid for planting were more satisfied with the outcomes than residents whose land were planted by city/outside agency or without an extra charge. Street planting sessions brought the neighbors close and made better acquainted (Sommer et al. 1994), and enhanced neighborhood solidarity. But, in reality, the tenants' awareness and appreciation of trees remains limited and any feelings of identification and responsibility for their publicly-owned trees are actually discouraged (Johnston 1985). Urban forestry can enhance community stability, pride and spirit, stimulate community stewardship for urban vegetation, natural resource understanding and conservation ethic (Deneke 1983).

The prospects and importance of community participation in environmental conservation and pollution control are recognized and advocated by the world leader foresters and academicians. In USA, Policy and legislative support for community participation was promulgated explicitly in 1990 Farm Bill that extended the authority of the Forest Service to work with states in developing and implementing urban and community forestry programme. National funding for urban forestry has increased each year since 1991, reflecting a commitment towards the improvement of the quality of community life, based on a strong partnership between federal, state and local government, volunteer organizations, urban foresters and local people (Schoeneman and Ries 1994, cited in Ryan 1997). Public involvement is strongly encouraged, with community members viewed as the most reliable motivation force for implementing successful urban forestry programme (Schoeneman and Doyle 1992, cited in Ryan 1997). Public participation in natural resources management can be a means of reducing social conflicts in urban area and strengthening neighborhood solidarity. Social forestry provides a conceptual and practical framework for urban forest resources management through people’s participation. During last two decades social/community forestry has been recognized as a strategy for forest development and conservation with people’s economic upliftment. In SF, people’s participation is a prerequisite for fulfilling people’s needs and aspiration. Similarly, urban social forestry (USF) means to involve urban resident actively in urban forest resources management beginning from community consultation an needs assessment to project design and implementation. USF can bring the urban residents onto one platform for social movement of tree plantation in urban area.

This document is about a proposal/concept paper how to initiate, sensitize, organize and actively involve urban community people into a body of strong support and action for development and management of USF programme. This article will also deal with the development of a model of USF that includes formulation of policy and legislation; strategy for community involvement; principles and guidelines of urban forests management through peoples’ participation; care and share, partnership, incentives and rewards; role of neighborhood groups, academic institutions, business establishment, private voluntary organizations (PVOs)/non-governmental organizations (NGOs); implementation and maintenance; participatory research and extension; and strategy to overall programme development and management. The strength of this proposition is that the concepts of ecosystem management and urban community forest management have attracted the foresters, arboriculturists, and legislators and administrators in various agencies of forestry resources management and private forestry enterprises/industries, and general people alike.

An Overview and Needs of Community Involvement in Urban Forest Development and Management

Due to rapid urbanization in world cities, the developer and owners have been destroying tree resources for construction of roads, houses, shopping malls, and institutions buildings. The residents of a modern city have become mechanical, and are unaware about urban tree resources development and conservation. The landlord, tenants, and the pedestrians are also kind of insensitive toward urban trees. For the development and management of urban forests, it is imperative to develop a concerted efforts of all the stakeholders and users of urban trees and green spaces.

Traditional practice of urban tree resources management is lying with the city arboriculture department equipped with limited manpower and fund. Their job is planting, protection and care, tending operation, and removal of diseased and uprooted trees. It is a common practice of many city administrations in developing countries that they plant trees and do not much care about survival and growth of the trees. The trees are destroyed or damaged by the pedestrians with no reasons, or the young seedlings may be stolen, or the gavions may be broken. Another important urban stress factor is vandalism. Vandalism is predominantly a social problem. Successful community landscaping and gardening in densely populated inner-city neighborhoods have shown that one deterrent to vandalism is to the development of a spirit of proprietorship in residents (Flint 1985, cited in Nilsson and Randrup 1997). Percentage of highest tree mortality is strongly correlated with unemployment and lower social status (Nowak et al. 1990). Social conflicts on urban forests (Konijnendijk 1997) strongly suggest involvement of local people in policy-making, planning and management of a successful urban forest (Nilsson and Randrup 1997). Dusan Mlinsek, the past president of IUFRO, stresses the need for a holistic approach in forestry, but also recognizes that the social aspects of forestry need particular attention if a holistic approach is to be achieved (cited in Marcin 1995). Management of the urban forest is the responsibility of public and private owners (Grey and Deneke 1978). Its success clearly lies with various departments of city administration and urban residents. Urban forest management decision should be based on a new ethic that responds to the desires of people, their involvement and politics.

In USA, community involvement in urban forest resources management were initiated in the city of Baltimore (MD), Philadelphia (Pennsylvania), Navajo Indians community (Arizona), New haven (CT), Raleigh (NC), Cincinnati (Ohio), and other cities in several states, and observed preliminary success. Community participation is gaining rapid momentum in city arboriculture, forest management, park service, and outdoor recreation and similar departments. Federal and state forest services and environmental agencies are involving citizens' concern in ecosystem management for better community benefits and environmental awareness creation. In recent years almost every state has developed a separate management unit under state forest service named Community forestry unit with an objective of involving community people in forest management.

Principles and Practice of Social Forestry: Fitting it into Urban Social Forestry Programme

Social forestry is a collaborative forestry development programme of the government and citizenry aims at alleviating rural economic distress and mobilizing the energies and efforts of the people to make them self-reliant. The aims and targets of social forestry are economic uplift, environmental protection and awareness creation toward environment. Social forestry aims to get people involve in forestry activities for their common and individual welfare (Ahmed 1999). It has viewed as social sciences tool with integration of forestry techniques in understanding and resolving the problems of human ecosystem. Social forestry projects are meant to bring social change, to ameliorate distortion in the economy and to ensure equitable distribution of income and decision making power of the community people through their active participation. Explicitly or implicitly social forestry programmes are oriented toward cultural changes in the behavior of large number of people toward tree planting and protection (Cernea 1991; Burch 1988). It concentrates on harmonizing the relations among tree, forest, and human society, and on building a dynamic balance among nature, economy, society and politics (Weichang and Pikun 1998).

People's participation in SF means that the target beneficiaries take part in all stages of the project development process; i.e., they participate actively in action research connected to the project, in decision making, planning, in the process of implementation, in sharing benefits of the project, and in monitoring and evaluation. Similarly, people's involvement in USF management can be a social movement for tree planting and conservation in urban areas. Enjoyment of participation and empowerment of urban community people can bring success in USF development. As social forestry is new and developing concept of modern forestry practice, it's applicability in various situation should be examined. It thrusts on motivating active participation, self-decision and empowering people into forestry activities. Social forestry practice can effectively be adopted in urban forest resources management.

Development of Urban Social Forestry Programme

Principles of Urban Social Forestry

Urban forestry is defined as a specialized branch of forestry that has as its objectives the cultivation and management of trees for their present and potential contribution to the physiological, sociological and economic well being of urban society (SAF 1974). Urban forestry embraces a multi-managerial system that includes municipal watersheds, wildlife habitats, outdoor recreation opportunities, landscape design, recycling of municipal wastes, tree care in general and the production of wood fiber as a raw material (Kuchelmeister and Braatz 1993). Urban forestry is a merging of arboriculture, ornamental horticulture and forest management. It is closely related to landscape architecture and park management and must be done in concert with professionals in these fields as well as with city planners.

The "green space" an/or "open space" concepts of city management for environment and quality of life for the city dwellers is very important. Urban forest is the "city's Lung" because of their role in oxygen balance, and removing carbon dioxide. The urban people living in dead environment of steel and bricks always try to come closer to the nature by visiting parks or green space to close to their home. Trees have long been used to beautify and ameliorate the urban environment but in view of the prediction that half of the planet's population are expected to be living in urban areas by the year 2000, the need for urban forests development is increasingly perceived. The primary function of urban parks and green areas is to ensure satisfactory surroundings for recreational and social activities (Nilsson and Randurp 1997). It is universally recognized that the invaluable role urban forests play are dispersing the wind, intercepting glare and noise, filtering air pollutants, and aerating soil and conserving energy. It has invaluable contribution of providing aesthetic outdoor recreation, psychic appeal, and cool resting-place and wildlife habitat and municipal watersheds. It is also noteworthy that it provides firewood, lumber, and chips from tending operations.

Throughout the history, the urban forests were developed and managed exclusively on the basis of its aesthetic and spiritual than on utilitarian benefits. Only recently has their full value to urban dwellers been considered. Now a closer look is given to the environmental services and economic benefits they provide. Urban forestry is a tool, which consider the role of trees in and around densely populated areas as well as the opportunities and challenges related to their planting, conservation and use.

Integration of various aspects of social science tools and methods in urban forest management practice for sustainable development of the community and the forests is imperative. Policy analysis in community participation in urban forest management and environmental education, and strategy for participatory development is important. The concept of USF lies with the integration of community people in urban forest management and development. The underlying concept of urban social forestry is public participation and decision making in urban forest resources management. As a developing concept of public participation in urban forestry management, this programme needs further exploration of its concepts and principles, application, and setting and development of strategy. According to United Nation's Economic and Social Council (ECOSOC), participation requires "the voluntary and democratic involvement of people in (I) contribution to development effort, (ii) sharing equitably in the benefits derived therefrom, and (iii) decision-making with respect to setting goals, formulation of policies, and planning and implementing economic and social development programmes (cited in Banerjee 1992). Promotion of USF needs much stimulation and encouragement among the public. It needs community resources mobilization and organization into a successful USF programme.

Goals and Objectives of the Urban Social Forestry Programme

Since an increasing part of the population lives in urban areas and receives its daily perception of nature therein, nature in urban areas is important to the environmental awareness and an understanding of nature (Nilsson and

Randrup 1997). People's awareness in environmental pollution control is important and it can be addressed through extension of education to general mass of a country about environmental ingredients that keep ecological balance and harmony in local climate as well as global climate system. Many cities in the world are facing environmental disastrous situation and is getting worse if it is allowed to grow unchecked. Modern cities need strategic planning to combat environmental pollution. It is very important to think about citizens' concern and involve them in combating environmental disasters in many cities in the world.

There should be manifolds objectives on social, cultural, economic and environmental considerations. Significant efforts should be undertaken to increase public awareness of benefits, opportunities, and problems associated with urban forests. Encourage maintaining and protection of tree resources, sensitize community identification of their own issues and problems, and design and implement management plan. The objectives of this programme are to provide training, education and communication about new knowledge of urban forest management, and to establish a coalition of individual and organization of community people. Education of employees and the public about the needs and benefits of urban trees, and about knowledge of urban forest management are some of the precondition of successful USF. Empowering community people with the feelings of proprietorship on public resources and contribution in tree resources management should be recognized.

Policy Formulation for Urban Social Forestry Development

Public awareness and citizens' concern about environmental/natural resources conservation and development plays a significant role in national environmental policy decision. The policy decisions always affect certain groups or individuals in the community either positively or negatively. Hence, it is imperative to seek citizens' views and opinions on any major decision that affect public life. A firm political commitment by the government to USF development and continuing involvement of the various services concerned is essential if any major break-through is to be achieved. Unwanted interruption in project activities by local group of touts and other vested interest groups creates serious problems in project management. Concerted efforts of owners, tenants, local institutions, and NGOs/PVOs should be formulated and adopted. Some of the important policies may be as follows:

- People should be actively involved in USF management.
- Land owners, tenants should maintain their land and premises.
- Acts and legislation of development, protection an management should be clearly spelled out.
- Incentives, skill development training, compensation, and awards should be provided.
- All available public/communal and private land should be brought under this programme.

Strategy for Sensitization, Mobilization and Community Organization

The most difficult task of any community forestry programme is to generate sufficient interest to motivate people to take the first crucial steps in realizing the benefits for themselves (Johnston 1985). Sensitization of the community people toward tree resources is important and their attitude toward the USF programme should be measured. Sensitization is a process of educating people by feeding them with adequate information and knowledge. Its effect lies in the fact that after sensitization, a person can take decisions based on realistic, dependable and complete information. Through sensitization process the acceptance of the programme by the community people, their reluctance or skepticism, indifference, and the programme initiator can realize objection about the programme. Community resource mobilization can only be possible through community organizations which the people themselves set-up and manage. Inadequate attention to dealing with social diversity, especially highly stratified social structure reduces formation of strong organization. The heterogeneity and linkage with external societies matter in community group formation. In many cases, peoples' perception and priorities of tree planting and management were ignored and community need assessment was not done before the project initiation. Motivation and extension efforts by the forestry department were minimum which bring failure in many SF projects. Role of extension, research and education linkages in maximizing social forestry project benefits are also issues counted for success. Communities' conceptions of their needs should be considered as high priority. Group process, cooperatives, group discussion, collective action, joint monitoring and evaluation are strategies for community mobilization and organization. Citizen-volunteer groups, capacity building programmes, and community level planning and action should be undertaken. Initiating sensitization activity, contact with community individuals, leaders, formal and informal groups, holding meetings with various groups, select target community are important for designing a USF programme. Programmes compatible with local needs as well as assured and immediate economic benefits can help mobilize people to participate (Swarup and Chand 1987).

Development of Partnerships

Exclusive management by "single entities" whether government, private, NGO or local community, has fairly frequently been inadequate, except in some limited cases (Anderson et al. 1999). Ecosocial linkages between the forest and the society are important as the forest stands at the middle of the society. Urban Forest management should consider public interest in decision making about USF development and utilization. Public institutions/organizations, neighborhood groups, academic institutions, business establishments, PVOs/NGOs are brought to make a coalition into formation of an effective organization for USF implementation and management.

Ensuring People's Participation

Recognition of a partnership between development programme and people must be ensured through people's participation. Public participation provides a forum whereby the scientific information and values of the publics and the agency can be integrated so that the final decision is viewed as both desirable and feasible by the broadest portion of the society (Daniels and Walker 1999). Community participation depends on social arrangements, political and power relation, on economic and non-economic benefits. Experience indicates that immediate and significant benefits to participant influenced active and meaningful participation of community people. What is stimulation of interest for participation? Specific actions? Recognition/appreciation of peoples' contributions, incentives, awards, empowerment can ensure peoples' active participation in USF programme.

The participation process should aim at mobilizing latent local resources effectively. It must aim at avoiding any kind of unilateral decisions by sponsoring agency, its staff members, and management and/or by it's technical experts – who usually neglect consultation with community people. It organizes community assembly/group meetings to determine local priorities, identify viable options to address its problems and prospects, develop an action plan and schedule, and mobilize members, non-members and local resources.

Training and Education Programme for the Community People

Training deals with development of knowledge, skills, techniques, motivation, attitudes and experience which enables an individual to contribute most effectively to the concerted effort of the team or group to which he belongs (Roy and Chatterjee 1994). Implementing agency should intensify information and education to create awareness and disseminate of knowledge about urban forestry. The research institutes, training academies, and universities should organize training programmes/workshops for the general people, extension workers, managerial staff, and policy makers. Training on group sensitization techniques, participatory rural appraisal (PRA), skill/technology development, etc. should be organized. The people should know working as a team, and develop organizational abilities.

Community Level Planning and Action

Initiating, selecting, planning, implementing, monitoring and evaluation of USF, urban community should share same interests and aspirations. Community people and neighborhood groups should be well informed and consulted before designing and implementation of USF programme. Representatives from local bodies, social associations, professional groups should be welcome in decision meeting. Community participants should prioritize the agenda to accomplish during the project period.

Care and Share, Incentives and Rewards

The partner organizations/groups will participate in selection of new planting area, landscape designing, tree species selection, planting and after care and maintenance with the professional assistance from the city arboricultue/forestry department. Their active involvement will uplift awareness about urban environmental conservation among the urban community people. Acting together strengthens community's ability to gather, organize and evaluate any programme with sharing ideas of work together and test the reality for future plans. People feel encouraged with the empowerment of working side by side with government/municipal agency.

Introducing various incentives and rewards should encourage people's initiative, enthusiasm, and active participation. Several incentives like cash/kind subsidy, presentation of gifts/souvenirs, T-shirt with blocks with words of appreciation, prizes or awards on various occasions. Tree planting or tree care competitions can be organized and certificates can be distributed among the winners.

Implementation and Maintenance

Trees that naturally grow in a region are kept intact, and trees of such species are often planted because of their natural suitability to the local environment and soil conditions. Responsibilities of tree planting schedule, site selection, landscape designing, species selection should be done by the specialized groups. Mass tree planting, protection should be handed over to the community people. Specialized works like pruning, pollarding and treatment of diseases should be done by the specialists. Various working groups should be organized for specified tasks.

Sustainability of the Urban Social Forestry Programme

Sustainability should mean that local community should not degrade its natural resources base at least in irretrievably, but rather maintains or even improves it. Sustainability means increasing the potential of community members to influence and control their future on a long-term basis, a goal that can be achieved by strengthening capacity, supporting equity and fostering empowerment. A project is socially sustainable if it is sufficiently adapted to local conditions that people can see the advances of making changes and modifying their practices to attain new benefits. In many social forestry projects benefits were not sustained once the external assistance ended. The city administration should monitor the programme on a continuous basis and inform the community groups in regular meetings. There should be interaction among the community, implementing agency, environmental advocacy groups and concern citizens on continuous basis.

Conclusion

Urban social forestry aims at the welfare that includes social, psychological, economic and ecological aspects of the city residents and the surrounding environment. It is the contention of this article that USF activities can establish bondage between human community and tree resources in a city for ecosocial development. The proposition of this article is that of a concerted effort of the citizenry including government agencies, resident people and voluntary groups/organizations for the promotion and management of urban forests. Community understanding and realization about the importance of tree resources in urban area and their active participation in tree resources management can invigorate and materialize USF programme.

Abstract

This paper presents empirical estimates of the many non-market economic values forests provide to people in United States and Australia. These values include a wide range of recreation values and passive use or existence values of forest protection from logging, insect damage and fire. The paper provides estimates of the absolute and relative magnitude of the recreation and existence values for old growth forest and wilderness protection in the United States and Australia. These studies demonstrate that passive use values such as existence and bequest are normally larger than recreation benefits.

Keywords: Recreation, Existence, Forest protection, Endangered species, Fire

Types of Benefits Provided by Forests

Direct Use and On-site Values

It is well known that forests provide marketed commodities such as lumber, and paper as well as on-site or forest-based recreation in the form of camping and hiking. Forests also provide habitat for game animals and sport fish, which are often enjoyed on-site as well.

Downstream Benefits

Forests are also watersheds that provide downstream benefits to instream and offstream water users. For example, the forest cover provides for more even releases of high quality water. This high quality water increases downstream enjoyment of water based recreation as well as reducing water treatment costs of downstream cities. Thus in evaluating the benefits of maintaining forest cover it is relatively well established that downstream physical effects must be accounted for (Loomis 1993).

Off-site Public Good Benefits: Existence or Passive Use Values

Additional downstream effects on society include the values to the non-visiting general public just to know particular forest ecosystems and their rare wildlife species exist and are protected. This benefit is called existence value and as the empirical examples below indicate it is likely to be one of the more dominant benefits of maintaining forest ecosystems. The second downstream benefit is the value the current generation obtains from knowing that protection today will provide forests to future generations. These benefits may arise primarily from the virgin forests themselves or from the structure of habitat these forests provide to unique species found nowhere else.

Existence and bequest values are sometimes referred to as non-use values, although this somewhat misleading term has been replaced by the term passive use values. I prefer the term off-site preservation values, but either passive use or off-site preservation values captures the public good notion of these values. That is, existence or passive use values of a specific forest ecosystem has all of the required characteristics of a pure public good: (1) such benefits are non-rival in that any number of people can simultaneously enjoy the satisfaction from knowing a particular forest exists; (2) non-excludable in the sense that no one can be prevented from enjoying the knowledge that a particular forest ecosystem is preserved, say as a Wilderness or National Park.

Commensurate Valuation of Market and Non-market Values of Forest Resources

Price is a readily acknowledged measure of the value in exchange for one more unit of the good. However, price is just one point on the demand curve for a good. The value in use for the first few units consumed, can be read from the demand curve, and often exceeds the market price. This difference between the maximum amount that consumers would pay for each unit and what the price they actually pay for all the units they consume, is their consumer surplus or willingness to pay in excess of price. This is a personal profit, analogous to what firms earn in excess of their costs. Market goods such as lumber which are traded in national and international markets, tend to have a relatively uniform price or value in exchange. Non-market goods do not have explicit prices, but may have implicit prices due to travel cost to the recreation site. The spatial market for recreation results in visitors living at different distances from the forest facing different travel costs or "implicit prices" for forest recreation. This presents the opportunity to estimate the entire demand curve and to directly calculate the consumer surplus of forest recreation. The consumer surplus represents the maximum amount visitors would pay for recreating at this site compared to the next best alternative. This consumer surplus can be compared to the businesses net income or producer surplus from logging the forest.

Measurement of Recreation Value

The most common approach to estimate the demand for forest recreation is the Travel Cost Method (TCM). This method uses travel costs as a measure of price and number of trips as a measure of quantity to statistically trace out a demand curve. From the demand curve, the consumer surplus or net WTP can be calculated. By pooling data across different forest recreation areas with different forest characteristics, the net WTP for those different forest characteristics can be estimated. Examples will be provided below.

The other main approach for estimating the economic value of forest recreation is the Contingent Valuation Method (CVM). This method uses a survey of visitors with regard to their maximum willingness to pay for recreating in the forest. CVM involves: (1) conducting a survey (either mail, telephone or in-person) of visitors; (2) describing the forest recreation resource the respondent is asked to value and if desired, the increase in quality of the recreation resource that would be provided if the respondent agrees to pay; (3) the means by which the visitor would pay, i.e., in higher entrance fee, travel costs, etc.; (4) whether the individual is asked to reveal their WTP by stating the maximum they would pay in response to an open-ended question, selecting a dollar value from a range of values (e.g., payment card) or responding yes or no to one particular dollar amount the respondent is given (e.g., dichotomous choice). Mitchell and Carson (1989) provide a complete discussion of the issues associated with 1-4 and numerous other issues in design and implementation of CVM.

Measurement of Passive Use Values Using Stated Preference Methods

At present the Contingent Valuation Method (CVM) and conjoint analysis are the only methods generally recognized as being able to capture the general public's total willingness to pay (WTP) for forest preservation. I emphasize total to indicate that often CVM surveys ask the public one valuation question requesting their WTP to protect the forest for all reasons including recreation use, the option for future use, existence and bequest values. The sum of these components is called Total Economic Value. In studies described below, some authors have used a follow-up series of questions to have the respondent prorate their total value into separate recreation, option, existence and bequest components. CVM and conjoint when applied to estimate either total economic value (TEV) or simply passive use values is similar to recreation with a few exceptions. First, the general public rather than visitors are usually surveyed. Second, the way the household would pay is broader such as higher taxes, product prices, utility bill, etc.

The central criticism of CVM and conjoint when applied to measuring non-use values is whether individuals would actually pay the dollar amount they state in the survey. This validity issue is difficult to test in the case of passive use values since there is, by definition of it being a public good, no market analog that responses can be compared to. Field experiments to directly test the validity of CVM estimates by performing cash comparisons have provided valuable insights (Champ et al. 1997) but are imperfect tests due to free riding and difficulty in excluding non-payers. In absence of perfect validity tests numerous researchers have turned to tests of reliability, a necessary condition for validity. Loomis (1989) has demonstrated the reliability of CVM when measuring total economic value.

Inclusion of passive use values in U.S. federal government analyses is becoming more frequent. In 1986 when the U.S. Department of Interior proposed its first procedures for valuing natural resource damages, it included passive use values (Department of Interior 1986). While the Department of Interior originally took a rather narrow view of when these values could be incorporated, the U.S. District Court of Appeals directed Interior to broaden its inclusion of passive use values to include all natural resources, even those with on-site use. That is, recreation use and passive use often be complementary, not mutually exclusive.

The U.S. National Oceanic and Atmospheric Administration (NOAA) to appoint a "blue ribbon panel" to hear the evidence whether a survey method called contingent valuation method could be used to reliably estimate passive use values. The panel was co-chaired by two Nobel laureate economists and included an environmental policy economist and a survey research specialist. The panel concluded that when carefully performed following guidelines they suggested, that contingent valuation was capable of reliably estimating passive use values (Arrow et al. 1993). Thus while neither the theory or measurement of passive use values is without controversy, the principle of including existence values in natural resource assessments is accepted by most mainstream economists.

Empirical Examples of Values of Forest Protection

Recreation

Table 1 presents the values of fishing, hunting, firewood gathering and Christmas tree cutting calculated from TCM and CVM studies in the literature. Big game hunting is one of the higher forest recreation values in Table 1. This table also presents the value of direct forest recreation such as hiking, camping and wilderness recreation. As can be seen, forests provide high values of forest based recreation. While these values per day seem modest, when multiplied by even conservative estimates of visitor use, the magnitudes are quite large. For example, at $39 per day, the economic value of recreation in officially designated Wilderness is $574 million per year. In 1996 there was about 153.78 million big game hunter days, which given the value per day of $38.63 per day yields nearly $6 billion in annual big game hunting benefits, most of which is likely attributable to forests.

Passive Use Values

The existing empirical estimates can be grouped into three categories. First are the estimates of the existence values of wilderness preservation. This represents both the earliest attempts to measure these passive use values of forests as well as an area of continuing application. The second main area represents valuation of old growth forests and dependent wildlife. Finally, the existence values of maintaining forest quality defined as healthy, living trees. We will summarize the results of the studies in each category.

Wilderness Passive Use Values

The U.S. Wilderness Act of 1964 emphasizes many societal benefits to wilderness preservation that go well beyond simply recreational use. Walsh, Loomis and Gillman (1984) represent the first attempt to apply CVM to measure the option, existence, bequest as well as recreation value of Wilderness. They conducted a mail survey of Colorado residents in 1980. In the survey booklet they asked households their annual WTP into a fund for continued preservation of the current (at the time of the study) .48 million ha of Wilderness in Colorado, and then WTP for 2 million ha and finally designating all roadless areas in Colorado (4 million ha) as Wilderness. Following these questions they asked what percent was for recreation use this year, maintaining the option to visit in the future, knowing that wilderness areas exist as a natural habitat for plants, fish and wildlife, and finally, knowing that future generations would have Wilderness Areas. The results are summarized in Table 2.

Table 1. Economic Value per Day of Forest Recreation in the U.S.

Activity	No. of Studies	Dollars per Day (in 1996 dollars)
Camping	36	$35.31
Picnicking	10	$36.92
Sightseeing	55	$25.06
Off-road driving	3	$21.78
Float boating	14	$31.26
Hiking/Backpacking	20	$26.84
Downhill Skiing	4	$21.25
Cross Country Skiing	12	$26.81
Snowmobiling	2	$69.97
Big game hunting	162	$38.63
Small game hunting	18	$26.43
Fishing	109	$32.83
Wildlife Viewing	109	$31.14
Wilderness recreation	20	$39.61
Christmas Tree Harvesting	1	$15.88
Firewood Cutting	1	$27.07

Two other findings are worth pointing out. First, WTP per household and in the aggregate increases with the number of acres protected, but at a decreasing rate as expected from diminishing marginal rate of substitution. Second, option, existence and bequest values represent about half the total economic value of Wilderness. Walsh, et al., also concluded that WTP exceeded the opportunity costs of designating 3.5 of the 4 million ha as Wilderness. The present value per ha of Wilderness ranged from a high of $3,077 per ha for .48 million ha to $543 per ha when 2-4 million ha was preserved.

The second study of the benefits of wilderness preservation was performed by Pope and Jones (1990) in Utah. They conducted telephone interviews of Utah households regarding designation of alternative quantities of land as Wilderness.

The only eastern U.S. wilderness preservation study was conducted by Gilbert, Glass and More (1992) to value the Lye Brook Wilderness area and other Wilderness Areas in the New England region of the U.S. One version of the questionnaire asked respondents to value continued protection and management of the Lye Brook Wilderness area; the other to value protection of all Wilderness areas east of the Mississippi River. The two separate samples composed of those individuals who had visited an eastern Wilderness area were apparently able to use this familiarity to distinguish between valuation of one area and all eastern Wilderness Areas. Table 2 also shows the breakdown of total value for all eastern Wilderness into the components, and yields a pattern similar to that of Walsh et al. i.e., a majority of the value of Wilderness being related to option, existence, bequest and the authors' new category, related to altruism, protecting it for use by others.

Table 2. Percentage Distribution of Total Economic Value per Household of Wilderness and Forest Protection

	Own Recreation	Option Value	Existence Value	Bequest Value	Altruistic Value
Colorado Wilderness (Walsh et al., 1984)	43%	16%	20%	21%	not asked
All Eastern Wilderness (Gilbert et al. 1992)	16%	17%	21%	29%	17%
S.E. Australia (Lockwood et al. 1994)	11%	19%	37%	33%	not asked
Total Economic Values of Protecting Forest Quality					
Colorado Forests (Walsh et al. 1990)	28%	21%	21%	30%	not asked
So. Appalachians (Haefele et al. 1992)	14%	not asked	30%	56%	not asked

As contingent valuation has spread internationally it has been used to estimate the value of placing public forest lands off limits to logging in national parks. One such study was performed by Lockwood, Loomis and DeLacy (1993) for preservation of wet and dry eucalyptus forests on the Errinundra Plateau in Victoria and New South Wales, Australia. A mail survey of households in the two states was sent out asking households their WTP to preserve roughly 100,000 hectares of old growth forests. Dichotomous choice CVM was used and the median WTP was $52 per household. As shown in Table 2, the distribution of total economic value is dominated by existence and bequest values, again illustrating the importance of including these values in economic analyses of forest allocation decisions.

A companion study by the same authors (Lockwood et al. 1994) addressed whether there was a significant passive use value for logging of these forests. The median WTP was zero, although 19% did indicate a positive WTP for logging. When asked to state the reasons, 70% was related to the economic activity generated or timber jobs. Since protection of old growth forests in the Errinundra Plateau will result in increased harvesting of timber elsewhere in Australia to meet demand, overall economic activity will likely not change and logging jobs will increase elsewhere in Australia by the amount they fall in the Errinundra Plateau. This is consistent with the conventional treatment of the level of economic activity (which is primarily determined by macroeconomic policies and trends) and treatment of regional economic activity in benefit-cost analysis (Loomis 1993). Only 30% of the WTP of those 19% offering a positive WTP was related to the benefits derived from knowing the forests are logged. This amounts to $6 per year, for the 19% that would pay. If this is replicated in other studies, this concern about a non-market WTP for development can safely be ignored as empirically small effect of a minority of respondents.

Passive Use Values of Protecting Forest Quality

Forests outside of wilderness areas have many characteristics that are of value to the general public. Having healthy, green, living trees is preferred to dying trees, whether they are dying from acid rain or insects. Up to some limit, having more trees per acre is preferred to fewer trees. The health of trees is one influence on the long run number of trees per acre. There have been several studies of the recreation benefits arising from avoiding dead and dying trees from beetle kill as well as how recreation benefits change with the number of trees per acre (Walsh et al. 1989). The next three studies measure the passive use values from keeping forests healthy. Walsh et al. (1990) used color photos of forest scenes in Colorado with varying number of trees per acre over 6 inches dbh. The photos supplemented verbal descriptions of the pine beetle and spruce budworm infestations that were the cause of the differences in number of trees per acre. In person interviews were conducted with Northern Colorado residents. Respondents' total economic value was elicited and then they were asked to prorate this value to recreation use, option, existence and bequest values. Table 2 presents the results in the range of 320-420 trees per ha. Once again, option, existence and bequest values make up a bulk of the total economic value.

Haefele, Kramer and Holmes (1992) used a mail survey of North Carolina residents regarding their WTP to reduce losses of red and frasier fir trees from insects and air pollution. Residents were shown photos and provided pie charts of alternative forest conditions. They were then asked annual WTP to provide protection for all spruce fir forests in the Southern Appalachian mountains. In addition, Haefele et al. asked respondents to partition their bids into recreation, existence and bequest values. As shown in Table 2 well over 80% of the total benefits are related to existence and bequest values.

Conjoint analysis is a marketing research technique that allows direct valuation of product or resource characteristics. Haefele (1999) used conjoint to estimate the economic value of reducing affected forest characteristics such as acres infested with insects (e.g., gypsy moth, spruce budworm). Haefele found that people would pay about $1.20 per ha per year to reduce infestations by forest insects such as gypsy moth and spruce budworm.

Benefits of Preserving Old Growth Forests and Dependent Wildlife

Recently several papers have presented the total economic value of preserving old growth forests as habitat for endangered species such as the threatened northern spotted owl (Hagen et al. 1992, Loomis and Gonzalez-Caban 1994). The northern spotted owl was chosen as a species that would serve as an indicator for old growth forests by the USDA Forest Service. In some sense, WTP for northern spotted owls is viewed by the public as WTP for preservation of old growth forests as well. Hagen, et al. (1992) used a mail survey of a random sample of U.S. households. The authors presented a map showing the approximately 2.83 million acre Habitat Conservation Areas recommended by the scientific committee. Adoption of these old growth protected areas was suggested as a means of preventing the extinction of the northern spotted owl. The CVM used the voter referendum approach with higher taxes and wood product prices as the means of payment. The results indicate an average household WTP of $189. Performing a sensitivity analysis of the benefits and the costs of spotted owl protection yields benefit-cost ratios ranging from 3.5 to 1 and as high as 42 to 1.

As the northern spotted owl debate has shifted from designation of critical habitat areas to their management, reducing the risk of fire in old growth forests has emerged as one of the key issues. Loomis and Gonzalez-Caban (1994) estimated the WTP of Oregon residents to reduce the number of acres of Critical Habitat Areas in Oregon that would burn each year. Using a voter referendum format CVM, the estimated annual value, adjusted for demographics of the Oregon population, is $77 per household for an reduction of 1417 ha burned. Expanding the sample just to Oregon's population results in a value per ha of old growth forests saved from burning of $59,280.

More recently, Loomis and Gonzalez-Caban (1997) estimated the value to both California and eastern U.S. residents of protecting habitat of the California spotted owl from fire. While the amount eastern residents would pay is less per household ($45.70, 90% confidence interval of $41-50) than California residents ($78.69, $72-88), the amount eastern residents would pay is significantly different from zero. This illustrates that the public good market for forest protection for rare species is often nationwide.

Conclusion and Recommendations

In general these studies show substantial existence and bequest values for protecting old growth forests from (1) logging by including in Wilderness areas or National Parks; (2) from damage related to air pollution and insects; (3) from fire. Public forest management agencies should recognize that much of the public comment they receive regarding current timber management practices are probably related to existence and bequest values. As such they should formally include these values in their economic analyses. This is particularly true as these agencies begin to use ecosystem management as a tool for maintaining biodiversity. Ecosystem management often uses tools such as Geographic Information System to track and manage different landscapes. Forests in various successional stages are part of different landscapes. Therefore, total economic values per acre for forests in different successional stages and stocking density should be incorporated into future USDA Forest Service's Resources Planning Act values.

Abstract

A model was developed to estimate the local demand for nature-based recreation, taking into account the composition of local populations. This composition was assessed in terms of a segmentation designed to maximise differences in demands between segments. The model has been applied on a nation-wide scale to generate a detailed spatial map. At the same time GIS-technology was used to create a database with characteristics of the local supply for each residential area within the Netherlands. Finally a nation-wide survey has been conducted, in which data were gathered on the individual's perception and evaluation of this local supply, and his recreational behaviour. The relationships between physical characteristics of the local supply of forests on the one hand, and subjective judgements as well as recreational behaviour on the other hand, were analysed. The main conclusions are that spatial differentiation in demand (based on the composition of the local population) tends to be rather small. With regard to the local supply, subjective judgements regarding forests are clearly related to physical characteristics of this supply. As for behaviour, it seems that in the Dutch case personal circumstances mainly influence participation level and intensity, whereas the local supply situation mainly influences the distance travelled in order to participate in activities or to visit certain types of natural environment. In other words, a bad local supply situation does not lead as much to a reduced participation, as to an increase in leisure mobility.

Keywords: Recreation, Demand, Supply, GIS, Regional differences

Introduction

Participation in nature-based recreation activities is generally believed to have beneficial effects on the individual's physical and mental health (see Ten Wolde, 1999). For this reason the Dutch government has facilitated participation in this type of activity for several decades. On the other hand, however, recreation in natural areas was often perceived as being incompatible with the goals of the government's nature management policy, such as conservation, sustainability and bio-diversity. But recently a change in this latter policy has taken place. In order to strengthen the social support for the government's policy on nature management, it is now believed to be important to have citizens experience nature, to let it be part of their life. This has made the facilitation of nature-based recreation more prominent. In the Netherlands, as well as in other West-European countries (e.g. Denmark), nature-based recreation most often takes place close to home. For example, according to Statistics Netherlands (1997) of all the day-trips of two hours or longer with walking or cycling as the dominant activity almost 60% takes place within 15 kilometres from home. Furthermore, it is a fair assumption that the number of times one walks or cycles for less than two hours is a multitude of the number of times one spends two hours or more on this activity. It is also reasonable to argue that the shorter the time that is spent on the activity, the smaller the distance travelled from home will be, at least on average. This makes the environment close to home even more important.

The short distances travelled away from home may imply that the local supply for this type of activity is usually good, or at least satisfactory. On the other hand, it may also be that the price that people are willing to pay for it, in terms of travel time or costs, is quite low. In the case of high distance sensitivity, a bad local supply situation will lead to lower participation levels and intensities of participation. To facilitate participation, it then becomes important to match local supply with local demand. The size of the demand not only depends on the sheer number of inhabitants of a residential area, but also on the composition of the population. If a rather high level of spatial detail is required, the costs of a survey among a representative sample of the population of each residential area of interest are likely to become prohibitively high. That is why a model was developed to estimate this local demand (see De Vries and De Bruin, 1998; De Vries, in preparation). In the next paragraph this model will be briefly introduced. In addition to modelling the demand, the local supply of areas suited for nature-based recreation was assessed, based on existing GIS-databases. We will also briefly describe this assessment. Finally, a nation-wide survey was conducted, in which over 3000 respondents were questioned regarding their local supply situation and their recreational behaviour. This survey will also be outlined. The main focus of this paper is the analyses based on these three different sources of information and what they tell us about regional differences in demand, supply and behaviour.

The Demand Model

The demand model focuses on the composition-effects of the population on the size and type of demand. The model was developed in three parts. The first part consists of a segmentation of the Dutch population. Each segment had to be as homogeneous in their demands regarding nature-based recreation as possible. Heuristic use of the Rational Choice approach led to a focus on constraints (see De Vries and De Bruin, 1998). This approach also led to a focus on generic constraints, as opposed to activity-specific constraints. Furthermore, because the demand model should not incorporate effects of differences in local supply situations, we concentrated on *personal* constraints: constraints that may differ between a person and his next-door neighbour. The final segmentation we arrived at classifies the Dutch population of 15 years of age or older into five groups. These five groups were labelled as follows (in order of ascending average age): the Busy, the Reluctant, the Family-oriented, the Satisfied, and the Weary.[1] Children below the age of 15 constitute an implicit sixth segment. The five segments are defined in terms of social-structural characteristics. They mainly differ on three dimensions: age, family stage, social-economic position (see Figure 1).

The second part of the model was the estimation of the composition of a local population in terms of the aforementioned segments. This estimation is based on data that is available for each of the over 10,000 neighbourhoods within the Netherlands. Two databases served as input, one of the Dutch census bureau, Statistics Netherlands, and one of a commercial direct marketing agency, Geo Marktprofiel. By means of linear programming and chi-square based automated interaction detection these input data were used to predict the segment composition of a neighbourhood. Attempts to assess the reliability of these predictions were made by using data from reasonably sized samples for several neighbourhoods (De Vries, in preparation). Of each respondent in the sample the segment membership was known, allowing sample estimates at a neighbourhood level. Several discrepancies between sample and model estimates were observed. Further analysis showed that these discrepancies were likely to be due to the sample not being completely representative for the neighbourhood population. So, relative to the sample estimates the reliability of the model estimates was rather high.

Because the model makes maximum use of census information, it is less sensitive to selective non-response than sample surveys. That is, in as far as the segment composition is concerned. The outcomes of the nation-wide application of this part of the demand model are presented in the results section of this paper.

[1] The labels are based on the dominant constraints as perceived by the individuals themselves. For example, the Busy mainly experienced a lack of (leisure) time. Two segments were not dominated by a single constraint. The Satisfies experienced few or no constraints, whereas the Reluctant saw many constraints, and even included the unpredictable weather.

Figure 1. The five recreation segments in order of ascending age.

The youngest segment is that of the *Busy*. These persons usually live in 1- or 2-person households without children. The socio-economic position, in terms of education and household income, is relatively high.

The youngest segment is that of the *Busy*. These persons usually live in 1- or 2-person households without children. The socio-economic position, in terms of education and household income, is relatively high.

This last aspect constitutes the most significant difference with the next segment, that of the *Family-oriented*. This segment is a little bit older on average, but socio-economically speaking much better off. The children within these households are younger than in the households of the Reluctant

The fourth segment is that of the *Satisfied*. This segment is dominated by people living in empty nest households. Of course the average age is higher than among the Family-oriented. Usually the couples involved have an above average socio-economic position.

The fifth and last segment is that of the *Weary*. Within this segment a high age is common. Many Weary live in 1-person households. The average socio-economic position is the lowest of all segments.

The third part of the demand model is the assessment of the demand characteristic at hand for each of the segments. The differences between the segments on such a characteristic, in combination with the differences between neighbourhoods in segment composition, determine the level of spatial differentiation in demand at the neighbourhood level. From an application-oriented perspective, the most useful demand characteristics are those than can be related to or translated into supply characteristics. Otherwise no confrontation between demand and supply is possible. At the same time the demand characteristic should not already take into account the local supply conditions. This would render a confrontation of demand and supply useless. The demand characteristics that we use, are behavioural in nature. It can be the participation in an activity, or the visiting of a certain type of area. Because at the individual level such a characteristic will be influenced by the local supply situation, it is important to calculate mean participation or visiting levels, averaged over a large number of different local supply conditions. We may note that the purpose of the demand model is not to predict actual behaviour. Conceptually we consider demand to be a latent variable, that, in interaction with supply conditions, determines actual behaviour. The demand characteristics can be based on a survey, in which special care is taken with regard to sampling local supply conditions.

Assessment of Local Supply Situations

Local supply assessments can be based on an inventory of physical characteristics of this supply, on expert perceptions and/or judgements of it, or on perceptions of local residents. Given the desired level of spatial detail (over 10,000 neighbourhoods), the expert option is not very feasible. A great number of local experts would be required. Moreover, it will be difficult to ensure that all these experts use the same criteria to evaluate the supply situation, and assign the same weights to these criteria. Using local residents to assess the supply situation also has a major drawback. Their perceptions may be influenced by their demands and by local standards. Therefore we have opted for the first approach: a straightforward inventory of physical characteristics. Based on recent literature, we selected types of physical characteristics that were likely to be relevant. For example, besides the type of land use also quietness and silence proved to be important aspects (see e.g. Reneman et al. 1999). Nowadays in the Netherlands a lot of information on land coverage, land use, infrastructure, and other characteristics of the landscape is available in GIS-databases. One of the main GIS-databases that we used, was the most recent version of the National Land Cover Classification of the Netherlands (LGN3). This database contains information on the dominant type of land use out of 24 categories for each grid cell of 25x25 metre (see Wit et al. 1999). This information was used to derive supply characteristics in the following way. The same neighbourhoods were used as in the demand model. The living environment of a neighbourhood was pragmatically defined as a circle with a radius of 12 kilometre around the centre of the neighbourhood. This choice was based on the radius of action of an average recreational cyclist taking a trip of two hours (speed of 16 kilometre per hour or less; correction factor for straight line rather than by road: 75%). The number of grids with a specific type of land use within the living environment was determined for each neighbourhood and converted into a percentage of the surface of the circle. This resulted in the percentage of deciduous forest within the living environment of the neighbourhood, the percentage of sea, of arable land and so forth. A foreign country correction was applied for those neighbourhoods with a part of their living environment situation in this country (Belgium or Germany). It was assumed that the land use in this foreign country had the same composition as on the Dutch side of the border.

Other GIS-databases were used to determine additional characteristics, e.g. the level of noise from traffic (road, railway, air) and industries, the density of bicycle path and roads suited for cycling and that for walking. Because the literature suggested that quietness (absence of other people) was a highly relevant aspect of the recreational quality of the environment, a special effort was made to find an indicator for this aspect. By way of a GIS-analysis the available amount of 'real' nature per capita within the radius of 12 kilometres was determined (‘real’nature: forest, heath, beaches & dunes and other natural areas). This indicator takes the number of people living in other neighbourhoods that are also within a distance of 12 kilometres of a particular natural area into account. In other words: each square metre of nature is assigned to only one inhabitant at maximum. The lower the number of square metres per capita, the more likely it is that one will encounter other people when visiting a natural area within the living environment. Because opportunities nearby might have special relevance, all characteristics were also determined for a circle with a radius of 3 kilometres.

The Nation-Wide Survey on Recreational Behaviour and Judgements of Local Supply Conditions

To determine the demand characteristics for each segment, use was made of a survey conducted by Reneman and others (1999). In this nation-wide survey, the Netherlands was divided in nine regions, each thought to be more or less homogeneous with regard to the dominant type of natural supply and landscape. Within each region further stratification took place. Three levels of urbanicity were distinguished. For each combination of region and urbanicity about 100 persons or more were interviewed. The total sample contained over 3000 respondents. This survey suited our purpose quite well, in that a wide variety of local supply conditions were sampled. The survey itself consisted of two parts. First a short telephonic interview was conducted. If the respondent agreed, a quite lengthy questionnaire was mailed. Probably partly due to the length of this questionnaire, the overall response rate was quite low: less than 20%. Lower educated people were underrepresented within the sample. For more information on the survey, see Reneman et al. 1999.

Within the survey the characteristics of the respondent that are needed to determine to which segment s/he belongs were assessed. This allowed us to determine the behaviour of a segment, averaged over a wide variety of (Dutch) local supply conditions. Furthermore also questions were asked on recreational behaviour. The participation data concern recreational activities undertaken in a green or natural environment. Respondents were also asked how they perceived and evaluated their own living environment, defined as the area within 16 kilometres of their home (by road). These questions were not intended to derive additional demand characteristics, but to see whether these perceptions and evaluations could be predicted by physical characteristics of this living environment, as assessed on the basis of available GIS-data. The evaluations can be considered a confrontation of local supply with local demand, using the citizen’s own norm. To the degree that this exercise is completed successfully, the resulting regression equation can be used to construct a nation-wide map of predicted judgements: the GIS-data used to characterise the living environment of the respondents are available for all neighbourhoods within the Netherlands. Of course the same type of analysis can also be conducted for the behavioural data.

Results

Demand: the Composition of the Population of Neighbourhoods

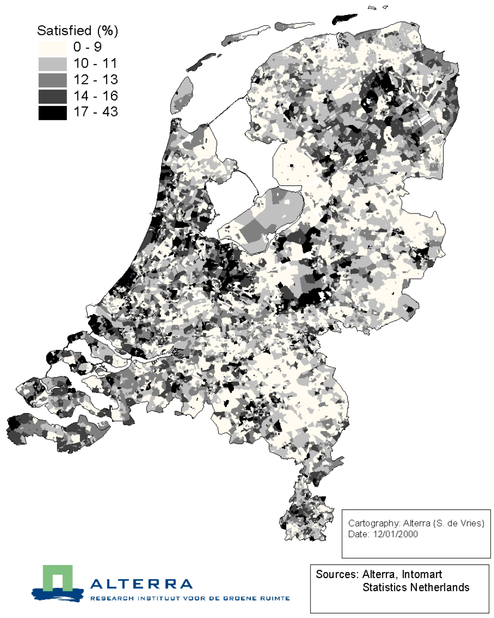
Within the demand model there are two sources of regional differentiation. The first source is the composition of the neighbourhood according to segment. If all neighbourhoods have the same composition, the model will tell us that there is no spatial differentiation, regardless the extent to which the segments differ in their demands. This latter factor, of course, is the second determinant of the degree of regional differentiation. If the segments have similar demands, spatial differentiation will be small, regardless the differences in the composition of neighbourhoods. We will first discuss the composition of neighbourhoods. This composition was determined by applying the second part of the demand model. Table 1 shows some characteristics of the distribution of segment percentages over neighbourhoods. In terms of standard deviations, the Reluctant show the lowest degree of spatial differentiation and the Busy the highest. In addition to these statistics, nation-wide maps were made for each segment, to see whether neighbourhoods within the same region were more likely to be have a similar composition or not. The Satisfied appeared to have the highest level of regional clustering (Figure 2). They are overrepresented along parts of the Northsea coast, in the regions “Gooi” and “Utrechtse Heuvelrug”, at the borders of the most famous national park “De Hoge Veluwe”, and in parts of Drenthe, a province in the north-east of the Netherlands. All these areas are well known for their natural scenery. The Busy, on the other hand, were overrepresented in city centres, especially if the city was a centre for higher vocational education or had a university. Although we did not have a clear criterion, we considered the differences between the neighbourhoods to be substantial enough to continue the development and application of the model.

Demand: Differences between Segments

The second source of regional differentiation is the difference between segments in scores on the demand characteristic at hand. Several types of demand characteristics may be distinguished. Behavioural demand characteristics are the participation in an activity, or the number of times a specific type of location is visited. Other types of demand characteristics can be stated preferences for certain activities, types of location, experiences, or combinations of the above. In order for the characteristic to be a *demand* characteristic, local supply conditions should have no effect on the score of a segment on the characteristic. In the case of behavioural characteristics this may be achieved by averaging out the effect of local supply conditions. We will now present the results for several characteristics, based on the aforementioned nation-wide survey, starting with participation in leisure activities conducted in a green environment.

Since the demand assessment is undertaken with the intention to confront this demand with the local supply of opportunities, it is desirable to express the demand in such a way that this confrontation becomes feasible. This makes the number of times an activity is undertaken on a per capita basis a useful characteristic. This amounts to the average participation frequency for the activity, with the *inclusion* of the non-participants.[1] Four out of thirteen activities undertaken in a green environment showed significant differences between the five segments ($p < 0.001$).

Figure 2:
percentage of Satisfied by neighbourhood



These were bicycling, sports activities, collecting/picking things from nature and experiencing nature (see table 2). The Reluctant stand out when it comes to (recreational) cycling. Their frequency is almost twice as high as that of the Busy. The Busy, on the other hand, have the highest frequency for sports activities. This frequency is five times as high as that of the Weary. Collecting or picking things from nature is especially popular among the Family-oriented, the segment in which young children within in the household are most common. Experiencing nature seems to be more popular among the two elderly segments, the Satisfied and the Weary.

Although only four activities revealed significant differences, in those cases the differences between the segments may be considered substantial. It may be noted that significant differences for participation levels

[1] The distribution of this participation frequency will usually not be normal. This has consequences for the statistical tests that are used. To compensate for the non-normality, a higher than usual significance level was required: $p < 0.001$.

were observed for eleven of the thirteen activities ($p < 0.001$). However, in many cases high participation levels go hand in hand with low participation intensities. For example, in general the Weary partake in the lowest number of activities, but if they participate the frequency with which they do so tends to be rather high. For the Busy this tends to be the other way around (see De Vries and De Bruin 1998).

The other type of demand characteristics on which we will present results here, are desired experiences in a green environment. The respondents had to (partially) rank order twenty-five potentially desirable experiences according to their attractiveness. Mean rank order scores showed significant differences between segments for fifteen of these experiences ($p < 0.001$). The largest differences were observed for:

- forgetting the day-to-day worries
- rejoicing at the beauty of nature
- enjoying nature
- relaxing

Together the results for these four experiences paint a clear picture (see table 3). The three younger segments consider forgetting the daily worries and relaxing more attractive experiences than the two older segments. When it comes to enjoying nature and experiencing its beauty, the pattern is reversed.

Table 1.Characteristics of segment percentages by neighbourhood (including children under the age of 15 as sixth segment)

	Child (< 15)	Busy	Reluctant	Family-oriented	Satisfied	Weary
Mean	19	22	12	21	12	15
St. deviation	4.8	5.3	2.4	5.0	4.1	5.1
Minimum	2	5	2	2	0	0
Maximum	44	75	23	41	43	62

Table 2. Participation frequencies (number of times in 1998) for four leisure activities conducted in a green environment, including non-participants ($p < 0,001$)

	Busy	Reluctant	Family-oriented	Satisfied	Weary
Cycling	47	83	50	54	55
Sports activities	25	18	18	11	5
Collecting things from nature	2.9	3.3	5.7	2.7	2.6
Experiencing nature	26	30	33	47	40

Table 3.Mean attractiveness scores for four selected experiences in a green environment ($p < 0.001$)

	Busy	Reluctant	Family-oriented	Satisfied	Weary
Forget worries	13	13	13	8	7
Relax	15	16	15	12	12
Enjoy nature	9	10	10	13	13
Rejoice at beauty	6	6	7	10	11

So, relatively speaking for the younger segments push factors are more important for visiting nature, whereas for the older segments the pull of nature is more important.

Also for other types of demand characteristics differences are found between the segments (see De Vries, in preparation). The overall conclusion is that the segmentation offers a convenient way to summarise interindividual differences on a broad range of recreational demands. Sometimes the age dimension is the most important, sometimes the family-stage or the socio-economic position. Depending on the demand characteristic that is used, the differences between segments may be large enough to, in combination with the differences in population composition, lead to regional differentiation in demands.

Demand: Differences between Neighbourhoods

The final step in assessing spatial differentiation in recreational demands is to combine the composition of each neighbourhood with the demand characteristic for each segment. This is done in the following way. For each segment the absolute number of members within the neighbourhood is multiplied with the average score of the segment on the demand characteristic at hand. For an activity, such as experiencing nature, this results in the total number of trips generated by the segment members within the neighbourhood. In the next step the total number of trips generated by the neighbourhood is calculated by adding the totals for each segment. Finally, this figure is divided by the total number of inhabitants of the neighbourhood, which gives a demand characteristic at the level of the neighbourhood that is standardised for the size of the population of the neighbourhood. Comparison of this characteristic between neighbourhoods indicates the amount of spatial differentiation due to the composition of the neighbourhoods.

To have a criterion to judge whether or not the amount of spatial variation was relevant, the deviation of a neighbourhood's score of the national average for neighbourhoods was calculated. This deviation was subsequently expressed as a percentage of this average score. In this way the effects of the composition of the neighbourhood can be compared with the effect of a change in the size of the population of the neighbourhood. After all, for a (quantitative) confrontation of the demand with the local supply, the demand in needed in absolute terms. This absolute demand consists of the multiplication of the demand characteristic for the average inhabitant of the neighbourhood with the number of inhabitants. A change with a certain fraction in the demand characteristic will have the same effect on this total demand as a change with the same fraction in the size of the population. This calculation was made for several demand characteristics based on participation in activities. For all these demand characteristics the level of spatial variation between neighbourhoods was rather small. For example, for experiencing nature there are only a few neighbourhoods with a frequency that deviates from the national average by more than plus or minus 5%, and almost no neighbourhoods with deviations larger than plus or minus 10%. Since experiencing nature was one of the activities with relatively large differences between the segments, our preliminary conclusion is that compositional effects on the spatial differentiation in recreational demand are rather small.

Local Supply Conditions and How They are Judged

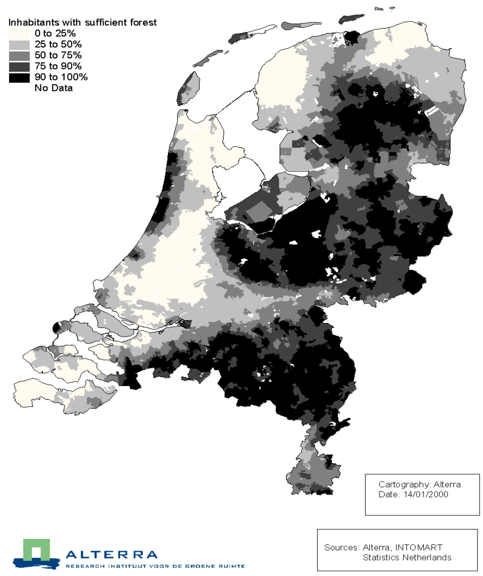
Another part of the study focused on differences in local supply conditions, or better, on the effects of these differences on how the own living environment was judged. The living environment was defined as the area within 16 kilometres from home (by road). In this paper we will concentrate on judgements regarding forests. Respondents were asked to indicate whether forested areas were present within their living environment, and if so, if the amount of forest was too limited, sufficient, or even more than sufficient. We reclassified these answers into two categories: absent & too limited versus (more than) sufficient. Subsequently a logistic regression analysis was performed on this judgement, in which physical characteristics of the living environment were used as predictors. Using a stepwise procedure, the following six characteristics were included in the final regression equation ($n = 3089$):

- percentage of forest within 3 kilometres: B = 0.12; exp(B) = 1.13
- percentage of forest within 12 kilometres: B = 0.05; exp(B) = 1,05
- percentage of nature other than forest within 12 kilometres: B = 0.13; exp(B) = 1.14
- natural logarithm of the number of square metres of forest available per capita within 12 kilometres: B = 0.19; exp(B) = 1.20
- amount of variation within the available forest within 12 kilometres:[1] B = 0.83; exp(B) = 2.30
- percentage of small-scale (closed) agricultural landscape within 12 kilometres: B = 0.03; exp(B) = 1.03

The amount of "explained" variance of this regression model is 30%. The answer, sufficient or not, is predicted correctly for 76% of the respondents. Each of the regression parameters is significant at the 0.001-level.

It is not surprising that most of the included supply characteristics have something to do with the amount of forest. Forests close home has a relatively large influence: they are counted twice (within 3 and 12 kilometre radius). The two supply characteristics that do not deal with forests are the percentage of nature other than forests and small-scale agricultural landscape. It is not clear whether these types of nature can compensate for the absence of forests, or that they also indicate of the presence of (small) forested areas, at least in the perception of the respondents. As usual, we have to be careful with the causal interpretation of correlational results. The regression equation was used to make a map for the whole of the Netherlands, indicating the percentage of inhabitants that is predicted to think there is (more than) sufficient forested area within their living area (see Figure 3). Each class of the legend contains about the same number of neighbourhoods. The map shows that there are large regional variations in the proportion of satisfied people. In some areas less than 25% of the population is satisfied, while in other areas over 90% is satisfied. To give a rough idea of the differences in local supply behind these two extreme legend classes, we calculated the amount of forest within 12 kilometres for the neighbourhoods involved.

Figure 3: percentage of inhabitants that is satisfied with the available amount of forest within the living environment, by neighbourhood



The highest legend class has about 6000 hectares more forested area within 12 kilometres on average than the lowest legend class.

Respondents were also asked to judge the quality of the forested area within their living environment on a 10-point scale (if forest was present at all, which was the case for over 80% of the respondents). A regression analysis of this judgement, using the supply characteristics as predictors, explained 15% of the variance. The following four characteristics were included in the final model (n = 2535), all with parameters significant at the 0.001-level:

- percentage of forest within 12 kilometres: B = 0.03, beta = 0.18
- amount of variation within the available forest within 12 kilometres: B = 0.61; beta = 0.16
- natural logarithm of the number of square metres of nature other than forest available per capita within 12 kilometres: B = 0.10; beta = 0.09

[1] This characteristic is based on the ratio of deciduous and coniferous forest. If no forest is present at all, or only one type of forest, the score is zero. If the ratio of deciduous and coniferous forest is fifty-fifty, the (maximum) score is one.

- natural logarithm of the number of square metres of forest available per capita within 3 kilometres: B = 0.07; beta = 0.08

The regression equation indicates that the more forest is available within the living environment, the higher the quality is judged: 30% more forest increases the quality score by 1 point, everything else remaining equal. For forests nearby especially the amount per capita seems to be important. This may be taken as an indication that quiet forests are more appreciated than crowded forests, with crowding being more likely close to large population concentrations. Also variation between deciduous and coniferous forests is appreciated. The last characteristic in the equation deals with other types of nature (dunes, heath, etc) within 12 kilometres on a per capita basis. The combination of the 12 kilometre radius and the per capita basis may be the result of this type of nature being less common in the Dutch situation, and therefore attracting people over longer distances. However, it remains somewhat unclear why this characteristic is related to the quality judgement of forests.

Effects of Local Supply Conditions on Behaviour

In the previous paragraph we saw that local supply conditions, in terms of GIS-based indicators, were related how people judge their living environment with respect to forests. Furthermore we observed quite large regional differences in (predicted) judgements. A next question is whether and how local supply conditions influence recreational behaviour. We will start by looking at participation in activities. Using the same type of regression analysis as for the judgements, now the dependent variable is the frequency with which one participated in activities such as walking, cycling, and experiencing nature. The analyses for the participation frequencies showed that the effect of the local supply condition tends to be rather small. Moreover, for seven of the thirteen activities under investigation, there was no significant effect at all ($p > 0,001$). The explained variance was never more than one percent. Respondents were also asked to indicate the distance travelled to the location were they performed the activity. Here the explanatory power of the supply characteristics is considerably higher, with a maximum of 10% for roaming natural areas (i.e. not being restricted to the paths and roads). For three activities no significant effect was found. So, local supply conditions have a stronger effect on the distance travelled than on the frequency of participation.

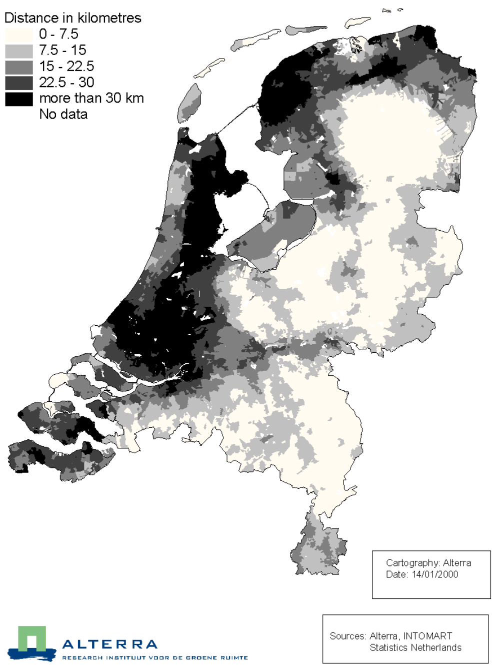
Besides the distance travelled to perform a specific activity, the respondents were also asked to indicate the distance travelled to the most often visited forest site. This question was only asked to those respondents that had visited a forest at least once in the last year. Note that this forest did not have to be located within the own living environment. The final regression equation (n = 2491) explained 17% of the variance in distances. The following supply characteristics were included in this equation (all parameters significant at the 0.001-level):

- amount of variation within the available forest within 12 kilometres: B = -9.64; beta = -0.15
- natural logarithm of the number of square metres of 'dry' nature, other than forest, available per capita within
- 12 kilometres: B = -2.78; beta = -0.15
- the surface of rural area with good cycling possibilities (paths, roads) within 12 kilometres (in 500x500 metres grid cells): B = -0.02; beta = -0.14
- natural logarithm of the number of square metres of forest available per capita within 12 kilometres: B = -1.69; beta = -0.10
- natural logarithm of the number of square metres of forest available per capita within 3 kilometres: B = -1.40; beta = -009

Three of the five characteristics have to do with the amount of available nature per capita. Once again this implies that quietness is an important motive to visit nature. This is supported by the fact that, when asked to rank order a list of potential aspects of natural areas according to attractiveness, quietness scores among the highest (Reneman et al. 1999). However, variation has the largest effect: no variation in forests within the living environment leads to an increase in distance by 10 kilometres, when compared with maximum variation between deciduous and coniferous forests (everything else remaining equal). Also this regression equation was used to generate a

map (see figure 4). Each legend class contains about the name number of neighbourhoods. The map shows a large resemblance with that for the satisfaction with available forests.
The correlation of the two predicted outcomes, calculated over neighbourhoods, is r = -0.89. The map shows the large effect the local supply condition has on the distance travelled. In the lowest legend class this is less than 7.5 kilometres on average, in the highest legend class it is more than 30 kilometres (single distance).

Figure 4: distance travelled to most visited forest area, by neighbourhood (predicted)



Conclusions and Discussion

One of the main conclusions of our study is that spatial differentiation in recreation demands due to the composition of the local population tends to be rather small. Of course this conclusion is based on the type of demand characteristics that we studied: participation in activities. This is a rather global type of characteristic. It is known that certain segments prefer certain types of location (De Vries and De Bruin 1998). If more specific demand characteristics are used, e.g. walking in large forest with a low level of facilities, the differences between segments may become larger, up to the degree that spatial differences become substantial. Another question regarding this first conclusion is whether the segmentation that was used, is optimal with regard to the demand characteristic at hand. It is possible that a more discriminating classification exists. By definition a classification based on the demand characteristic itself will discriminate optimally. However, we would like to make two comments. The first comment is that if this demand characteristic is behavioural in nature, the question arises to which degree the characteristic will still be a *demand* characteristic. Behavioural characteristics may easily incorporate local supply effects. For example, people living close to an important national water sports area are likely to show a higher frequency of participating in water sports activities.

The second comment has to do with using the segmentation to arrive at a detailed demand map. An essential part of the demand model we developed was that the composition of local populations could be estimated by the use of nation-wide available data. This type of data is usually only available on socio-structural characteristics such as age, household composition, level of education, etc. Since our segmentation is defined in terms of this type of characteristics, assessing the composition of local populations according to these segments went rather well. It is possible that the gain of using a more discriminating classification will be lost by a less accurate assessment of the composition of local populations in terms of this classification.

As for differences in local supply conditions, these clearly do exist. More interesting is the conclusion that these objective differences, defined in physical terms, also can be shown to lead to differences in judgements of the own living environment, in this case regarding forests. The observed relationships were quite strong. This suggests that different people in different regions of the Netherlands use more or less the same criteria to arrive at their judgements, for example regarding the amount of forest in their living environment. Furthermore, errors in prediction on an individual basis are likely to average out at the neighbourhood level. This justifies the use of the regression equations to make nation-wide maps, also including neighbourhoods out of which no inhabitants participated in the survey. Nevertheless, there may be some distortions in these maps. Although it is likely that the errors in prediction are not correlated on a person-to-person basis, they may be spatially correlated. The supply characteristics that we have used may not fully characterise the local supply condition. In this respect systematic deviations are possible. For example, older forests may be appreciated higher than younger forests. A first, visual inspection of a map of errors showed no regional clustering of errors in a specific direction. However, further research in this direction is needed.

With regard to the effect of local supply conditions on recreational behaviour, the most striking conclusion seems to be that the local supply has a stronger effect on the distance travelled to the location where the activity is performed than on the frequency with which the activity is performed. Bad local supply conditions do not lead to a drop in demand, as much as to a flight of demand. The analysis of and the map for the distance travelled to the most often visited forest area clearly shows that a bad local supply condition may lead to a considerable increase in leisure mobility, at least on a one trip basis. Unfortunately we did not have data on the frequency with which forests were visited. Therefore it remains the question whether a bad local supply will have (almost) no negative effect on this frequency also, in the same way as for the activities. Note that this implies that the distance that has to be travelled has no strong negative effect on the frequency with which the activity is undertaken. What the available data do enable us to do, is to analyse the effects of demand and supply characteristics on behaviour simultaneously. This is something we hope to report on in the near future.

A Framework for Relating Aesthetics and Perception for Advancing Research

by
Simon Bell
Senior Research Fellow
School of Landscape Architecture

Lauriston Place, Edinburgh EH3 9DF, United Kingdom

Abstract

A framework for relating different approaches to landscape perception and aesthetics is presented. This considers 2 aspects, the means and the nature of the aesthetic response. Each of these is elaborated and connected, using 4 types of aesthetic response, the sensory, the formal, the expressive and the symbolic, to the work of a range of different perception psychologists and aesthetic philosophers. This framework is then developed to propose a number of areas for research, especially in the field of forestry in general and urban forests in particular. As well as research into perceptions and aesthetics, links to other key areas are suggested, including applied landscape ecology and environmental ethics.

Keywords: Landscape, Perception, Aesthetics, Psychology, Philosophy

Introduction

There are many ways in which people interact with their environment, including economic exploitation, subsistence activities, leisure and pastimes. This paper considers the nature, character and importance of the aesthetic relationship between people and their environments, especially forests and in particular urban forests.

Many authors cite a sense of alienation as existing between many people and their environment, especially in urbanised areas of developed countries. The lives of a large number of people are dominated by the indoors, by the enclosed worlds of transport, by the rhythms set by their working lives and so on that remove them from an everyday meaningful direct interaction with nature and with natural forms. At the same time there is an increasing interest in "the environment" but this is, in many ways, a separated world, only experienced vicariously through secondary media such as TV, film etc. That is not to say that urban people do not get out and experience nature. Many do, but they frequently need to make a conscious effort to do so unless they have the good luck to live within easy reach of a park or similar area. Parks provide a number of opportunities for interactions with nature but the size, layout and design of many of these do not permit this to the greatest degree possible. Forests also provide this and possibly do so in particular ways due to their enclosed nature that cut us of from the external scene when we are within them.

When we examine the character of the relationship between people and nature in terms of experiences, there are many interesting themes, only some of which have been thoroughly explored or researched. Urban forests are becoming an increasingly popular vehicle for providing ready access to nature for the large urban populations of many countries. The themes that concern the relationship of people to nature also apply to urban forests but have added contexts due to the possibly special character of forests as entities in their own right.

One of the main ways we experience such landscapes is an aesthetic one. The aesthetic experience can act as the filter through which we move on to build up other relationships. However, because the realm of aesthetics has largely been confined to philosophy, although the mechanisms of perception and the range of preferences exhibited by people comes under psychology, it has not been examined very rigorously, if at all, by mainstream forest research agencies. However, this misses a rich vein for research that should be pursued because unless we thoroughly understand the relevance and importance of aesthetics we will overlook a number of significant aspects which affect secondary modes of preference which may be more likely to be influential on policy and management. These include publicly expressed preferences for certain forms of management that may be argued superficially on rational scientific grounds but unless the aesthetic angle is properly addressed the resulting solutions are likely to miss their mark. Recent examples in forestry include the preservation of old growth or the practice of clear cutting.

The question of aesthetics has often been treated with less than the importance it deserves. This is possibly due to the following reasons:

- Society's concern for style and surface appearance as opposed to the deeper aspects defined here.
- The fragmented and apparently contradictory theoris of aesthetics.
- The tendency to link the subject of aesthetics with art and not with nature
- The prevalence of the traditional scenic mode of landscape aesthetics which sees the experience as separate from everyday life.

What has been lacking is a framework for understanding the relationships between the various schools of aesthetics as they pertain to the environment of the forest, especially the urban forest. The need for this arises because before we can explore more deeply into aesthetics we need to be able to demonstrate that there is a rational basis for further development. We also want to be able to use the tools provided by environmental psychologists in order to work out more of the perceptual mechanisms in terms of their relationship to aesthetics. There has not, to date, been any firm link between perception and aesthetics because they belong to different disciplines. Perception psychology has developed much understanding, particularly in terms of the urban environment (Ulrich 1979,1983, Nasar 1994), but more is needed on the forest landscape.

A framework is therefore proposed that sets out in a logical structure the various schools of aesthetics, in terms of, on the one hand, the **means** of aesthetic response, and on the other the **nature** of the aesthetic response. These represent spectra that enable often apparently opposing aesthetic theories to co-exist. From this links are constructed that relate factors such as the role of knowledge about the environment, the mechanisms of perception and the different approaches for research. For example, these can be divided into those concentrating on looking for general preferences for landscapes in populations versus those that concentrate on the aesthetic experience as purely personal, and those that concentrate on characteristics inherent in landscapes over those concentrating on cognitive aspects.

These links are currently being explored in the context of forests in the UK and are included in a new research strategy being developed. The purpose of this is to help us understand not only what people prefer but why they prefer it, to disentangle aesthetic preference from other preferences and to help develop guiding principles to refine the tools available to designers and managers of the new urban forests that are under development.

A Framework for an Aesthetic Structure

There are a number of apparently conflicting approaches to landscape aesthetics that have caused some degree of confusion amongst the professional and academic community. In fact all these approaches are merely facets of a bigger picture.

The first component of this framework is the **means** of aesthetic response. The second is the **nature** of that response. The following diagrams set the skeleton of this out and will be used as a basis for further development.

Figure 1 shows a gradation or spectrum of response from the position of observer separated from the observed scene (always the case in a landscape painting and scenery becomes the same in this traditional situation) to position of observer as active participant in the landscape. Figure 2 also shows trends or tendencies, but these work in two directions. The list of responses is sometimes shown as a descending order. However, as explained below, movement in the nature of the aesthetic response can occur in both directions. Each part of these diagrams has one or more aesthetic philosophical or psychological movements associated with it. These associations, as elaborated below, demonstrate how the proposed framework brings these competing theories together.

The distant mode of viewing includes the sense that the observer is physically distant from the scene, and therefore cannot use senses except sight and possibly hearing, or "psychically distant" (Bulow), where the observer is psychologically separated (typical of an experience of art but also of some landscapes.)

Figure 1. Means of Aesthetic Response

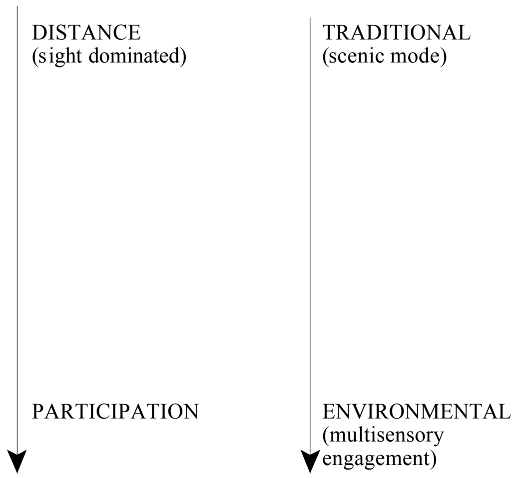

Figure 2. Nature of Aesthetic Response

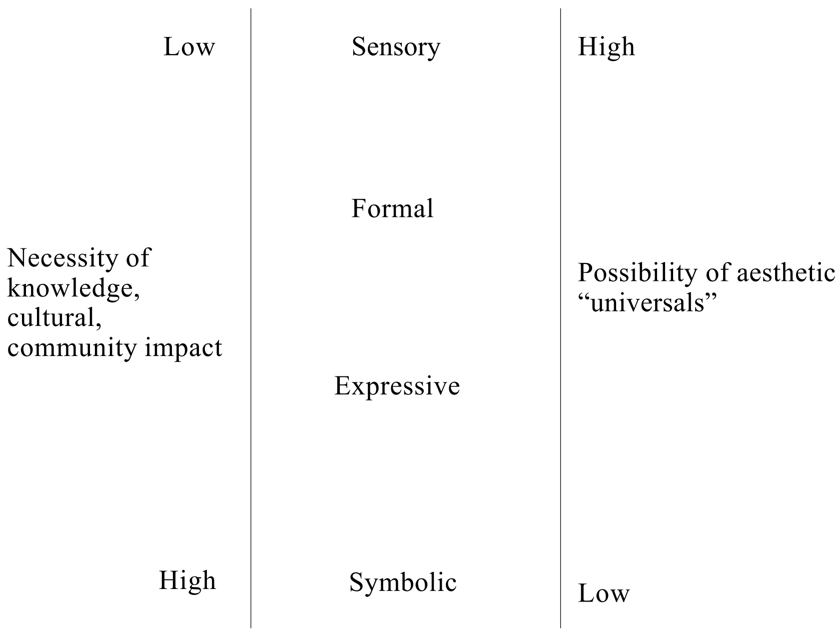

Figure 3. An elaboration of the means of aesthetic response.

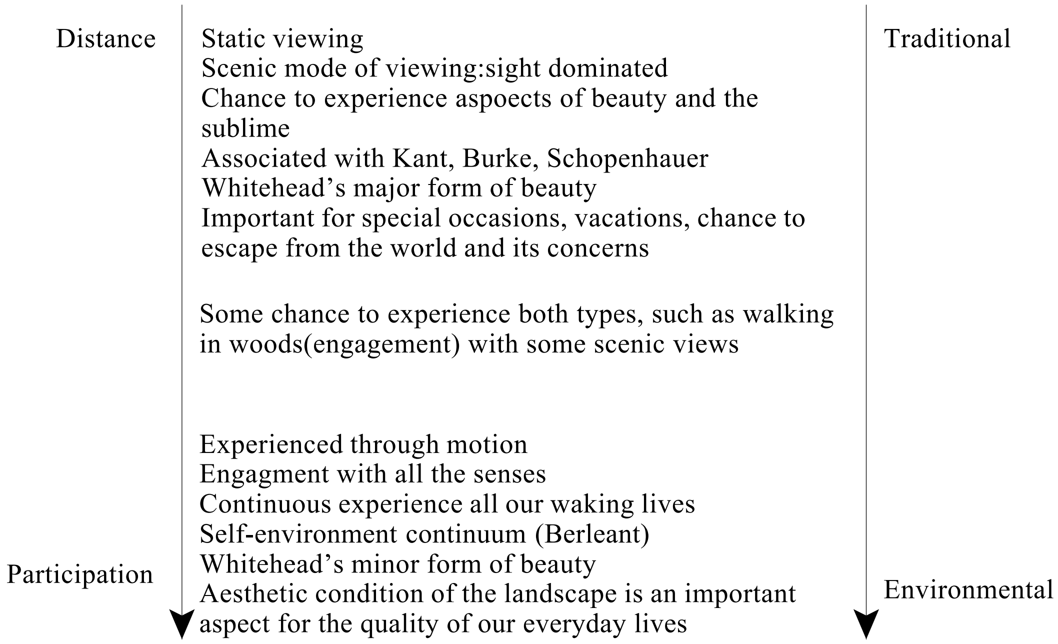

This type of viewing is the kind that we tend to experience when at a viewpoint overlooking some dramatic vista or prospect. The occasions where this is experienced do not tend, for most people, to be available everyday. It can be argued that many natural landscapes have been identified and designated as scenically important, for example as national parks. Soaring mountains, yawning abysses, thunderous waterfalls and other large scale scenes demonstrating the power of natural forces offer opportunities to experience the beauty of nature or to generate a sense of the sublime. There has been an aesthetic tradition as far back as Kant (1981), Burke (1958) and Schopenhauer (1969) that has explored and discoursed on these concepts. In the early twentieth Century, Alfred North Whitehead developed a metaphysical theory of aesthetics based on the interactions of organisms (such as ourselves) and our environment. He identified concepts such as "massiveness", "intensity proper" and "strength" as attributes of such landscapes, the culmination of which lead to "the major form of beauty" (Whitehead 1960).

Scenery and landscape aesthetics of this variety have a lot to offer and should not be undervalued, even though more recent trends have emphasised the other end of the spectrum, that of participation in the landscape.

Participatory aesthetics concentrates on the non-static mode of perception, exemplified by the approach of the psychologist J. J. Gibson and his theory of optic flow (Gibson 1966). It also focusses on the use of all the senses (sight, smell, hearing, taste and the haptic or kinaesthetic senses of touch, temperature/humidity detection and spatial awareness through movement and balance using the organs of the inner ear). This multisensory engagement ensures that, as well as many other experiences of everyday life, the aesthetic is a constant response. The main exponent of this approach is the aesthetic philosopher Berleant who describes our relationship to the landscape (or environment) as a self-environment continuum, as opposed to the separation inherent in the traditional types of response (Berleant 1992). The argument that leads from this is that the aesthetic condition of our everyday world is an important contributor towards the quality of our everyday lives. Whitehead's metaphysical theory also applies here: his "minor from of beauty".

The participatory aesthetic is a particularly important concept for forestry, especially urban or community forestry. In many countries such as USA, UK, Canada, New Zealand, the main focus of effort has been on the planning, design and management of forestry landscapes in the context of the traditional type of aesthetic response. The US Forest Services' Scenery Management System (Anon 1995) and the GB Forestry Commission's Forest Landscape Design Guidelines (Forestry Commission 1989) both emphasise this mode. There are good reasons for this: forests are very visible, scenic viewing is a popular pastime and forest landscapes have undergone often quite drastic change through logging or planting.

However, many countries such as Finland or Russia who have vast forests on flatter land do not experience (except in rare places) the scenic prospect. Their people engage with forests on a daily basis: the forest often is the landscape for everyday lives. Thus the participatory aesthetic is the main type of response. Similarly, urban people who venture into urban forests undergo the same experience. The unfortunate thing is that little research so far has been carried out into this field compared with the traditional type of aesthetics.

Figure 4 shows a progressive shift from the first moment of observing a landscape when sensory information is paramount, to the time when we have assimilated this with our knowledge, beliefs and cultural conditioning. The steps progress through a formal stage, by which is meant a discovery of the form, and patterns and underlying structure of the scene, to a stage where we consciously or unconsciously try to come to terms with and understand what we observe, reconciling our pre-existing knowledge with our new perceptions. Finally, in this model, we apply associations to what we observe; these may be meanings or values. However, in reality the actual experience is unlikely to occur in precisely this order and most viewers are unlikely to be aware of these stages. Several authors point to a 2 stage response where the first immediate impression is involuntary and then there is a considered appraisal stage (Purcell 1986, Harvey *et al* in press). In the framework presented in this paper the 4 stages can be deemed to be subdivisions of the second stage of Purcell.

Different people place emphasis on different aspects. Foster emphasizes the initial sensory input (Foster 1992), while I have concentrated on the formal aesthetic (Bell 1993, 1999). Carlson has emphasized the role of knowledge (Carlson and Sadler 1982) and the historian Schama has focussed on the symbolic (Schama 1995). However, each of these types of response can be linked further to other work, particularly in the field of perception psychology (Fig. 5).

Figure 5 shows how each of the stages of response are directly linked to previous or ongoing research. The sensory aesthetic championed by Foster finds links with environmental psychology where some researchers seek universal preferences or responses to certain types of environment as a result of our evolution as a species. Some have suggested that open savannah-like landscapes are such a type as a result of human evolution in such landscapes in east Africa. The psychology and to some extent physiology of perception have pointed to evidence that we seek out and try to understand our environment in terms of patterns. This has been most developed in terms of visual perception by Marr (Marr 1982) and his "primal sketch theory" where he tries to explain how images are processed in the brain so that we form an understanding of the real structure of our environment. Gestalt psychology has been successful in describing many key attributes of how we understand and react to patterns (Kohler 1947). It is not a big step to see that we might respond positively to certain types of pattern because they are easy to understand compared with others. The Kaplans have concluded that coherence and legibility are key features of all attractive landscapes (Kaplan 1988).

The expressive aesthetic has been explained in various ways. Both Kant and Schopenhauer considered the role of knowledge. Schopenhauer considered the presence or absence of the "will" in our aesthetic experience. The psychologist J. J. Gibson developed a theory of "affordance" where we perceive our surroundings in a structured way, looking for what the environment affords us in a utilitarian sense. Carlson is most insistent that knowledge is vital for the aesthetic experience.

An aspect that is of particular concern to forestry aesthetics is that of "deep time", a sense and appreciation of the longevity of the landscape. Rolston has developed this theory and it can be seen to apply to trees and ecosystems whose life spans are many times that of humans. During the internal critical debate that is part of the expressive aesthetic the sense of time and our relationship to the landscape can be a profound element.

Figure 4. Elaboration of the Nature of Aesthetic Response (1)

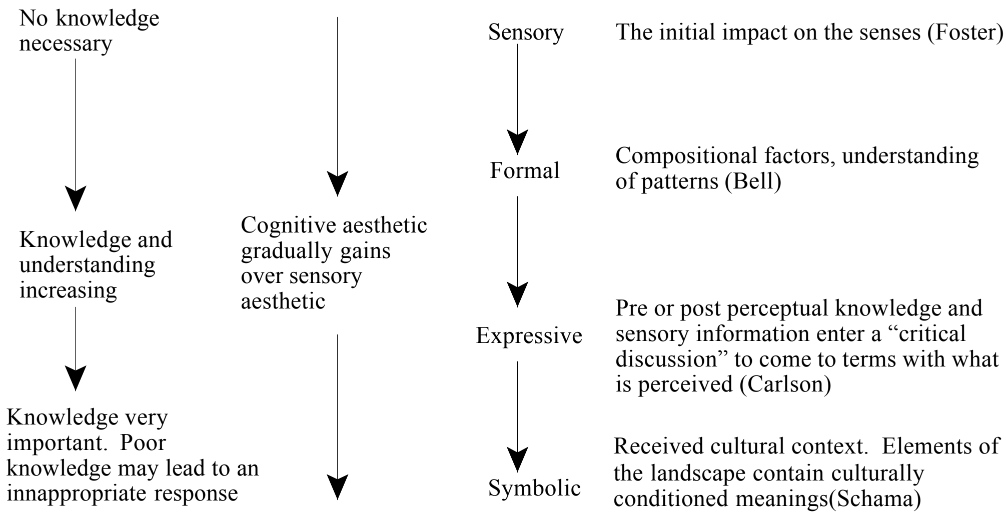

Figure 5. Elaboration of the Nature of Aesthetic Response (2)

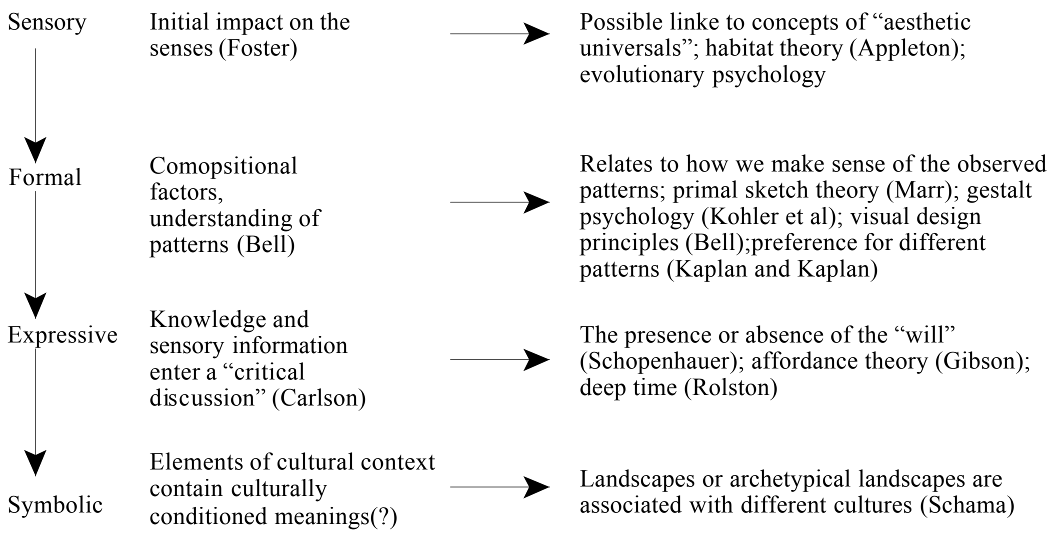

Cultural symbolism and landscape has been powerfully demonstrated by the historian Schama who has examined forests one of several archetypal landscapes (Schama 1995). Other cultural geographers and archeologists point to similar examples. Work on fear of forests in the UK by Burgess has demonstrated that forests act as a repository for various fears that remain deeply rooted in society (Countryside Commission 1995). Symbolism can operate in other ways, for example geometric patterns in forests represent man-made intrusion and symbolise something bad, whereas naturalness is equated with goodness.

Application of this Framework to Forests

Forests still cover significant areas of the globe and, in countries where populations have become urbanised and divorced from the land, forests represent, or symbolise, wildness and the means to escape from the stresses of city life. Wilderness is a powerful concept but to have any real utility wild places must be readily accessible. Hence urban forests have an important role to play in providing a means of escape for urban populations, but only as long as they actually contain the potential for a deep aesthetic experience amongst the other possible experiences (recreation, exercise, watching wildlife etc).

If what Berleant says is true, that the quality of the environment has a direct effect on the quality of life, then while forests *per se* may provide benefits merely by their presence, the aesthetic content depends on their characteristics (layout, size, species, structure, degree of naturalness etc) and how well they fulfill the 4 types of aesthetic response (sensory, formal, expressive and symbolic). Complications arise because many large urban centres contain multi-ethnic, multi-cultural populations who are split into a number of different types of community. If urban forests are to satisfy as many people as possible they need to relate to the different ethnic, cultural and social backgrounds. Clearly, approaches to planning, design and management that derive from one single forestry or design tradition are likely to fail. Hence there is a need to explore a variety of aspects relating to preferences for forest landscapes that are generic or cross-cultural.

Within the over-arching context of sustainable management of forests, urban forests must fulfill their role. However, little is really known of the aesthetic implications of many sustainable management practices, such as mimicking or emulating disturbance patterns, or, for that matter, the long term ecological implications of certain practices carried out for "aesthetic" reasons (such as preserving old trees, retaining screens to hide cutting along roadsides, tidying dead wood).

The power of cultural symbolism in landscape can lead to situations where what people are willing to accept as landscape change (manifested as a range of forestry practices) is not conditioned by knowledge of the possibilities contained within a given situation, but by preconceived notions, some of which may be based on erroneous information. Well meaning "eco-warrior" tactics to save trees from development may overlook other significant reasons why the loss of such trees is acceptable in the longer term. This is where aesthetics and ethics start to blend together. Concepts such as equating truth with beauty blur the distinction.

These scenarios suggest several important themes for research aimed at improving the planning, design and management or urban forests. These themes emerge directly from the framework described above but have, in some cases, important linkages to other areas of research. These links, if they currently exist at all are likely to be weak. Most of these themes apply equally to the traditional, distant means of aesthetic response and the participatory, multisensory aesthetic of engagement. However, much of the existing work has concentrated on the scenic mode, so that there is probably more mileage to be obtained from exploring the participatory mode further. These research themes are structured around the 4 types of aesthetic response.

The Sensory

This response is based on the immediate sensory impact and has been linked, in the framework, to the potential to find certain aesthetic universals. Research here should concentrate on the developments arising from evolutionary and environmental psychology to explore how far such generic or cross-cultural preferences can be discovered. This is needed due to the multi-cultural condition of most large urban centres today.

A secondary link is with landscape ecology, where studies of ecological patterns and processes for sustainable ecological management of forests is one focus of research. If at some point the human ecology of forest use can be incorporated more fully, using the output of research outlined above, this will better ensure that conflicts between management objectives can be reduced.

The Formal

Approaches to forest landscape planning, design and management have concentrated on the scenic mode, applying formal design principles to larger scale "exterior" forest landscapes. Such approaches, pioneered in Britain and the US have been empirically based and only tested in limited circumstances. These principles represent the modification of those used in architecture and other fields of applied design. They are often used to promote a certain style of design and to some extent this is also true in forestry, where these principles are used, successfully, to develop "natural appearing" plantation forests (Forestry Commission *ibid,* Lucas 1991).

This use of formal design principles is of interest to designers of urban forests, faced perhaps with planting a new forest from scratch, where the kind of layout, species composition and internal structure must be legible, convey certain qualities to the intended users and offer the greatest aesthetic potential. Research here therefore should concentrate on aspects of pattern reading and understanding, "spatial syntax" and internal navigation of forest landscapes, using techniques developed in environmental psychology.

A secondary link here is with the research into aesthetic universals outlined above, ensuring that the results are converted into practical design tools.

An alternative way is to use the principles to understand the sensory (primarily visual) expression of landscape pattern and how they have evolved, leading to a design approach based on working with the landscape (Bell 1999).

The major research issue here is to develop better means of incorporating human perceptions and needs with the landscape ecological models developing for natural patterns and processes. These models, using geographic information systems, dynamic process models and alternative, probabilistic scenario development, do not yet incorporate sufficient human "habitat" requirements. These requirements need to be described and analysed so that they can properly be taken into account.

The Expressive

This type of response is where the sensory information is mixed with knowledge. At present there is a large body of work on landscape preferences, some of which has examined the differences between people who know about how the landscape has arisen and those who do not. The importance to the aesthetic response of other factors in the reasons people visit or use forests has not been explored, for example if people regularly use such forests for berry and mushroom picking to supplement their diet, is their response different? Research into this area is needed in order to help understand the range of ways people interact with forests, an important area of knowledge when public participation is becoming a key aspect of forestry planning, particularly in, for example, the development of so called community forests. It is another field for environmental psychology.

A secondary aspect here concerns the sense of time inherent in forests. Tree lives often cover several human generations and project a sense of continuity with the past (Rolston's "deep time"). However, modern forest management often curtails that span and, in the urban situation, old trees are often removed for safety reasons. Since this sense of age is a significant aspect of forests and time is an element of our expressive aesthetic (the internal, subconscious discussion to come to terms with what we perceive) this subject deserves further study.

The Symbolic

Earlier in this paper a brief mention was made of the links between aesthetics and ethics. Not enough is known of the ways in which knowledge, ethics and cultural norms are created that lead to the adoption by individuals, communities or whole societies of certain strongly held ethical positions. It would seem that many of the problems of acceptability of various types of forest management hinge on the relationship between professional planners, designers and managers to various levels of communities. This is an area where psychology and philosophy need to work together.

A secondary link here is with applied landscape ecology and the emerging search for an "ecological aesthetic". This could be important for working towards sustainable management and the development of models of management that try to allow for less than tidy, manicured urban forests.

Conclusions

In this paper a framework has been presented that brings together many superficially different elements of theory and practice that, to the uninitiated, seem confusing and contradictory. This framework demonstrates that it is possible to see a much bigger, coherent structure that leads towards a well-defined set of research directions. These directions can be applicable to many aspects of forestry. However, given the growing importance of urban forestry and the issue of dealing increasingly with urban communities who are not part of the land using population, these research topics become more important. Some of this research is already underway in a number of countries. What is needed now is a better network of interdisciplinary workers to exchange information and ideas.

Long Term Nutrient Budgets in Forests: Lessons from Chronosequence Studies.

Abstract:

Variations in nutrient budgets with forest age are compared in two chronosequence studies of conifer plantations. Over the rotation, nutrient budgets are negative at both sites, but the variation with stand age is quite different in relation to soil fertility, stand health and past land use. These variations with stand age demonstrate the need for such studies for forcasting long term soil fertility changes in forests.

Keywords: Forest age, Nutrient cycling, Deposition, Leaching, Budgets

Introduction

Flux budgets in ecosystems are needed both for basic understanding of ecosystem function and for feeding applied models of sustainable management.

Changes of soil fertility associated with forest management are difficult to evaluate due to the combination of both the high spatial variability of soil properties, and the variations of nutrient pools and fluxes across the forest rotation. For this reason it is necessary to have information on the spatial variability of studied parameters and on the dynamics of the system during the the main phases of the stand development including the harvesting and regeneration stages.
Three main approches are generally used:

The diachronic approach consist in observing the same ecosystem during the whole of the rotation time. This method is the most interesting in short rotation forestry, because the whole rotation can be covered, while it is not suitable in classical forestry, where rotation times may reach several hundred years.

Among the synchronic approaches, two main possibilities are offered.

Flux budgets in a chronosequence of stands which represent the main stages of development of a single stand. The major difficulty consist in selecting sites where the only difference is the stand age. All other parameters need to be constant *e.g.* tree species and provenance, past land use, soils, climatic and pollution context. If not, it is of paramount importance to connect the results to the theoretical dynamics of the ecosystem, which is unfortunately unknown and which can vary with time according to systematic constraints. The advantage of this method is that it provides insight in the functional links between changes in fertility and ecological factors.

The statistical comparison of soil properties in a large set of stands is the most often and traditionally used approach (Page 1968). It provides quicker answers than the former method, but does not link changes and assumed causes.

Here, we present two case-studies of flux budgets in chronosequences of productive coniferous plantations, representative of the medium mountain situations in France. The objectives were to measure rotation weighted budgets of soil nutrients and to analyse the main causes for changes in order to give practical recommendations for sustainable management of forests. Results are discussed and compared with data from the literature.

Material and Methods

Sites

- the Aubure chronsosequence is composed of three Norway spruce stands aged 15 (S15), 35 (S35) and 85-year old (S85) in 1988. It is situated in the Vosges mountains at an elevation of about 1100m. Stands are located side by side, on the upper southern facing slope of the Strengbach catchment (Probst et al., 1990). The climate is characterized by a mean annual rainfall of 1400 mm and a mean annual temperature of 6°C. The stands are either a first (S15 and S35) or a second rotation of Norway spruce planted on a former fir forest, that was partly grazzed. The soils have developed from the Brézouard granite, very poor in Ca and Mg. Soil types vary from Alocrisol (S90) to Podzosol (S15), but spatial variability is high. Soils are coarse-textured, strongly acid and desaturated, with a very limited available pool of nutrient (Table II). Texture is slightly richer in clay in S90 than in S15 and S45, because of the influence of a local outcrop of gneiss. Wood production is 22 m^2 $ha^{-1}yr^{-1}$ in S35 and 7 m^2 $ha^{-1}yr^{-1}$ in S85. Needle nutrient content is low at S15 but trees are not deficient. Needle Ca content is very low at S35 and trees are yellow due to Mg deficiency. Needle N contents are higher in S85 but Ca and Mg are very low (Table I).

- the Vauxrenard chronosequence, composed of three Douglas-fir stands 25, 45 and 65-year old, is situated on the Beaujolais Mounts, at an elevation of 750m. The climate is characterized by a mean annual rainfall of 1000 mm and a mean annual temperature of 7°C. Douglas fir plantations were established on previously cultivated land. The rock is a Visean consolidated volcanic tuf, rich in Ca. The soil is a typical Alocrisol, acidic and desaturated. Soil caracteristics are given in Table II. Wood production is 7, 17 and 15 m3 ha-1 yr-1 in D25, D45 and D65 respectively. Trees are healthy and needle nutrient contents are adequate (Marques 1996).

Methods

Inputs of nutrients by atmospheric deposition and outputs in drainage were measured in each stand for generally 3 years.

- Atmospherical deposits were estimated from monthly rainfall and throughfall measurements. At both sites, Na or SO_4 in net throughfall were supposed to derive only from dry deposition. Base cation dry deposition was calculated assuming that the base cation to Na ratios in rain and dry deposition were similar. Dry deposition of N was calculated assuming that NH_4 and NO_3 to SO_4 ratios in rain and dry deposition were similar. Additional studies at Aubure have shown that these assumptions were reasonable (Dambrine et al., 1998, Ignatova and Dambrine 2000).

- Drainage below the rooting zone was quantified from the concentration of elements in soil solution collected by zero-tension plate lysimeters (Probst et al., 1990, Marques 1996) and water flux estimated from a soil water model calibrated for the sites by climatic data and soil water retention curves (Biron 1994; Marques et al., 1997)).

- Biomass and stand nutrient content were quantified using a destructive sampling of 3 (S15), 10 (S35), 12 (D25, D45, D65) and 15 (S85) trees per stand. Regressions between biomass, nutrient content and tree DBH established from these samples were than applied to the stand inventory. Nutrient uptake and immobilization according to tree compartments were calculated for each stand (Le Goaster et al., 1991, Ranger et al., 1995). At each site, the nutrients removed in harvested biomass over the complete rotation were obtained by adding to the amount of nutrients in the standing wood biomass of the older stand, the amounts of nutrients removed during the clearings.

- Nutrients originated from the weathering of soil minerals were estimated using different methods: the average historical rate of release of base cations was computed from the vertical variations of the amonts of base cations, Si and Zr. The current rate was calculated using the Profile model (Sverdrup and Warfvinge, 1988). Input parameters were quantitative soil mineralogy, localization of nutrients in the mineral structures, processes of mineral transformation, soil exchangeable phase and solutions characteristics (Fichter et al., 1998 ; Ezzaïm et al., 1999). The weathering flux was considered constant during the rotation time.

Results and Discussion

Table 3 shows the mean annual weighted fluxes of nutrients and budgets in each stand as well as the rotation weighted budgets for the two chronosequences. Open field precipitation brings about 8, 3, 0.6 and 2 kg ha^{-1} yr^{1} of N, Ca, Mg and K respectively. Throughfall N, Ca and Mg increase with stand age. The increase of N in throughfall with stand age is related at Vauxrenard to a higher foliar uptake of N in young stands, while total deposition remains stable. At Aubure, where the stands are close to the mountain ridge and are submitted to frequent wind, this increase is also related to an increase of dry deposition with the development of the canopies (Ignatova and Dambrine 2000). At both sites the increase in throughfall Ca and Mg with stand age seems mainly related to an increase of deposition. Over the whole of the rotation, N deposition is much higher than N requirements for stand growth, while Ca and Mg deposition are closer to stand requirements. Although the contents of Ca and Mg of the rocks differ considerably between the two sites, the mineralogy of the soils is rather similar and poor in weatherable minerals: the clay fraction is dominated by illites and Al-interlayered vermiculites (HIV) and smectites (Aubure). Minor amounts of apatite and albite in the silt fraction are the only sources of Ca. Combining measured Ca, Mg, K and Na fluxes in soil solution, detailed mineralogy and modelling provides a Ca flux lower than 1 kg ha^{-1} yr^{-1}. Weathering of illites or/and smectites from the silt and clay fractions provides about 0.8-1 kg ha^{-1} yr^{-1} of Mg, but a rather large flux of K (6-8 kg ha^{-1} yr^{-1}). The uncertainty in the weathering fluxes are in the range of ±0.5kg for Ca, ± 0.2kg for Mg, and ±2 kg for K.

Growth is much higher at Vauxrenard than at Aubure in relation to tree species and climate. Hence nutrient immobilisation is higher at Vauxrenard. Immobilisation of most nutrients in wood is the highest at mean current increment (MCI). The lowest rate are obtained at Aubure in S85, in relation to the age and bad health of the trees.

Drainage of N, Ca and Mg is much higher at Vauxrenard than at Aubure. Nitrate drainage is the highest at D25 (39 kg N) and decrease continuously to low values (6 kg ha^{-1} yr^{-1} N) at D65. Ca, Mg and K drainage follow the same trend which shows the driving role of nitrate drainage for base cation drainage. We hypothetize that this high nitrate drainage at Vauxrenard reflects the high N mineralization and nitrification potential of formerly cultivated soils and the availability of a labile organic matter pool previously accumulated in the soil when it was cultivated (Jussy 1998). Similar high nitrate drainage was obtained by Mohamed and Ranger (1994) in a mature healthy productive spruce forest planted on formerly cultivated land. Nitrate drainage below the young stands is very low at Aubure. This results from both a very poor nitrification potential in the soil and the uptake of most of the deposited N by the growing stands. N drainage increases strongly in S85 as a result of its poor health and low growth requirements while the deposition is the highest. High leaching of nitrate below declining stands has been demonstrated at many sites.

Base cation drainage is the lowest in S35, when growth is the highest. Base cation concentrations in soil solutions decrease strongly between -5 and -30 cm depth, in relation to root uptake (Dambrine et al., 1992). Base cation drainage is higher at S15, while N drainage is very low and soil solution pH is relatively high (close to 5) in comparison to the other stands (closer to 4.5). As soil minerals are even poorer at this site than at S35, weathering should not be responsible for this flux. This base cation flux in soil solutions might be attributed to the mineralization of the slash from the previous harvest. Base cation and nitrate drainage are the highest in S85.

Across the rotation time, the Vauxrenard plantation on formerly cultivated land continuously loses nutrients but the rate of loss decreases with stand age. Hence, the rotation budget may become equilibrated during the next rotation, except possibly for Ca, which is still curently lost in the older stand. In comparison, over the whole of the rotation, the spruce soil at Aubure loses Ca and accumulates N, while the Mg and K budgets (given the uncertainties) are almost equilibrated. The Mg balance could be expected given the extremely low amounts of exchangeable Mg, but successive soil exchangeable measurements confirmed a current loss (Dambrine et al., 1999). Budget values are questionable as they rely on a number of hypothesis. Deposition is the most uncertain data. The N deposition values used may be overestimated. Using Throughfall N as input, the budgets are still negative at Vauxrenard, but become equilibrated at Aubure. Using throughfall Ca as input, Ca budgets are still negative at both sites and it is unlikely that weathering could compensate the deficit because total Ca amounts in the soils are very low.

Hence, nutrient budgets across the two chronosequence differ widely (Figure 1): Although at Vaurenard, nutrients are lost at a high rate, budgets tend to an equilibrium, which may be reached during the next rotation. On the opposite, at Aubure, N accumulates and Ca is lost continuously during the rotation (Dambrine et al., 1999).

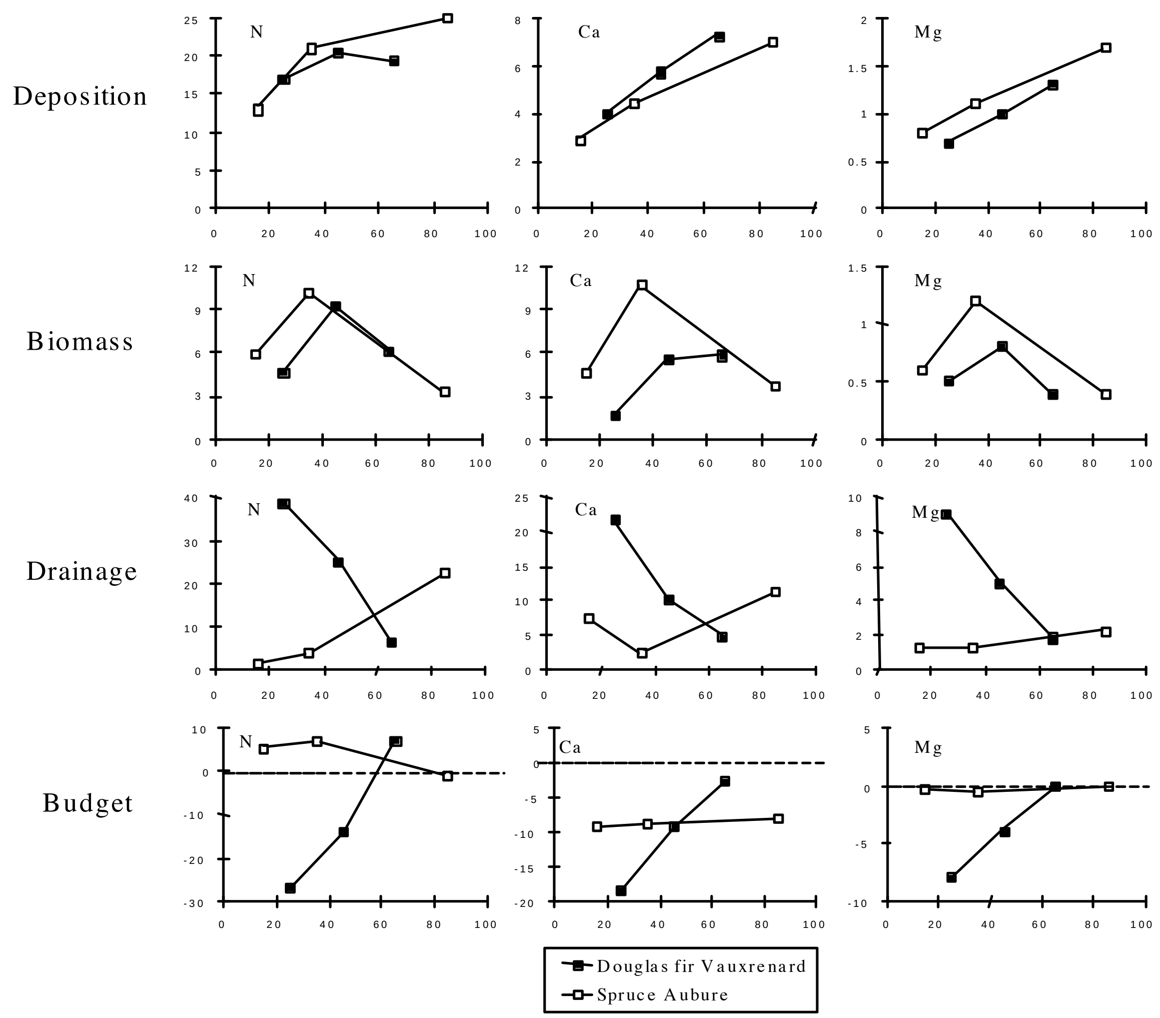

Figure 1: Variations of mineral fluxes and budgets with forest

Comparison with Other Studies

A number of chronosequence studies have been published but rather few offer complete nutrient budgets. There is a general agreement on the increase of base cation, sulfur and nitrogen amounts in throughfall with stand age (Stevens 1987, Helmisaari 1995, Carleton and Kavanagh 1990). This variation with stand age is attributed either to an increase in deposition with the development of the canopy, or to a reduction of N foliar uptake (but the opposite was observed by Carleton and Kavanagh 1990), and/or to an increase of foliar leaching. Nutrient immobilization in wood varies mainly with stand growth and can be derived from growth curves and average wood concentrations. Nutrient drainage increases strongly with stand age in 5 chronosequences of Sitka spruce on former unimproved grasslands in Wales (Hugues et al., 1994). The main cause was the increase in dry and occult deposition of sea salts, nitrogen and sulfur with stand age. Past land use by agriculture and ploughing before plantation was suspected causes for nitrate losses, but N drainage increased with stand age, in contradiction to the Vauxrenard chronosequence. The contradiction may be related to the higher fertility status of the soil at Vauxrenard, in comparison to the Wales. In a chronosequence of Scotts pine in Finland, Helmisaari (1995) measured a strong increase in sulfate and base cation drainage in the older stand, but causes were unclear.

Conclusion

From the results presented here, it appears that one should not expect one single variation in nutrient budget with stand age, but various evolutions in relation to the main ecological factors such as climate, deposition and deposition history (Schaaf et al., 1998), soil fertility, stand health and past land use. Budget variations with stand age highlights the need for such studies for forcasting long term soil fertility changes in forests, but also the difficulties associated to this approach.

Abstract

The development of pine ecosystems was studied at 2 - 60 years old mine spoils on two typical substrates of the lignite mining area of Lusatia/Germany in a "false-time series" approach. Pyrite contents of varying amounts in the original overburden material can result in extremely phytotoxic site conditions. Soil solutions are often characterized by low pH, high electrical conductivities and high element concentrations. Reclamation of these sites was traditionally carried out using large amounts of bottom or fly ash from lignite power plants.

The temporal development of soil solution composition along the "false-time series" can be explained as a combined effect of intensive weathering of primary minerals including pyrite oxidation, transformation and precipitation of secondary salt and mineral phases, and leaching of salts. Additionally, ash amelioration affects soil chemical properties at least in the topsoils. The element outputs from the systems on pyritic substrates can reach extraordinary high amounts and are manifold increased to comparable sites on natural soils of the region. The chronosequence approach to study post-mining sites has proven to be a very useful tool to identify dominating processes on the ecosystem level.

Keywords: Element budgets, Leaching, *Pinus sylvestris* L., *Pinus nigra* Arnold, Pyrite oxidation, Reclamation, Secondary minerals, Soil solution chemistry

Introduction

In Lusatia, an area of more than 77,000 ha is affected by open-cast lignite-mining activities (Drebenstedt, 1998, Hüttl, 1998). Prior to mining, forestry was the dominating land use in the region. In the post-mining landscapes two main types of substrates can be identified: lignite- and pyrite-containing substrates stemming from Tertiary sediments and lignite- and pyrite-free substrates from Quaternary sediments. The majority of these substrates are pure sands and loamy sands. Due to the mining technology using overburden-conveyer bridges (Häge 1996) about 60 % of the land surface today consist of at least partially lignite- and pyrite-containing substrates and are characterized by low nutrient content and poor water retention capacity (Katzur 1998).

The pyrite content in these substrates exposed to the atmosphere leads to a high potential for acid production and consequently very phytotoxic site conditions. To reclaim or recultivate these sites, high amounts of ashes from lignite power plants were used for amelioration and neutralization of actual and potential acidity (Katzur and Haubold-Rosar 1996). Since reclamation measures lagged behind mining activities during GDR times, an area of about 30,000 ha remains for recultivation. In this context, "recultivation" is defined as supporting "the development of the soils, the vegetation, the wildlife, the water balance and water quality in order to allow future land uses such as agriculture and forestry" (Hüttl 1998). Due to the poor substrates forestry is also the dominating land use in the post-mining landscape covering about 60 % of the area (Preußner 1998). Main tree species are pine (*Pinus sylvestris* L. and *Pinus nigra* Arnold) followed by oak (*Quercus rubra* L. and *Quercus petraea* Matt.) with 54 % and 16 % of the forested area, respectively (Preußner 1998). These forest ecosystems virtually start very close to the "point zero" of development, especially with regard to soil development, plant-soil interactions, and establishment of biogeochemical cycles.

To study the ecosystem development, a chronosequence approach with several pine stands on different mine spoil substrates of different ages was used (Hüttl *et al.* 1999). Water and element fluxes in different ecosystem compartments along these "false time series" were measured, analyzed with respect to differences between substrates, and compared to pine ecosystems on non-mined sites of the region. The main objectives were to identify the dominating processes and temporal trends in ecosystem development and to use flux budgets as an indicator of ecosystem functioning.

Materials and Methods

Seven sites on comparable substrate representing the two prevailing site types were chosen as chronosequences covering periods of up to 60 years of development (Table 1). The lignite- and pyrite-containing substrates (LPCS) were ameliorated with different amounts of lignite ash depending on their calculated potential lime requirements (Katzur 1998). The different incorporation depths represent the available technology at the time. The lignite- and pyrite-free substrates (LPFS) were either left unameliorated or had been limed. All sites received an initial mineral NPK-fertilization before afforestation. For comparison, element cycling data from a 45-year old Scots pine stand on non-mined glacial outwash sands (Spodi-dystric Cambisol) were used (site name: TA; for detailed description see Schaaf *et. al.*, 1995 and 1999b)

Soil samples from different depths were taken at five points within each site and analyzed for pH (1:2.5 water extract), total carbon (C_T), nitrogen (N_T), and sulfur (S_t) content (LECO – CNS analyzer). Effective cation exchange capacity (CEC) was determined with an unbuffered $BaCl_2$ exchange solution based on the original method of Mehlich (1942) modified as a percolation procedure (Meiwes *et al.* 1984) and included specially adapted leaching steps to remove easily soluble salts. Amorphous and crystalline iron and aluminium oxides and hydroxides were determined using the oxalate (Fe_o, Al_o) and dithionite (Fe_d, Al_d) extraction methods (Blume and Schwertmann, 1969).

All sites were intensively instrumented for water and element flux measurements with meteorological stations, bulk and throughfall samplers (10 each), ceramic suction cups (P80 material) for soil solution sampling in 2 - 4 soil depths (6 cups per depth), pressure transducer tensiometers (5 per depth) and TDR/FDR probes (2 per depth) for continuous registration of soil tension and volumetric water content.

The solutions were usually sampled every two weeks and analyzed for pH (Beckmann pH34 glass electrode), electrical conductivity (Hanna HI 8733), main cations (Unicam 701 AAS and Unicam 939 ICP-AES) and anions (Dionex 500 and 120 IC), NH_4-N (Flow Solution Alpkem 301), and dissolved organic carbon (DOC; Shimadzu TOC 5000 Analyzer). Sampling period was 01/1996 – 04/1998 for the LPCS-sites and 04/1996 – 10/1998 for the LPFS-sites.

Daily meteorological data (air temperature, relative air humidity, wind speed, global radiation, and precipitation) were used as driving variables for a one-dimensional soil water model (SOIL, Jansson 1994). The model was parameterized with soil physical data, stand data (root depth distribution, tree height, leaf area index) and calibrated with measured tension data for each site. Simulated soil water fluxes were multiplied with measured soil solution concentrations for each sampling interval to calculate element fluxes.

Results

The geochemistry of the substrate types is very different as reflected in soil solution compositions. Gast *et al.* (2000), Schaaf et al. (1998), and Wilden *et al.* (1999, 2000) described and discussed soil solution chemistry of the sites in detail. Ion pairs and complexes play an important role in highly concentrated solutions (Knoche *et al.* 1999; Schaaf, 1999a), therefore the values given here are total element concentrations.

(for detailed site descriptions s. Hüttl *et al*., 1999 and Schaaf *et al*., 1999a)	

At the LPCS-sites the solutions show high concentrations with electrical conductivities (EC) up to 16 mS cm^{-1}. pH values vary from 4.3 - 5.5 in ameliorated topsoils down to 2.3 – 3.3 in the subsoils (1,0 – 1,3 m depth).

Dominating mean element concentrations are calcium (up to 12.5 mmol Ca_T L^{-1}), magnesium (up to 13 mmol Mg_T L^{-1}), aluminium (up to 105 mmol Al_T L^{-1}), iron (up to 50 mmol Fe_T L^{-1}), and sulfate (up to 160 mmol SO_{4T} L^{-1}).

With increasing site age these high values decrease and clear depth gradients are observed with higher concentrations in the subsoils (Schaaf *et al*., 1998). After amelioration and the induced pH increases in the topsoils especially, Al_T and Fe_T concentrations are reduced considerably. Despite high total carbon contents due to lignite in the substrate, the DOC concentrations are relatively low (10 – 30 mg L^{-1}). Elevated values up to 100 mg DOC L^{-1} paralleled by high ammonium concentrations (up to 2.5 mmol NH_{4T} L^{-1}) were found in extremely acid layers (pH 2.2).

At the LPFS-sites the mean total elemental concentrations are manifold lower compared to LPCS-sites. Mean pH values are 4.0 – 6.6, and EC varies between 0.2 and 1.0 mS cm^{-1} (Schaaf *et al.*, 1998). Soil solution composition is dominated by calcium and sulfate at these sites also , but at very much lower levels (0.5 – 3.8 mmol Ca_T L^{-1} and 0.5 – 5.6 mmol SO_{4T} L^{-1}). Due to the higher pH, aluminium and iron concentrations are below 10 ?mol L^{-1}. Only the youngest site (SB) shows higher concentrations than the two older LPFS-sites. No clear depth gradients can be identified in the soil profiles.

The substrates also differ in a number of other important soil chemical parameters. The lignite content results in higher C_T and N_T contents in the LPCS-sites compared to the LPFS-sites (Table 2).

The higher lignite contents of the LPCS also increases the cation exchange capacity (CEC) of the sandy substrates, with CEC values 10- to 30-fold higher than both the LPFS-sites and the non-mined site (Table 2). Iron and Al contents, as determined by oxalate and dithionite extraction, were clearly elevated also throughout the profiles.The Fe_o and Fe_d values especially were 2- to 5-fold higher even when compared to the contents found in the Bhs horizon of the Cambisol. The low values at the LPFS-sites are comparable to those found for the BC horizon of the non-mined site and are characteristic of low weathering and early stages of pedogenic processes.

Generally, the element input rates with bulk deposition show no significant differences between the investigated sites. Differences between bulk and throughfall deposition are mainly due to differences in water fluxes (interception losses) except for nitrogen where there were indications of N uptake in the canopies of dense stands (about 20 years of age) and potassium which is typically leached in considerable amounts from the needles (Gast et al., 2000). Aluminium and Fe input rates were negligible, with concentrations in precipitation samples are often below 5 mol L^{-1}.

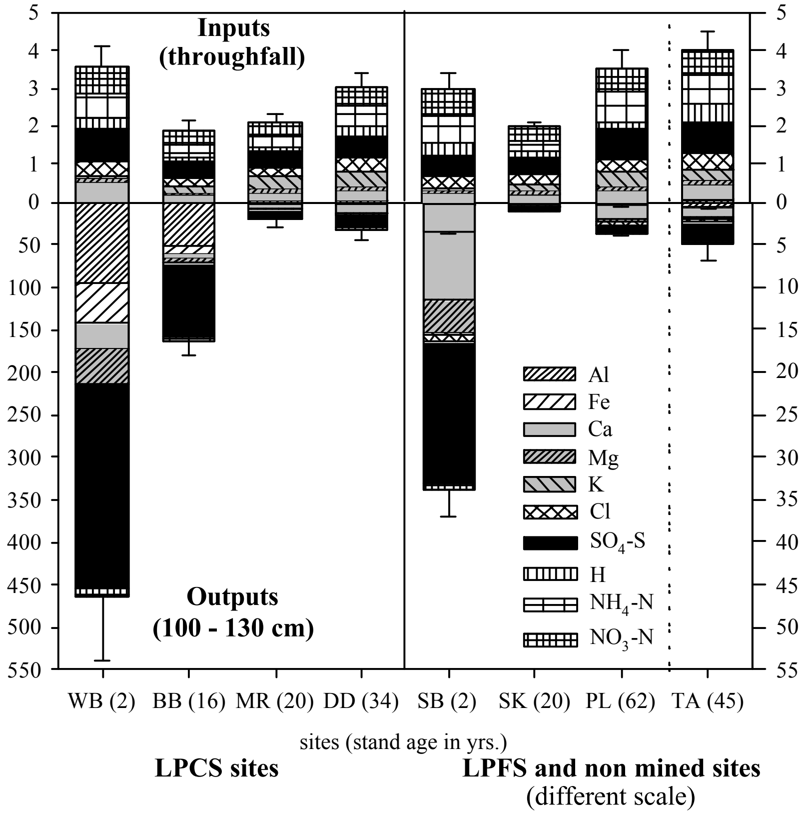
However, these similarities disappear abruptly as soon as soil fluxes are considered. Despite the low water fluxes through the soil profiles, very high element fluxes are calculated for the LPCS-sites as a consequence of the high soil solution concentrations. Output fluxes are generally 10 times higher at the LPCS-sites compared to the LPFS-sites and the non-mined site.

Calcium fluxes in the soil show two trends: the fluxes from the topsoils at the LPCS-sites (ameliorated layers) decline with site age whereas the outputs from the subsoils reflect the amount of water fluxes quite well (Fig. 1). Despite the high fluxes, the Ca outputs (up to 30 kmol Ca $ha^{-1}yr^{-1}$) are generally below 1% of the total stores within the substrates. At the LPFS-sites, Ca outputs are only elevated at the youngest site SB. At the older sites the fluxes are at levels comparable to the non-mined site (TA). Although the Ca budgets are negative for all sites, outputs at the sites SK, PL and TA are much closer to the level of actual inputs compared to all LPCS-sites.

The S fluxes in the soils show a similar pattern. LPCS-sites are characterized by extremely high S outputs up to >200 kmol $ha^{-1}yr^{-1}$ (Fig. 1). Despite decreasing water fluxes, the S fluxes are increasing with soil depth. At the youngest site (WB) S outputs are more than 300-fold above actual deposition inputs. These figures decrease with site age, but at the oldest site (DD) the outputs are still 25-fold above inputs. The S budget is also negative at all LPFS-sites (especially at SB) and at the non-mined site (TA), but on much lower levels. For both Ca and S the budget data of the oldest LPCS-site is very similar to the youngest site on LPFS despite large differences in water fluxes. The differences between the two substrates are even larger for Al and Fe. Both the LPFS-sites and TA show very low input and output fluxes for both elements due to low concentrations that are often below the detection limit. In contrast, Al and Fe fluxes at the LPCS-sites can reach extremely high amounts at the younger sites (up to 95 kmol Al $ha^{-1}yr^{-1}$ and 50 kmol Fe $ha^{-1}yr^{-1}$). Iron fluxes decline very rapidly with site age, especially in the ameliorated topsoils, whereas Al outputs are elevated at the two youngest sites WB and BB. Aluminium fluxes from the topsoils of the older sites show reductions similar to Fe and from the subsoils they are comparable to the non-mined site (TA).

Nitrogen budgets show interesting differences between the sites. In deposition inputs, inorganic N is found in almost equivalent amounts as NH_4-N and NO_3-N at all sites. Generally, N outputs are well below inputs, and at some sites almost zero (Fig. 1). With two exceptions, the dominating $N_{inorg.}$-form in soil solution at all sites is NO_3 (usually > 90 % of $N_{inorg.}$). Elevated NH_4 fluxes from the subsoils (2.4 – 3.4 kmol NH_4-N $ha^{-1}yr^{-1}$) that exceed deposition rates are found only at the younger LPCS-sites. At the site DD, high NO_3 fluxes are detected, especially in the topsoil (1.7 kmol NO_3-N $ha^{-1}yr^{-1}$), resulting in N outputs at the level of deposition inputs.

Figure 1: Budgets of the major elements at the chronosequence sites on lignite and pyrite containing substrates (LPFS-sites: WB – BB – MR – DD), on lignite and pyrite free substrates (LPFS-sites: SB – SK – PL), and at a non-mined site (TA); Inputs: throughfall deposition, except at WB and SB: bulk deposition; Outputs: fluxes in 1,0 m (BB, MR, DD, SK, PL, and TA) or 1,3 m (WB and SB) soil depth; all fluxes are mean values of 2 years in kmol ha^{-1} yr^{-1} (but note different scales), error bars indicate variation between single years



Discussion

The high element concentrations in soil solutions from LPCS-sites are similar to those reported by Knoche *et al.* (1999) at lignite and pyrite containing sites under oak and by Katzur and Liebner (1995) in lysimeter studies with LPCS. Concentrations of comparable magnitudes are also found in soil solution samples from the mining area around Leipzig (Feldhaus and Wilczynski 1998). Low pH and high SO_4 and metal concentrations in surface and ground waters from pyritic dumps and tailings are frequently reported in literature related to acid mine drainage (Karathanasis *et al.*, 1988; Wieder, 1993; Evangelou, 1995; Miller *et al.*, 1996; Banks *et al.*, 1997; Geldenhuis and Bell, 1998).

The temporal development of soil solution composition along the ”false-time series” can be explained as a combined effect of intensive ”weathering” processes (including pyrite oxidation, transformation and precipitation processes) and leaching. Additionally, ash amelioration affects soil chemical properties, at least in the topsoils. Pyrite oxidation as the major source for Fe, SO_4, and acidity is completed within the time frame of the chronosequence as could be shown by the declining pyrite-S contents in the subsoils (Heinkele *et al.*, 1999). Intensive weathering of primary minerals within the substrates explains the high Al and Si concentrations (Gast *et al.*, 2000) and could be verified by microscopy e.g. for feldspars (Heinkele et al., 1999). In the ameliorated layers of the profile, Fe and Al precipitate in the form of oxides and hydroxides (e.g. goethite, gibbsite or copiapite) due to the elevated pH (Wisotzky, 1994; Miller, 1995; Li 1997). This is supported by the elemental composition of precipitates detected by scanning electron microscopy (Schaaf *et al*., 1999a) and explains the low Fe and Al concentrations in the topsoils. Other precipitates of secondary salt and mineral phases found at the LPCS-sites include gypsum, Fe- and Al-sulfates, and K-jarosite (Heinkele *et al*., 1999; Schaaf *et al*., 1999a). Gypsum, found at all sites and all soil depths, controls the Ca concentrations in soil solution which are frequently at the level of maximum gypsum solubility (Schaaf *et al*., 1998). Formation of gypsum as a result of pyrite oxidation and primary mineral weathering is commonly found in acid mine drainage, but also in naturally formed acid sulfate soils (van Breemen 1973; Dent, 1986; Karathansis *et al*. 1990; Evangelou, 1995; Boulet and Larocque, 1998). Sulfates like alunite, basaluminite, jurbanite or schwertmannite could also occur as possible solid phases (Bigham *et al*., 1996; Lin, 1997). This is supported by results from geochemical equilibrium modeling (Schaaf *et al*., 1999a), but could not be clearly identified by scanning electron microscopy (Heinkele *et al*., 1999). These transformation processes for Fe and Al from primary to secondary minerals is further supported by the high amounts of oxalate and dithionite soluble Fe and Al throughout the LPCS profiles.

The lower elemental concentration in soil solutions from the LPFS-chronosequence are comparable to results from oak ecosystems on mine sites derived from Quaternary sediments reported by Knoche (1998). The elevated C_T and N_T content of the LPCS-sites underline the high stability of lignite. Investigations by Rumpel *et al*. (1997) enabled the separation of pedogenic and geogenic carbon in these soils. They showed that pedogenic organic matter derived from recent litter fall contributes to C_T only in the uppermost centimeters of the profile. Although lignite decomposition is much lower compared to pedogenic organic matter due to its composition and high C/N ratio (Rumpel *et al*., 1998), it may play an important role in long-term nutrient cycling. The positive influence of lignite on (potential) CEC is reported by Katzur and Haubold-Rosar (1997). This increase is of high importance for soil ecological functions in these sandy and nutrient poor substrates. The extraordinary high CEC in the topsoil of the oldest site may be a result of the high ash amount used for amelioration. Input rates of all major elements to the soils by throughfall deposition are at the lower end of the range reported for forest sites in Germany and western Europe (cf. Dise *et al*., 1998; Feger, 1998). Differences between bulk and throughfall deposition point to important processes within the canopy, especially for nitrogen (possible uptake) and potassium (leaching).

Besides deposition inputs, litter fall contributes considerably to element cycling in forest ecosystems. Annual pine litter input increases with stand age and amounts to 1.9 - 5.2 t d.m. ha^{-1} yr^{-1} at the LPCS-sites (Dageförde et al., 2000) and 3.4 – 4.2 t d.m. ha^{-1} yr^{-1} at the LPFS-sites (Wilden, pers. comm.). This is in good agreement with the value of 4.9 t d.m. ha^{-1} yr^{-1} reported for the 45-year old reference site (TA) by Bergmann (1998). Additional litter inputs vary between 0 and 2.9 t d.m. ha^{-1} yr^{-1} depending on ground vegetation biomass (Bergmann 1998; Dageförde *et al*, 1999). These litter input rates are mainly influenced by stand age and stand density, but show no significant differences between substrate types. Total element inputs to the soil via litter are high for N (11 – 65 kg ha^{-1} yr^{-1}), Ca (12 – 45 kg ha^{-1} yr^{-1}), Mg (2 – 6 kg ha^{-1} yr^{-1}), and K (2 – 9 kg ha^{-1} yr^{-1}) [cf. Dageförde *et al*. (2000) and Wilden (pers. comm.), no data are available for both youngest chronosequence sites WB and SB]. Litter fall inputs of these nutrients are generally higher than atmospheric deposition rates and up to 3-fold higher than throughfall inputs.

Changes in the N fluxes in the topsoils indicate differences in mineralization and nitrification. Whereas at most sites both NH_4-N and NO_3-N fluxes at 0,2 m soil depth are very low, the oldest LPCS-site shows elevated nitrate fluxes resulting in an internal proton production of 1.8 kmol H^+ ha^{-1} yr^{-1} that is more than 5-fold above actual deposition input and exceeds by far all other measured proton fluxes at that site. The elevated NH_4-N outputs from the subsoils at the younger LPCS-sites can not be connected to input or topsoil processes and can only be explained by NH_4 release from lignite under very acid conditions. High NH_4 concentrations in leachates from pyritic spoils are also reported by Katzur and Liebner (1995) and Cravotta (1998). Hons and Hossner (1980) found that lignite has a high potential for NH_4 sorption. It remains to be shown whether this nitrogen originally derives from lignite or if it is only adsorbed to its surface. The same question has to be asked regarding the original source of Ca that is found in high amounts throughout all LPCS-sites in the form of gypsum that is formed after aeration of the substrate and pyrite oxidation. With regard to plant nutrition it is important that most sites on both substrate types act as a sink for N and K. Increasing amounts of both nutrients are moving within a ”small cycle” between plant uptake, growing biomass, accumulating organic surface layer, and the ameliorated topsoil as stands grow in age. However, the exception at the oldest LPCS-site (DD) with clear net N losses makes it difficult to predict future development and long-term ecosystem stability.

Conclusions

The chronosequence approach to study ”false-time series” of post-mining sites has proven to be a very useful tool to identify dominating processes at the ecosystem level. The results reveal fundamental differences of element budgets between the two substrate types due to their different geochemistry. The fluxes of almost all elements under investigation at the LPFS-sites are similar or even lower compared to a non-mined site which can be explained by low weathering rates of the dumped material consisting mainly of quartz and low atmospheric input rates. In contrast, the LPCS-sites show very high dynamics of initial development induced by substrate composition and are characterized by high element flux rates and intensive transformation processes, i.e. changes and redistribution of element pools.

Summarizing the major processes over time at these sites it is important to note that, with regard to transformation processes, the development starts before the actual mining and dumping activities. Pumping of groundwater and leveling of the groundwater table below the lignite seam leads to an aeration of the pyritic sediments resulting in initial pyrite oxidation and partial in-situ buffering of produced acidity, e.g. by feldspar weathering (Heinkele *et al*., 1999). This is important, because it shows that initial processes of transformation have already taken place when the substrate is dumped. At the well aerated dump sites the major processes are:

> Continued pyrite oxidation resulting in the release of large amount of acidity, sulfate, and iron, intensive weathering of primary minerals within the substrate releasing considerable amounts of Al, Ca, Mg or K depending on the specific mineral composition of the substrate, and precipitation of secondary salt and mineral phases like gypsum or oxides, hydroxides and sulfates of alumnium and iron. Since pyrite oxidation can be a rather fast process depending on its control by chemical or microbial oxidation, a pyrite-free zone is developing from the surface to increasing soil depths over time.
>
> Leaching of easily soluble or labile secondary salt and mineral phases like gypsum, anhydrite or epsom salt. Over time this zone develops down the profile, too, forming a zone free of pyrite and salts.
>
> Both processes are affected by the amelioration measures undertaken as a part of the recultivation practices. Large amounts of lignite ash are incorporated in the topsoils resulting in an input of high amounts of Ca and Mg, but also to a lesser extent sulfur. This introduces a large acid neutralization capacity compared to the substrate-internal buffering and also enhances formation of gypsum and other sulfate salts like $MgSO_4$ that is leached very fast in high amounts from the profiles. The raising of soil pH on the other hand induces precipitation of Fe - and Al – oxides/hydroxides.

Within the time frame of the chronosequence a trend at least in the topsoils towards ”undisturbed” conditions can be found, but for the prediction of future soil and ecosystem development there are still some important questionmarks left. First, even after complete pyrite oxidation and leaching of salts, the geochemistry of the LPCS remains quite different from LPFS-sites as well as from non-mined sites of the region. The lignite particles show a high stability and resistance to microbial or fungal decomposition. They will therefore resemble a long-term constituent of the soil with the effects discussed above. Secondary minerals may be stable or labile in further soil development. The stability of some of them, like aluminiumhydroxosulfates, is strongly pH-dependent. Reaction kinetics of amorphous forms but also of the incorporated ashes are very difficult to predict. The formation of Fe and Al oxides and hydroxides due to intensive weathering provides increased sorption capacity. Although actual base saturation is high only in the ameliorated topsoils, the potential for sorption of base cations available for plant uptake is clearly elevated compared to the LPFS-sites.

Second, to fully understand processes and to enable reliable predictions it is necessary to know the real ”zero point” of geochemistry – that is the mineral composition at the pre-mining state before ground water leveling and aeration. Finally, it should be stressed that the chronosequences are indeed ”false” time series and the approach is limited by site-induced differences like substrate composition, amounts, incorporation depths, and composition of amelioration ashes, micro-meteorological conditions, and seasonal or stand induced differences in water fluxes. A number of processes discussed above have to be investigated in more detail both in quality and quantity. In addition, despite the high dynamics that are observed especially at the LPCS-sites, the time frames of our chronosequences obviously are too short to reliably predict long-term soil and ecosystem development. However, at the very least, the chronosequence approach on an ecosystem level provides a very useful tool to find the right questions.

Abstract

The dynamics of nutrients are compared in a clonal eucalypt plantation and in a native savanna in Congo. This paper focuses on the changes of the precipitation chemistry during the transfer of solutions in both ecosystems. During the rainy and the dry seasons rainfall was on average respectively 151 mm and 7 mm per month. Chemical analyses performed during 17 months show that the concentration of all the elements in rainfall increases sharply during the dry season. Precipitation solutions are acid with a dominance of Ca^{2+} and Cl^- Throughfall and stemflow are enriched for most of the elements but a N foliar uptake was observed in both stands.

The concentration of the majority of elements increases during the transfer of the solutions through the litter. This enrichment is particularly marked for H^+ and DOC in both stands. A severe water repellency observed at the surface of the soil in the eucalypt stand increases the time of contact between the solution and the forest floor and a net uptake of Ca^{2+} is observed. In the savanna, a net uptake of $N\text{-}NH_4^+$, K^+ and Mg^{2+} is also measured. The soil solutions are collected by ceramic cups connected to a succion of -600 hPa, between the depths of 15 cm and 6 m. The concentrations of all the elements are very low in these “capillary solutions”, excepted for Si and DOC. These results show a very efficient uptake of the elements by both stands and losses by deep drainage very low in this poor ferrallitic soil.

Keywords: Eucalyptus, savanna, biogeochemical cycles, precipitation, soil solution.

Introduction

Eucalyptus species were introduced in the littoral savannas of Congo in the early fifties. A tree breeding program has been carried out since that time and highly productive varieties of 2 hybrids were developed. Since 1978, 42 000 ha of clonal plantations have therefore been set up around Pointe-Noire. Their main outlet is the production of pulpwood.

In southern Congo, savanna soils are very poor chemically. In order to assess the sustainability of the eucalypt commercial plantations, a study of biogeochemical cycles started in 1997. It is based on a model which stratifies the ecosystem into homogenous compartments linked by flows (Ranger et Bonneau 1984). The native ecosystem of savanna is compared with an adjacent mature stand of clonal eucalypt. The aim of this study is to establish nutrient budgets in both ecosystems and to assess the impact of the plantation on soil fertility. It should contribute to adapt the fertilisations to the requirements of the stands for a sustainable yield.

This paper focuses on the changes of the precipitation chemistry during the transfer of solutions in both ecosystems. Special care was taken to identify the processes contributing to the chemical composition of the solutions.

Materials and Methods

Site Characterization

Both ecosystems studied are located on a plateau at an elevation of about 100 m and a distance from the sea of 10 km. The area is flat and the distance between the experimental designs in the eucalypt stand and the savanna is about 500 m.

The geological bedrock is composed of thick detritic formations of continental origin dated from plio-pleistocene. The soils are ferrallitic and highly desaturated on sandy material. These acidic soils are very deep and (>50 m) are characterised by their homogeneity in color (greyish on the surface and ochre in depth), texture (the sand content is more than 85%), structure and chemical poverty (CEC < 0.5 $cmol_c\ kg^{-1}$ even in the upper horizons). Their water retention ability is very low.

The climate is mainly characterised by an atmospheric humidity of about 85 % on average with low seasonal variations (2 %), an average annual rainfall around 1200 mm with a dry season between may and september. The average temperature is high (25 °C) with seasonal variations around 5 °C.

Vegetal Material

The experimental design was set up in a stand of the most productive clone of the hybrid *E. PF1*. This hybrid comes from natural crosses in Congo between 2 or 3 individuals of *Eucalyptus alba* Reinw. ex Blume (female tree) and a group of Eucalypts hybrid not well identified (male tree). The stand was planted in January 1992 at a density of 530 stems per hectare. A starter fertilisation (150 g per cutting of NPK 13-13-21) and chemical weeding were applied. The stand was mature at the start of the study (6 years old). It had a mean height of 26 m and a mean circumference at breast height of 58 cm.

In Congo the herbaceous savanna is burnt every year during the dry season. The graminaceae *Loudetia arundinacea* represents more than 80 % of the aerial biomass which reaches about 5 t ha^{-1} of dry matter at the end of the rainy season. In the experimental design, the savanna was burnt each year at the beginning of august. The savanna growth occurs mainly at the beginning of the rainy season, between september and january.

Collection and Analysis of Solutions

Precipitation Solutions

The results presented here concern the collection and measurements made from april 1998 to july 1999. Rainfall was collected above the savanna by 3 PVC gutters (area 0.23 m^2) connected to polyethylene containers. Throughfall was collected by 3 replicates of 3 PVC gutters (the same as mentioned previously) in the eucalypt stand to integrate the discontinuity of the canopy. In the savanna, throughfall was collected by 4 replicates of 2 polyethylene collectors (0.8 m x 0.15 m). Throughfall collectors were connected to plastic containers. Stemflow was collected by plastic collars around 10 tree trunks, connected to polyethylene containers.

The containers collecting rainfall, throughfall and stemflow were placed in closed pits where they were protected from light and sharp variations in temperature.

Soil Solutions

Gravitational solutions were collected in each stand at the forest floor level by 4 sets of 9 thin tensionless lysimeters (40 x 2.5 cm). In the savanna, owing to the annual fires, the litter layer was very thin. Therefore the lysimeters were installed in the soil at a depth of about 2 cm. At the depths of 15 cm, 50 cm, 1 m and 2 m, 4 replicates of zero tension plate lysimeters (ZTL, 40 x 30 cm) were introduced in december 1997 in a pit which was backfilled after installation with the horizons in their natural arrangement. Solutions were collected in polyethylene containers situated downhill in closed pits.

Soil solutions were also collected between the depths of 15 cm and 6 m from ceramic cup lysimeters connected to a vacuum pump. A constant succion of about –600 hPa was maintained (when soil moisture was sufficient). Four replicates of tension lysimeters (TL) were set up horizontally at the depths of 15 cm, 40 cm, 1 m, 2 m, 3 m and 4 m, from the side of the pits where the plate lysimeters were installed. The soil solutions were collected in glass bottles. Four replicates of ceramic cups where also installed at the depth of 6 m in this soil in order to assess the deep seepage flux below the eucalypts.

The average distance between the replicates of lysimeters was 15 m in the eucalypt stand and 5 m in the savanna.

Solutions Analyses

Once a week, after volume measurements and sampling, the solutions were collected and carried to the laboratory where they were maintained at + 4 °C. These solutions were four-weekly bulked for chemical analyses. Each replicate of solution collected was analysed separately, excepted for Dissolved Organic Carbon (DOC). The solutions were filtered (0.45 µm) in Congo and measurements of pH (HI 9321) and SO_4^{2-} by colorimetry (ANA 8 Prolabo) were performed as quickly as possible. The samples were then acidified with H_2SO_4, sent to a laboratory in France where nitrate and ammonium were measured by colorimetry (INTEGRAL PLUS – Alliance instruments), chloride was also measured by colorimetry (TECHNICON I) and total Si, P, K, Ca, Mg, Na, Al, Mn, Fe by ICP emission spectroscopy (JOBIN-YVON JY50). DOC was measured on a SHIMADZU TOC 5050.

Results

Composition of Solutions

The ionic charge was calculated to verify if the attribution of ionic-charge to elements was correct (part of them were measured in their atomic form). Negative and positive charges were rather well balanced for the majority of samples but for the other ones a general trend of deficit of negative charges was observed (data not presented here). A significant correlation (p<1‰) between DOC and charge balance deficit was noticed, indicating that organic ions would participate to the charge balance.

Nutrients in the Precipitation Solutions

The amounts of precipitation are very different according to the season in Congo. Thus the compositions of solutions are given for both seasons : the rainy season from September to May and the dry season from June to August.

The composition of solutions is modified during the transfer of precipitations through the canopy (Table 1). The differences between solutions are significant (p<5%) for P-H_2PO4^-, K^+, Mg^{2+}, Na^+, Mn^{2+}, Cl^-, DOC and pH in the eucalypt stand and for P-$H_2PO_2^-$ and K^+, Si and pH in the savanna. During the rainy season the behaviour of both stands is similar for most elements and an enrichment of throughfall and stemflow for N-NH^{4+}, P-H_2PO4^-, K^+, Mg^{2+}, Na^+, Mn^{2+}, S-SO_4^{2-} and DOC is noticed. Enrichment factors (Table 2) are very close for P-$H_2PO_4^-$, K^+ and Mg^{2+} in throughfall in the savanna and in stemflow (between 8 and 24). In the eucalypt stand, when an enrichment of the solutions occurs through the canopy, the enrichment factors are usually 2 to 5 times higher in stemflow than in throughfall. In both stands, a foliar uptake of N-NO_3^- and H^+ is observed. Main difference of behaviour between stands concern Cl^- with an enrichment of solutions in Cl^- through the eucalypt canopy while in the savanna the concentrations are lower in throughfall than in rainfall.

Seasons affect the composition of solutions. A significant increase (p<1‰) of the concentrations of all elements (excepted Si) is measured in both ecosystems in rainfall, stemflow and throughfall during the dry season, when the volume of solutions are very low. The main changes of behaviour observed in both stands between the seasons are a high enrichment during the dry season of throughfall and stemflow for Al and a foliar uptake of N-NH_4^+ and S-SO_4^{2-}. In the savanna, the enrichment of throughfall for most elements observed during the rainy season does not occur anymore excepted for Al^{3+} and DOC. A foliar uptake of N-NH_4^+, N-NO_3^-, Ca^{2+}, Na^+, Mn^{2+}, H^+, S-SO_4^{2-}, Cl^- and Si is on the contrary noticed.

Nutrients in the Soil Solutions

Changes of the Soil Solution Composition with Depth

The composition of soil solutions collected between the depths of 15 cm and 6 m with tension lysimeters (TL) are given without distinction of the seasons (Table 3). During the dry season, the very low soil moisture prevented from collecting solutions (excepted in the deep layers of soil in the savanna).

Mean and standard deviation () from 17 months and 4 replicates of samples collected at each depth in each ecosystem. Different letter between solutions composition indicate significant difference at the 95% level of confidence.

In both stands, the solutions collected at the litter level are dominated by the cations Ca^{2+}, Na^{+}, H^{+} and the anions S-SO_4^{2-}, Cl^{-} and DOC. In the solutions collected at the depth of 15 cm, a decrease of concentration is observed for all the elements excepted N-NH_4^{+}, N-NO3^{-}, S-SO_4^{2-}, Si and DOC. This decrease is marked for P-$H_2PO_4^{-}$, $K^{+,}$ Ca^{2+}, Mg^{2+}, $Na^{+,}$ Al^{3+}, H^{+} in the eucalypt stand and K^{+}, Ca^{2+}, Mg^{2+}, Al^{3+}, S-SO_4^{2-} and H^{+} in the savanna. Throughout the profiles the concentration of all the elements remains very low excepted for Si and DOC. Very high concentrations of DOC are observed in the eucalypt ecosystem with 188 mg l^{-1} on average at the depth of 6 m. In the savanna the DOC concentrations decreases sharply beyond 2 m deep

The solutions collected in each soil layer are compared between stands. At the litter level the concentrations of $K^{+,}$ Ca^{2+}, Mg^{2+}, S-SO_4^{2-} and Si in the solutions are significantly higher (p<5%) in the savanna than in the eucalypt stand. By contrast, the Na^{+} concentration is significantly higher in the eucalypt stand.

In the A_1 horizon (depths 15 and 50 cm), the concentrations of N-NO_3^{-}, Ca^{2+}, Mg^{2+}, $Cl^{-,}$ Si, DOC and H^{+} differ significantly between the ecosystems. They are higher in the eucalypt stand excepted for Ca^{2+}. Even if the differences between the stands are not significant, the concentrations of Na^{+}, Al^{3+} and S-SO_4^{2-} are also higher on average in the eucalypt ecosystem.

In the intermediary layer (depths 1 and 2 m), the differences of soil solution composition between the stands are lower. Mainly, higher concentrations of Mg^{2+} and Cl^{-} in the eucalypt stand are observed, as in the A_1 horizon. The trend observed in the upper layers of higher N-NO^{3-} concentration in the eucalypt stand become reversed beyond the depth 1 m.

In the deep layers (> 2 m), the concentrations of N-NH_4^{+}, P-$H_2PO_4^{-}$, S-SO_4^{2-}, Si and DOC are significantly higher in the eucalypt stand while the concentration of N-NO_3^{-} and Na^{+} is higher in the savanna.

The concentration of all the elements excepted DOC and Si is extremely low in the deep seepage waters (< 60 µeq l^{-1}) compared with other forests (Cortez 1996, Marques *et al*. 1997a, Ranger *et al*. 1993). In both stands, H^{+}, N-NH_4^{+} and Na^{+} are the dominant cations in these solutions and S-SO_4^{2-}, Cl^{-}, DOC the dominant anions.

Comparison of the solutions collected by ZTL and TL

In this soil, gravitational solutions were collected by ZTL only at the depth of 15 cm. In deeper layers the number of samples collected was very low. At 15 cm deep, the concentration of H^{+}, Ca^{2+}, K^{+}, Na^{+}, Al^{3+} and Si is significantly higher (p<5%) in the gravitational solutions than in solutions collected by TL in both stands (Figure 1). The concentrations of Mg^{2+} and Cl^{-} are also significantly lower in the solutions collected by TL in the savanna, by contrast the concentration of DOC is higher in the "capillary solutions" in the eucalypt ecosystem.

In both stands the respect for the electrical neutrality of the gravitational solutions show that the dominant anions are organic while H^{+} and Na^{+} are the dominant cations. In the "capillary solutions" collected in both ecosystems, the marked decrease of the cationic charge shows that changes of the organic compounds occur, leading to a decrease of their anionic charge.

Discussion

Precipitation Solutions

The amounts of precipitation are very limited during the dry season (<10 mm month^{-1}). Therefore, the mean concentrations during the rainy season are very close to the annual mean concentrations weighted by the fluxes of precipitation in these ecosystems.

Rainfall

During both seasons the composition of rainfall is dominated by the cation Ca^{2+} and the anion Cl^{-}. Total deposition (dry plus wet) of rainfall are collected by gutters. With another collector opened only during the rain events, only wet depositions were collected during 2 months. The comparison with the total deposition collected in the gutters showed a very similar composition of rainfall for all the elements excepted for Ca^{2+} and Cl^-. The concentrations of Ca^{2+} and Cl^- were much lower in the wet depositions. These results and the comparison with a pyramidal collector designed to assess total depositions in West Africa (Orange *et al*. 1990) showed that high concentrations of Ca^{2+} and Cl^- measured in rainfall are probably an artefact due to the characteristics of the gutters, increasing the dry depositions of these elements.

The washout of gases and particles from the atmosphere by rainfall events of very low intensity (<1mm) during the dry season leads to a considerable enrichment of the precipitations for all the elements. The negative relationship between the amount of precipitation and the concentration of the majority of elements was also pointed out in a previous study of precipitation chemistry carried out in an area situated 100 km North(Lacaux *et al.* 1992). The enrichment was mainly attributed to biogenic sources due to annual fires of the savanna. However the concentrations measured were lower than in the present study for all the elements and particularly for Ca^{2+} and Cl^-. In this work only wet depositions were collected and the distance from the sea of about 100 km led to lower depositions from marine source.

Throughfall

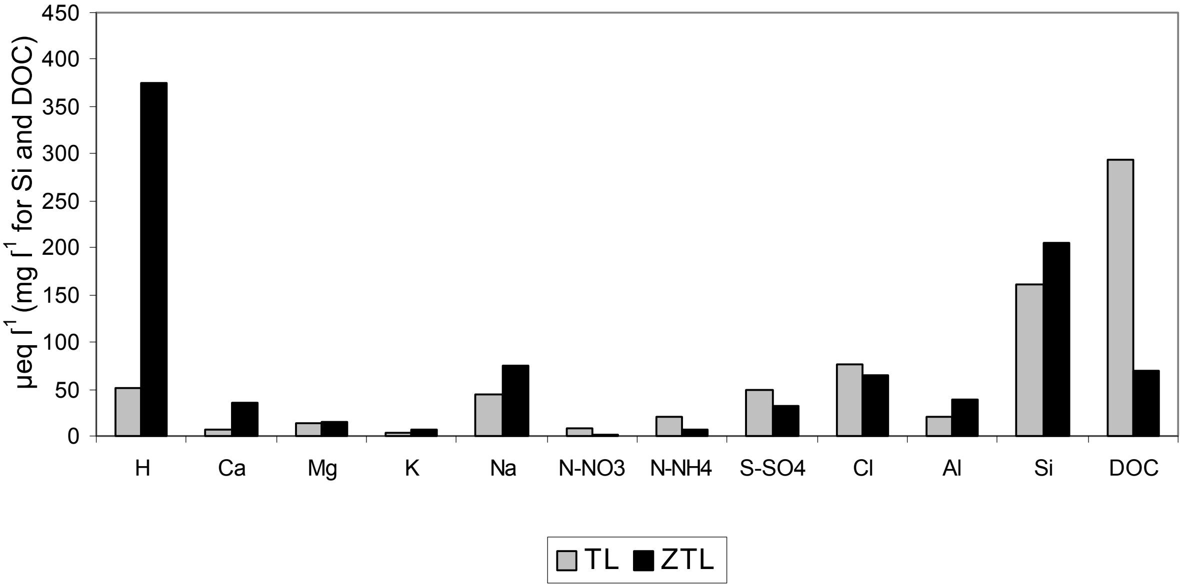
The chemical changes between rainfall and throughfall are attributed to the dissolution and washoff of aerosol and particule deposits on the leaves or to ionic exchanges between rainfall and elements in the internal plant parts (Lovet and Lindberg 1985). The interception of rainfall by leaves leads also to an increase of the concentrations of elements.

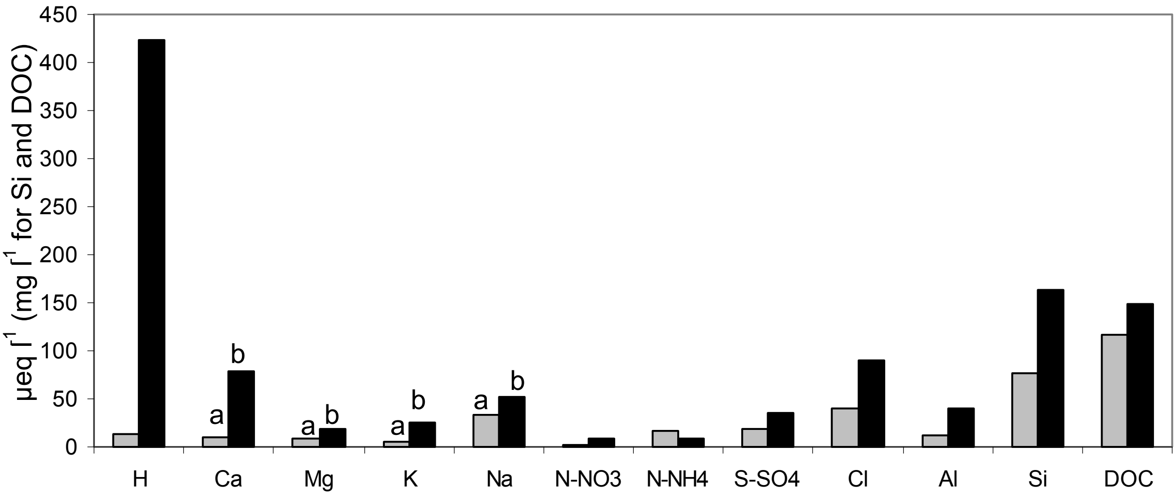
In the savanna, a comparison of Ca^{2+} and Cl- concentrations in throughfall and in rainfall shows a considerable foliar uptake, of the same extent as the accumulation of these elements in the biomass. However, it is likely that the foliar exchanges of Ca^{2+} and Cl^- are negligible if the inputs of Ca^{2+} and Cl^- in rainfall were over-assessed of about 30 µeq l^{-1} (table 1), due to the characteristics of the gutters which enhance the dry deposition of these elements. Whatever the season, a high foliar uptake of N-NO_{3-} and H^+ is observed in the savanna, associated with an enrichment of throughfall solutions for P-$H_2PO_4^-$, K^+, Mg^{2+} and DOC. By contrast, the foliar exchanges of N-NH_4^+, S-SO_4^{2-} and Si differ according to the season. Owing to the low height of the savanna (1 m) dry depositions in this stand are likely to be of the same extent (or lower) than in gutters. Therefore, the enrichment of throughfall solutions might mainly originate from internal cycle (leaching process). An enrichment of throughfall for P, K^+, Mg^{2+} and Cl^- was also observed in a savanna with *Loudetia* sp. in Ivory Coast (Villecourt and Roose 1978).

Dry depositions in the canopy are usually high in forest stands. The depositions differ according to the elements (size of particles, vapor) and are likely to be highly superior to the atmospheric inputs measured by collectors of bulk deposition (Lindberg *et al.* 1986). Thus, it is difficult to assess the importance of canopy exchanges *vs* dry depositions in the enrichment of throughfall. The most rigorous methodology would be i) to measure the aerosol concentrations in the air, ii) to establish a model of dispersion of air masses and more difficult, iii) to establish a deposition model fitting with the characteristics of the canopy. A similar methodology should be used for the deposition of particles. In some studies an assessment of the extent of dry depositions is calculated considering one (or several) element(s) tracer(s) for which one(s) canopy exchanges are assumed to be negligible (Marques *et al.* 1997b).

Figure 1 :Composition of solutions collected by TL and ZTL lysimeters in the eucalypt stand (A) and the savanna (B). Different letters between solutions composition indicate significant difference at the 95% level of confidence.

.





Then, the proportion of enrichment of throughfall solutions for the tracer is attributed to dry depositions and this proportion of dry deposition is assumed to be identical for the others elements. In the eucalypt stand if Si is considered as a tracer, the dry depositions in the canopy would represent 40 % of the atmospheric inputs measured with gutters during the rainy season and 34 % during the dry season. These dry deposition proportions are intermediary during the rainy season between the values calculated if $S\text{-}SO_4^{2-}$ or Cl^- were considered as tracers. With these proportions of dry deposition, a foliar uptake of $N\text{-}NO_3^-$, Ca^{2+} and H^+ occurs during the rainy season and of $N\text{-}NH_4^+$, Ca^{2+}, $S\text{-}SO_4^{2-}$ and Cl^- during the dry season. A nitrogen foliar uptake has been observed in many forest ecosystems when the N requirement of the stands are high (Lindberg *et al.* 1986, Adams and Attiwill 1991, Brumme *et al*. 1992, Marques *et al.* 1997a). A foliar uptake of Ca^{2+} is also reported in the literature (Lovet and Lindberg 1985) but an uptake of $S\text{-}SO_4^{2-}$ and Cl^- is more unusual. This behaviour has to be confirmed because measurements concern only one dry season in this study.

During the rainy season, the tracer Si shows that the enrichment of throughfall solutions for $P\text{-}H_2PO_4^-$, Mg^{2+} and Na^+ originates mainly from internal cycle while for the other elements the origin is mainly dry depositions. During the dry season, the enrichment for P, K^+, Mg^{2+}, Na^+, and Mn^{2+} in throughfall solutions comes mainly from internal cycle while dry deposition is the main source of enrichment for the other elements. This information is relevant if input-output budgets are established in the ecosystem.

Stemflow

The changes of rainfall chemistry observed in throughfall solutions are more pronounced in stemflow but they follow the same patterns (Table 2). The solutions flowing along the trunk surface already contain the solution caught in the canopy but also collect large amounts of elements during contact with the stembark. The uptake of $N\text{-}NO_3^-$ and H^+ observed in throughfall is much higher in stemflow while the enrichment for $P\text{-}H_2PO_4^-$, Mg^{2+}, Na^+, Mn^{2+}, Cl^- and DOC is much more pronounced. A greater enrichment of stemflow solutions relative to throughfall is usual in forest ecosystems (Cortez 1996, Marques *et al.* 1997a). A $N\text{-}NO_3^-$ uptake was also observed in an eucalypt stand in Cameroon. (Harmand 1998). It probably indicates an absorption by the epiphytic vegetation (Mina 1965 cited by Marques *et al.* 1997a).

During the dry season most elements behave like during the rainy season. However an uptake of $N\text{-}NH_4^+$ and $S\text{-}SO_4^{2-}$ is observed. These concentrations in stemflow during the dry season must be interpreted cautiously because the number of samples collected was very low.

Soil Solutions

The composition of soil solutions collected is the result of the inputs of elements by throughfall and stemflow, mineralisation of organic matter, weathering, the ion exchange complex equilibrium and the outputs with the uptake by roots and microbiota and the leaching.

Great modifications of the solution chemistry are observed during the transfer through the litter. In both ecosystems, a marked increase of the concentrations compared with throughfall is observed for Na^+, Al^{3+}, $S\text{-}SO_4^{2-}$, Si, DOC and H^+. An enrichment for $N\text{-}NH_4^+$, K^+ and Mg^{2+} is also measured in the eucalypt stand and for Ca^{2+} in the savanna. This enrichment can be partially attributed in the savanna to the deposition of large amounts of ashes at the surface of the soil after the annual fires and in the eucalypt stand, to the mineralisation of organic matter. Bernhard-Reversat (1999) has shown that large amounts of acid organic compounds are released during the eucalypt litter decomposition. The Si and Al^{3+} enrichment in the soil solution originates generally from weathering processes (Marques *et al.* 1996).

However, it is also interesting to notice a marked decrease of Ca^{2+} and $N\text{-}NO_3^-$ concentrations during the transfer through the forest floor in the eucalypt stand. A high water repellency was observed at the surface of this soil, which leads to an increase of the time of contact between the solution and the forest floor, specially when the soil is dry (Laclau *et al.* 1999a). A high density of thin roots was observed inside the forest floor (about 500 kg ha^{-1} of dry matter). The uptake of nutrients inside the forest floor is likely to be relevant for the mineral nutrition of the stand during the dry season when the rainfall is very low and the soil moisture in the upper layers at wilting point. In the savanna, an uptake of K^+ and Mg^{2+} is also observed in the surface soil.

A soil moisture monitoring using TDR probes in both stands showed preferential drainage ways in the upper layers of soil and a drainage much more uniform beyond a depth of 2 m. Soil water repellency leads to these type of drainage (Ritsema 1998).

Preferential drainage ways lead to a fast drainage in this sandy soil, with very weak ion exchanges among the gravitational solutions, the soil and the vegetation. These characteristics of drainage are consistent with the low changes of composition observed between the gravitational solutions collected at the forest floor level and at a depth of 15 cm. In the deep layers of soil, the difference between gravitational solutions and the solutions collected with TL should be much lower, owing to the uniformity of the drainage flux.

At the depth of 15 cm, the concentration of most elements in the solutions collected by TL was lower than in the gravitational solutions. This result is original because solutions collected by TL are usually enriched by weathering processes and the activity of micro-organisms (Ranger *et al.* 1993, Marques *et al.* 1996). With a succion of –600 hPa, gravitational solutions but also solutions located in a lower soil porosity, in equilibrium with the soil and the vegetation are collected by TL. In this ferrallitic soil, the release of base cations by weathering must be very low. Furthermore, the availability of exchangeable cations is weak in this soil and the very low concentrations of $N\text{-}NO_3^-$, $N\text{-}NH_4^+$ and base cations measured in solutions collected by TL show a very efficient uptake by the vegetation. A very dense network of thin roots in the upper layer of soil was observed in both stands and allows a very quick uptake of nutrients. When the time of contact between the solution and the soil increases, the H^+ concentration decreases sharply in both stands. The main processes of H^+ neutralisation can't be attributed to a desaturation of the ion-exchange site because the CEC is very low (<0.5 $cmol_c$ kg^{-1}) or to mineral breakdown because Si and Al^{3+} concentrations are lower in solutions collected by TL than in gravitational solutions. By contrast, changes of organic compounds leading to a H^+ fixation and a decrease of the anionic charge of DOC are likely to be involved in this neutralisation.

The changes of "capillary solutions" composition with depth is low in both stands. In the savanna, 80% of the underground biomass is observed in the 50 cm of surface soil but roots have been found up to a depth of 2.50 m. In the eucalypt stand, even if thin roots were observed up to a depth of 9 m, most of the volume of soil is not prospected beyond a depth of 3 m. Whatever the depth, the dominant cations remains H^+ and Na^+ while the dominant anions are $S\text{-}SO_4^{2-}$, Cl^- and DOC. The lack of significant increase of the base cations concentration in the deeper layers of soil where the uptake by roots is absent (or very low) confirms that the nutrient release by weathering must be very weak in this soil.

Conclusion

The general trends of the impact of canopy and soil in the modification of precipitation chemistry are similar in a mature stand of eucalypt and a native savanna, even if differences of behaviour are observed for some elements. Rainfall composition is dominated by Ca^{2+} and Cl^-. An enrichment during the transfer through the canopy is observed for most elements but a N uptake is observed in both stands. In the savanna, changes of Ca^{2+} and Cl^- concentration in throughfall solutions are difficult to interpret owing to high amounts of dry deposition of these elements in rainfall. In the eucalypt stand, the enrichment observed in throughfall is much more prounonced in stemflow (excepted for N) but this flux represents only 1.5% of the amount of solution reaching the soil.

During the transfer through the litter layer, an enrichment of solutions is observed for most elements (and particularly for H^+) but an uptake by roots occurs also in both ecosystems. A water repellency of the surface soil more severe in the eucalypt stand increases the time of contact between the forest floor and the solution during the dry season. It must also lead to preferential drainage ways in the upper layers. The composition of gravitational solutions is not very modified in the upper layer of soil owing probably to a very fast drainage. When the time of contact with the soil increases, the H^+ and base cations concentrations decrease sharply, excepted for Mg^{2+} in the eucalypt stand. A modification of the organic compounds with protonation might be responsible for the increase of pH.

The sharp decrease of concentrations of mineral N and base cations in the solutions collected by TL compared to the solutions collected by ZTL underscores the efficiency of the savanna and the eucalypt stand to take up the nutrients available in the soil solution. In these ecosystems, the function of external inputs seems fundamental. The extremely low losses of nutrients by deep drainage show that an optimisation of silviculture adapting the inputs of nutrients (fertilisations, management of organic matter) to the requirements of the stands should improve the production of the eucalypt plantations without damage on the quality of surface waters.

Abstract

On a heavily karstified site in the Northern Limestone Alps (Austria) water- and nutrient household of Norway spruce stands was investigated along a chronosequence (clearcut, 10 year old artificial regeneration, mature stand). Both nutrient stores in soil and in biomass were calculated. Bulk deposition, throughfall and seepage were sampled weekly during three growth periods (4-5 months each) and analyzed for main chemical constituents. Water fluxes were calculated using the BROOK90 model (Federer et al., 1995). The soils (lithic Leptosols) consisted of moderhumus overlaying a very pure limestone. Only in the regeneration plot signs of a mineral soil horizon could be dedected. In the mature stand twenty percent of nitrogen, thirty percent of phosphorus, nineteen percent of sulfur and fifty-eight percent of potassium pools were stored in biomass. Assuming an utilization of eighty percent of stemwood with bark, conventional harvest removed approximately four percent of the nitrogen, seven percent of the phosphorus, seven percent of sulfur and twenty-three percent of the potassium pools. Despite inorganic nitrogen inputs during these periods between 5 and 10 kg.ha^{-1} with precipitation, inorganic nitrogen output with seepage from the mature stand and the regeneration plot was only 0.5-1.2 kg.ha^{-1}. In the first and second growing season after clearcut, inorganic N fluxes with seepage increased to 20 and 30 kg.ha^{-1} respectively, declining in the third growth period to 8 kg.ha^{-1}. DON output was between 3 and 6 kg.ha^{-1} in the mature stand and 7 to 11 kg.ha^{-1} at the clearcut and the regeneration plot. Therefore, DON is an important fraction of the N-cycle of this ecosystem. Total differences between nitrogen stores of the mature stand and the regeneration were 270 kg.ha^{-1} of N. Less than half of the difference can be attributed to biomass removal, the rest may be attributed to leaching losses. However, total annual N-input is high at this site and will over-compensate losses. The P-stores were only affected by biomass removal, not by leaching of inorganic P-compounds. The mature stand seems to be S-saturated, input and output rates of sulfate are balanced. Regeneration is a net sink for inorganic S, as can be seen from declining fluxes with seepage for both the clearcut and the regeneration with time. K losses were between 30 kg.ha^{-1} in the first, 20 kg.ha^{-1} in the second and 9 kg in the third growth period after clearcut while output rates were less than 2 kg in the mature stand and the regeneration plot. K pools in the humus layer were only 150 to 200 kg.ha^{-1}, total pools in the mature stand were 360 kg.ha^{-1}. With annual input rates of less than 2 kg.ha^{-1} of K, harvesting and post harvesting losses may cause problems. Since precipitation is high in this area, forest growth is rather limited by nutrient than by water supply. Needle analyses show already deficient potassium supply. Harvesting and post harvesting losses of K, in combination with elevated nitrogen deposition may have negative influences on the stability of forest stands on these sites. Subsequently, negative influences on water supply from such areas are possible. As the demand on drinking water resources from karst regions is increasing, a careful evaluation of forest management practices on vulnerable sites in the limestone Alps is necessary.

Abstract

People usually know *how they want their situation to change* to secure a better future – but they do not always know *how to change their situation*. Initiatives intended to secure a better future do not always work as intended, and may have unintended side effects. Computer models can help advocates explore consequences of proposed initiatives, so they can make informed selections of alternatives, secure in the knowledge that consequences have been thoroughly investigated. By encouraging people to explore scenarios, models empower people to be more innovative and less dependent on technocrats. New software solves technical limitations, but the real issue is not software, but rather the provision of a supportive framework within which people can express and experiment with ideas. FLORES, the Forest Land Oriented Resource Envisioning System, provides such a framework to stimulate interdisciplinary collaboration between researchers, practitioners and clients. A recent prototype demonstrated the feasibility of FLORES. However, FLORES is not about software; it is about providing the means to explore the consequences of alternative scenarios. Ultimately, FLORES is not a physical package, but a user group and the interactions they have amongst themselves, and with the people involved in policy-making. Fostering this emerging network through workshops and technical support will enhance FLORES by offering a better understanding of the concept, and by allowing more people, especially those from developing countries, to influence the development of FLORES and the issues that can be explored within it.

Keywords: Decision support system, Adaptive modelling, Land use alternatives, Policy analysis

Introduction

Policies and incentives to promote sustainable forestry and better land use do not always achieve the desired effect. Proponents rarely foresee all the consequences, and that those best able to offer alternative views may be unable to contribute to the decision-making process. This leads to inefficient, and sometimes counter-effective, initiatives. How can we better equip policy makers and their advisors to envisage fully the efficacy and consequences of initiatives? One way is to provide a simulator that helps people to visualize possible outcomes of proposed initiatives. FLORES is an attempt to build such a simulator. Work on FLORES is still in progress, so a traditional methods-results format is inappropriate, and we offer a narrative highlighting trials, tribulations and insights gained.

What is FLORES, and where did the idea come from?

FLORES, the Forest Land Oriented Resource Envisioning System, aims to improve our understanding of land use patterns in time and space, especially in forested landscapes, and to facilitate rigorous analyses of policy options intended to manipulate these patterns.

The idea for FLORES arose from several initiatives, among which were the desires to create a platform that would allow researchers to integrate their research, to make it possible for them to work together to reveal the bigger picture, and to provide the ability to test propositions rigorously within a realistic framework. These remain important influences in the development of FLORES. Accordingly, FLORES is spatially explicit, and operates at the landscape scale, spanning both forest and agricultural lands. Agricultural lands and villages form a critical component of the landscape, and must be modelled to fully understand the processes at work in and near the forest.

The basic concepts of this work are not new; what is new is the way concepts are integrated and applied. FLORES seems most closely related to work by Bousquet *et al.* (1993, 1994), who constructed a multi-agent simulation (MAS) model of an inland fishery in the Central Niger Delta as a basis for focusing discussion, evaluating options and formulating recommendations. There is an interesting contrast between FLORES and MAS: both are concerned with *agents* that can modify and respond to their environment, but the emphasis differs. Generally, MAS attempts to find the simplest set of rules that can reproduce a particular pattern from a defined scenario. In essence, the usual question for MAS is: what are the rules that might explain this pattern that we have observed? FLORES considers the converse: given what we know about human behaviour, can we predict future outcomes for a range of scenarios? Generally we do not know what future outcomes should look like, except in a few specific cases that may be used to test the model. FLORES also recognises that people may have complex reasons for their behaviour, and attempts to represent our present understanding of those reasons, rather than seeking the simplest rules that may reproduce a given pattern.

Why do we need FLORES?

We offer some analogies to illustrate why FLORES is important. Anyone who has played Fish Banks[1], the Beer Game[2] or a similar management game should appreciate the need for up-to-date information. With Fish Banks, a game about sustainable resource utilization, players often destroy a fishery because they rely on information from a previous game cycle. It is only when players learn to predict current and future fish stocks that they can achieve a sustainable outcome. Using old information for resource management is like driving a car without forward vision, and relying on rear-view mirrors for information. Up-to-date information (cf. looking out of the side mirrors to see the side of the road) helps, but we can only drive safely when we can see forwards (cf. predicting future outcomes).

We can also draw a useful contrast with air travel. What makes air transport so safe and pilot error so rare? Good design, careful planning, diligent maintenance and competent supervision are factors, but pilot training is crucial. Before crew members take the controls of a commercial airliner, they will have studied the theory of flight, trained in light aircraft, spent hours in a flight simulator, and flown with more experienced colleagues. They know how to read the indicators, what every button and every lever does, and when and how these controls should be used. They know instinctively how to respond when something goes wrong, and what to do if the plane deviates from its planned course. And they rarely need to use their training, because our knowledge of flight has been synthesised into an autopilot that takes care of most situations.

Now contrast this with our management of forests:

> Do we know what to do when things go wrong?
>
> Can we tell when things are beginning to go wrong?
>
> Do we know which controls we can use to change things?
>
> Do we know what the controls are, where to find them, and how to activate them?
>
> Can we recognise and interpret the indicators?
>
> Why don't we have an "autopilot" to give advice?

Why is it that so many amongst those who make important decisions about the world's forests have never raised a tree, tended a garden, gathered food from the forest, or used a simulator to explore the implications of an impending decision? Would a forest landscape simulator make a difference?

The computer game SimCity[3] provides an interesting analogy for a user interface that we would like to develop for FLORES. The Maxis Corporation provides a simulator in the form of a game. The game offers the player an "aerial view" of a city, a menu of policies and incentives (e.g., expenditure on education, transport, sanitation, etc.), and indicators of performance (e.g., unemployment, GNP, pollution, etc.). Scenarios are available freely on the Internet[4], and range from real cities to fantasies.

In FLORES, we replace the cityscape with a landscape of forest and non-forest land. Its menu includes a range of options to manipulate the forest and land use patterns, and performance indicators could include biodiversity and rural poverty. It must have a strong factual basis, and must be able to be customised to suit different situations. It will:

- synthesise existing knowledge and identify gaps and other deficiencies;
- express present knowledge concisely, completely, explicitly and unambiguously as a model;
- create a framework to promote collaborative interdisciplinary research;
- provide a basis for strong empirical tests of hypotheses relating to land use policy;
- create a planning tool to allow planners and policy makers to explore future scenarios; and
- provide an educational game to improve general knowledge of tropical forest environments.

What has been Achieved?

The FLORES concept was developed during 1995 (Vanclay 1995), but it was not until 1997 that work began in earnest and a prototype[5] was produced (Muetzelfeldt *et al*. 1997). Significant progress[6] was made during 1999, and at the time of writing, the FLORES team are about to embark on another workshop to test the applicability and ability to adapt the Rantau Pandan version to a Zimbabwe situation. Progress to date is the outcome of collaboration between the Institute of Ecology and Resource Management at the University of Edinburgh and the Center for International Forestry Research (CIFOR), and a group of fifty people[7] who contributed to a model design workshop held in Sumatra in 1999 with support from the UK Department for International Development.

The present version of FLORES is still rather simplistic, but provides the basis for on-going work over a long period. This platform is not, and must not be, a "black box", opaque to participants. It is not enough that it should be transparent; it should be enlightening, and should empower participants to make better analyses and draw more revealing insights than they could working in isolation. We have tried to provide this, and hope that it will be used as a basis for testing a wide range of propositions, and will be modified as necessary to make these tests and incorporate findings into the model. We must begin with simple models, and should progressively enrich these as we refute inappropriate simplifications. Models excel at exposing counter-intuitive consequences of simple assumptions. Even if initial prototypes of the model are of little practical relevance, they may offer valuable insights, and their main purpose may be to focus questions rather than to provide answers. The challenge is to construct a framework that is broad enough to accommodate a wide variety of propositions, and sufficiently accessible that researchers from a range of disciplines are stimulated to collaborate and test their propositions in this integrated way.

How does itWwork, and will it give the Right Answers?

FLORES relies on four basic assumptions, namely that:

1. Land use patterns are created by *actors*, individuals or groups of individuals who collaborate as families, clans, associations and corporations.

2. These actors make *rational* decisions based on available information, obligations and expectations, social as well as economic. Note that an actor's *perception* is what influences decision-making.

3. When choosing an *activity*, actors explore all options available to them, within the constraints imposed by resources (land, time, capital, etc.), knowledge, and their comfort zone (cultural attachments, willingness to attempt novel activities, etc.).

4. Actors tend to undertake activities that maximise expected benefits or minimise anticipated risks to themselves and their beneficiaries (families, clans, shareholders, etc.). It may be possible to model both benefit-seeking and risk-avoiding behaviour by considering risk-adjusted benefits.

The constraints implied by an actor's comfort zone and previous experience mean that many actors consider a rather small number of activities, often only those done in the past, plus a few new activities pursued profitably by neighbours. However, there are usually a few innovators who consider an extended list of activities and may attempt a diverse range of enterprises. Typically, innovators are more willing to attempt risky enterprises than their more conservative fellows. Disposition is only one determinant of willingness to accept risk, and age, assets and income also feature prominently in many explanations.

Decision-making by actors is just one component of FLORES, and several other sub-models are needed to predict the growth of trees and crops, changes in the soil and water balance, interactions between key plant and animal species, and other ecosystem processes. Fortunately, many such models already exist (e.g., Vanclay 1994, Anon 1997), and some are amenable to calibration and integration within the FLORES framework.

We have implemented FLORES in AME to minimize the amount of computer code, in the hope that we can engage potential participants who are not conversant with computer languages. AME[8], the Agroforestry Modelling Environment (Muetzelfeldt and Taylor 1997), has a graphical interface that makes the model accessible to researchers who are not fluent in computer programming, while allowing access to the underlying code. Thus it offers a powerful and flexible platform that does not exclude less computer-literate participants in the project. There are other advantages in using AME, some of which include the ability to:

represent relationships as simple sketches, mathematical equations, or as sets of rules;
substitute alternative models easily via the Windows click-and-drag facility; and
create customised user interfaces with software "helpers" that can be developed independently and "plugged in" later.

So what does it mean for Resource Managers and Planners?

Too many models languish, under-utilised, because they do not satisfy the needs of potential users and because system developers did not explicitly contact clients, ascertain their needs, and stimulate their interest. To encourage uptake, potential users must be involved in the development of the model. Obviously, users may not be interested in all aspects of model design and construction, but they should have the opportunity to participate in specification and design of the user interface. It is not enough to ask them what they want and how they want it. Team members have to engender enthusiasm and involvement through mutual understanding and collaboration. This means that the model has to be explained in an accessible way, and that simple prototypes and mock-ups need to be built so that ideas can be demonstrated, tested and modified.

[8] See http://www.simile.co.uk

FLORES will provide a range of outputs to suit different user requirements. One output will be the forested landscape of a SimForest implementation. One great contribution that information science could make for conservation and wise use of forests would be to provide a virtual reality interface for forest management planning (Vanclay 1993). This could allow a minister and his advisors to put on a virtual reality headset and take a “magic carpet” ride over a forest estate. They could observe the spatial pattern of their forest and watch how it changes over time, and under different scenarios. They could “zoom in” to examine particular issues, and stand back to get an overall perspective. The technology to do this exists, and it is possible to link forest inventory systems, growth models, geographic information systems and virtual reality systems in this way. However, it has not been done at this time, and awaits further software and hardware development to make it more affordable. In developing FLORES, we have been mindful that the eventual user interface may well be a virtual reality system, and we should deliberately design an open and flexible system that does not foreclose this possibility. However, the SimCity-style interface is adequate for many applications, and would be particularly useful for educational applications and general information dissemination.

What’s next? When will it be Useful to Others?

There are several specific problems that need to be addressed before this model can be realised as anything more than a simple prototype. Many of these challenges can be addressed as separate tasks, and are amenable to research by others, including students. Some of the more obvious issues are listed below.

In the proposed model formulation, the underlying functional relationships may be relatively simple, but the data requirements are rather demanding. Most utility functions appear innocent enough, but they require a lot of data: anticipated yields and prices of all possible crops under a range of situations, detailed tenure and demographic data, and a good understanding of the socio-economic culture of the community. This is a major undertaking, and may be one limitation of the model. We envisage that initial prototypes will be restricted to a limited geographic area, allowing a complete census of all inhabitants for thorough model testing. However, subsequent operational implementations may sample only selected actors to reduce the burden of data acquisition. Crop yields may be inferred from models, but prices and elasticities must be gleaned from field survey work. This task may be particularly onerous for non-timber forest products such as medicinal plants.

Superficially, the model appears tractable, but it involves many challenges. Is it really possible to quantify the social profile of all actors in a community in sufficient detail to provide meaningful predictions from a simple utility function? There is no clear answer, and only an empirical test can elucidate if numerical approximations of complex social structures provide an adequate basis for planning. Two further issues for methodological research are evident at this stage: whether to model individual actors or classes of actors, and how to quantify risk and willingness of actors to accept risk. Both are central to the FLORES approach, and in both cases, the issue is whether the preliminary approach is a necessary and sufficient representation of reality. There are some advantages in modelling individual actors: it is conceptually elegant and facilitates empirical testing, but it imposes a substantial computational load. Simulation based on a few classes of actors (e.g., classified by age and gender) would speed up simulations, and may ease data input requirements, but it is not clear if this would lead to the same result as individual-based modelling. The issue may be best resolved through empirical trials and sensitivity tests.

It is presently assumed that an actor’s willingness to accept risk can be quantified, in part through the historic variation in benefits accruing from a particular activity, and from the actor’s age, tangible assets and income. However, this assumption warrants closer scrutiny since attitudes to risk have a major influence on land use decisions. Our ability to quantify risks and attitudes to risk will have a major influence on the accuracy of FLORES predictions.

Satisfactory ways to value the intangibles involved with land use decisions pose a major challenge. One particular aspect that needs to be addressed is how to value prestige. Prestige may take many forms, and may explain land purchases at prices inconsistent with production (e.g., prestige of owning a bigger estate), herd sizes (e.g., prestige of large flocks leads to overstocking, even though smaller flocks may offer equivalent returns and lower risks), and possession or production of certain items.

A further challenge for later versions will be to model selected species interactions in both plant and animal species, especially for apparently pivotal or keystone species. It is not sufficient to model the food web, because energy flows are only one of the aspects. It is also important to consider relationships such as mycorrhizal and other symbiotic relationships, pollination and transport of seeds, microclimate and other modifications of the environment that may facilitate the establishment of plant and animal species. It is probably impossible to model all of these relationships in a tropical forest, but it is important to recognise and include the pivotal relationships in our model.

A FLORES-type model is easy to conceive for a small village, where we can simulate every individual actor. However, when we scale up our efforts to model larger landscapes, it may become impractical to examine decision-making by all actors, and it may be necessary to extrapolate from a sample of actors. The choice of sample may be critical to the outcome, and suitable sampling strategies must be investigated before the approach can be scaled-up to the provincial or national level. A crucial part of this investigation will be to identify the minimum essential set of prime determinants.

FLORES seeks to provide a framework for testing and refining ideas. This means that the basic framework of FLORES must be carefully tested, and that baseline data should be acquired for detailed empirical testing. Two components of these tests warrant special attention and preparation: sensitivity tests and benchmark tests (Vanclay and Skovsgaard 1997). Ideally, a thorough program of sensitivity testing should examine each input, every parameter, and all assumptions to see how much influence they have on predicted outputs. This is useful information that can be used to direct further development of a model, with a lower priority assigned to parameters and assumptions that have little influence on predicted outputs.

Thorough benchmark testing is another big job that requires planning and preparation. It requires comprehensive data about a series of sites for at least two points in time, preferably over a reasonable interval. Ideally, the situation at some sites should remain more-or-less unchanged, while substantial changes should be evident at other sites. There are always difficult issues to be addressed if these sites involve only passive monitoring, and empirical tests are strengthened if experimental data are available. In agricultural situations, it is customary to use paired and replicated experiments to compare treatments against control plots. Such data are more difficult to obtain at the landscape scale and when people are involved, so greater ingenuity is required. Survey data pose special problems, since many factors may vary and it can be difficult to make reliable inferences. In theory, it is possible to conduct experiments to gather rigorous data to test FLORES, but there are ethical questions that would need to be considered carefully. For example, it is feasible go to a village and buy locally produced goods at prices higher than the prevailing market rate, and watch how the community responds. Fortunately, this experiment is not necessary, because in many developing countries, governments conduct such “experiments” all the time. For instance, new bridges and roads can markedly change transport costs. Thus the data required for model testing may be obtained by strategically choosing and monitoring selected communities over an extended period.

Perhaps the best test of a model is how well can the modeller answer the questions ‘What do you know now that you did not know before?’ and ‘How can you find out if it is true?’. FLORES has many limitations, but it provides a fertile test-bed for ideas, and offers ample scope for furthering our knowledge of policies, incentives and land use patterns in forested landscapes. We need the product, and we need the process. We need to bring together scientists from diverse disciplines to work towards a common goal. We also need to add more rigour to forest policy research. FLORES can help realise it.

Where can I get it and how can I use it?

FLORES, its documentation, and the AME software are available freely via the internet from http://helios.bto.ed.ac.uk/ierm/flores/. You will need a PC running Linux or Windows 95, 98 or NT.

How can I help to make it better?

FLORES is a continuing research project, the product of close collaboration by many individuals, and we invite others to participate. For more information on the current status of FLORES or on how to become involved, contact one of the authors.

Abstract

The interactions between natural forest dynamics and social dynamics have to be taken into account when managing the use of forest resources. We have developed simulation models to improve our understanding of this complex system of interactions. Models of multiagent systems are effective tools for studying the dynamics of complex adaptive systems. We have developed several simulation models in order to study the use of forest resources. This paper presents a model designed to understand the interaction between fuelwood consumption and landscape dynamics. The hypothesis put forward suggests that fuelwood consumption can explain the landscape changes that occur in the Kayanza region of Burundi. The second hypothesis is that a sustainable use of resource must keep steady the fuelwood consumption level per capita over time. A preliminary map was outlined: agents use fuelwood, have access to different parts of space and have the capacity to exchange use rights. The population increases and agent migration — from overpopulated areas to unoccupied plots — is simulated. The impact of changing rules on foraging, exchange and access is then observed on a landscape level. The model describes here the behaviour of different agents (farmers, local consumers, exporters and traders). The impact of their behaviour and interactions are evaluated on different scales, ranging from the individual plot to the forest and the landscape. Models and multiagent systems can effectively represent processes that occur at levels of varying complexity and simulate their interactions so that landscape dynamics can be understood from the bottom up.

Keywords: Multi-agent systems, Fuelwood, Access rights, Social exchanges, Spatial scales

Introduction

At the interface between natural and social dynamics, environmental research is tackling development problems by examining questions that relate to resources and externalities. These include the management of renewable resources, externalities of production (pollution, effluent, etc.) and areas with multiple uses. Natural dynamics are made up of numerous interweaving processes involving different resources on different spatial and temporal scales. Social processes involve different stakeholders at various levels of organization, ranging from individuals or communities that use resources and spaces to large development institutions. The issues focus on the regulation of resource use — that is adapted to natural dynamics — through the application of economic, legal or institutional management tools. In all cases, the issues relate to problems of collective management where ecological processes have to be reconciled with social processes for resource use.

The essence of ecology is to examine ways of approaching the study of complex systems. A complex entity (Fogelman Soulié 1991, Gell-Mann 1994) is made up of different elements that interact and combine in such a way that is not immediately obvious: the complexity of a system is in the eye of the beholder. The idea that perception is inextricably linked to the notion of complexity is not impartial: it reflects the importance of the levels chosen for observing a given system. In ecology, there is no natural scale for observing all types of phenomena. Conventionally, the hierarchy of scales (Allen and Starr 1982) refers to levels of organization: cell, organism, population, community, ecosystem, landscape, biome and biosphere. One of the major challenges facing ecology is being able to take into account a multiplicity of scales of study in order to integrate — during a phase called "transfer of scale" — each of the phenomena studied at their specific level. Indeed, one of the problems facing modelling is how to represent dynamics on different scales.

Natural resource and environmental economics propose a range of theories and concepts with tools for monitoring, analysis, evaluation and regulation (Dales 1968, Arrow and Fisher 1974, Bromley 1991). In particular, economics provides a model for the use of renewable resources that aims to control sustainability of use by applying regulatory or incentive mechanisms, such as taxes, quotas, licences, grants, standards, permits, definition and exchange of property rights. It is also important to understand decision-making processes which are defined as the interactions between stakeholders with different representations and power. The problem is understanding how resource use is regulated. This can be achieved by modelling the representations and exchanges (of goods, services, currency and information) and the global constraints expressed by the use of regulatory or incentive mechanisms.

Therefore, the interaction between ecological and socioeconomic dynamics can be understood by modelling interactions on different scales. We have chosen multiagent systems (MAS) for this purpose. In this article, we start by introducing the MAS that we used. We then go on to describe an example of a model that takes into account ecological dynamics on several levels as well as the exchanges between agents with different representations.

Materials and Methods: Multiagent Systems

Multiagent Systems

The aim of multiagent systems (Ferber 1999) is to understand how independent processes in direct competition are coordinated. An agent is thus a computerized process, something that comes between a computer programme and a robot. An agent can be described as autonomous because it has the capacity to adapt when its environment changes. A multiagent system is made up of a set of computer processes that occur at the same time, ie several agents that exist at the same time, share common resources and communicate with each other. The key issue in the theory of multiagent universes is formalizing the necessary coordination between agents. The theory of agents is therefore a theory of:

1. Decision-making: what decision-making mechanisms are available to the agent? What are the links between their perceptions, representations and actions ?
2. Control: what are the hierarchic relationships between agents? How are they synchronized?
3. Communication: what kinds of message do they send each other? What syntax do these messages obey?

for which elaborate formulas are put forward.

Multiagent systems can be applied to artificial intelligence. They simplify problem-solving by: dividing the necessary knowledge into subunits, by associating an intelligent independent agent to each subunit, and by coordinating the agents' activity. Thus, we refer to distributed artificial intelligence. This theory can be applied to monitoring an industrial process, for example, where it adopts the sensible solution which consists of coordinating several specialized monitors rather than a single omniscient one. Fundamental research is being conducted on the problems associated with the representation of agents' decisions and protocols for communication. The main applications for MAS are in telecommunications, internet and physical agents, such as robots (Weiss 1999). There is a group of scientists that specializes in the simulations of agents' societies in ecology and social sciences.

Research has been conducted in parallel by computer scientists, ecologists and social scientists on the principle of modelling distributed systems. Here, we discuss a few references and some of the issues involved.

MAS and Ecology

In ecology, the distributed approaches, known as individual-based models (IBM) were developed at the end of the 1980s. The article written by Huston *et al.* (1988) is the most frequently quoted. The authors argue that there are two reasons for developing this approach: first, the need to take into account the individual because of their genetic uniqueness and, secondly, the fact that each individual is situated and their interactions are local. The argument clearly had an impact because numerous publications refer to this approach. Shortly after this publication, Hogeweg and Hesper (1990) published a similar article on "individual-oriented modelling". This had more influence on scientists working in the field of artificial life. Then, in 1990, there was a congress in Knoxville on "Individual-based models and approaches in ecology". The congress' proceedings were published and have since been the main reference text on the subject (DeAngelis and Gross 1992).

Above all, truly individual-based models, or so-called i-state configuration models (Maley and Caswell 1993), have been used for the object-oriented approach, for example, the work by Silvert (1993), Derry (1998) and Roese *et al*. (1991). There are several models of forests (Deutschman *et al.* 1997, Liu and Ashton 1998). The most striking application is undoubtedly the Across Trophic Level System Simulation (ATLSS) model which attempts to simulate the ecological function of the Everglades in Florida (Abott *et al*. 1995). This model represents abiotic factors — such as hydrology, fire and hurricanes — and different trophic levels simultaneously. Within the models, which can be mathematical compartmental models, different animal populations are simulated (deer, cats) with the help of individual-based models.

MAS and Social Sciences

MAS are developing rapidly in the field of social sciences. Society simulation is the subject of numerous conferences, for example, Multi Agent systems and Agent Based Simulation (MABS) (Sichman *et al.* 1998) among others (Conte *et al*. 1997). Research on the subject is published in the electronic journal Jass (Journal of artificial societies and simulation). In addition, a group called Agent-based Computational Economics (ACE) (Tefstation 1997) has been set up.

In social sciences, the application of the theory of multiagent universes to simulate social phenomena is generally associated with the methodological individualism (Havelange 1994, Lenay 1994) in which the singular individual is considered as the elementary unit or the atom of society (Weber 1971). The overlap is, in fact, in the bottom-up approach which characterizes MAS. However, the assimilation between individuals from a society and agents from a multiagent universe can be misleading: it is quite possible for social groups and institutions to be considered as agents with their own standards and rules for functioning (Livet 1987). The agents are directed by constraints or rules that are expressed on a group level, ie they are no more than entities that act and are placed in a dynamic environment.

This straightforward comment — which is natural when MAS are used for modelling — shows how the simple duality that exists between individualism and holism can be called into question, which is a major preoccupation for researchers working on renewable resource management and MAS:

(i) individuals, products of history are driven by collective values and rules,

(ii) collective values and rules evolve because of the interaction between individuals and between groups,

(iii) the individuals are neither similar nor equal but have their own specific roles and social status.

How do individuals make up a group? How is an institution created? The individual cannot be considered as an autonomous entity that is independent of its social environment. How are individuals constrained by collective structures that they themselves have set up and how do they make these structures evolve (Gilbert 1995)? What degrees of freedom are given to the definition of individual practices? Here are just some of the questions that can be explored using MAS and which can be expressed as follows: "how are collective structures set up and how do they function when they are based on agents with different capacities of representation, that exchange information, goods or services, etc., draw up contracts and are thrust into a dynamic environment which responds to their actions?"

MAS and Interactions between Societies and Resources

The problem with modelling common resource management is the simulation of the interaction between groups of agents and dynamic resources. Empirically, there are several ways of modelling these interactions.

The first method involves simulating how social networks are managed. Here, we consider that the relationships between people and resources should, in fact, be formulated as the relationships between people that concern resources. Agents that exchange messages within networks or so-called contact networks can be simulated with MAS. In this way, exchanges of information and services, contracts and agreements between agents can be simulated. For example, in the case of irrigated systems, farmer agents can send each other messages so that they know what the water levels are in different plots, they can ask for or exchange services or addresses. In this way, it has been shown (Barreteau and Bousquet, in press) that the evolution of a system can be very sensitive to the structure and dynamics of social networks.

In the second method, emphasis is put on the cognitive processes or representations that determine how agents and resources interact. Each agent develops and then acts on its own representation of a resource. In so doing, the agent transforms the resource for the other agents. This model represents interactions that are close to what economists call externalities. We study the problem of managing common renewable resources by examining the different representations of actions that affect the resources in question. The resulting resource use may or may not be satisfactory for the agents. This can be described as coordination through the environment.

This method of classification provides a framework, but there have been studies that take into account the agents' interactions as well as systems of exchange through the environment.

Cormas: Multiagent Simulation Software

For several years now, multiagent simulation software has been available. User groups (including ecologists and sociologists) are organized around generic tools that facilitate the construction of models and offer facilities ("virtual laboratories") for monitoring and analysing simulation trials. The example of Swarm[1]—which uses the object-oriented language Objective-C for writing code and Tcl/Tk for developing interfaces—clearly reflects the current trend. Since the launch of the project at the Santa Fe Institute in 1994, groups using Swarm have joined forces to try and resolve common problems. As a result, new software based on Swarm, with specific applications for different disciplinary fields (ecology, for example), has been developed.

Our team is particularly interested in models for resource management. Hence, the multiagent simulation software that we have developed is based on the concept that space holds resources. The software Cormas is an environment for constructing multiagent models based on the software VisualWorks which, in turn, is a programming environment within Smalltalk. Cincom, the American company that markets VisualWorks distributes the software freely (for educational and research purposes). Cormas is also available to the scientific community[2] in the form of a set of programmes that are downloaded in VisualWorks.

Cormas is made up of different sets of programmes. The first is for modelling agents and interactions; these interactions are mediated either through a simulation space in the form of a set of cells or via messages. The second set of programmes involves the control of the dynamics of the simulation, whereas the third set of programmes is for defining the observer's different points of view.

Several types of entity can be defined using Cormas. All the entities in Cormas possess **primitives** (programmes) which allow the exchange of resources on request (be it *pro rata*, **the most sought after** or as a function of the agents' characteristics, etc.).

Here, we describe the entities used for the model presented below.

> The first is called the situated agent. A situated entity has spatial references (the cell). It is characterized by its perception range.

[1] http://www.swarm.org

[2] http://www.cirad.fr/presentation/programmes/espace/cormas/

The second is the cell. Space is a component that is taken into account by Cormas. Above all, it is the support for situated agents. Thus, the cell has a list of located agents that are situated on it. The cell provides primitives for access to neighbouring cells within a varied radius. The space also has its own dynamics. As with cellular robots, the cells are characterized by a state that can change dynamically depending on rules that take into account the state of neighbouring cells.

The third is the spatial aggregate. When MAS are used to simulate spatial dynamics, the question is how can the spatial agents and the rules that govern their spatial interactions be simulated on different levels? We simulated spatial dynamics—with their own specific behaviour patterns—based on geographic entities (forest, town, road, etc.) at a higher level of organization than that of the cell.

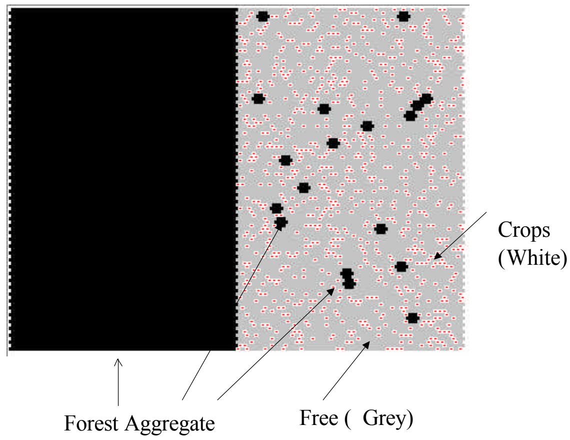
An Example of Results: a Model for Fuelwood Consumption

The model described here was developed for research concerning fuelwood consumption in the Kayanza region of Burundi.

The Model

We developed a model with three different entities: the cell — which represents 1 ha of space — the forest, which is an aggregate entity that represents forests — and the household agent, which represents a family living on one cell. We describe the three entities and then go on to describe the control algorithm which determines how the three different entities behave. The time step chosen for the simulation is equal to 1 year. The space under study is made up of a set of 10 000 hexagonal cells which have six adjacent cells. Thus, a region of 100 km² is represented (Figure 1).

Figure 1. Initial state.



Description and Dynamics of a Cell

The cell is characterized by six variables:

- state: this variable relates to one of five values (forest, degraded forest, pasture, cropland and agroforestry). The transitional function of the cell, ie the rules that determine a change of state, is outlined in Figure 2.
- Live wood: this variable represents the quantity of standing wood (measured in m³) on the cell. When the cells are initialized, the variable is set at 300 m³ if the cell is in the forest state. The dynamic of this variable is simulated according to the logistic model. When a cell is in the agroforestry state, which simulates the fact that the agent on the cell has planted trees, the initial stock of live wood is 20 m³.

The Household Agent

The household agent is characterized by six variables:

- Population: Population growth is simulated at 3%. For every time step, a random distribution simulates this growth. The phenomenon of migration is also simulated. The probability of migration is 10% for a household of four people, 30% (five people), 50% (six people), 70% (seven people), 90% (eight people) and 100% for households of nine or more. There is a random draw in these distributions and the population size is eventually reduced by one unit. There are four people per household to start with.

- Wood space: this corresponds to the agent's spatial perception. It consists of all the forest cells within a perception range of 2 km (Figure 3).
- Live wood: the amount of live wood collected during one time step.
- Dead wood: the amount of dead wood collected during one time step.
- Consumption: the total amount of green and dead wood collected.
- Satisfaction: this has a true or false Boolean value depending on consumption. If consumption is greater than 90% of potential consumption ($1m^3$ $person^{-1}$ $year^{-1}$), satisfaction is equal to the true value otherwise it is equal to the false value.

Three supplementary programmes were written for the household agent. They relate to behaviour patterns for harvesting wood. The agent calculates how much live wood (consumption of live wood) or dead wood (consumption of dead wood) they need. It then asks the cells in its perception range (wood space) for this amount of wood. The third programme (local consumption) corresponds to the amount of wood consumed by agents on an agroforestry cell. The quantity of consumable wood on the cell is the quantity of surplus live wood compared to the maximum production level (75 m^3). In this way, the sustainable management of the agroforestry cell is simulated

Controlling the Simulation

Once the different interacting entities have been defined, the programmes needed to organize the simulation have to be defined. These are as follows:

- Initialization: to initialize the simulation, a map has to be downloaded (Figure 1). This represents the initial spatial situation. The household agents are then positioned on the cropland cells. Each household agent has four members (population = four). The aggregates are then created in order to group together the sets of contiguous forest cells. Lastly, the agents develop their perception on the forest cells that are in their variable wood space within a 2 km radius.
- Control: (Figure 4) at every time step, a number of operations are carried out in order. First of all, the cells calculate wood production. Then, the agents activate the local consumption programme. The cells process the demand. If the agents are unsatisfied, they consume dead wood. The cells process the demand. If the agents are still unsatisfied, they consume live wood. The cells process the demand. Eventually, the cells change state. The cells that belonged to the forest aggregate and which are no longer in a forest state are removed from the forest aggregate. Lastly, for each migration, a new population agent equal to one is created and set up on a cell in a free state. This agent's perception range is calculated.

.

The Scenarios Tested

In this article, we test different scenarios. The first scenario (sc1) corresponds to the model described above. In the second scenario (sc2), simple rules of exchange of use rights are taken into account. Thus, every agent that is unsatisfied with its wood harvest has a look at agroforestry cells in the immediate vicinity to see if there is any surplus wood, before planting trees and transforming their own cell into an agroforestry state. If this is the case, the agent makes a request for wood. In the third scenario (sc3), rules governing access are taken into account. Thus, in the small natural forests in the east (right hand side of the map) cutting live wood is prohibited. Finally, a fourth scenario (sc4) combines rules of exchange and rules of access.

Figure 2. Transitional function. Each circle represents a potential state that a cell can adopt. The arrows represent the possible transitions and the text describes the conditions necessary for the transitions.

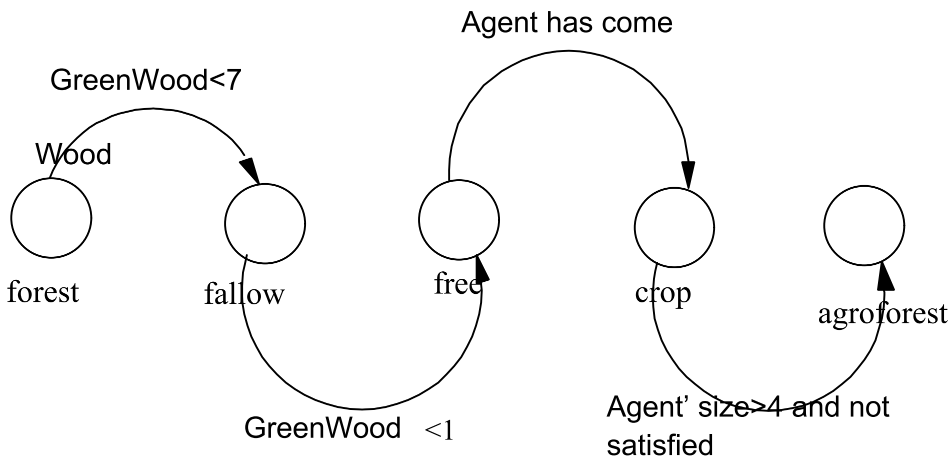


Figure 3. An agent's perception range

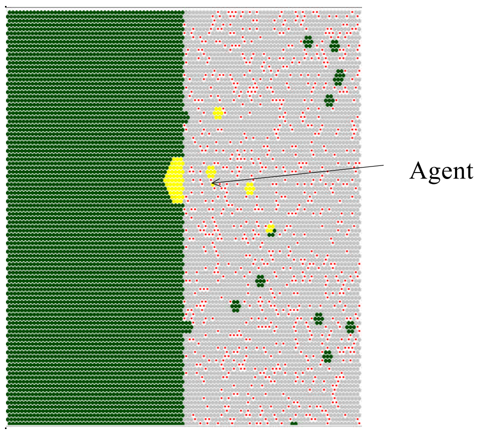

Figure 4. Sequence diagram.

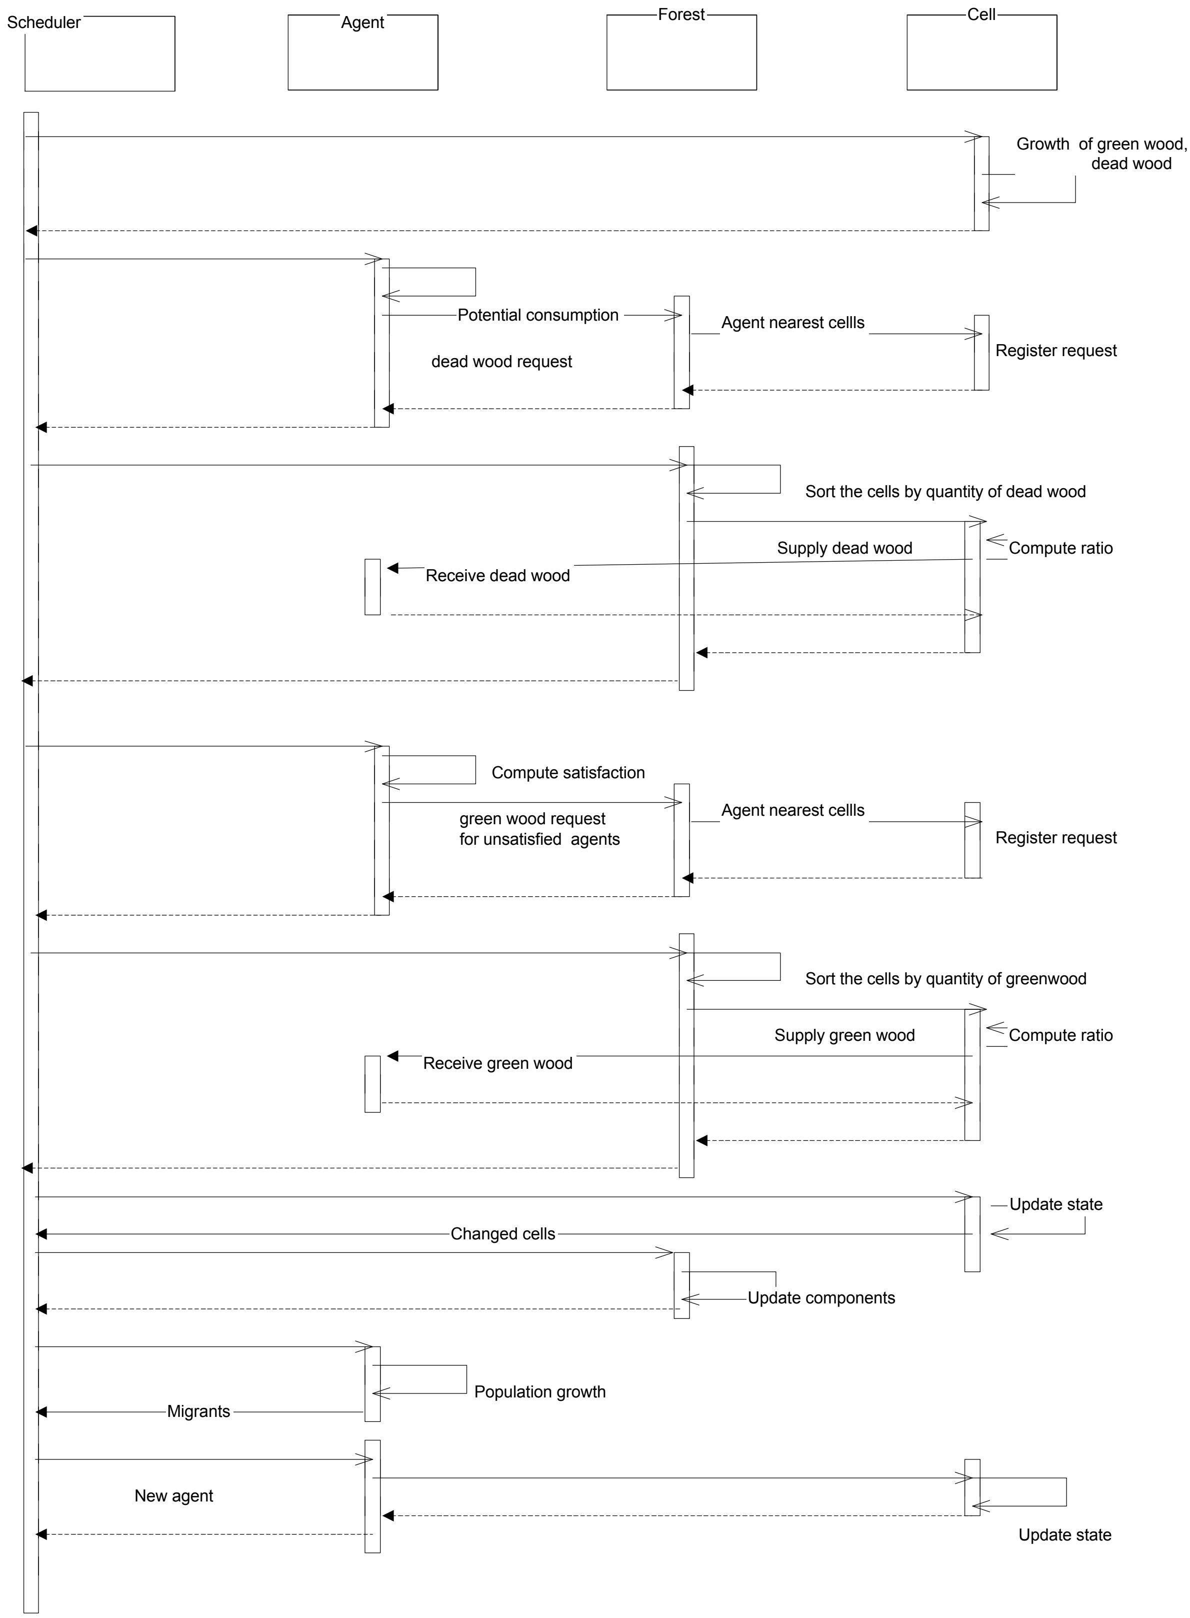

Results

We have identified three indicators to compare the results from the different scenarios.

- Consumption/inhabitant: this is the total amount of wood consumed divided by the total population. It reflects the degree of satisfaction. Potential consumption is 1 $m^3person^{-1}$.
- The number of forest cells: this measures deforestation.
- The number of agroforestry cells: this is the number of cells where agents have planted trees.
- Population density in the region: this indicates the control of the simulation.
- Results are shown in Figures 5, 6 and 7.

Figure 5. Individual consumption.

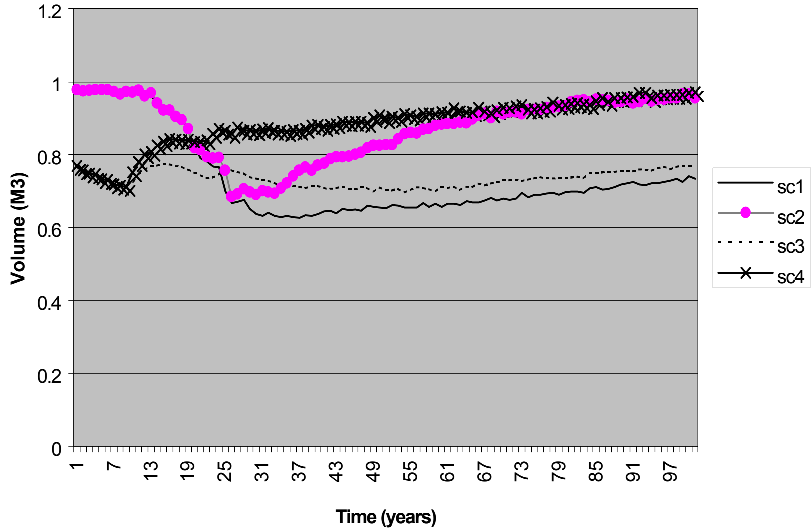

Figure 6. Deforestation: evolution in the number of forest cells.

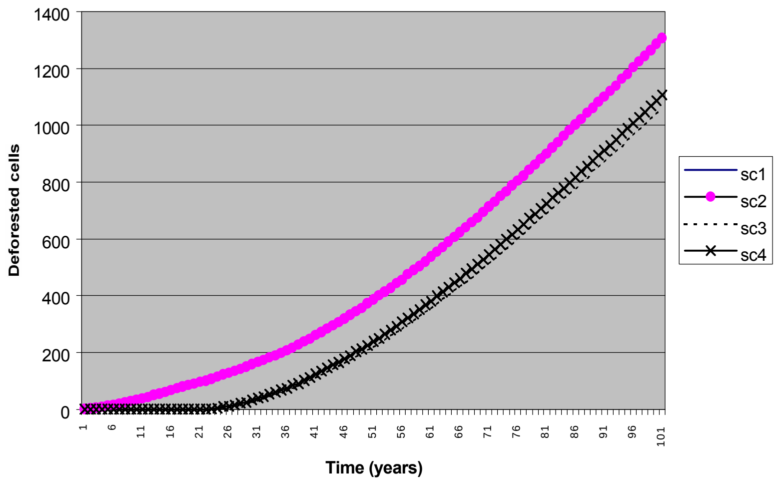

Figure 7. Evolution in the number of agroforestry cells.

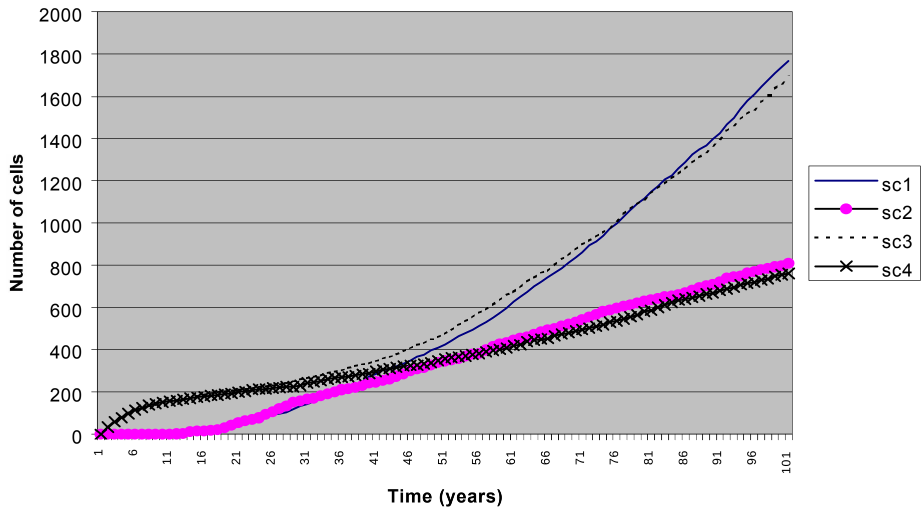

The figures show the different evolutions which can be divided into two periods, namely, when consumption falls and when it increases again.

The Drop in Consumption

At the start of the simulation, the simulations can be divided into those with free access (sc1 and sc2) and those with differentiated access (sc3 and sc4).

In the case of free access, a few agents use the small forests in the east as a resource and take live wood (Figure 6). Around 100 forest cells disappear which corresponds to the small forests. The small forests satisfy the agents' demand and the agents consume 1 m^3 wherever possible. There is a crisis after about 10 years because, once the small forests have disappeared, all the agents in the east (right hand side of the map) find that they are too far away from the forest. Agents that are able to plant trees on their plots do so (Figure 7). It takes 10 years for the planted trees to start producing, which explains why the drop in consumption levels out after about 25 years.

In the case of differentiated access, the crisis is immediate because there is not enough dead wood in the small forests in the east to satisfy demand. Consequently, the agents plant trees quickly (Figure 7). There is not much pressure on the forest to start with (low population density and wood is taken from a wide area, cf. Figure 6). Therefore, there is less deforestation.

Increase in Consumption

The increase in consumption is different in each simulation. In the case of the scenarios with differentiated access (sc3 and sc4), consumption goes up sooner because trees are planted earlier. However, we observed that the evolution is influenced by whether or not wood can be exchanged. The two simulations involving exchanges (sc2 and sc4) produce much better results and satisfaction is almost perfect at the end of the simulation. In the simulations without exchange, results from sc3 are slightly better at the end of the simulation. This is due to the fact that the small forests in the east that are not cut down continue producing dead wood that the agents collect. We also observed that the possibility for exchange limited the need for planting (Figure 7). We observed that in the cases with differentiated access, deforestation did not occur until year 40. The difference between differentiated access and free access is in the order of 100 cells, which corresponds to the number of cells in the small forests that were felled. The rate of deforestation is the same in the four scenarios.

Discussion

The results obtained from the above simulations can be interpreted logically by reconstructing the past. However, when the results are examined from a wider perspective, one can see that the observed changes seem paradoxical when considered at a different scale and with static reasoning.

The simulation with the most forest cover (sc1) experiences the most severe crisis (in terms of consumption). This calls into question the logic of matching the supply of natural resources with demand. In fact, in these simulations, once the small forests have been destroyed—their resources are exhausted because of free access — each household independently attempts to deal with the crisis. With the simulations involving exchange mechanisms, fuelwood can be distributed.

In the simulations, the fact that wood cutting is prohibited in certain places does not exacerbate deforestation in other areas. A number of complex phenomena arise. The small forests that are not cut down provide dead wood. If this is insufficient, agents who are in a position to plant trees on their cells have time to do so and this provides a new source of wood for exchange in future.

In this example, we can see that the spatial distributions of initial resources are combined with stakeholders' behaviour. With this type of methodology, it is possible to study problems that relate to:

1. Fragmented spaces where resources are renewed, which can be observed on several organizational levels.
2. Exchange mechanisms (for goods, services, currency and information) between heterogeneous agents that have different representations.

Complex tools, particularly MAS like the ones described here or by Epstein and Axtell, are effective for representing knowledge of processes and for simulating their interactions.

Without going into too much detail, one of the milestones of economic theory — which does nonetheless have an important contribution to make to the debate — is the theory of the tragedy of the commons (Hardin 1968). Hardin suggests that a common resource subject to rational economic forces is condemned to disappear from overexploitation because of free access. This problem can be solved by privatization or by setting up a central authority responsible for managing access to the resources, in other words by controlling access using regulatory or incentive mechanisms (Krutilla *et al.* 1983). In our model we can see that controlling access (scenario 3 and 4) delays deforestation but without modifying the rate of deforestation.

Another interpretation of resource degradation conversely focuses on under-exploitation or under investment in natural resources. In this model we can see that differentiated access allows a rapid investment in agroforestry. But a satisfying level of consumption is rapidly reached only when the control of access is associated with exchanges of use rights on agroforestry cells. Then this investment does not allow a global sustainable consumption when available only to an individual.

A number of authors including Ostrom (1990), Berkes *et al.* (1989) and Stevenson (1991) disagree with the privative management theory. They describe the foundations of an institutional approach which involves the application of formal or informal regulatory mechanisms for governing the viability of ecosystems. The word govern refers to representations of stakeholders and is based on a principle of negotiation of use or property rights. The model shows how the issue of exchange of local use rights is of importance in the management of renewable resources.

It can be difficult to put a local approach into practice because of outside interference or restrictions imposed at different levels, therefore, the current trend in research is to support the idea of co-management (McCay and Jones 1997). Co-management can be applied to resource management within a user group (fishermen) or between several groups that use the same resource for the same purpose (association of catchment areas). Therefore, with other forms of regulation and collective decision-making, it could be extended and applied to the management of resources with multiple uses. This is a question of coordinating the local and global processes involved in managing resources with multiple uses. We consider that simulations using MAS have an important role to play here.

Abstract

In many developing countries, tree fodder is important for increasing protein supplies for livestock and improving the utilisation of poor quality straws during dry seasons when little feed is available. Farmers in Nepal possess a considerable breadth of indigenous knowledge (IK) to assist them in making effective use of tree fodder. Attempts by researchers to support the development of tree fodder resources need to account for this IK in order to both avoid re-inventing the wheel and to ensure the acceptability of any innovations. This paper describes the use of model, based on fuzzy logic, for integrating the Nepalese tree fodder IK system with quantitative descriptions of the biological processes associated with tree fodder use in order to facilitate this process. In Nepal, farmers describe tree fodder quality using two scales, *posilopan* and *obanopan*. *Posilo* fodder is said to promote milk and butter fat production in lactating animals, rapid liveweight gain and animal health. *Obano* fodder "fills the animal", is highly palatable, particularly during colder months, and is eaten voraciously, although causing constipation if fed in excess. An earlier study examined the nutritional implications of these farmers' terms and suggested that the *obanopan* criterion relates to a fodder's digestibility and the *posilopan* criterion to its ability to supply protein. These observations were consistent with the characteristics assigned by farmers. The model described here used these associations to examine the outcomes of feeding strategies for dairy cattle formulated with reference to farmers' criteria and based on the information available to them regarding the quality of tree fodder. The model's predictions were consistent with farmers' expressed objectives of optimising milk production whilst ensuring that animals remained adequately fed in times of feed shortage.

Keywords: Tree fodder, Indigenous knowledge, Fuzzy logic, Dairy cow, Nutrition

Introduction

In many developing countries, tree fodder - from forest land and on-farm plantings - plays an important role in increasing protein supplies for livestock and improving the utilisation of the poor quality straws that predominate in diets during dry seasons when feed is in short supply. In turn, livestock support production from and sustainability of crops and trees on arable land through the provision of labile plant nutrients in manure and draught power to ease the difficulties of land preparation and maintenance. In short, these tree-crop-livestock systems are often highly integrated and, as a result, highly productive too.

Such tightly integrated systems, in which management decisions with immediate impacts in one component can have considerable knock-on effects in others, clearly require quite sophisticated managerial skills based on a reliable, if empirical, knowledge of the likely outcomes of the management decisions that are made. An appreciation of this "indigenous knowledge" (IK) is now seen by many as a prerequisite for researchers to make a tangible contribution to the generation of technologies that can be seamlessly integrated into existing, complex agricultural systems to promote long-term improvements in the sustainability of livelihoods (Sillitoe 1998). Indeed, a lack of this appreciation in the past may have at least contributed to the limited extent and durability of impacts generated by applied agricultural research targeted on the farming systems of developing countries.

A detailed discussion of the historical perspectives and methodological intricacies associated with the assimilation of IK by social and biological researchers is beyond the scope of this paper. However, a key constraint to achieving such assimilation would appear to lie in the difficulties associated with generating comprehensible interpretations of indigenous knowledge systems that can be interfaced with the "biology" in order to underpin relevant research and improve its focus. This paper describes the use of fuzzy logic to facilitate the integration of IK, in particular, and qualitative information, in general, with quantitative descriptions of biological processes. A case study based on the interpretation and assimilation of an IK system for tree fodder quality, applied by farmers in Nepal, is presented in illustration of the potential utility of the approach.

Why use Fuzzy Logic?

The notion that bi-modal or boolean logic may be extended to include values between true and false may be traced back to Plato. A little more recently, the application of an "infinitely-valued" logic to classical set theory led to the development of the mathematics of fuzzy sets (Zadeh 1965) and its associated branch of logic, fuzzy logic. Fuzzy logic has now found widespread practical application in situations where there is uncertainty, or disagreement, about the semantic interpretation of a set variable.

Figure 1 illustrates the specification of an intrinsically fuzzy concept in agriculture using both boolean and fuzzy sets. In this simple example, it is assumed that there is a need to characterize crop production as high or low yielding, perhaps in order to target, more effectively, interventions aimed at increasing yield. Clearly, the restriction on the crisp membership function to a value of zero or unity (i.e. true or false) necessitates that a crisp value is assigned to the level of yield at which a crop may be considered to be high yielding. This approach has two major limitations:

The selection of a value of, for example, 4.5 t ha^{-1} as the threshold for a "high yielding" crop may be used as a premise for statements such as "crop A, yielding 4.4 t ha^{-1} is low-yielding, and crop B, yielding 4.6 t ha^{-1}, is high-yielding". Semantically, this is nonsense;

Conceptualizing the term "high yielding" as a moveable feast implies that the threshold should depend on a variety of factors such as crop variety, type of farm, production objectives and perhaps even external factors such as marketability. The complexity of these factors and their interactions means that a deterministic approach to including them implicitly in the crisp specification of the concept is likely to be infeasible.

In contrast, the fuzzy set allows a perception of a growing degree of "high yieldingness" from a situation in which, for any variety and by anyone's standards, the yield may be viewed as low to the other extreme at which yield may be considered to be unequivocally high. A membership function may be specified that includes the effects of factors such as those described above and, depending on the situation, a set of decision rules may be formulated according to the degree of membership calculated.

Fuzzy Sets for the Representation of Indigenous Knowledge

In general, there is a lack of certainty attached to statements of IK that makes them suited to representation as fuzzy sets. This arises, in the first instance, from their diverse sources. For any individual, these are likely to range from personal experience to orally transferred information from others who, because of distance or even death, may never have been in direct contact.

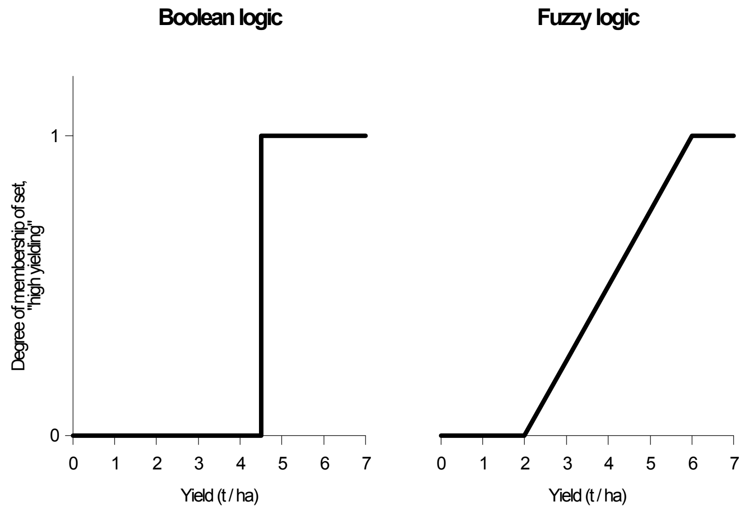

Figure 1. Applying boolean and fuzzy sets to the characterisation fo crop yield

The dynamic nature of the farming system constitutes a further source of uncertainty in indigenous knowledge systems. Levels of production from any agricultural enterprise must generally be maintained under environmental and market conditions that fluctuate, often in multiple cycles of varying amplitude. On top of this short-term variability are superimposed the long-term degradation that arises from increasing population pressures or climatic changes and the long-term improvements achieved, it is to be hoped, through agricultural development in the broadest sense. It must not, of course, be forgotten that *people* manage farms and that their objectives may also change independently of the need to respond to extraneous changes such as those described above. Currently, the pace of change in resource availability in smallholder farming systems is generally perceived to be escalating. It seems likely that, given its diffuse derivation, indigenous knowledge may not, in all cases, be sufficiently responsive to these changes. In this situation, practicable methods for systematically integrating indigenous and scientific knowledge would appear to offer the potential for improved support to farmers' decision making.

Case Study: A Biological Model of Ruminant Digestion Driven by Indigenous Technical Knowledge of Tree Fodder Quality

Fodder Quality Knowledge Systems in Nepal

Resource-poor farmers in Nepal have a detailed IK system for describing the nutritive value of the fodder from a wide range of tree species that are used as dietary supplements for ruminant livestock (Rusten and Gold 1991, Thapa *et al*. 1997). These studies revealed two local classification systems for tree fodder; *posilo* - *kam posilo* (*posilopan*) and *obano* - *chiso* (*obanopan*) which were found to be fundamental to farmers' perceptions of tree fodder quality.

The literal translation of the Nepali terms *posilo* and *kam posilo* are nutritious (high nutritive value) and less nutritious (low nutritive value) respectively. Farmers state that *posilo* fodder promotes milk and butter fat production in lactating animals, rapid live weight gain and animal health. They are generally considered to be palatable and to satisfy appetite although these effects are, at least to some extent, dependent on the type of livestock involved. In contrast, feeding *kam posilo* fodder does not result in high milk yields and rapid growth rates of animals and, if fed as a sole fodder, may cause weight loss, reductions in milk and butter fat yields and a general deterioration in health.

Obano is translated as 'dry and warm' and *chiso* as 'cold and wet'. The terms have been taken by Rusten and Gold (1991) to refer, specifically, to the consistency of dung produced by animals consuming the different types of fodder. However, farmers also state that *obano* fodder is highly palatable, particularly during colder months, and is eaten voraciously, often causing constipation if fed in excess. *Obano* fodder is said to improve animal health and generally contributes to milk and *ghee* (clarified butter) production. It produces (literally) dry, firm dung - which must be viewed as significant in a system in which the manual collection and application of manure-compost is the primary means of maintaining soil fertility. C*hiso* fodder is less palatable and, if fed in cold months, often result in animals producing watery dung that is difficult to collect and spread.

Walker *et al.* (1999) and Thorne *et al.* (1999) have described a biological interpretation of the *obanopan* and *posilopan* IK systems. These studies suggested that the knowledge of tree fodder quality possessed by farmers is quite consistent with the level of information that may be generated from the laboratory analyses that are commonly used by nutritional researchers for the same purpose. The *obanopan* system appeared to relate to digestibility of tree fodder (as predicted by an *in vitro* test) whilst the *posilopan* system was perceived as an indicator of general nutritional quality related to the ability of a tree fodder to promote the supply of protein at the duodenum. These findings appear to be consistent with farmers' descriptions of the characteristics of *obano* and *posilo* fodder. Interestingly the relationship observed in the study between *obanopan* and *in vitro* digestibility indicated that Nepalese farmers, in preferring to use *obano* fodder, also preferred a less digestible fodder. This highlights the paramount importance of interpretation of nutritional information against farmers' objectives under any particular set of circumstances. This point was strongly reinforced by the fact that recommendations derived from a panel of nutritionists viewing a set of laboratory indicators describing the tree fodder studied did not appear to account, in any way, for the *posilopan* criterion judged important by farmers.

An initial analysis of complementarity (Thorne *et al.* 1999) between the information provided by farmers' perceptions of fodder quality and those that might be generated in a laboratory was encouraging for a the more integrated approach to assessing fodder quality for the smallholder farmer that is addressed in this paper.

Model Construction

Four fuzzy variables were used to define farmers perceptions of the quality (*obano* and *posilo* status) of the eight tree fodders for which data were available (Walker *et al.* 1999) and the outcomes associated with their use (Table 1). The membership functions (FV1 - FV4) for the linguistic values associated with each of the fuzzy variables are shown in Figure 2. For each of the linguistic values of each fuzzy variable, the membership function was used to calculate a degree of membership (DOM) as follows:

FV1 *obano* status – the degree of membership of the *obano*, intermediate and *chiso* linguistic values were inferred from the farmers' mean ranks for *obano* status. In general, farmers exhibited a relatively high degree of consensus regarding the status of the most obano and most chiso tree fodders. Therefore, a hedge $FV1^2$ was used to generate the two, further linguistic values, very *obano* and very *chiso*;

FV2, *posilo* status – the degree of membership of the *posilo*, intermediate and *kam posilo* linguistic values were inferred from the farmers' mean ranks for *posilo* status. Again, hedging $FV2^2$ was used to generate the linguistic values, very *posilo* and very *kam posilo*;

Table 1. Fuzzy variables used in the model and their linguistic values.

Fuzzy variable	*Linguistic values*
Obano status	*Obano*, intermediate, *chiso*
Posilo status	*Posilo*, intermediate, *kam posilo*
Ability to satisfy appetite	Acceptable, low
Level of milk production	High, medium, low

Table 2. Assignments of values for fill units to the linguistic values describing obano status.

Obano *status*	*Fill unit*
Very *chiso*	0.6
Chiso	0.75
Intermediate	1
Obano	1.25
Very *obano*	1.4

FV3, acceptability of fill ratio – the acceptability of a range of fill ratios (actual intake / potential voluntary intake) to unity was inferred from a longitudinal monitoring dataset described by Thorne *et al*. (1998);

FV4, level of milk production – DOMs for levels of milk production were assigned on the basis of observed values on typical farms in the eastern hills of Nepal contained in the dataset of Thorne *et al*. (1998).

The inverse relationship observed between *obano* status and digestibility (Thorne *et al*. 1999) was used to associate the values of the linguistic variable for *obano* status with a mean level of fill units (UEL; as defined by Jarrige 1988). These are used in the "French" rationing system for ruminants, on which the biological component of the model is based, to describe the maximum voluntary intake of a feed by a defined animal relative to that of a reference material. These assignments are shown in Table 2.

]

Similarly, the association of *posilo* status and protein supply at the duodenum postulated by Thorne *et al*. (1999) was used to establish the protein component of the model. Values for PDIN (degradable, nitrogen limited microbial nitrogen supply) and PDIE (energy limited microbial nitrogen supply) were assigned to different values of the linguistic variable for *posilo* status using the data of Pozy and Dehareng (1996) as a reference point (Table 3).

Calculated values for PDIN and PDIE were used in the calculation of PDI (duodenal protein supplies) using the equation:

PDI = MIN[PDIN, PDIE]

PDI was then used to derive a crude prediction of milk yield:

Milk yield = MAX[PDI intake – PDI required for maintenance, 0.5

Figure 2. Membership functions for the four fuzzy variables used in the model.

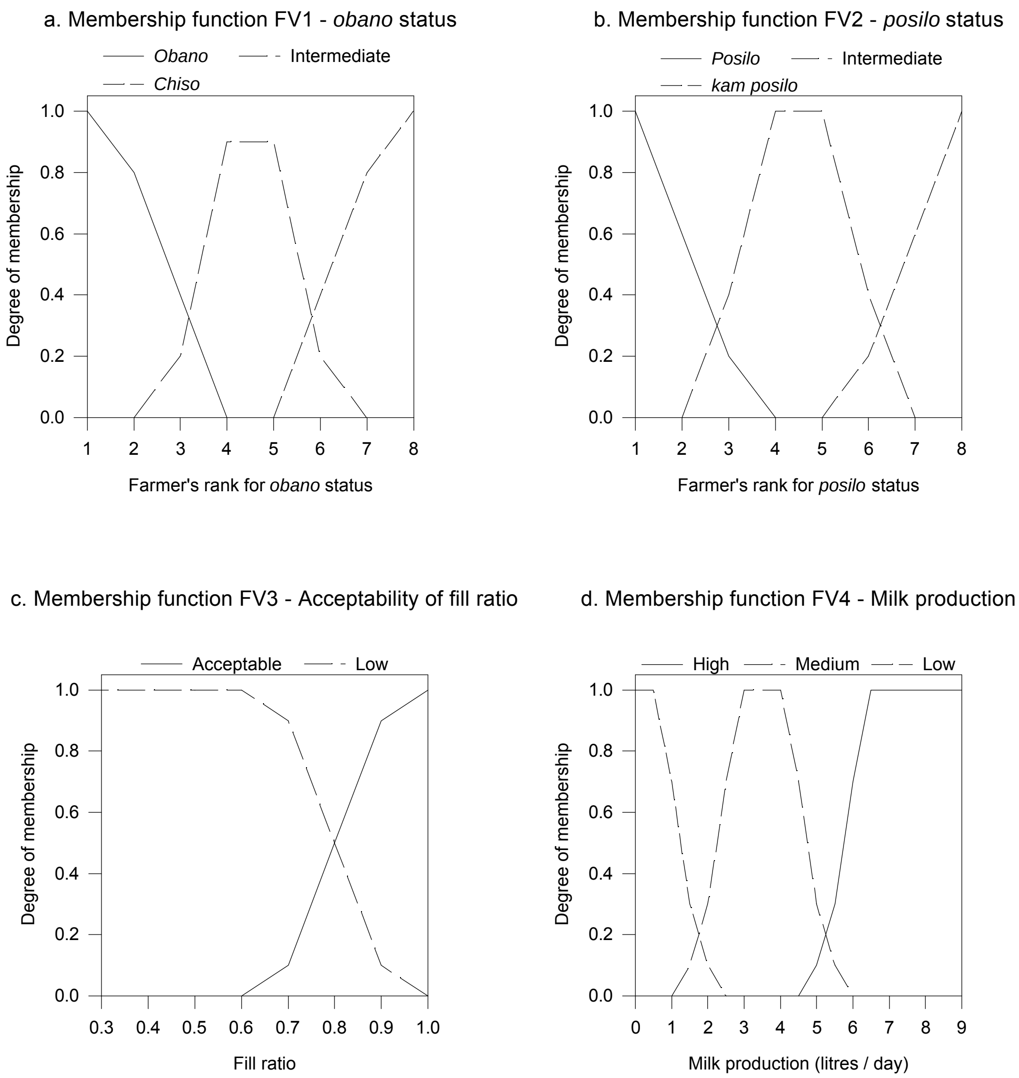

Table 3. Assignments of values for parameters describing nitrogen supply to the linguistic values describing posilo status.

Posilo *status*	*PDIN*	*PDIE*
Very *kam posilo*	53	138
Kam posilo	84.5	123
Intermediate	116	108
Posilo	162	121.5
Very *posilo*	208	135

Omitting the relatively complex contribution of body reserves to milk production was justified in this simplified model as it was proposed to use the model in the prediction of trends and not absolute values.

Dietary UEL values were used to determine the fill ratio for the current ration and describe the extent to which the appetite of the animal would be satisfied. These could then be integrated into a set of rules to suggest interventions in feeding strategies that would allow increased milk production whilst maintaining adequate fill ratios.

The Model's Predictions

In this section, two aspects of the predictions suggested by the model in relation to fill effects and trade-offs with potential stimulation of milk production are examined. In order to test the potential utility of the model it was assumed that, during periods of feed shortage, farmers will wish to maintain milk production at as high a level as possible. However, they are operating under difficult management conditions under which animals are confined in stalls. This means that the actual intake of a particular combination of feeds needs to match potential intake quite closely in order to avoid the behavioural problems that can arise in hungry animals. As feed supplies decline during a dry season, successful matching of intake to appetite implies a need to reduce feed quality that can compromise milk yields.

Figure 3 illustrates how the model can be used to predict the implications of this situation as the supply of rice straw available for animal feeding diminishes. *Ficus nemoralis* is a *chiso* fodder and is therefore less valued by farmers for satisfying appetite during feed shortages. In contrast, *Albizzia julibrissin* is regarded as *obano*. As fodder supply is reduced, the model predicts that the ability to satisfy appetite will be sustained until rice straw availability falls below 2 kg day^{-1} (see membership function for FV3) when the *obano* tree fodder is used as a supplement. However, using the *chiso* tree fodder would require levels of rice straw availablity of 4 kg day^{-1} in order to avoid the risk of behavioural problems. This assessment of trade-offs suggest that this modeling approach might be used in deriving more dynamic recommendations on tree fodder use that take better account of the changing availability of basal feeds as seasons progress.

The predictions summarised in Figure 4 illustrate how the model has been used to consider both the *obanopan* and *posilopan* criteria applied by farmers for most effective feeding in times of relative plenty. Points on the plot represent predicted milk yields for three types of fodder, of contrasting *posilopan* characteristics), at different levels of supplementation. Points falling on the lines represent feasible levels of supplementation in terms of the appetite restrictions imposed by the *obanopan* characteristics of the different fodders. A simple interpretation of *posilopan* (which we suggest correlates with protein supply) is that the use of a *posilo* fodder should promote milk yields. However, the model predicts that a fodder that is intermediate in terms of the *posilopan* criterion, *Ficus nemoralis*, ought to deliver maximum milk production as the animal is able to consume more of it. Whilst this prediction may be unremarkable in itself, the fact that it has been generated by a model that uses only data provided directly by farmers to describe the feeds used suggests considerable potential for this approach.

Discussion

Research on the interpretation of indigenous knowledge has been variously criticized for its folksy-romanticism or, almost conversely, for ethnocentrism, for a reliance on the inferred validity of, possibly dubious, cross-comparisons, and for a general irrelevance resulting from a perception that this knowledge is entirely context-sensitive.

It is, perhaps, not surprising that there have been few structured attempts to derive biological interpretations of indigenous knowledge systems and even fewer studies directed at the methodical integration of indigenous and deterministic parameters. This study, and the IK evaluations on which is based, demonstrate at least the feasibility of integrating deterministic biological knowledge and IK in a complementary manner.

Figure 3. Effects of obano status on the ability of crop residue-tree fodder combinations to satisfy appetite (point labels are fill ratios where a value of unity represents a combination fed at satiety).

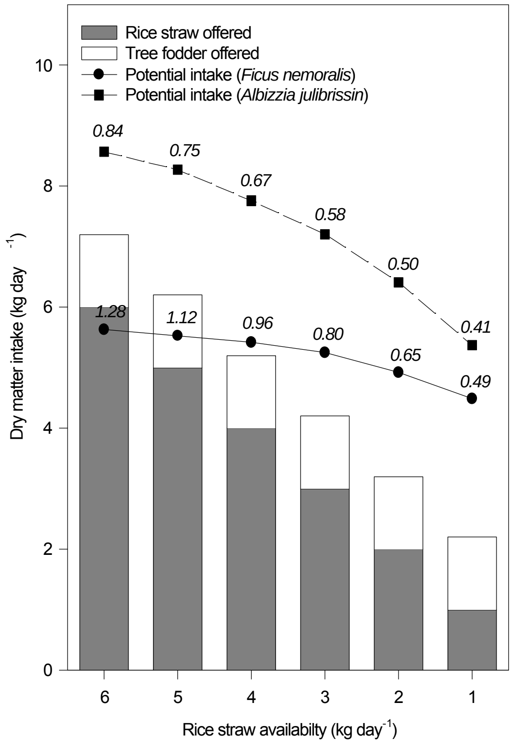

Figure 4. Prediction of the milk yield-appetite satisfaction trade-off for fodders with differing combinations of obanopan and posilopan status.

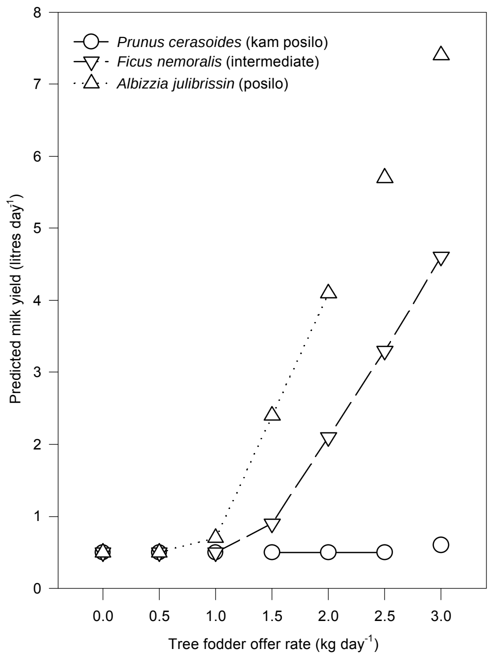

This approach could confer a number of potential advantages. The work has broad implications for research aimed at the development of improved feeding strategies. For example, routine data on the chemical composition of tree fodder are difficult to collect because of the range of trees used by farmers and the extent to which their nutritive value varies as a result of seasonal and other environmental factors. Farmers' knowledge encompasses this range of fodder types and environmental effects and the objectives of feeding strategies are implicit in their perceptions of the relative value of different fodders. Provided that a sound biological interpretation of farmers' knowledge systems is available - and currently, we stand at the beginning of this process - it should be possible to integrate this knowledge with more mechanistic descriptions of nutrient utilisation in livestock. Such an approach could provide the types of predictive systems that we require to promote more effective utilisation of tree fodder on farms. Conversely, some of the laboratory methods used in this study are also used routinely by breeding programmes in the assessment of new species or lines for fodder quality. A more detailed knowledge of the biological basis of farmers' knowledge will allow us to focus these evaluations more effectively on farmers' objectives and to deliver their results to farmers in terms that they can understand.

The model described in this paper was developed to illustrate an approach and is simplistic in practical terms. However, a number of initiatives have sought to develop the approach further. Notably it has been adapted to the assimilation of a set of qualitative indicators of fodder quality (e.g. forage colour, days of regrowth) into a predictive rationing system for dairy cattle (Thorne 1999). This system (DRASTIC) has already been applied with some success to the planning of practical management strategies under field conditions.

Abstract

Current levels of deforestation suggest that the rising demand for tree products will have to be met by increased levels of tree planting. While traditional forest plantations will satisfy some of this demand, it is likely that there will be a substantial increase in the planting of trees on farmland. Farmers in areas of increased population density are already motivated to plant trees on their land because of the benefits they bring and this trend will continue. However, a great deal of potential exists to improve the tree species cultivated on farmland through a process of tree domestication, which involves not only tree breeding but species priority setting, nursery work, tree management, extension, marketing and policy interventions, and it is important that farmers participate in this process. Domestication of trees with high value products (timber, fruit, medicinal products) will provide small-scale farmers with income and an entry point to the commercial marketplace.

Keywords: Farmers, Tree products, High value

Introduction

Trees provide a wide variety of products (timber, poles, paper, fuelwood, fruit, medicines, fodder, etc.) as well as services (erosion control, carbon sequestration, soil fertility replenishment, hydrological functioning, boundary delineation, cultural significance, etc.). Traditionally there was no need to cultivate trees, as the nearby forest was a vast entity to be exploited but human population pressures have radically changed the situation. The world's forests are declining at unprecedented rates (30,000 ha day^{-1}). Massive changes in forest cover in the tropics will continue as rural populations and forest concessions continue to expand. Reports indicate that well over half of remaining forests are under threat for conversion to agriculture, to logging, and to meeting energy needs (WRI 1998). Agriculture, already the dominant land use in the tropics, will take over another 90 million hectares by the year 2010, a large proportion of which is now in forests (FAO 1997). Although improved management of natural forests may contribute to their more sustainable use, it is clear that if the increasing demand for tree products is to be satisfied, there must be increased deliberate planting of trees.

Although the total area under tree plantations in developing countries doubled between 1980 and 1995 from 40 to 81 million hectares (FAO 1997), reductions in Forestry Department budgets in many parts of the tropics have resulted in poor management of these plantations. In Africa, current afforestation efforts are unable to keep pace with loss of natural forests (FAO 1997). Plantations in most tropical countries consist of fast-growing exotic species such as eucalypts, pines and acacias. In Kenya, of the total plantation area of 164,000 hectares only 15,800 hectares is planted to indigenous hardwoods (Muchiri 1997) and this is a relatively high percentage compared to other countries. In tropical America, pines and eucalypts alone make up over 80% of the total plantation area (FAO 1997). The low species diversity of plantations is thought to make them more susceptible to pests and diseases then trees in natural forests or in agroforest ecosystems, where a greater number of species provides more of a buffering against pest attack. It is worrying, although perhaps not unexpected, that the vast *Eucalyptus camaldulensis* plantations in Asia are proving to be susceptible to leaf blight, and *Acacia mangium* plantations are being increasingly attacked by a heart rot fungus (Old *et al*. 1995).

Community forestry has enjoyed significant donor investment in Asia and to a lesser extent in Africa. While some successes have been noted in Asia, they apply mainly in hillside areas protecting valuable valley bottoms and where forest products are relatively low-value, requiring little management. In Africa, community forestry programmes have been much less successful. Some, such as the Village Forest Areas in Malawi, are very small in size and operate under strict conservation rules. In addition to shrinking niches for the development of community forests, generating proper incentives for productive investment in these types of schemes is notoriously difficult.

This suggests that other tree planting options need to be explored. Agroforestry broadly defines tree planting on farms in all its various forms: single trees, scattered trees in fields, lines or small blocks of trees, farm forestry, tree-crop rotations, trees in multistrata systems or trees in home-gardens. Governments and donors are already looking to agroforestry to provide simultaneously tree products and environmental benefits. More importantly, farmers themselves are planting more trees than commercial forestry enterprises in the tropics as a result of increased returns to land and labour. For example, in Sri Lanka currently 73% of timber and 80% of fuelwood is produced in home-gardens and trees on farmlands (Gunasena 1997). In China, there are estimated to be 1.8 billion eucalyptus trees planted on farms compared to only 0.95 billion trees in industrial plantations and in Thailand and Vietnam, there are 15 times more trees planted on farms than in plantations (Harwood 1997). A recent study in Uganda based on aerial photos from 42 parishes found that in 1960 agriculture contributed 35% of total tree cover, but this had risen to 58% by 1995 (Place and Otsuka 1997).

Trees on Farms

The revised Forestry Master Plans of tropical countries are now recognising the contribution that agroforestry can make to the supply of timber, fuelwood and non-wood products for both domestic and industrial needs (FAO 1997). The Indonesian Forestry Action Plan projects that for wood alone, the total demand for both domestic and export markets will double within the next 25 years, leaving an annual shortfall of approximately 30 million m^3. To help meet the shortfall, Indonesia plans to establish the equivalent of 500,000 hectares of forested land on farmers' fields (Moestrup 1997).

Following the application of traditional benefit-cost analyses to afforestation projects in Africa, donor agencies are also encouraging such initiatives (Anderson 1987). This is in recognition of the fact that agroforestry compares favourably with other development options (e.g. agriculture, livestock) when forest services (effect on production, preventive expenditure/replacement cost, and contingent valuation) are valued. Even when only conventional financial analysis was done in 56 agroforestry projects in Central America and the Caribbean, 75% of them produced positive net present values at 20% real discount rate (Current and Scherr 1995).

Current Situation

Several studies have shown that tree planting increases with human population densities in continuously cultivated small farms (Bradley *et al*. 1985, Patel *et al*. 1995, and Pretty *et al*. 1995 in Kenya; Place 1995 in Burundi; Place and Otsuka 1997, in Uganda; Cline-Cole *et al*. 1990 and Harris 1996 in Nigeria; Gilmour 1995 in Nepal). When populations have risen to the extent that most off-farm sources of tree products are exhausted, there is economic incentive for farmers to increase tree cultivation on farm to have access to fuelwood, fodder and other products. Therefore, areas of low tree cover or high population density are logical places to target additional reforestation.

There is also evidence that farmers plant a variety of tree species on their farms. A full woody inventory carried out on 200 farms in four villages in western Kenya recorded a total of 190 tree species (Kindt and Lengkeek 1999). Even though average farm size was less than two hectares, a mean of 16 tree species per farm was observed. Scherr (1995) reported that trees were planted in Siaya and South Nyanza districts for building poles, fruit, green manure, shade, fencing, fuelwood, timber, ornamental, fodder and other uses. Although many of these tree species provide several products and services ("multipurpose trees"), on-farm products and services are typically sourced from several tree species. Having several species and varieties on one farm (with its limited space) providing a number of products and services at different times implies that farmers are applying a useful diversity concept comparable with that described in the crop diversity literature (e.g. Kindt and Lengkeek 1999). Arnold (1995) states that farmers plant trees in pursuit of their livelihood goals of income generation, risk management, household food security and optimum use of available land, labour and capital.

Most trees in Kindt and Lengkeek's (1999) survey were planted (78%) rather than natural regeneration (22%), indicating a strong tree-planting culture although the species of trees planted were dominated by species available in nurseries in the area (e.g. *Cupressus, Eucalyptus, Grevillea* and *Pinus*), not necessarily those that would be preferred by farmers (Kindt 1997). This suggests that there would be potential to increase the number of higher value species planted if material was available. Similarly, the genetic base of trees planted on farms appears to be narrow: 82% of the trees planted on farms in the area studied by Kindt and Lengkeek (1999) were sourced from the farmers own fields or the fields of neighbours and Weber *et al*. (1997) found that 75% of farm trees in Peru came from on-farm sources of germplasm.

We can conclude that there is great scope for improving those tree species currently planted through participatory domestication (Simons, 1997) as well as for introducing new species, particularly those that provide high value products. Unlike agricultural crops, most of these high value tree species are wild or near-wild and urgently require domestication to realise fully their benefits. Household surveys have shown that farmers seek to diversify their income but are often unaware of opportunities. This is due to unavailability of options and is also partly due to inadequate market information. In Cameroon, Ndoye (1995) found that 79% of farmers selling non-wood tree products in Cameroon were not aware of the prices that prevail in urban markets since a market information system does not exist (e.g. publishing/advertising prices).

Domestication of Agroforestry Trees

As trees come out of the forests and onto the farm, five main features have to be considered:

1. their function (fodder, timber, fruit, etc)
2. their value (economic, social, other)
3. their diversity (within and between species)
4. their number (as there is a finite number of planting holes per farm)
5. their niche on farm (boundary, contour, cropland, homegarden, woodlot, etc)

Taking these into account, intervention may be in one of four ways:

A. Replacement – when species A is harvested, replant with species A (improved or not)
B. Substitution – when species A is harvested, replant with species B
C. Expansion – increase number of planted trees on a farm (species A, Species B, etc)
D. Management – better manage existing trees on farm

Whilst much can be gained from experiences with industrial plantation species, agroforestry trees require different approaches, which involve social and political inputs as much as biological ones. To encourage tree planting amongst a diverse client group of resource-poor farmers requires better understanding of farmer's decision-making processes. The modest resources for tree domestication efforts have to be focused on priority species which have been determined following objective methodologies. Common to the domestication of all species is a need to accelerate the process to deliver appropriate improvement early on. The pro-active multiplication of germplasm is required to reduce the lag phase between identification and adoption of improved material.

Farmer-Driven Process

Perhaps the most important aspect in the domestication of agroforestry trees is that it must be done in a participatory way with farmers rather than as the provision of cultivars or germplasm developed on-station. Key questions which should be addressed before formal tree domestication commences include:

- is the research addressing farmers' problems?
- are farmers involved in all relevant aspects of the work?
- do farmers recognize the benefits of domestication?
- do farmers appreciate the benefits of domestication?
- are the approaches used sustainable?
- is the objective to increase production or maximize stability of production?
- are we skewing priorities with incentives or raising anticipation of markets which are by nature speculative?
- do we understand farmers' decision making processes?

Farmers' perceptions of the benefits of domestication affect greatly the strategy that should be developed. Consider a case of identifying an improved provenance of a priority fodder species. The biological threshold for improvement is fixed, whereby the best provenance may be say 45% more productive in terms of leaf biomass than the existing landrace material. The farmers' threshold for improvement is not fixed and can change. Farmers may not be able to perceive a 5% difference in leaf production but many may have a threshold for perceiving differences of above 20%. Since 45% is greater than 20% there is no problem and the new material may be actively promoted.

On the other hand, if the biological threshold for improving timber volume for say *Cordia africana* is 20% and the average farmers' threshold for improvement is 25%, then gains cannot be promoted as farmers will not perceive the superiority of the material. In this case, improvements will be hidden but nevertheless can still be important. The approach here would be to ensure that as far as possible only superior material was available in nurseries and seed stores since what is planted is what is available. The problem is that in most situations we are unaware of farmers' thresholds for improvement, and assume that new material can simply be promoted.

Which species to domesticate will depend on the objectives of domestication, and will differ if it is for income generation, germplasm conservation, forest conservation or farm diversification. It is important, however, that the limited resources available for tree domestication are directed towards priority species.

Species Prioritisation

Until recently research priorities among tree species were determined largely by researchers alone. Such subjectivity has led to sub-optimal use of resources although this does not mean that no successes have occurred (Simons 1996). Rigorous priority setting, however, requires understanding of user needs and preferences, technological opportunities and systematic methods for ranking species (Jaenicke *et al*. 1995). Published guidelines on species priority-setting represent a great advance in procedural methodology (Franzel *et al.* 1996). These methodologies have now been used in a number of ecoregions and in all these regions the lists of the top priority species for participatory domestication have contained mostly food or timber producing trees, or other cash-generating species (Jaenicke *et al*. 1995, Kindt 1997, Weber *et al*. 1997). The paradox is that a species may not be able to prove itself until its full intraspecific variation has been tested (Dunsdon and Simons 1996).

It should be emphasized that the number of priority species should not be restricted to only a handful of species. In priority-setting in the Peruvian Amazon where individual farmers were asked to name their top ten species, more than 200 species were recorded (ICRAF 1996). Clearly, what is a priority to one farmer may not be so for another. In the Sahelian zone of Niger, 470 farmers were polled for their priority trees and it emerged clearly that different sectors of the community had different priorities. Women were different from men in their preferences, whilst old men were different from younger men (ICRAF 1996).

Domestication Strategy

It is evident from the arguments presented above that tree domestication cannot be equated exactly with tree breeding. Whilst tree domestication also involves trials and selection, it is also about:

- species priority setting with farmers
- proactive seed multiplication
- best nursery practices
- tree management
- extension messages (especially on seed collection)
- germplasm delivery pathways
- processing and marketing
- policy interventions

The critical point is that tree domestication is not about single activities but a coordination of a wide range of activities. Perhaps previously researchers felt that evaluation of provenances on station was tree domestication. The problem is that NGOs may then ask for 4 tonnes of seed and if no consideration has been given to this the research may be wasted.

To significantly increase the numbers of high-value trees under cultivation, constraints such as inadequate information on cultivation and management, lack of planting materials, policy barriers, paucity of choice and poorly functioning markets need to be removed. In this regard, research on input markets (e.g. planting material) is as important as research on output markets in understanding smallholder investment in tree cultivation.

Encouraging a Tree Planting Culture

ICRAF and other organisations promoting sustainable natural resource management through the incorporation of trees into the agricultural landscape essentially have two client groups of small-scale farmers: those with a tree planting culture and those without one. For the first group, the current niches for tree planting may be nearly saturated or approaching this condition. However, saturation is relative and, as centrally planned economies move towards market-based economies against a background of trade liberalisation, the removal of agricultural subsidies and the opening up of new markets may make agroforestry more attractive.

To engender a tree planting culture amongst diverse groups of farmers that do not have it requires a good understanding of their prevailing economic, social and environmental situations. Poverty and food insecurity are two compelling influences on many of these farmers. Through the cultivation of high-value trees on farm there is the opportunity to contribute directly to food supply and nutritional well-being as well as providing income which can be used to purchase food or give protection to the agricultural base upon which food production depends. Global trade now exceeds $US3400 billion and even the most remote regions are being increasingly exposed to commerce. Whilst rural landscapes in the tropics should not become subordinated to the needs of the world's industrial marketplace, the entry point for many small-holder poor farmers to the marketplace may well be intensification through high-value trees (Sanchez and Leakey 1997; Sanchez *et al.* 1997).

The main functional uses of trees with a high economic value will be those providing high-grade timber, fruits and medicines. Here economic value refers to three aspects: (1) consumptive use value (value of products consumed directly without passing through the market e.g. fruits, firewood); (2) productive use value (value of products commercially exploited); and (3) and non-consumptive use value (indirect values of ecosystem functions, such as watershed protection, climate regulation, biodiversity preservation).

Timber Trees

The influence of international trade for timber is now very high and has been for some time. Yet, the consumption growth rates for forest products are highest in developing countries, and in Africa as a region (FAO 1997). Interestingly, of the 22 countries where wood products account for more than 10% of GDP, 18 of these are in Africa (FAO 1997). Even for a small industry such as woodcarving in Kenya, more than 60,000 carvers generate an annual return of US$20 million (Cunningham 1998). It is clear that in Africa, as elsewhere, decreased levels of timber harvesting from natural forests will ensue as increased access to markets, depleted stands and environmental concerns make it less attractive.

The opportunities to grow timber on farmland are great, especially of species with established markets such that on-farm plantings have the potential not only to supplement and but eventually to supplant supplies from natural forest. Mahogany (*Swietenia macrophylla*), one of most prized timbers in the world illustrates this point well. For centuries, the tallest and largest trees have been removed from the wild leaving few, if any, trees behind. This has caused local extinctions as well as dysgenic selection with remaining trees being small or of poor form. It has recently been placed on Appendix II of CITES, and Brazil, the country with the largest natural stocks, has put a moratorium on further logging). Although plantations have been established in several tropical countries over the past 50 years, when grown at any significant density it is attacked by the mahogany shoot borer (*Hypsipyla grandella*). In contrast, when trees are grown at low densities such as in agroforestry systems (Mexico, Brazil, Indonesia and Philippines) trees have a greater chance of escaping devastating attack.

Fruit Trees

Fruit trees are often extremely attractive options for farmers since they not only provide opportunities to generate income but can be consumed by the small holder's family. As with timber trees, the fruits do not have to be marketed internationally to generate significant income. One such example would be the Baobab tree (*Adansonia digitata*). Both leaves and fruit command high prices, as they are often the only available food sources during periods of drought. In Burkina Faso more than 40% of households use *A. digitata* leaves as a vegetable and 85% of what is used is bought in the market where it can fetch up to US$0.70 per kilo (Lamien *et al*. 1996). In Cameroon, Gockowski *et al.* (1997) found that indigenous fruits were ranked as number 1 among non-crop sources of revenue and that 51% of farmers in the humid forest zone were selling indigenous fruits. Ndoye (1997) concluded from a further study in Cameroon that structural adjustment policies and devaluation of the CFA franc have discouraged agricultural intensification and farmers have turned to tree products for income generation. This is in turn has placed enormous pressures on the wild genetic resources of fruit trees necessitating for many species their conservation through use on farm.

Woody Phytomedicinals

Medicinal products from trees can also either be sold or used directly by the farmer. An often understated benefit of growing medicinal trees is that if farmers are able to supply and treat themselves with locally grown medicines they are healthier and thus can work more productively on their food growing enterprises. In Cameroon, sixty percent of the population use tree products of traditional pharmacopeia to treat themselves (Leakey 1997). Many of these people as well as others in Africa and Europe use compounds in bark extracts of *Prunus africana* to treat prostate gland disorders. The pharmaceutical products derived from *P. africana* now fetch more than US$220 million annually (Dawson 1997). Several authors (e.g. Cunningham 1995, Dawson 1997) have pointed out the inadequacy of the natural populations to even meet current demands and the need to plant large numbers of trees, a fact reflected by its inclusion on Appendix II of CITES in 1995. A major bottleneck to on-farm cultivation is sufficient quantities of planting stock and difficulties in handling the recalcitrant seed. This shortage is reflected in the high rural price for seed (US$2 – 8 kg^{-1}) and seedlings (US$0.20 – $0.50 each).

Markets

Whichever tree species is grown on farm, the markets want tree products with a constant, uniform characteristics and elastic supply. Most tree products extracted from natural forests have a relatively inelastic supply whereas farmers can be more elastic in their supply and switch to new species/products. Encouragingly, industry (small-scale and large-scale) have expressed the desire to enter into collaboration to ensure stable and quality supplies of tree products (Leakey 1997).

Dewees and Scherr (1996) provided a comprehensive review of the extent and deficiencies of policy and market studies of tree products. They concluded that of greatest importance is that market information systems are adequate to enable domestication efforts to respond quickly to change. Greatest stability of income will accrue to farmers when a large number of species are cultivated. It is crucial that researchers find ways to ensure that a broad array of genetic diversity in trees is delivered to and maintained by farmers. Strategies for this are evolving (Simons 1996) recognizing that no single approach will suffice for the wide range of species and circumstances.

Agroforestry approaches to poverty alleviation, nutritional security and environmental rehabilitation will become increasingly reliant upon the presence of high-value trees in the system. Considerable scope exists to increase the number and type of these high-value trees in agroforestry systems. To increase the frequency of high-value trees under cultivation, constraints such as inadequate information on cultivation and management, lack of planting materials, paucity of choice and poorly functioning markets need to be removed. The development of tree products from new high-value tree species is a challenge to link tree domestication research with marketing to ensure income generation and food security. Research on input markets (*e.g.* planting material) is as important as research on output markets in understanding smallholder investment in tree cultivation (Koffa and Roshetko 1997).

Conclusion

Although large advances in the domestication and commercialisation processes of agroforestry trees are possible, some caution is required to ensure small-scale farmers benefit. The excessive commercialisation of agroforestry species could lead to outside capital investing in large-scale plantations at the expense of the small-scale farmer (Leakey and Izac 1996). In some situations, the pre-existence of large plantations of a certain species can ensure industries develop sufficiently to make it profitable for small-scale tree growing enterprises to emerge (Cossalter 1996). Attention will also need to be given to the weak bargaining power of many small-scale farmers who face monopolistic buying. This can be done by organisation of producers and primary traders in order to strengthen their positions.

The contributions of tree products grown on farm to local economies, livelihood security and dietary risk minimisation are great. Profitability, equity and sustainability are key advantages over products derived from natural forests or plantations. For these, and other, reasons the future of trees is on farm.

Abstract

In industrialised regions, there is at present a trend towards a reduction of the areas devoted to intensive agricultural landuse. Many farmers maintain trees on their properties, while others innovate, by updating traditional agroforestry techniques. One main difference between silvicultural management of small- or large-scale forestry and farm forestry is the presence of a farm (and tree) manager within the system, available for supervising and tending the trees, due to differences in time scales between agricultural and forestry components. Trees are often considered by the general public as a panacea for reducing the adverse effects of industrial development, and even in the scientific literature, the virtues of agroforestry are often described with little reliable scientific background. However a number of well documented scientific studies show the ability of trees to enhance the environmental value of an area. The contribution of trees and agroforestry systems to sustainable management of the natural resource base has been widely proven, in particular to combat widespread land degradation including salinity, soil erosion, soil acidification and soil structure degradation. Despite the difficulties faced when studying the economics of trees on farms, due to the self-consumption of woody products, and to the difficulty in studying the non-commercial value of environmental benefits, many farmers adopt agroforestry for motivations other than financial or direct environmental benefits, such as the social and cultural value of trees within a landscape.

Keywords: Farm forestry, Agroforestry, Sustainable management, Landscape, Multiple-use

Introduction

Although multiple use of land prevailed world-wide at prehistoric times, the expansion and intensification of agriculture since the Middle Ages has resulted in separating forests from fields. Both in the Old World and in the New World, land use has largely specialised, some areas being devoted to agriculture and others to forestry, with the exception of some agroforestry practices which were maintained despite the pressure of industry and mechanisation. However, even nowadays, many farmers still maintain trees on their properties, distributed over pasture land, within hedges or shelterbelts, or as small woodlots.

In many industrialised countries, economic and political pressure as well as environmental concern are now causing a reduction of the areas devoted to intensive agricultural land-use. Some policy-makers consider that the land set aside is now becoming available for small- or large-scale plantation forestry, thus maintaining the barrier between agriculture and forestry.

However, a strong message is being given by dynamic farmers who have started to innovate, by updating traditional agroforestry techniques in order to diversify production, reduce costs, and improve the environment. Farmers generally plant or retain trees on their land for multiple benefits. For example, agroforestry plantings can provide shelter to stock, potentially reducing stock mortality, and protection to crops in extreme wind conditions. These benefits are most relevant to cropping/grazing systems. Surveys carried out in different countries demonstrate that the main reasons for maintaining trees on farms are the following: shade and shelter, conservation and land protection, landscape and farm environment, and more generally reduction of agricultural overproduction, increased diversity of rural production, reduction of timber imports, maintenance of rural employment/rural infrastructure, increased environmental diversity (Anon 1995, Sibbald *in* Étienne 1996, Étienne and Rapey 1999).

In most industrialised countries, there is increasing recognition that many of the current agricultural systems are not sustainable in the long term. Moreover, there is a strong environmentalist pressure against timber extraction from native forests, as well as reforestation with exotic species. In Australia, the widespread clearing of native vegetation, resulting from the introduction of European agricultural systems, has led to widespread land degradation including soil erosion, soil acidification, salinity, and loss of biodiversity. These combined factors have led to an increasing interest in farm forestry and agroforestry systems.

Although the scope of this presentation is not to give a classification of "trees on farms", we will briefly cite a few practices. Traditional "farm forestry" may include small farmer woodlots, hedgerow management, and some aspects of community forestry. Traditional agroforestry includes forest grazing, "dehesa" or "montado" in the Iberian peninsula, wooded rangeland, and various mixtures of agricultural practices with orchards, including grazing and growing vegetable crops, such as central European "Streuobst". "Modernised agroforestry" includes tree plantations on pasture, tree plantations with crops, "timberbelts", alley cropping, "forest farming", riparian buffer planting, "contour plantings", windbreaks, "special products" such as Christmas trees or short rotation biomass production. Large scale afforestation of agricultural land will not be addressed here, as it has been widely studied in other circumstances (*i.e.* Savill *et al*. 1997) and is well documented within IUFRO. Trees which are mainly treated as agricultural crops (with annual harvests) will also be excluded, such as fruit orchards managed solely for fruit production. For further discussion on agroforestry systems and agroforestry practices, on community forestry, farm forestry, and social forestry, readers can refer to Nair (1993) and Sinclair (1999).

Despite the very wide range of practices, from conventional or newly planted farm woodlands through silvopastoral and hedgerow management to individual tree cultivation on pasture or arable land, a number of important issues are common to all types of "trees on farms". In this presentation we shall focus on the tree component of the systems considered, although this may be considered by our fellow-agroforesters as a heresy: it must be kept in mind that agroforestry and farm forestry systems are multiple-agent, multiple-use systems, and that interactions between components are their main characteristic.

Silvicultural Issues

Silviculture is the art and science of cultivating forest crops for all their diverse range of uses and objectives (Savill *et al*. 1997). These objectives may be production of timber or wood products, shade and shelter, protection of the natural resource base, or various other services. Silvicultural activities include site preparation, choice of species, plantation and restocking, weed control, fertiliser use, thinning and pruning and protection from biotic or abiotic damage. A number of questions concern the management of trees on farms. They concern not only silvicultural aspects, but more generally the entire farm or "agroforestry estate" management.

One first question to be raised concerns the type of ***land available for farm forestry***. More precisely, what type of land will become available for i) large scale afforestation, ii) farm forestry, iii) agroforestry? This point has been largely debated in various workshops (Bock and Rondeux 1990, Anon 1992, Welte *et al*. 1994). A statement commonly put forward is that forestry in industrialised countries is a marginal activity: good soils are reserved for agriculture, while forestry is confined to soils on which agriculture is impossible.

Jarvis and Sinclair (1990) stress that up to now good land has been reserved for agriculture, and forestry has been practised on poor land, deemed unsuitable for agriculture. In farm forestry we could therefore be concerned with tree production on good quality deep brown soils of moderate to high fertility. However, Lloyd (1990) argues that the type and location of land potentially "available" will mostly be that which would be designated as "SSSI" (Sites of Specific Scientific Interest), requiring special protection measures. Establishment of small woodlands on such sites would therefore be regarded as of very serious concern for nature conservation, whereas establishing coppice woodlands on land previously in use for cereal production would greatly benefit nature conservation. Bulfin (1990) reports that in Ireland forestry is more profitable, in the long term, than agriculture throughout extensive areas of marginal agricultural soils – particularly the wet mineral lowland soils. But certain areas are likely to be unproductive and possibly not worth planting, and where that land area is also marginal for agriculture, then serious consideration should be given to bringing about a change in land use. In Australia, there is a general perception that farmers will be/are unwilling to devote the most productive parts of their farming systems to agroforestry or farm forestry plantings. However, owing to the increasing emphasis on the potential multiple benefits of trees on farms there has been a considerable amount of research into evaluating the best place in the landscape to locate trees for a range of outcomes including improved water balance, shelter, and biodiversity benefits (Schofield and Bari 1991, Clarke *et al*. 1998).

At the urban – rural interface there is a high urban pressure for residential and/or recreational purposes. The price of land is generally higher when sold for development than maintained for forest or agricultural use. Agroforestry practised in these areas could relieve some of economic and ecological pressures placed on landowners (Nair 1994). This situation has given rise to the concept of "buffer-zone agroforestry systems", in addition to more conventional "urban forestry" or "community forestry". To summarise, marginal land? good quality land? - probably both, depending on the socio-economic context.

Many textbooks concerned with ***silviculture*** provide some indications on farm woodland management (see for example Savill *et al*. 1997). In addition, several handbooks are specifically devoted to farm woodland planning (Insley 1988, Abel *et al*. 1997), farm woodland practice (Hibberd 1988) or farmland afforestation (Bazin 1992), as well as urban forestry (Hodge 1995).

In many areas abandoned by agriculture spontaneous growth of trees leads to poor quality stands, overstocked, heterogeneous from a forester's point of view, but with poor biodiversity, with high fire hazard, and a "closed" landscape (Anon 1999). Introducing grazing — and a livestock farmer — can improve many of these aspects. In some state or community forests, farmers may use the forest for extensive grazing at some periods in the year. This requires a specific agroforestry management — management of the forest and management of the animals — with positive feedback i) to the farmer, as additional fodder, available at specific periods where it would otherwise be lacking, and ii) to the forest manager, for fire prevention, conservation and biodiversity, or landscape management. In rural, and especially upland areas, community forests are most often tended by the local population, mainly farmers, for firewood and possibly grazing, and/or amenity. (Decaix 1994, Bland and Auclair *in* Étienne 1996). Small farm woodlots, representative of most traditional farm woodlands, are very often managed by the farmer as conventional coppice with standards, producing firewood, posts and other services, and sometimes a small amount of timber. An important aspect of farm forestry is the fact that farmers generally do not consider trees as a merchantable crop (contrary to agricultural production), but maintain them for a large number of non-commercial aspects (Étienne and Rapey 1999, Nougarède *in* Cailliez and Lecomte 1999, see "economic issues"). Farm woodlands are very often managed as mixed, multi-purpose stands, generally as coppice-with-standards which offers a large flexibility. Jarvis and Sinclair (1990) propose single-stem coppice, as producing stems of larger diameter is likely to be a more important option today for the production of marketable industrial feedstock. Riparian forests can be managed also for annual non-timber products, such as fruits, nuts, ornamentals or latex (Robles Diaz de Leon and Kangas 1999).

In many newly planted, modern agrisilvicultural plots — "alley-cropping" in the US or "silvoarable" in the UK — trees can often be managed specifically for timber. This requires a high level of tending (i.e. form pruning), but in general in farm forestry, the ***presence of a farm (and tree) manager*** within the system is extremely favourable compared to conventional small- or large-scale forestry. In France in the 1960s a widespread forestry policy of afforestation of abandoned farmland led to a multiplication of "stamp-size" woodlots, (un-)managed by absentee owners. Nougarède (1994) states that afforestation "pulverised into a great number of small dispersed woodlots is irrational and leads to a hostile climate and an irreversible disorder which definitively compromises a balanced management of rural areas". As farm woodlands are very often managed as mixed, multi-purpose stands, this heterogeneity demands high levels of commitment, skill, research, and resources. These can be available in farm forestry, but rarely in the case of absentee owners. Gathy (1990) observed that the majority of species involved in small-scale forestry require pruning and thinning to be carried out rapidly and carefully, and that very often this is unfortunately not performed in conventional small-scale forestry, even in the case of species that tend to fork. Bazin and Guinaudeau (1990) noted that although it is possible to pay contractors it is better to induce farmers to plant trees themselves as it makes them feel responsible for them, and this turns out to be more efficient, and therefore more economical, as labour represents 70 to 80 percent of the total cost of a plantation.

It must be stressed that little is known concerning ***timber yields*** in farm forestry, mainly because forest growth models are generally based on measurements obtained from plots situated within homogeneous forest areas, in order to be representative of a given situation, and to avoid "border effects", which is rarely the case in farm woodlots. Most of the research on farm- and agroforestry is quite recent, and much of this contains data for relatively young growth. There is only limited information available about the long term impact of silvicultural treatments on growth rates (Cabanettes *et al*. 1999). It has been shown that with a "taungya"-type practice, as well as many agrisilvicultural situations, the agricultural crop often benefits the trees (Dupraz *in* Auclair and Dupraz 1999, Gavaland and Cabanettes 2000). This can be attributed to the specific care taken to cultivate the crop, with weed and/or pest control and fertilisation, which are not usually practised with the same intensity — if at all — in conventional forestry, and which spread beyond the crop to benefit the trees. The effect of grazing among trees is unclear, as contradictory results have been observed. Clason (1999) found that grazing improved timber production, but Cutter *et al.* (1999) observed neither improvement nor reduction of wood production.

The management of trees on farmland presents particular ***technical aspects***. The presence of livestock among the trees, in agroforestry, along hedgerows or on plot borders generally requires tree protection: individual "tree-shelters" or fences (Booth 1990). In agrisilvicultural situations individual tree-shelters can also be beneficial, as they serve as indicators of the exact place of the trees at the establishment phase, when they can be smaller than the surrounding crops, and they also protect the trees from mechanical damage due to machinery and from herbicide applications on the crop (Dupraz 1994). Arable land is always transversable by a tractor, unlike some forestry terrain, thus leading to a highly mechanised industry. The adaptation of farm machinery and the use of some agricultural methods, such as weed control, can greatly reduce establishment costs of trees, whether in agroforestry situations or as pure plantations. Agricultural machinery can be either used directly or adapted at a relatively low cost for tree management (Booth 1990). The ever-increasing size of farm machinery has led detractors of agrisilviculture to ban this practice from modern systems, however, it has been clearly shown that planting trees within agricultural crops is quite feasible with examples of silvoarable systems in the U.K., of "agroligniculture" in France, or of alley-cropping in the U.S. (Beaton *et al.* 1999, Dupraz and Newman 1997, Gordon and Newman 1997). Disposal of farm waste products, due to intensive livestock production, by spreading in wooded plots is possible. This is, however, debated, as forest managers are not eager to see their forests converted into landfills. Irrigation is never available in forests, but often on farms, and this can be of great benefit to trees in dry situations. Fertiliser combined with irrigation on the arable plot can spread out to the trees. Weed control is well developed in farming, and much less — and is exposed to great resistance from the public — in forestry. The trees can benefit from the weed control within the crop, however if herbicides are to be used, great caution must be taken not to damage the trees. In agrisilviculture or alley cropping, crop cultivation maintains weeds at a low level, thus benefiting the trees.

Due to large ***differences in the time-scale*** between agricultural and tree components of the system, ***labour*** can become available for tree tending at periods when the demand for agricultural labour decreases. There is more flexibility in tree tending operations than for animals or crops. Jarvis and Sinclair (1990) point out that one advantage that farm forestry may have over large scale afforestation is that it could be designed and managed to spread labour requirements more evenly and fit in more closely to existing annual cycles. Although farm woodlands can have a number of different objectives — shelter for grazing animals, firewood from coppice — the production of high quality timber can be expected, thanks to individual tree care, such as pest survey and management, or form-pruning.

In addition to the tending of trees, the presence of trees within a farm can modify some ***farm management*** techniques. Étienne *et al.* (1994) have pointed out several management constraints with forest grazing. Large forest areas must be grazed, because the forest provides little fodder, often of poor nutritional value. It is often necessary to plan for buffer areas in case of exceptional climatic events (drought, frost). The establishment of areas improved by cultivating, oversowing and fertilising is required to produce fodder of higher nutritional value, and thus allow a higher stocking rate. This entails a stronger grazing impact on the vegetation, which is necessary when grazing is practised with the aim of decreasing fire hazard. Grazing open, cultivated areas is also an alternative for obtaining higher quality fodder. More generally, pastoral management must be adapted to face multiple use as well as multiple users of the forest (Gillet and Gallandat *in* Étienne 1996).

The production of energy from ***biomass from short rotation tree crops*** is one of the promising solar based renewable energy sources currently available to replace the use of fossil fuels. Biomass can be converted into a range of energy forms, including electrical and heat energy, liquid and gas fuels, and charcoal. On a world scale the International Energy Agency estimates that biomass energy sources have the potential to meet 40% of all present energy consumption, and that already these sources are second only to hydro-electricity as a supplier of renewable energy to commercial users. There are already a significant number of projects which involve the utilisation of biomass for renewable energy and other products. In Sweden *Salix* sp. have been extensively planted on farmland as “energy forests”, producing an average yield of 10 to 12 t ha^{-1} yr^{-1} of dry matter in 3- to 5-year rotations (Christersson *et al.* 1993). However, such production can only be reached on soils with sufficient water and nutrient supply, not contaminated by heavy metals. But where energy forestry has been implemented, the farmers have obtained satisfactory results: recovery of the investment is possible in relatively short times, and if necessary it is very easy to return to agricultural or other land uses. A large number of biomass-energy projects include:

- The production of heat through ecologically acceptable wood-energy plants both at the homestead scale and at the community scale;
- The generation of electrical and heat energy by the combustion of biomass residues from sawmills and agricultural crops (co-generation and co-firing);
- The production of combustible gases which can be used to power small scale electrical generators (wood gasification);
- The production of ethanol and methanol for use as a solvent, or as a liquid fuel which can be added to petrol or diesel for use in conventional vehicles;
- The production of oils for use as a pharmaceutical product, and as an alternative to ozone depleting industrial solvents such as trichloroethane;
- The generation of electrical power in tandem with the production of high quality

charcoal for specialist smelting, and for use as a cooking fuel;

The production of activated carbon for use in the purification of water, air and oil, and for the extraction of gold in the mining industry.

Environmental Issues

Trees are often considered by the general public as a panacea for reducing the adverse effects of industrial development, and care should be taken by scientists not to overstate the positive effects of trees. Even in the scientific literature, the virtues of agroforestry are often described with little — or poor — reliable scientific background, with no consideration for the drawbacks. In this respect, Huxley's book (1999), although concerned mainly with tropical agroforestry, provides a large scope of reflection and of sound scientific data applicable world-wide. Given this restriction, a great number of scientific studies show the ability of trees to enhance the environmental value of an area. The contribution of trees and agroforestry systems to sustainable management of the natural resource base has been widely studied, in particular to combat widespread land degradation including salinity, soil erosion, soil acidification, soil structure degradation (Prinsley 1993, Auclair and Dupraz 1999, McAdam *et al*. 1999).

Since European settlement in Australia there has been widespread clearing of native vegetation. Large areas that were previously forested were converted to traditional European agricultural cropping and grazing systems. These shallow rooted cropping and pasture systems generally do not use as much water as the deep rooted native vegetation, resulting in significant increases in recharge to the groundwater system. An increase of recharge of up to two orders of magnitude is typical (Walker *et al*. 1998). This has resulted in a rise in the water-table of more than 1 metre per year in some dryland agricultural areas (Davis *et al*. 1999). This is in part because the patterns of seasonal water use of the introduced agricultural systems are considerably different from native vegetation. The problem is most pronounced in southern Australia which is characterised by a winter dominated rainfall regime. During the winter months when rainfall is greatest, and atmospheric demand is low, evapotranspiration rates are low. While this factor applies equally to native vegetation and agricultural crops and pastures, deep-rooted native vegetation is able to exploit the stored soil moisture. Shallow rooted cropping systems cannot fully exploit this stored soil moisture, resulting in increased rates of deep drainage and groundwater recharge. The introduction of trees into the landscape has been identified as one of the key ways to address this ***hydrological imbalance***. The difficulty, however, is determining where trees need to be placed in the landscape to have the maximum benefit and minimum cost from a sustainability and production perspective. If trees are planted over shallow saline water-tables they may not be sustainable in the long term because of salt accumulation in the root zone of the tree. Trees remove water from the soil leaving the salt behind in the root zone. If rainfall and/or irrigation are not sufficient to flush this salt away from the root zone, trees may eventually die. This process has been modelled in a 21-year-old eucalypt plantation in southern Australia, showing that increases in salt storage resulted in a decline in leaf area index (LAI) and stem growth. The work also demonstrated that in certain scenarios, if the plantation is harvested and the area is returned to pasture, there may be a severe reduction in pasture growth. In the scenario modelled, pasture growth was suppressed for eight years after plantation harvest (Davis *et al.*1999).

The establishment of trees in areas that were previously dominated by pasture is likely to have an effect on ***catchment runoff***. This is because trees generally have higher evapotranspiration rates than pastures owing to a number of factors, including more persistent and higher leaf area, greater rainfall interception and deeper rooting depth than pasture systems (Vertessy and Bessard 1999). The extent to which the introduction of farm forestry activities results in a decrease in catchment runoff is dependent on the proportion of the catchment planted to trees, and the location of these plantations. Upland high rainfall (>800 mm) areas are the most productive regions for the establishment of large scale farm forestry plantations. Reduction of runoff from these upland catchments is likely to result in decreased dilution of salt loads in rivers in the medium to low rainfall areas. ***Soil acidification*** is another significant problem in intensive agricultural systems, which causes significant annual losses of production. There is evidence that trees can help reduce soil acidification, and that some species appear to be more effective than others. However, it should be noted that a reduction of acidity in the soil surface layers results in an increase in acidity deeper in the soil profile (Noble and Randle 1999). ***Water quality*** issues arise from the concern about high levels of fertilisers, pesticides, and other agrochemicals getting into streams and groundwater. The enhancement of root density per unit volume of soil, and better stratification of rooting depths resulting from the species diversity of agroforestry systems provide greater capture and filtering of chemicals moving through the soil to groundwater (Nair 1994). Along riparian buffer zones, trees have proved efficient in reducing pollution of water courses, and particularly for nitrate control (Caubel-Forget and Grimaldi *in* Cailliez and Lecomte 1999). However, Puech *et al*. (*in* Cailliez and Lecomte 1999) have shown that a small number of woodlots scattered among intensive crops were poorly efficient for nitrate reduction, because of drainage systems which concentrate pollutants in streams. If afforestation does indeed reduce nitrates due to lower fertiliser requirements, the afforestation of marginal land not previously fertilised will have little impact. Similarly, arguments in favour of afforestation as a less intensive land-use than agriculture, with a longer cycle of establishment and harvesting, can be counterbalanced by the fact that there will be little impact if agriculture is maintained on the best agricultural land and marginal sites are brought into forest use (Lloyd 1990).

The widespread loss of ***biodiversity*** is a great concern for the general public. There is a strong impulse to improve wildlife habitat by the re-introduction of woody perennials into agricultural land in Europe. Balent *et al*. (*in* Cailliez and Lecomte 1999) have shown that the presence or absence of a roe deer, robin, chaffinch, and song thrush were highly correlated with forest fragmentation, each species exhibiting a favourite spatial distribution of forest patches. One advantage claimed by agroforestry is that it can bring into farmland some of the biodiversity benefits associated with woodland (Stamps and Linit 1998). In the U.K., Burgess (1999) has demonstrated that the development of silvopastoral agroforestry can increase the diversity of invertebrates and maybe birds in grassland systems, and that agrisilviculture can increase the diversity of airborne arthropods, small mammals and possibly birds within arable agriculture. Nevertheless, it must be kept in mind that an increase in diversity may also increase the number of organisms formerly designated as pests — phytophagous insects, slugs, small or large mammals which very often feed on trees or create various types of damage. It is also difficult to attach significant environmental benefits to an increase in common field margin bird species where this results from a loss of the more sensitive species dependent on extensive grazing and woodlands (Lloyd 1990). There remains an important lack of diversity criteria. At the time of writing this manuscript the IUFRO conference on “Criteria and Indicators for sustainable forest management” in Nancy has not yet been held (March 2000), but it is hoped that important results will emerge.

Trees are generally considered as important features of the landscape. Most people consider rural landscapes to be timeless, and resistance to any change is often very great. Forest management can arouse public antipathy, and in areas of great natural beauty can lead to outspoken criticism. Conversely, depending on how land-use management is carried out, there are many opportunities for enhancing the ***landscape value*** of woodlands. Sustainable management should therefore take into account the visual impact on the landscape. The European agricultural landscape is fundamentally an artificial mosaic of fields, wood and water of various sizes or shapes. Jarvis and Sinclair (1990) suggest that the introduction of new areas of woodlands provides considerable opportunity for manipulating the basic features of the landscape in relation to particular design criteria. On the other hand, some valleys in the French Vosges or Jura mountains have in the past been submerged by forests planted by non-resident (urban) landowners, greatly reducing aesthetics and diversity. By re-introducing cattle the extension of wooded areas has been stopped, and some woodlands have been re-spaced and opened up to grazing, resulting in a greater amenity value (Douchet *in* Anon 1999, Letzelter *in* Anon 1999).

It is often thought that trees have a positive effect on the global carbon balance, by means of ***carbon sequestration***. However, this is largely disputed as the carbon balance must be considered over the long term (Dupraz and Auclair 2000). Carbon fixation within timber is in fact only temporary, as furniture or housing lumber has a half-life estimated as 80-100 years, and paper products have a half-life of 1-6 years (Skog and Nicholson 1998). Tree plantations do indeed fix carbon according to their growth rate — usually the land is replanted to trees which fix carbon rapidly in the first years of growth — but when harvested (or at the end of their life) a large amount returns to the atmosphere by decomposition of leaves, litter, branches, roots or processing residues, and only the amount effectively used as wood products is fixed for a certain time. Firewood, paper, posts, and small packages do not fix carbon for very long (van Kooten *et al.* 1999). Carbon fixation within soils is considered more important than within the living biomass, with small amounts in cultivated crop fields, larger amounts in natural grasslands, and relatively large amounts under woodlands, which however lose most of the carbon when they are clear-cut. Van Kooten *et al.* (1999) consider that there is no difference in carbon storage between land-uses. Nevertheless, substituting wood for fossil fuels can greatly reduce the consumption of carbon-producing fuels. This is probably the best manner of reducing carbon emission to the atmosphere, but wood is not the only source of bio-energy, energy-rich annual crops can also contribute positively to the carbon balance.

Agroforestry is being increasingly practised in Mediterranean regions to help ***prevent wildfires***. In silvopastoral systems there are less trees, better managed — pruned, thinned, and generally tended by the farmer — than in natural forests. The lower vegetation, which is generally the site of birth of wildfires, is controlled either by weed control in arable crops, or grazed in silvopastoral systems, therefore is less prone to fires. However, shrub dominant species are more or less palatable according to the type of animal and grazing management — stocking rate, grazing season, supplementation, herding technique. Therefore grazing is not the only solution for maintaining effective fuelbreaks, it must be combined with at least one other fuel reduction technique (Étienne *et al. in* Étienne 1996).

To summarise, there is a general concern that industrialised regions will suffer profound environmental modifications in the near future, with a loss of agricultural and rural employment, a closure of landscapes, and an increase of various ecological imbalances. The integration of forest and agricultural activities can be a solution to help face the problems liable to appear in such a situation, by:

- reducing hydrological imbalance,
- reducing catchment runoff,
- reducing soil acidification and nitrate levels,
- improving water quality,
- increasing biodiversity,
- improving landscape value by diversification,
- improving the carbon balance by fossil fuel substitution,
- participating in fire prevention

However, it must be stressed that if the final objective concerns only one of these points, other, simpler systems may be better adapted. Complex systems such as agroforestry are able to contribute simultaneously to a number of aspects of interest to the environment, and can provide answers to a series of questions which may even appear contradictory.

Socio-economic Issues

The economics of trees on farms are extremely difficult to apprehend, for many reasons. ***Self-consumption*** of woody products, as firewood, posts and sometimes timber, rarely enters into agricultural statistics. Taking into account the ***non-commercial value*** of environmental benefits poses problems, and much remains to be investigated. In most industrialised countries, agricultural and forest production are driven by ***regulations and incentives*** or dis-incentives, which make it impossible to compare different productions on a purely economic basis. Several characteristics of agroforestry systems make them difficult to compare economically and financially with alternative enterprises. They are long term; they offer multiple benefits, many of which are difficult to quantify; and they involve many complex interactions between the tree and non tree components (Prinsley and Moore 1993). ***Legal aspects*** often render tree plantation or harvest, as well as the adoption of agroforestry practices, very difficult, if not impossible. Nougarède (1994) concludes that "in fact, it is impossible to determine the economics of any “agro-silvo-pastoral equilibrium”.

Nevertheless, economic calculations have been attempted in many different situations. Sibbald (*in* Étienne 1996) noted that economic results vary with authors and/or economic models, and Price (1995) concluded that agroforestry does not offer extraordinary benefits of the financial or non-financial kind at the farm scale, but there could however be differences at the community or regional scale. Thomas (1990) stated that on good grazing land agroforestry would not be an attractive option for farmers, but that on poorer quality land the situation alters dramatically. In an case study in Scotland, Sibbald (1990) concluded that the best economic option would be to reduce the original livestock farm area by 63 percent in favour of afforestation, and with 10% of the land improved the flock number could increase and annual income be maintained. In a case study in Australia, Campbell *et al*. (1999) showed that eight out of the ten farms studied can expect direct positive returns from their agroforestry enterprise. In three of the cases, the annualised value of income was 25% greater than that which would have resulted without tree planting. Analysing hedgerows, Bazin (1992) found that timber production in well managed hedgerows is far from insignificant in the economics of a farm as well as at a larger regional scale. Dupraz (1999) found that in some situations agroforestry can give greater economic benefits than monocrops, even with no biological benefits from the plant association. From an extensive study of agroforestry farms, he noted that some biologically successful agroforestry systems may be rejected, whereas some poorly efficient agroforestry systems are readily adopted by farmers. In a comparison between agricultural, agroforestry, and forestry practices, Gavaland and Cabanettes (2000) found that a pure agricultural crop produced in the short term higher financial benefit than the same crop in association with high quality timber, or in association with short rotation woody trees for energy, afforestation with high quality timber trees producing the lowest benefit. Robles Diaz de Leon and Kangas (1999) however noticed that non-timber products, such as fruits, nuts or ornamentals, can add some financial value to trees which would otherwise be of little value.

Economics are difficult to compare between different systems on an equality basis, without distortions by competing grants. For instance, various incentives often exist in favour of agricultural crops or farming, and in favour of forestry, but are non-existent for agroforestry. Sibbald (*in* Étienne 1996) noted that without subsidy for the forestry component, silvopastoral systems could generate returns at least equal to sheep-based farming systems, but according to the type of incentive, one can obtain either a small reduction in return from the silvopastoral compared to the purely agricultural system, or a higher return from the silvopastoral system than from pure farming.

Many economic analyses do not take into account the positive ***effect of trees on agricultural productivity*** due to water management, the provision of shelter and reductions in erosion. To account for this, in their case study concerning ten farms in Australia, Campbell *et al*. (1999) modelled a basic ‘degradation’ scenario, which assumed that, without trees, farm productivity would decrease with a 10% decline over the time of the project. When incorporated into the evaluation, the sustainability analysis showed that environmental benefits from the trees may translate to significant economic benefits that will be realised through increased agricultural production.

A major difficulty in comparing different management options concerns the ***time scale***. Most agricultural productions are apprehended on an annual basis, whereas the other economic characteristic of investment in trees is the long-term nature of the investment. The establishment costs, combined with cost of taking land out of annual agriculture, has a doubled effect on farm cashflow. Farm cashflow can be significantly reduced in the first few years, followed by sustained lower annual cash incomes until harvest. However, Mary *et al.* (1999) suggest that economic evaluations can be envisaged in the short- or medium-term, instead of long-term, because a farmer's decision is taken in a very uncertain context concerning the value of timber harvested at the end of the rotation.

Due to the difficulty of determining the economic benefits of farm- and agroforestry generically, the case study approach has been implemented by several authors (Étienne and Rapey 1999, Campbell *et al*. 1999). Their aims were to identify, describe and where possible, quantify the economic, environmental and social impacts of farm- and agroforestry on the farm family and business. They were based on descriptions of land-use, farm and livestock management, agroforestry and forestry techniques, valuation of agroforestry and forestry realisations, and farm, forest and household perspectives. Key decision criteria, priorities for forestry and agroforestry development actions and professional perspectives for the farmer were identified. The logic was that tree planting (and associated costs) indicates a conviction by the farmer that there are positive benefits to be gained from integrating trees into the farming system (Campbell *et al*. 1999).

A key factor determining the economic viability of trees is where they are placed in the landscape. This is often not dictated by the best soil type for growing trees. The opportunity cost of the investment (the land use displaced by farm forestry) drives the need to match farm enterprises to the land capability. Farmers that have planted trees on land with the lowest opportunity cost are getting the best economic performance from the farming system as a whole because they are endeavouring to match land capability with enterprises that maximise the per unit return on that land (Campbell *et al*. 1999).

In most cases, trees are actively employed to address economic and environmental issues simultaneously. In every case, both environmental and economic issues are considered. However, the final emphasis on environmental or economic motivation varies depending on the current physical and financial state of the farm, as well as individual perceptions of the challenges that face the farmer and the tools available to address these challenges (Campbell *et al.* 1999). When studying farmers' attitudes towards agroforestry, Étienne and Rapey (1999) observed many other motivations than financial or direct environmental benefits. Mid-term and long-term expectations not necessarily linked with forest production are generally combined, such as:

- a reduction of farm activity,
- a means of securing succession,
- timber capitalisation,
- preservation of the environment for future generations,
- creation of a diversified landscape and improved aesthetics for ecotourism,
- use of woodlots as shelter for grazing animals,
- wildlife management,
- reduction of the risk of crop loss through diversification
- reversibility of agroforestry, contrary to afforestation which is less "reversible" both biologically and legally.

The above case studies demonstrate that effective planning and ex-ante evaluation at the project and the whole farm level can prevent costly mistakes. Effective planning and basic economic evaluation can be used as tools to optimise the economic aspects of a plan with environmental objectives. A number of economic decision support tools have been developed in many countries, aiming at:

- reducing landholder uncertainty in relation to financial impacts of implementation of farm forestry or agroforestry on the farm business, and
- improving the ability of farmers and farm advisers to interpret complex biological, financial and legal information into information that can be used to support their decision making.

Several economic models are now used to support agroforestry decision making. Among others, we can cite FARMTREE, developed in Australia and "Agroforestry Estate Model"

(AEM), developed in New Zealand, which provide a sophisticated definition of the proposed planting program, silvicultural regime and integration of the forestry component with the existing agricultural land uses. Several forest stand growth models and simulation packages (STANDPAK, CAPSIS) have integrated modules which take agroforestry practices into account. Most models cover a comprehensive array of project outcomes with considerable scope for sensitivity analysis of results. However, for these models to be directly accessible to farmers or advisers, extensive training would be required. Spreadsheet based models such as ARBUSTRA (Dupraz and Liagre 1997), BEAM (University of Wales, Bangor, U.K.), BLUEBELTS or AGROFORESTRY CALCULATOR (Campbell *et al*. 1999) are more user friendly but less comprehensive. They provide economic evaluations of agroforestry in comparison with existing land uses, on the basis of predefined production cost and management information associated with agricultural and forestry enterprises. They do not directly simulate tree growth but rather draw heavily on the expertise of local advisers who can provide a "best bet" estimation of how trees will perform in a variety of conditions.

The above models provide economic evaluations, however, Étienne and Rapey (1999) noted that a strictly market-based assessment is largely insufficient, even if it takes into account patrimonial aspects and amenities, because farmers' decisions are often influenced by spatial organisation. They used a resource dynamics model (RDM) developed by Étienne and Herlant (1997) to predict the effects of agroforestry development on livestock and timber production as well as on labour organisation and amenities. It is based on observed and simulated changes in the farming layout, related to productive and non-productive resource dynamics. The simulation of various scenarios resulted in new questions being raised by the farmers, concerning for example the types of future landscapes and their conceivable dynamics, or the efforts required for management of the new woodlands. With the increasing value given to environmental and aesthetic objectives, there is still a need to develop new adapted indices such as biodiversity, wildlife management and valuation, landscape beauty and living conditions quality. This work has been pursued further by applying landscape visualisation and design software to the farmers' projects (Auclair *et al*. 2000). The effects of various scenarios on the visual aspect of the landscape provide a basis for discussion between partners concerning spatial organisation, such as the layout of forest and agricultural plots.

The ***social and cultural value*** of trees within a landscape is often very important (Herzog 1998), if not always explicitly described. There is a positive social impact at the personal and family level. The most common community impact comes through increased involvement with the community, but in some cases agroforestry produces positive economic benefits to the community as well (Campbell *et al*. 1999). Nougarède (*in* Cailliez and Lecomte 1999) observed that farmers manage their woodlands as they grow older (>50), whilst the young generation devotes itself to agriculture and breeding. In the context of rural decline, one of the advantages of agroforestry is the fact that the trees remain within the farm management system, contrary to afforestation: the farmer therefore benefits from annual income from the farm as well as the other expectations from the trees. Maintaining rural employment is a key issue within industrialised countries.

Gillet and Gallandat (*in* Étienne 1996) point out that the social and cultural value of trees has a global impact on a great number of multiple "users". From an economic point of view, the main users of wooded pasture are agricultural businesses, even though in some regions the revenue generated by trees is quite significant. But a wide variety of occasional users are appearing in growing numbers and importance: walkers, skiers, horse riders, cyclists, picnickers, hunters, gatherers, etc. The tourist attraction of wooded pastures is considerable, although difficult to measure. The sometimes divergent interests of these different types of users generate conflicts which are often difficult to reconcile.

Legal aspects concerning trees on farms, and particularly agroforestry, can vary greatly not only between countries, but also between small regions within a country. For instance in the US agroforestry implementation is very much linked with natural resources conservation

(Buck 1995). In Europe, up to recent times, a very conservative position has been maintained by the pressure of both forestry and farming interest groups, but innovative farmers are progressively leading the way towards the adoption of better adapted regulations (Dupraz 1994).

Discussion and Conclusion

At the conference on "Agroforestry and land-use change in industrialised nations" in Berlin, P.K. Nair (1994) underlined the rather rigid focus of land-use institutions on long-established conventional agriculture and forestry disciplines. At that time it was considered impossible to revamp the existing strong and influential infrastructures for agriculture and forestry, and, while great strides were being made in the developing world, institutions in industrialised countries were unable to direct agroforestry program development.

Nevertheless, research programmes have been implemented in several countries in collaboration between governments, industry, and research organisations (Auclair and Cailliez 1994), to address some of the barriers to commercial farm forestry development. An Australian national strategy framework for agroforestry (RIRDC 1996) identified four groups of impediments:

lack of farm forestry culture,

economic uncertainties,

public policy issues,

distorted markets.

The strength of these new research and development strategies in Australia has been the close working relationship that has been developing between researchers, advisers and policy makers, local government and processors, educational institutions, landholders, farmers and industry at the national and regional levels.

Forest scientists are now facing new issues, with new types of land available, new types of silviculture — or more precisely, of farm- and agroforestry management. As Jarvis and Sinclair (1990) pointed out, there is now a range of interesting species and silvicultural options not previously practical, and for which there is little or no background knowledge. We are facing not one single system, but many (silvi)cultural options according to the objectives — immediate income, capital building, amenity, conservation. Using a single piece of land for multiple objectives increases management complexity, but allows continued flexibility with regard to the balance of tree and agricultural production in the future. This complexity is another challenge to research, which was until now very mono-disciplinary. Foresters, and forest scientists, will have to consider not only trees and tree stands, but also farmers, whose objectives will mould the most suitable set of designs and management regimes for farm trees in each particular situation. Forest scientists will need to open up to multidisciplinarity. As Nougarède (1994) stated, biological and technical research must produce applicable models, new management objectives must be socially — and economically— acceptable, if new regulations and incentives are implemented they must not hinder classical agricultural and forest activities.

Confronted to these new challenges, we not only join T. Simons in stating that ***the future of trees is on farms***, but also that ***the future of forestry research is on farms***.

Abstract

Two of the most important changes in the agroforestry research agenda over the last 20 years have been with respect to the attention given to perennial rather than just annual crops, and the commercial productivity of trees in addition to their service functions. Interest in the potential of timber trees on tropical farms has increased, and in the humid tropics more emphasis is now given to agroforestry systems with perennial crops. Partially as a result of this shift of focus, agroforestry is now widely studied and promoted for diversifying and sustaining productivity of high quality agricultural land in addition to the previous emphasis on the recovery of degraded land or making productive use of marginal land. Interest in alley cropping systems has been reduced drastically, especially in the dry tropics, while there is an increasing recognition of the existing role and potential of silvopastoral systems and agrisilvicultural timber plantations, both for diversified production (in order to improve cash flow and reduce risk) as well as a means to improve site conditions; i.e., the potential contributions of trees to both ecological and economical sustainability of Central American farms has been recognized. In this paper, three examples of tropical agroforestry systems, which produce timber products, are discussed: multistrata agroforestry systems with perennial crops (e.g., coffee, cocoa); small woodlots on private farms, established with the Taungya systems; and silvopastoral systems which include a timber component. After presenting data from case studies, emphasizing the regional importance of timber productivity from these systems, some of the lessons learned from these medium-long term experiences are discussed. These include research methods (both experimental and survey approaches) and the selection of components and systems. The integration of socioeconomic and biophysical research, and of the results obtained at different scale levels, is also discussed.

Keywords: *Cordia alliodora*, Research methodologies, Selection criteria, Shade trees, Silvopastoral systems, Taungya

Introduction

Tropical timber production statistics usually only refer to the productivity of pure tree plantations and natural forests (FAO 1999) and texts on silviculture concentrate on plantations (e.g., Evans 1992) or natural forest management (e.g., Dawkins and Philip 1998). Nevertheless, in the case of some valuable timber species, such as *Cordia alliodora* in Latin America, a high percentage of the harvested volume comes from farms, usually from agroforestry systems such as associations with pastures (silvopastoral systems) (Souza de Abreu *et al*. 2000, Berti 1999) or with perennial crops (agrosilvicultural systems; e.g., with coffee (*Coffea* spp.) or cacao (*Theobroma cacao*)) (Somarriba and Beer 1987). Furthermore, the establishment of small timber plantations (woodlots) on farm may be carried out with crop association during the establishment phase; i.e., the Taungya system (Jordan *et al*. 1992). Due to continuing deforestation of the natural forests in the region, these systems are increasing in importance (Current and Scherr 1995). The potential of agroforestry systems for sustainable land use has long been recognised (Young 1989) but their potential to produce commercial timber has only been reported in a small percentage of the agroforestry literature (e.g., articles in the journal *Agroforestry Systems*). This paper provides an overview of the principal agroforestry systems that contribute to timber production in Central America, their productivity and some of the considerations involved in their successful adoption, such as germplasm selection criteria (socioeconomic and biophysical) that take into account crop characteristics and management.

Agroforestry Systems with Perennial Crops

In the lowland and mid-elevation humid tropics of Latin America, perennial crops such as cacao (*Theobroma cacao*) and coffee (*Coffea* spp.) are of huge economic and ecological importance because of their contributions to export earnings and employment, as well as their service functions (e.g., C sequestering, biodiversity conservation, water yields) (Beer *et al*. 1998). Timber, fruit and/or "service" (do not provide commercial products; managed only for the benefit of the crop) shade trees are included in the majority of these plantations (Perfecto *et al*. 1996). In the five principal coffee producing countries of Central America, coffee plantations cover 857,000 ha of land (Galloway and Beer 1997) and if they were all to produce an average commercial timber yield of 4 m^3 ha^{-1} yr^{-1} from the shade trees (Beer *et al*. 1998), the potential production would be close to 3.5 million m^3 ha^{-1} yr^{-1} of valuable cabinet timbers such as *C. alliodora* and *Cedrela odorata* (Table 1). This estimate may be exaggerated since most of the available data on timber production in coffee plantations comes from the more humid lower (hence hotter) zones, where growth rates are presumably higher. Moreover, in optimal coffee zones (generally >1000 masl) farmers use less or no shade in their plantations. On the other hand, much higher timber productivity from shaded coffee plantations has been recorded (Beer *et al*. 1998), and since the service functions of coffee agroforestry systems (for society) are becoming recognized and financially rewarded, the farmers' motivation to retain or increase the tree (and hence timber) component of their coffee plantations is increasing. This is especially apparent in Costa Rica, once the regional leader in the conversion of shaded to unshaded coffee (Perfecto *et al*. 1996), but now a leader in planting timber species in coffee (Tavares *et al*. 1999, Viera *et al*. 1999). A second example can be found in El Salvador, where a World Bank supported project is promoting environmentally friendly coffee production, particularly to benefit migratory birds (Wille 1994). The coffee produced in this way will be certified and will receive a premium price in North America.

The widespread occurrence of farmers protecting and managing naturally regenerated timber trees in pastures, perennial crop, and even in sugar cane plantations (Somarriba and Beer 1987), demonstrates that they do recognize the value of trees in their farming systems; e.g., to diversify their farms and hence reduce financial risk (Ramirez *et al*. 2000). The indigenous Ngöbe people of Panama successfully adopted the technology of inter-planting *C. alliodora* in semi-abandonned cacao once they recognized that this timber species could be managed as another crop (Neri *et al*. 2000). One reason for this success is that growth rates of *C. alliodora* can be exceptionally high in the optimal conditions provided in perennial crop plantations (drainage, weed control and fertilization plus wide tree spacing), especially in the lowland alluvial soils in humid areas which are often used for cacao production; e.g., in cacao-plantain (*Musa* AAP) systems in Bocas del Toro, Panama, average *C. alliodora* dimensions of 36.6 cm and 25.6 m have been recorded after eight years (Somarriba *et al*. 2000b).

Factors which mitigate against timber production in perennial crop plantations include tree felling damage to underlying crops; e.g., in Costa Rica, the net income from the timber was reduced by \$10 – 17 m^{-3}, depending on the coffee productivity and its price, to compensate for coffee damage due to tree felling and extraction (Somarriba 1992). Coffee or cocoa yield reductions, due to competition from trees (light, water, nutrients; Beer *et al*. 1998), limits the number of mature timber trees to less than 100 ha^{-1}, even for small crowned species such as *C. alliodora* (Beer 1992). On the other hand, real timber prices are likely to increase in the future while crop prices are gradually declining (Gomez 1995, Ramirez *et al*. 2000), and there are many options to minimize tree felling damage in these systems (Somarriba 1997).

Woodlots Established with Annual Crop Interplanting (Taungya)

The intercropping of tree plantations with annual crop species is still an exotic agroforestry system in Latin America, in contrast to Asia where the system became widespread in the 19th century, or Africa where it was introduced by the British colonial governments during the last century, in both cases to transform natural forests into timber plantations.

The involvement of farmers, who practised shifting cultivation, in the management of state plantations, stabilized migration and increased the livelihood of many rural landless households, although the creation of dependence of landless farmers on these systems was strongly criticized (Jordan *et al*. 1992). In the new world, most of the experience with intercropped tree plantations has been on-station or in on-farm trials. These have focused on tree establishment in association with annual crops in order to achieve early financial returns and provide incentives for reforestation without completely losing the agricultural productivity of the reforested land of small or medium sized farms (e.g., von Platen 1996). However, the system has also been used on larger commercial private farms; e.g., the field workers of a 250 ha farm in San Carlos, Costa Rica were allowed to cultivate annual crops in forest plantations during the establishment phase and sell the products. Compared to pure reforestation, this practice lowered soil preparation, weeding, pest and fire control costs by 51 to 68% (Rodriguez 1998). During the last 20 years about 10,000 ha yr^{-1} were reforested with incentives in Central America (Godoy 1997). Growth rates have been estimated at 10 to 30 m^3 ha^{-1} yr^{-1}, depending on site quality, tree species and plantation management (Volkart and Cano 1982, Vásquez and Ugalde 1995) and hence the potential timber production from these plantations can be estimated at 2,000,000 - 6,000,000 m^3 yr^{-1} (Table 1).

Timber species such as *Acacia mangium, Alnus acuminata, C. odorata, C. alliodora, Eucalyptus camaldulensis, Eucalyptus deglupta, Eucalyptus grandis, Gmelina arborea, Pinus caribaea, Swietenia macrophylla, Tectona grandis* and *Terminalia ivorensis* adapted well to association with annual crops such as *Colocasia esculenta,* Cucurbitaceae, *Dioscorea alata*, *Manihot esculenta, Oryza sativa, Phaseolus vulgaris, Xanthosoma sagittifolia, Zea mays* or *Zingiber officinale*; i.e., compared to pure tree plantations, tree survival after transplanting and early growth were only slightly reduced or even were improved by association with crops. Positive effects were due to partial shade for facultative pioneers and an improvement of soil humidity, structure (result of soil tillage for crops) or fertility (result of crop fertilization and/or crop legumes) (Somarriba *et al*. 2000b).

Table 1. Potential timber production from three agroforestry systems in Central America.[1]

	Coffee plantations[2]	Taungya	Silvopastoral systems
Area (ha)	857,000	200,000[3]	9,200,000
Average productivity (m^3 ha^{-1} yr^{-1})	4	10 – 30	2
Potential productivity (m^3 yr^{-1})	3,428,000	2,000,000 - 6,000,000	18,400,000

[1]Commercial saw log volume only
[2]Costa Rica, Nicaragua, Honduras, Guatemala and El Salvador only
[3]Total area of tree plantations established in Central America with reforestation incentives (average of 10,000 ha yr^{-1} during the last 20 years; Godoy 1997)

The initial densities of pure and mixed timber plantations were often the same (2.5 x 2.5 to 3 x 3 m), although initial tree spacings of 3 x 6 m extend the cropping period and can rapidly produce saw logs of good quality (stem diameter and stem form) (Kapp and Beer 1995). The optimal tree-crop distance depends on the competitive behaviour of the tree and crop species; e.g., with *Z. mays*, a 1 m separation gave good results for *C. alliodora* seedlings but *E. deglupta* competed successfully with only a 40 cm separation. However, when combined with *M. esculenta,* a minimal tree-crop spacing of 120 cm was needed for both tree species (Schlönvoigt and Beer 2000).

C. alliodora is a species that responds well to improved soil conditions, especially to drainage and soil fertility (Schlönvoigt and Schlönvoigt 2000); i.e., benefits that can obtained directly from association with crops if competition for light is correctly managed. Five-year-old *C. alliodora* on alluvial soils in the humid lowlands of Costa Rica, which had been interplanted with three *Z. mays* crops, followed by one *Z. officinale* crop and finally interplanted with the fruit shrub *Eugenia stipitata*, compared to a pure *C. alliodora* stand, had stand densities and total stem volumes of 258 and 465 trees ha^{-1}, and 96 and 65 m^3 ha^{-1}, respectively (Kapp and Beer 1995). Timber yield increases from crop association may be lower for species adapted to poor soil conditions because their response to soil improvement is poor; e.g., *A. mangium* on the same site only produced 65 *vs.* 62 m^3 ha^{-1} in Taungya and pure plantations, respectively. High productivity, short rotation systems of species with a high resprouting potential (reduced reforestation costs) have high adoption rates by farmers (Nascimento de Almeida *et al*. 1999).

In Central America, the productivity of woodlots associated with annual crops has been studied mostly for short rotation firewood species. The association of *A. acuminata, Eucalyptus globulus* and *Casuarina equisetifolia* with annual crops, in the Achiguate watershed, Guatemala, produced 152, 362 and 125 m^3 ha^{-1} of firewood, respectively, after five years (Leiva 1993). Even when firewood production was similar or slightly higher in pure plantations (135, 366 and 125 m^3 ha^{-1}, respectively) the best financial return was achieved with the Taungya and the pure agricultural systems compared to pure forest plantations. Nevertheless, when the environmental services of trees in watersheds are considered, then the Taungya system is the most attractive land use system.

Silvopastoral Systems

In Latin America, more than 90 million hectares of land is under pasture, mostly as a result of forest conversion to cattle ranching (FAO 1999). Nevertheless, valuable timber species, such as *C. odorata*, *C. alliodora*, *Pithecellobium saman* and *Albiza* spp., retained at low tree densities (4 to 15 trees ha^{-1}), are common in the tropical lowland pastures (Camargo *et al*. 2000, Souza *et al*. 2000) and in the highland regions, where intensive dairying is practised, there are good examples of planted and natural regeneration of *A. acuminata* in pastures (Russo 1990) and *Cupressus lusitanica* wind breaks (Harvey and Haber 1999). Livestock farmers in the region recognize the potential of valuable timber trees in their pastures to generate income to buffer low animal product prices on the national and international markets (Pomareda 2000). Profitability of small Costa Rican dairy farms is increased, especially when labour costs increase, by diversification with high valued timber species such as *C. alliodora* (2,188 *vs.* 1,478 US$ $farm^{-1}yr^{-1}$ for farms with and without the trees) (Holmann *et al*. 1992). Small cattle farms may be more dependent on timber resources to generate income; e.g., timber extraction per unit area in Esparza, Costa Rica was higher on small cattle farms (1.35 m^3 ha^{-1} yr^{-1}) compared to medium (0.55) and large (0.13) farms (C. Viera and C. Barrios, pers. comm. 1998). Small and medium cattle farmers in Matiguas, Nicaragua, can use their timber stock as a guarantee to obtain credits to improve pastures and to plant more timber trees (Barrios, pers comm. 1999).

Silvopastoral systems have an estimated commercial timber productivity of 2.0 m^3 ha^{-1} yr^{-1} (Holmann *et al*. 1992, Camargo *et al*. 2000) and hence the estimated 9.2 million ha of pasture land in Central America (Kaimowitz 1996) have the potential to produce 18.4 million m^3 yr^{-1} (Table 1). These estimates were based on the fact that about 50% of these pastures are found in the drier areas where timber productivity was assumed to be 40% lower than that of the humid sites (Stewart *et al*. 1992). However, timber production potential may have been overestimated because a high percentage of these pastures are on degraded land. For example, the productivity of *C. alliodora* in pastures is low due to the low stocking rates and in some cases infertile compacted soils (0.6 to 2.0 m^3 ha^{-1} yr^{-1}) (Lopez *et al*. 1999, Camargo *et al*. 2000).

The recent interest of developing countries to purchase carbon sequestered in forest and agroforestry ecosystems may provide tropical farmers with further incentives to adopt silvopastoral technologies. Traditional silvopastoral systems in San Carlos, Costa Rica, have about 50 tons carbon ha^{-1} stored in the commercial timber which could generate an additional US$400 income if the price for sequestered carbon was $8 ton^{-1}. Trees also provide other ecological services in pastures including a reduction of heat stress of animals and nutrient cycling. Milk yields of dairy cows with access to tree shade were 20% higher compared to yields obtained from cows without shade (Souza *et al*. 1999).

Cattle farmers may select timber species with small crowns (e.g., *C. alliodora*, *C. odorata*, *Albizia* spp. and *Platymiscium pleiostachyum*) to reduce competition with grasses for light and to sustain high yields of animal products (Harvey and Haber 1999, Souza *et al*. 2000). Nicaraguan and Costa Rican cattle farmers may protect timber tree seedlings in pastures (C. Barrios, pers. comm. 1999) but in one study in Costa Rica, more than 60% of the damage observed on young timber trees was due to indiscriminate chopping and herbicide use (Camargo *et al*. 2000). In Cuba, the exotic timber species *Khaya nyasica* and *Khaya senegelensis* grew moderately well in mixtures with *Panicum maximum* grass, with mean tree height and breast height stem diameter of 8.5 m and 11.9 cm, respectively, at age nine years, but sheep grazing resulted in debarking of trees (Renda *et al.* 1999). Studies conducted in the Chaco region of Argentina also showed that grazing management is crucial to promote natural regeneration of valuable timber species (*Geoffroea decortican, Schinopsis balansae* and *Prosopis nigra*) in pastures. The percentage of tree damage decreased from 65 to 48% when pasture availability increased from 3.1 to 5.0 ton DM ha^{-1}, though some tree species were more tolerant of grazing (Simon *et al*. 1998). Direct seeding in cow dung instead of in the soil resulted in less browsing (0.4 *vs.* 6.5%, respectively) and trampling (17 *vs.* 56%, respectively) damage of *P. saman* in grazed pastures (Barrios *et al*. 1999). Establishment of timber species with improved exotic grass species, such as the Brachiarias that are being promoted in Latin America, may not be successful because these grasses are very competitive. For example, in the acid soils of Caqueta, Colombia, *Enterlobium cyclocarpum* had lower growth rates in mixtures with *Brachiaria decumbens* (0.4 m yr^{-1}) compared to combinations with native grasses (0.7 m yr^{-1}) (Cipaguauta *et al*. 1999).

Evaluation of Timber Productivity in Agroforestry Systems

Traditional experimental designs and approaches, used for agricultural and forestry research, are frequently inadequate for the study of timber production in agroforestry systems (Somarriba *et al*. 2000a), especially since the majority of the studies have to be carried out on-farm. Major limitations are:

1. Wide tree spacing (8 m) results in large plots and experiments (0.25 and 2.25 ha, respectively, for only three complete blocks of three species). This is not feasible on most farms, or an inadequate number of core plot trees per plot (<16) is used if plot size is reduced.
2. Most small-medium farms require spatially variable management of irregularly sloping and inhomogeneous sites where the underlying assumptions of traditional designs are not fulfilled (e.g., variances may not be homogeneous; variance intra-plot > intra-block > inter-block).
3. In the case of medium-long term tree species trials in agroforestry systems, it is usually impossible to maintain all factors (except species) constant because the permanence of the system will depend on adapting pruning and thinning, as well as other management activities (e.g., weeding), to the characteristics of each tree

and the needs of the underlying crop or pasture. Hence trials become contrasts of systems, in which many factors vary, rather than species comparisons (e.g., Boulay *et al*. 2000).

4. The time frame required to establish and evaluate a complete harvest cycle for timber trees (usually >10 years; often >20 years) is unacceptable for the clients of the results, such as development programmes and farmers' groups.

The alternative is to use survey rather than experimental approaches (Coe 1999), where one attempts to describe and quantify site and management factors, in addition to tree productivity, and hence infer conclusions such as identifying the optimal growth conditions for each tree species and/or the effect of key factors on tree productivity, such as the nature and management of associated crops/pastures. The risk that confounding factors compromise the reliability of results, and the need for a large number of samples, is obvious. Valuable information can be obtained by quantifying tree volumes during commercial harvesting if there is reliable information on tree ages (e.g., Somarriba and Beer 1987). Permanent plot studies can be used to complement and check data obtained during logging but again the heterogeneity and small size of tropical fields limits extrapolation of the results (Somarriba *et al*. 2000b).

The socioeconomic factors (laws, traditions, regulations, incentives, etc.) that influence the removal or establishment of timber trees on resource poor tropical farms (Kaimowitz 1996, Berti 1999) are inadequately understood even though they are probably the main barrier to adoption of improved land use. This is one research area where scaling issues, and integration of information from different scales (farm, community, national) must be considered.

Selection of Agroforestry Systems and Timber Species for Specific Biophysical and Socioeconomic Conditions

In the case of small farmers, the criteria to select on-farm sites and methods to plant timber trees may be completely different to the traditional approach to reforestation; e.g., instead of using the worst land available for high density tree plantations, the small farmer will often prefer a rapid, less risky timber production from permanent low tree density agroforestry combinations on better agricultural land (Current and Scherr 1995). The failure of alley cropping, at least in the seasonally dry tropics (Carter 1995), clearly demonstrated the need to pay more attention to matching agroforestry systems to local conditions. Even within the same ecological zone, the interaction of biophysical and socioeconomic factors leads to clear differences in the way a particular agroforestry system is managed; e.g., the shade structure of coffee plantations (Llanderal and Somarriba 1999). Within a farm and even plantation, micro-site differences are important for species selection; e.g., *C. alliodora* mortality in one line planting trial varied from 0-100% per plot due to minor differences in the water table (Kapp *et al*. 1997). Finally, farmers in the tropics often take advantage of heterogeneity within their fields (e.g., to mix species in home gardens; Mendez *et al*. 2000) while modern intensive farming and research methods are usually designed to eliminate heterogeneity within a field (Guharay *et al*. 2000). The selection of on-farm sites, where timber trees could be incorporated with crops/pastures, also has to take into account neighbouring land use; e.g., timber species, such as *E. deglupta* and *Terminalia ivorensis* in boundary lines, can reach 20 m height in as little as five years (Kapp *et al*. 1997) resulting in significant shade, and maybe root competition, for the same horizontal distance (Akbar *et al*. 1990). If an adjacent farm is used for cacao or coffee, the possibility that tree-crop competition will provoke future conflict between neighbours will be much less than when shade sensitive annual crops are planted.

Although species-site matching (biophysical characteristics) is a basic concept for any reforestation activity, the decisions are much more complicated in agroforestry programmes, especially those dealing with small-medium tropical farms where the socioeconomic factors can lead to very different decisions on adjacent farms. For example, many coffee farmers in Costa Rica replaced traditional "service" shade trees with *E. deglupta* in the late 1990's, apparently because this reduced management costs (pruning of the "service" shade trees) rather than because of the timber value of the fast growing *E. deglupta* (Tavares *et al*. 1999). In silvopastoral systems, the ability of a species like *A. mangium* or *T. grandis* to tolerate physical damage (e.g., animals rubbing against tree trunks), browsing and compacted soils (Kapp *et al*. 1997, Bolivar *et al*. 1999) are important criteria if early grazing amongst the trees will occur.

Compared to pure forestry operations, in agroforestry systems there are additional criteria for timber species selection due to crop needs (e.g., allowable shade levels) and/or as a result of agricultural management (e.g., intensity and timing of grazing). Again different scales need to be considered. "Organic" certification will usually be at the farm rather than crop (plantation) level and hence on "organic" farms, tree selection criteria will include potential to sustain associated crop production in the absence of inorganic fertilizers as well as tolerance/resistance to pest/disease problems that would require agrochemical protection (e.g., leaf cutter ant [*Atta* spp.] damage of *E. deglupta*). In the tropical lowlands, where there are rice, banana and other agroindustrial crop plantations, aerial spraying limits the planting of any tall trees on surrounding farms.

Agricultural practices can modify site conditions to favour certain timber species. Planting *C. odorata* or *S. macrophylla* in pure plantations or open grown conditions (e.g., in pastures) invariably fails because of attack by the shoot borer *Hypsipylla grandella* (Newton *et al*. 1993, Rodgers *et al*. 1995). In contrast, merchantable trees of these species are often found in multi-strata agroforestry systems such as coffee or cacao plantations. Again, in contrast to pure timber plantations, where the potential to modify site conditions such as soil chemical and physical properties as well as weed management is very limited, in agroforestry associations it is possible to significantly improve site index (quality); e.g., for *C. alliodora* at age five years in Talamanca, Costa Rica, from 14.1 to 17.5 m (Kapp and Beer 1995). This has led to the suggestion that valuable tropical timber species, such as *C. odorata* and *S. macrophylla,* should be planted in agroforestry associations rather than in pure plantations because success depends upon intensive management which can only be provided in an agricultural context (Leakey, pers. comm.).

In genetic improvement programmes of timber species for agroforestry systems, as well as for species-site matching, tree species selection criteria should include: local preferences; timber value; low competitivity (with the crop); wind firmness and resistance to stem breakage in open grown situations; narrow crowns to reduce competition for light, wind fall and breakage risk (lower wind resistance) as well as underlying crop damage during harvesting or wind fall; and, in the case of silvopastoral systems, tolerance of soil compaction/water logging (Boshier and Beer 1997). Most timber trees in agroforestry systems are open grown; i.e., tree crown interactions are insignificant. Hence, selection for traits such as stem form, degree of stem taper and canopy characteristics become even more important than for pure forestry plantations since the silvicultural interventions of selective thinning and using competition from neighbouring trees are not options. Furthermore, considerations of acceptable wood density under conditions of maximum diameter increment will be of increased importance. Below-ground characteristics, which indicate which tree species are likely to compete more with associated crops (e.g., rooting depth and fine root density) are important considerations in agroforestry systems since the farmer will usually give priority to crop over timber production. When associated agricultural land use involves tillage, especially the inclusion of root crops in Taungya systems, below ground characteristics such as rooting depth and susceptibility to root diseases (e.g., *Terminalia ivorensis* [Kapp *et al*. 1997]) increase in importance. Many other characteristics are used to select shade tree species for coffee and cacao plantations (Beer 1987), illustrating the complexity of choosing appropriate timber species (or germplasm) for agroforestry systems. The importance of agroforestry systems to produce timber in Latin America is increasing and should be promoted at all levels from international markets down to individual farms.

Abstract

In Central America, most landscapes consist of a mosaic of pastures, agricultural fields, and forest fragments interspersed with residential and urban areas. Although these landscapes are highly fragmented and altered, they often retain a remarkable diversity of tree species within forest patches, isolated trees, and planted windbreaks. The forest patches, isolated trees and windbreaks are important for conserving both local and regional biodiversity because they provide important food sources, nesting sites and habitat for a variety of animal species (particularly birds), and may serve as stepping stones or corridors that facilitate animal movement across the agricultural landscape. They also help conserve plant diversity, both because the trees themselves often represent forest species that would otherwise be absent from the landscape and because the trees serve as hosts for numerous epiphytic plants. By acting as foci for seed dispersal and seedling establishment, the trees also facilitate the regeneration of forest plant species within the agricultural landscape. We present a case study of the importance of forest fragments, isolated trees and agricultural windbreaks for the conservation of both local and regional biodiversity in Monteverde, Costa Rica, summarizing and synthesizing the work of more than 20 years of ecological research in the region.

Keywords: Altitudinal migrations, Biodiversity, Forest patches, Isolated trees, Windbreaks

Introduction

One of greatest challenges currently facing land managers is how to maintain and conserve biodiversity within fragmented, human-dominated landscapes (Bennett 1999). In Central America, as in many other parts of the world, natural landscapes are increasingly being converted into complex mosaics of pastures, agricultural fields, forest fragments, and residential areas, threatening the status of many plant and animal species (Forman and Godron 1986, Forman 1995). Because deforestation is rarely complete, most landscapes retain scattered forest fragments, isolated trees or other fragments of natural vegetation. In addition, agricultural lands often include windbreaks, fence rows or borderline plantings that were planted by farmers. Although these landscape elements are usually overlooked in conservation strategies, they may play critical roles in maintaining and conserving both local and regional biodiversity by providing habitats and resources that are otherwise lacking within the agricultural landscape (Crome *et al.* 1994, Forman 1995, Corbit *et al.* 1999). In some cases, they may also serve as stepping stones or corridors that facilitate animal movement across agricultural lands (Bennett *et al.* 1994, Haas 1995, Guevara *et al.* 1998).

While there is growing recognition of the potential importance of forest fragments, isolated trees, and agricultural windbreaks in the conservation of biodiversity within fragmented landscapes, there are few studies that have examined their role in conserving biodiversity at both a local and regional level. We present a case study of the importance of forest patches, isolated trees and windbreaks in the agricultural landscapes surrounding the Monteverde reserve complex in north-western Costa Rica, for the conservation of both local and regional biodiversity. We focus primarily on the Pacific slope of the Monteverde region, both because this is where the most research has been conducted and because the Pacific slope has been heavily deforested and influenced by agricultural activities. In addition, we briefly discuss the value of the forest fragments, isolated trees and windbreaks for local farmers in order to highlight their agricultural and economic importance.

The Monteverde Landscape

The Monteverde region lies within the Tilarán mountain range, a north-south volcanic mountain chain in central, northern Costa Rica (10 18'N, 84 48'W; Holdridge 1967), and encompasses an elevational gradient from 200 m to almost 1800 m. The communities of Monteverde and Santa Elena occur between 1250-1500 m. The region has a mild, montane climate (annual temperature 18.5°C, annual rainfall 2500 mm), with a dry season from November to May (Haber *et al.* 1996). At the lower elevations, temperatures are slightly warmer and the dry season is more pronounced (Clark *et al.* 2000).

At the top of the mountain range, there is a complex of reserves (hereafter referred to as the Monteverde reserve complex) that straddles the continental divide and encompasses roughly 28,000 ha, primarily on the Atlantic slope. This complex is composed of the Monteverde Cloud Forest Biological Preserve (10,500 ha), the Bosque Eterno de los Niños (BEN, 17,000 ha), and the Santa Elena Reserve (310 ha), of which all but the Santa Elena reserve are privately owned and operated (Haber *et al.* 1996). Two important isolated protected forests exist on the Pacific slope: Bajo del Tigre (30 ha) and the San Luis Biological Research Station (239 ha), administered by the Monteverde Conservation League and the Tropical Science Center respectively. On the Atlantic slope, the reserve complex is contiguous with the Arenal National Park (12,123 ha; Garcia 1996).

Outside of the reserve complex, most of the land has been converted to pasture for dairy farming or developed for ecotourism, and the landscape is a mosaic of pastures, coffee fields, sugarcane fields, small forest patches and residential areas. In the area immediately adjacent (3-10 km) to the reserve on the Pacific slope, dairy farming is the principal economic activity (with the exception of ecotourism activities generated by the reserve complex). It is estimated that roughly 60% of the area occurs as pasture, 15% exists as coffee or sugarcane fields and forests cover the remaining 25% (Harvey and Haber 1999). Most of the dairy farms in the region are small (mean=16.5 ha, range=5-40 ha), family-owned, and intensively managed with fertilizer inputs, exotic grasses (primarily *Cynodon nlemfuensis*) and a rotational grazing system (Harvey and Haber 1999). At lower elevations, cattle raising is the principal source of income and farms tend to be much larger and less intensively used.

Importance of Monteverde for Conserving Regional Biodiversity

The Monteverde region is crucial for conserving regional biodiversity because it contains one of the few intact, protected high-elevation forests in Central America (LaBastille 1978). Due to its rough topography and steep environmental gradients, the Monteverde region has seven different life zones (tropical wet forest, tropical moist forest, premontane wet forest, premontane moist forest, premontane rain forest, lower montane wet forest, and lower montane rain forest) within a relatively small area of roughly 250 km^2 (Bolaños and Watson 1993). Like other montane forests, it includes a high diversity of both plant and animal species, many of which are endemic to cloud forest habitats (Balslev 1993). The Monteverde Cloud Forest Preserve alone includes >100 species of mammals, 400 species of birds, 120 species of amphibians and reptiles, >3000 plants (including >700 trees, >870 epiphytes, >500 orchids, and >300 ferns) and >500 species of butterflies (Lawton and Dryer 1980, Wheelwright 1986, Haber *et al.* 1996, Haber 2000).

Many of the species present in the Monteverde area occur only in cloud forest habitats of Central America and a significant number of species are endemic to the Tilarán mountain range (Wheelwright 2000). A ten-year study of the flora of Monteverde found a total of 166 plant species new to science, about half of which are endemic to the Monteverde region (Haber *et al.* 1996, Haber 2000). A few tree species (e.g., *Ilex haberi*, *Pleurothyrium guindoni*, *Ocotea monteverdensis*) have only been identified from a few specific sites and have extremely small populations. The Monteverde flora and fauna also includes a considerable number of species that are endangered or threatened, both nationally and/or regionally. For example, Young and colleagues (1998) found 19 resident and three long-distance migrant bird species in the Monteverde region that are considered threatened regionally.

Within the Monteverde region, the diversity of plants and animals changes rapidly over the elevational gradient, and species turnover between life zones (even those located in narrow bands occurring over short distances) is high, indicating the importance of conserving forest along the entire elevational gradient (Wheelwright 2000). Among trees, the proportion of tree species shared among two adjacent life zones is estimated to be roughly 20% of the number of species that occurs in either life zone separately (Haber *et al.* 1996). There is similarly a high turnover across life zones among animal species. In various studies of the Monteverde avifauna, a total of 235 bird species were found in the five upper life zones, yet the number of species in each individual life zone ranged from 72 to 126 species and the Jaccard similarity indices for adjacent life zones were low, ranging from 0.30 to 0.47 (Young *et al.* 1998).

Importance of Forest Fragments, Isolated Trees and Windbreaks for the Conservation of Biodiversity

Although the current reserve complex protects roughly 28,000 ha of forest, it is unable to conserve the diversity or plant and animal life present in the region because it protects only a fraction of the elevational gradient on the Pacific slope, extending only down to 1500 m, and also includes a very limited area (<2000 ha total; Powell and Bjork 1995). Of the seven Holdridge zones that occur in the region, only three life zones (lower montane rainforest, premontane rainforest, tropical wet forest) are protected by more than 600 ha in the reserve complex (Powell and Bjork 1995). Two additional life zones (lower montane wet forest and premontane wet forest) are poorly represented, and two (premontane moist forest, tropical moist forest) are not represented at all (Powell and Bjork 1995, Haber pers. obs.). As a result, numerous species of plant and animals that only occur in the lower-elevation forest remnants of the Pacific slope are not represented within the reserve complex's limits. Conservation of many of Monteverde's migrating species is also not assured since the survival of these species depends not only on the protection of the reserve complex, but also on the protection of their seasonal habitats and travel paths within the fragmented landscape outside of the reserve boundaries (Powell and Bjork 1995).

The maintenance of forest patches, windbreaks, and isolated trees within the agricultural landscape may be critical for protecting the diversity of plant and animal life within the Monteverde region as these elements provide resources, habitats, nesting and roosting sites that may enable some (though clearly not all) forest species to persist within the fragmented landscape. In the lower regions of the Pacific slope, where there are no large contiguous tracts of forest remaining, the forest fragments, windbreaks and isolated trees represent the main habitat available to forest species. The presence of isolated trees, windbreaks and forest patches may also considerably enhance the connectivity of the landscape (reducing the distances that animals must travel between forested areas) and act as stepping stones or corridors that facilitate animal movement. For migrating species, the presence of trees, whether in forest patches, dispersed in pastures, or planted in windbreaks, may also provide critical resting and foraging sites on their migrations from the highlands to the lowlands, or from the Atlantic to the Pacific slopes.

Forest Patches and the Conservation of Biodiversity

One of the most important landscape features for the conservation of biodiversity outside of the reserve are the small forest patches scattered throughout the agricultural landscape. Most of the forest patches in the Monteverde region occur along streams or on steep slopes that are unsuitable for farming (Guindon 1997). Although their shape, size and location vary considerably, a survey of 30 patches on the Pacific slope, at an elevation of 1000-1500 m, found that forest patches ranged in size from 0.2 to 7.9 ha, with an average of 2.4 ha (Guindon 1997). Often, the patches have been degraded by selected removal of timber species, or by grazing, trampling and physical damage by cattle (Guindon 1997).

Forest Patches and Plants

Despite their disturbed nature and small size, the forest fragments on the Pacific slope are important for the conservation of biodiversity because they host a high diversity of plant life and often contain species that do not occur in the existing protected areas. In a survey of trees of 30 forest fragments on the Pacific slope, a total of 225 tree species representing 130 genera and 59 families were found (Guindon 1997). Tree species diversity within individual forest patches ranged from 14-100 species, with trees in the Lauraceae family being dominant (Guindon 1997). A significant portion of the species found in forest fragments do not extend their ranges into the reserve complex: a total of eighteen tree families, 64 genera and 138 tree species found in the Pacific slope forest fragments (Guindon 1997) were not found in a one-ha sample within the contiguous forest in the Monteverde Cloud Forest Biological Preserve (Nadkarni *et al.* 1995).

Forest fragments are also important for conservation because many of the tree species that occur within the fragments in the seasonally evergreen forest (premontane wet forest and premontane moist forest) on the Pacific slope adjacent to the reserve are endemic and undescribed species that do not occur within the reserve complex. Over the past 15 years, a total of 35 tree species new to science have been discovered in the Pacific slope fragments adjacent to the reserve, of which none occur within the protected area (Haber 2000). To date, 12 of these have been described and 23 still await the publication of scientific names (Haber pers. comm.).

Species turnover between forest fragments is high, indicating that it is important to conserve forest fragments along an elevational gradient. For example, two forest fragments that differed by only 200 m in elevation and were separated by a physical distance of less than 2 km, shared only 12 of 105 identified tree species and had no lauraceous species in common (Guindon 1997).

Forest Patches and Birds

In addition to serving as important habitats for forest plants, the forest fragments provide key habitats and resources for animal species. Although the fragments are thought to be important for a variety of animal species (such as howler monkeys, white-faced monkeys, sloths, coatimundis, agoutis, margays, olingos, kinkajous and many species of bats), most of the research in the Monteverde region has focused on their importance for both resident and migrating birds.

Avian diversity within the Pacific slope forest patches is considerable. In a mist-netting survey of 13 Pacific slope fragments (including 1120 mist-net hours), a total of 62 bird species were found (Hamilton DeRosier unpublished data). This represents >10% of all the bird species within the Monteverde region (DeRosier 1995). The diversity of birds within forest fragments depends, among other factors, on the availability of fruit resources, the degree of connectivity of the forest fragment with the intact reserve or other forest patches, the size of the forest fragment, as well as the individual requirements, dispersal abilities and behavior of each bird species (Guindon 1988, 1997, DeRosier 1995, Hamilton DeRosier and Nielsen in prep.).

In addition to serving as habitat for resident bird species, the forest fragments are also critical habitats for bird species that migrate seasonally out of the reserve down to lower elevations in search of food or nesting areas. Bird species that are known to migrate seasonally and to depend, at least to some degree, on the protection of the forest fragments include resplendent quetzals, three-wattled bellbirds, keel-billed toucans, black guans, emerald toucanets, mountain robins and some species of hummingbirds (Guindon 1988, 1997, Powell and Bjork 1995). Of these migrations, the two best-documented seasonal migrations are those of the resplendent quetzal and the three-wattled bellbird. Both of these species nest in the cloud forest between January-June, and then undertake seasonal migrations to both the Pacific and Atlantic slopes following the temporal availability of fruit, especially of Lauraceae trees (Guindon 1988, Powell and Bjork 1995). By July, most individuals of both species have moved into the Pacific forest patches and isolated trees of adjacent farms. Because these forest fragments occur at lower elevations and experience warmer temperatures, they host different tree species from the reserve and have different fruiting phenology, providing fruits at a time when fruits within the reserve are limiting (Guindon 1997). During the several months that the bellbirds and quetzals visit the forest fragments, large congregations of birds within small forest patches are common. Powell and his collaborators, using Jolly-Seber mark-recapture formulas (Nichols *et al.* 1981) estimate that as many as 300 bellbirds may depend on several Pacific slope fragments that total less than 20 ha in size during this period (Hamilton DeRosier pers. comm.).

Forest Patches and Butterflies

The forest patches scattered over the Pacific slope buffer zone of the Monteverde reserve complex also hold considerable importance for the conservation of butterfly diversity. In an intensive, three-year census of butterflies in the Monteverde region, Haber and his colleagues recorded 645 butterfly species on the Pacific slope in the Monteverde area between the Pacific coast and the Continental Divide (ranging from 70 to 1600 m), of which 625 species were found outside of the reserve complex. A total of 150 species were recorded within the Monteverde Cloud Forest Preserve (above 1500 m), but only 20 of these species were found only within the Preserve (Haber in prep.). About 50 of the butterfly species found within the forest fragments on both the Atlantic and Pacific slopes are classed as rare (DeVries 1987, 1997). In addition, seven species of undescribed hairstreaks have been collected from the Monteverde region, of which three were collected within the reserve complex and four were found only outside the reserve (Haber pers. comm.). While the conservation status of these species is poorly known at present, it appears likely that the forest fragments are critical for their persistence in the region.

In addition to the many resident butterflies occurring within the forest fragments, a large number of butterflies pass through the fragments each season during altitudinal and cross-country migrations (Haber 1993). The migrating butterflies spend part of the year in the lowlands of western Guanacaste and northern Puntarenas Provinces, where the habitat consists primarily of tropical semi-deciduous forest. During the dry season (November-May), these forests lose anywhere from 0 to 90% of their leaves, and many of the butterflies leave the area and migrate to less seasonal (cooler and moister) habitats in the nearby Tilarán mountains or over the Continental Divide to the Atlantic slope. It is estimated that roughly 75% of the butterfly species found in the Monteverde region migrate seasonally in response to seasonal changes in climate and plant phenology (Haber in prep.). The eastward migration from the Pacific to the Atlantic peaks from October to January (transition from wet season to dry season), whereas westward migration is concentrated in April and May (transition from dry to wet season) (Haber 1993). Especially during eastward migration, many of these species depend on the forest fragments for food resources and intermittent protection from the storms and strong winds of the early dry season. The prevalence of butterfly migration illustrates the importance of protecting habitat along the migration route, as well as at both ends of the migration path.

Isolated Trees and the Conservation of Biodiversity

Another common feature at Monteverde that may play an important role in the conservation of biodiversity within the agricultural landscape are the isolated or dispersed trees that occur within the pastures, agricultural fields and road banks. Although often overlooked in conservation strategies, isolated trees provide key habitats and resources for both plant and animal species and serve as stepping stones that facilitate animal movement within the agricultural landscape (Guevara *et al.* 1992, 1998, Guevara and Laborde 1993, Harvey and Haber 1999). Within the Monteverde landscape, the density and diversity of isolated trees varies considerably among different farms and between the higher and lower elevations of the Pacific slope. In the dairy farms adjacent to the reserve complex on the Pacific slope, isolated trees are a common and conspicuous element of pastures: a survey of pastures on 24 farms (400 ha total) found that pastures had an average of 25 isolated trees ha^{-1} (range: 5-80 trees ha^{-1}; Harvey and Haber 1999). At lower elevations, where the main activity is cattle ranching for meat production, casual observations and aerial photos suggest that the tree component is much less abundant (Guindon pers. obs.). Historically the grasses on these farms were burnt on an annual basis at the end of each dry season, to stimulate the production of new grass with the first rains and clear the pastures of shrubs and trees (Guindon pers. obs.).

Isolated Trees and Plants

The isolated trees represent a high species diversity and significantly increase the plant diversity within the agricultural landscape. In a survey of >5,500 trees occurring in pastures of 24 dairy farms on the Pacific slope, a total of 190 tree species were found, of which 57% were primary forest species (Harvey and Haber 1999). This represents roughly 60% of all the approximately 320 tree species occurring within the study area (Harvey and Haber 1999). The most common families represented in pastures included Lauraceae (28 spp.), Myrtaceae (17 spp.), Fabaceae (15 spp.). Meliaceae (7 spp.), Solanaceae (7 spp.), Euphorbiaceae (6 spp.) and Moraceae (6 spp.) - all of which are families commonly found in intact, adjacent forests (Harvey and Haber 1999).

Many of the isolated trees in pastures, particularly those that are relicts of the original forest, maintain rich communities of epiphytic plants, including woody shrubs, tank bromeliads, herbaceous epiphytes and mistletoes, thereby further increasing the diversity of plant species present within the pastures (Nadkarni and Matelson 1989, pers. obs.). These epiphytes, in turn, provide important foraging resources (fruits, nectar, invertebrates, and water) and nesting materials for forest birds and other animals (Nadkarni and Matelson 1989, Hietz-Seifert *et al.* 1995).

Isolated trees may also help conserve plant diversity by serving as foci for seedling recruitment and regeneration in pastures, both by providing local sources of propagules and also by attracting seed-dispersing birds and bats into agricultural areas (Guevara *et al.* 1986, Guevara and Laborde 1993, Harvey 1999). In a recently abandoned pasture in Monteverde, for example, recruitment of tree seedlings and saplings was greater beneath remnant trees than in open sites within the same pasture but without overhanging vegetation (Murray *et al.* unpublished data). Mean species richness was also much greater beneath remnant trees (6.4 ± 2.12 species vs. 0.7 ± 0.94 species; Murray unpublished data). Recruits included both pioneer and primary forest species, many of which were represented in the surrounding forest but not as reproductive individuals within the pasture. This finding parallels those in other locations (e.g., Guevara *et al.* 1986, 1994, Uhl *et al.* 1991, Guevara and Laborde 1993) and reinforces the emerging consensus that remnant pasture trees greatly enhance the rate of forest regeneration on abandoned pastures. In active pastures, isolated trees similarly serve as foci for regeneration, however few of the regenerating trees actually survive and establish within the pastures because cow grazing, trampling and manual weeding by farmers destroy most of the regenerating seedlings (Harvey and Haber 1999).

Isolated Trees and Birds

In addition to enhancing the floral diversity of pastures, isolated trees also help maintain faunal biodiversity within the fragmented landscape by providing fruits, leaves, and nesting, roosting and perching sites to birds, bats and other animals (Lynch 1989, Saab and Petit 1992, Estrada *et al.* 1993a, 1993b, Perfecto *et al.* 1996). Of the isolated trees surveyed in the pastures of 24 Monteverde farms, more than 94% of all trees are known to provide fruits for frugivorous species (Harvey and Haber 1999), and some of the most common isolated trees (*Acnistus arborescens*, *Citharexylum costaricensis*, *Ficus pertusa*, *Hampea appendiculata* and *Sapium glandulosum*) provide fruits for more than 20 bird species each, thereby constituting an important food resource within the landscape (Wheelwright *et al.* 1984). Dead isolated trees may also serve as nesting sites for birds such as masked tityras, emerald toucanets, woodpeckers, parrots and quetzals (Hamilton DeRosier pers. obs.)

Casual observations of birds in isolated trees and studies of individual bird species suggest that fruiting isolated trees in pastures are visited by a large number of bird species, particularly when fruit availability within the reserve is low (Murray pers. comm., DeRosier pers. comm.). Studies of isolated trees in pastures, coffee fields and agricultural lands in other areas of Central America have similarly noted the importance of isolated trees as habitats and food resources for bird species (Powell *et al.* 1989, Robbins *et al.* 1989, Perfecto *et al.* 1996, Greenberg *et al.* 1997). During the months of June-September, when food resources within the Monteverde complex reserve are limiting, it is common to see clusters of birds within isolated, fruiting trees: as many as eight quetzals have been observed in a single Lauraceae tree (*Ocotea monteverdensis*) and as many as five bellbirds have been seen simultaneously in a single isolated pasture tree during this period (Hamilton DeRosier pers. comm.). Similarly, in a bird survey in July 1997, 18 of the counted 23 quetzals were found in three remnant trees (Hamilton DeRosier pers. comm.).

The importance of isolated trees depends on their fruiting status, as well as their distance from the nearest forest patch. In many cases, the isolated trees act as 'stepping stones' that facilitate bird and animal movement across the agricultural landscape; however species that are unable to cross the distances between the forest and the isolated trees cannot benefit from their presence. Studies in other areas have shown that the presence of isolated trees effectively enhances landscape connectivity, thereby making it easier for some bird species to move between forest patches (Guevara *et al.* 1998).

Agricultural Windbreaks and the Conservation of Biodiversity

Like forest patches and isolated trees, the agricultural windbreaks in the Monteverde landscape may play a critical role in the maintenance of biodiversity by providing habitats, resources and serving as corridors for animal movement. Although there are some 'natural' windbreaks consisting of strips of forest that were left for wind protection when the original forests were cleared, most of the windbreaks in the region are recent additions to the landscape, planted as part of a reforestation effort led by the Monteverde Conservation League between 1989-1995. The windbreaks were planted primarily to protect the cattle from physical stress by the trade winds and prevent grass desiccation, however they also serve to reforest a previously bare landscape. The windbreaks consist primarily of four species (*Montanoa guatemalensis*, *Cupressus lusitanica*, *Croton niveus* and *Casuarina equisetifolia*, of which only *Montanoa* is native to the region), are generally 2-4 rows wide (mean width=5 m; Harvey 1999) and are planted perpendicular to the strong NE trade winds that hit the area from November to April (Clark *et al.* 2000). An estimated 186 km of windbreaks were established in the Monteverde region during this period, turning a previously very open pastoral landscape into one criss-crossed by lines of trees (Varela pers. comm.) Especially at the lower elevations, the windbreaks represent some of the only wooded areas present in the landscape and serve as important refuges for forest regeneration and as critical links that facilitate the movement of some bird species across the landscape.

Windbreaks as Habitats for Forest Trees

The agricultural windbreaks are narrow, relatively young habitats (consisting of mainly of exotic tree species) that differ greatly from intact forest in species composition, structure and microclimate, yet they nevertheless provide important habitats for forest tree recruitment within the agricultural landscape. This is accomplished in part because the microclimate within the windbreaks is more favorable to plant species and in part because they represent some of the few fenced areas where cattle cannot enter and destroy regenerating seedlings (Harvey 1999). Birds visiting the windbreaks or using them as corridors to cross the pastures often defecate seeds, which may later germinate and establish as seedlings. An intensive one-year study of seed dispersal within the agricultural windbreaks and adjacent pastures in Monteverde found that windbreaks received more than 40 times as many tree seeds and more than twice as many species of tree seeds as adjacent pastures, indicating the importance of these windbreaks as foci for forest regeneration (Harvey 2000). Surveys of the understories of established windbreaks revealed that a wide variety of forest tree species are colonizing and establishing within the windbreaks. A total of 91 tree species (including both primary and secondary forest species) were found as seedlings within the windbreaks, just 5-6 years after they were established (Harvey in press). The mean density of seedlings was 2.14 per m^2. Although it is not clear how many of these tree species will survive and become reproductive individuals, at least there is a strong potential for the windbreaks to serve as conservation tools for forest tree species.

Interestingly, the position of the windbreak within the landscape appeared to have an important effect on tree recruitment patterns. Windbreaks that were directly connected to forests had significantly higher densities and diversity of forest tree seedlings in their understories than windbreaks that were separated from forests by 20-50 m (Harvey 1999, in press). These differences reflect the greater activity of frugivorous birds within connected windbreaks and the presumably higher input of forest tree seeds.

Windbreaks and Birds

In addition to providing sites for forest regeneration, the planted windbreaks may help maintain animal species within the fragmented landscape. The windbreaks are frequently visited by birds and other animals because they provide perches, shelter from predators, foraging sites for insects and nectar, and serve as corridors that enable forest animals to cross the otherwise open, agricultural landscape. In addition, the natural windbreaks (but not the planted windbreaks, which consist of exotic species) also provide fruits for frugivorous species. A three-year mist-netting study of birds using both planted and natural windbreaks found a total of 84 bird species using windbreaks, of which 64 species were found in natural windbreaks and 74 were found in the planted windbreaks consisting of *Montanoa guatemalensis* and *Cupressus lusitanica* (Hamilton DeRosier and Nielsen unpublished data). Although the overall species diversity of birds was similar in natural and planted windbreaks, natural windbreaks appeared to serve as habitat for bird species whereas the planted windbreaks appeared to be only transient foraging sites or travel paths. In natural windbreaks, several nests were found and several bird individuals were repeatedly captured, suggesting that these birds actually reside within the windbreaks. In contrast, no nests of any birds were found within the planted windbreaks (even though the windbreaks were sampled during the primary breeding season of the local bird species) and recaptures of individual birds within the same windbreak were rare (Hamilton DeRosier and Nielsen unpublished data).

Because many of the windbreaks are joined to forest fragments (on one or both ends), they greatly enhance the overall connectivity of the landscape and can potentially serve as corridors for some animal species. Mist-netting and mark-recapture studies suggest that some bird species use the windbreaks as corridors to travel from one forest patch to the next (DeRosier 1995). Windbreaks that were connected to forest patches contained a higher percent of forest-dwelling birds and frugivorous birds than those windbreaks that were isolated from forest patches (Hamilton DeRosier and Nielsen, unpublished data). In addition, bird capture rates within windbreaks were positively correlated with distance to the nearest forest fragment and many individuals were recaptured moving through the windbreaks, indicating that the windbreaks serve as passageways for birds moving between forest patches. Perhaps the strongest indication of the corridor usage by birds was that capture rates remained high over the five consecutive days within each windbreak, suggesting that the birds being captured were new arrivals rather than residents.

Aside from birds, a variety of other animals have been observed in windbreaks including sloths, monkeys, mice, kinkajous, opossums, squirrels and snakes (Hamilton DeRosier pers. obs, Harvey pers. obs.). Some of these animals may forage in the leaf litter, branches of the windbreak trees or in the windbreak/pasture edges, while others may simply pass through the windbreak on their way to other habitats.

The Importance of Forest Patches, Isolated Trees and Windbreaks to Farmers

While it is clear that the forest patches, isolated trees and agricultural windbreaks play critical roles in the conservation of plant and animal diversity in the Monteverde landscape, at both local and regional scales, it is also important to consider their roles within the farm context because ultimately the retention and management of forest patches, isolated trees and windbreaks depends on the land use decisions of the local landowners who own them. Decisions to retain or remove trees from the landscape are likely to be closely linked to agricultural considerations and differences in the abundance of forest fragments, trees and windbreaks among farms reflect personal differences in the perceived value of these elements.

In general, local landowners in Monteverde are well aware of the benefits of retaining trees (whether as dispersed individuals, forest patches or in planted windbreaks) within their farms, and value them not only for the agricultural functions they provide but also for their roles as habitat for wildlife. In a survey of 40 landowners on the Pacific slope outside of the Monteverde reserve, Guindon (1988) found that farmers retained forest patches for both utilitarian reasons (provision of timber, firewood, and fence posts; protection of water springs; wind protection), as well as non-utilitarian reasons (wildlife protection and personal enjoyment). Sixty percent of the farmers considered their forest land to be more valuable than pasture or land under other uses and many had taken steps to protect their forest patches or increase the size of the forested land: >77% of the farmers interviewed had invested in fences to protect their forests and 42.5% had planted trees to increase or protect their forested areas (Guindon 1988). Because of the perceived high value of forests, most landowners planed to leave their forested land for the next five years; only 12.5% planned on reducing their forest area (Guindon 1988).

Landowners are also conscious of the agricultural and ecological benefits of retaining trees within their dairy pastures. A survey of 22 dairy farmers found that farmers leave trees primarily to provide shade for their cattle, thereby preventing heat stress in the dry season that can significantly reduce milk yields (Harvey and Haber 1999). Farmers also leave isolated trees as a potential sources of timber, firewood and fence posts and to ensure that the grass stays green in the dry season (due to lower temperatures and higher humidity below tree crowns). Perhaps of most conservation interest, 64% of the farmers surveyed mentioned that they often retain isolated trees in pastures because they provide fruits for birds and wildlife (Harvey and Haber 1999). Although farmers recognize the importance of having isolated trees in their pastures, if the density of trees within a pasture is high, they will selectively remove some trees to prevent the grass from being overshaded (Harvey and Haber 1999). In addition, most farmers harvest a few trees each year for timber or fence posts (Harvey and Haber 1999). This selective removal of trees, combined with the poor regeneration of trees in pastures that are active, is likely to decrease the remnant tree component in future years, unless active management is taken to facilitate tree regeneration within the pastures.

While there have been no formal studies documenting the importance of planted windbreaks to farmers in Monteverde, casual conversations with farmers suggest that the windbreaks play a valuable economic role in dairy farm production (Harvey unpublished data). Windbreak establishment in the region has greatly improved milk yields, both by reducing the physical stress to animals and by keeping the grass greener for a greater proportion of the dry season (Harvey unpublished data). The proliferation of windbreaks within the landscape (windbreaks now occur on >90% of all dairy farms in the area) and the high interest of farmers in establishing additional windbreaks to further protect their animals, also attest to their perceived importance. Interestingly, farmers are now eager to use native tree species within windbreaks. If native species are indeed incorporated into existing or future windbreaks, the ability of the windbreak to support animal species is likely to be greatly enhanced (Capel 1988).

Conclusions

By providing habitats, resources and habitat corridors that are otherwise lacking in the agricultural landscape, the forest patches, isolated trees and windbreaks play a critical role in conserving both local and regional biodiversity within the Monteverde region. Although the forest fragments are generally small and isolated, they nevertheless retain a high diversity of plant species and provide habitat and refuges for many animal species, including many altitudinal migrants that are currently threatened. The isolated trees - whether relicts of the original forest canopy, newly regenerated individuals or planted by farmers - also provide critical habitat and resources within the agricultural landscape for both plant and animal species. Perhaps most interestingly, the agricultural windbreaks, despite being composed of primarily exotic species, also appear to enhance local biodiversity by serving as foci for seed dispersal and forest tree regeneration, and by functioning as corridors that facilitate bird movement across agricultural areas. While the forest patches, isolated trees and windbreaks are unlikely to conserve all of the biodiversity present in the region, they appear to help maintain a significant portion thereof. Since all three of these landscape features also serve important agronomic functions and are highly valued by farmers, there is a unique opportunity to integrate conservation goals with farm management and to manage tree cover within the landscape to both conserve local and regional biodiversity, while maintaining farm productivity.

Abstract

Mountains and uplands occupy a quarter of the Earth's land surface. About one tenth of humankind lives in them, and they affect the lives of over half the world's population. The global significance of mountain forests is recognised by the inclusion of a specific chapter in "Agenda 21", endorsed at the 1992 Earth Summit. The values of mountain forests to mountain people, those living downstream, and much of the remainder of humanity, including their roles as centres of biodiversity; the storage and supply of water; the provision of fuelwood and many other wood and non-wood products; essential complements to agriculture; sites for recreation; and protection against natural hazards and soil erosion. These values are underlined in documents resulting from regional meetings around the world, and emphasised in many recent and ongoing projects. They are the focus of the Task Force on Forests in Sustainable Mountain Development of the International Union of Forestry Research Organizations (IUFRO), which has prepared a state-of-knowledge report for the XXI IUFRO Congress.

Keywords: Mountains, Forests, Sustainable development, IUFRO.

Introduction

Mountains occupy approximately a quarter of the Earth's land surface (Kapos et al., 2000). About one tenth of humankind lives in them, and they affect the lives of more than half of the world's population (Ives, 1992). Building on a number of initiatives over the past three decades (Ives and Messerli, 1990; Stone, 1992), their global significance was specifically recognised at the UN Conference on Environment and Development (UNCED), or 'Earth Summit', in Rio de Janeiro in June 1992 by the inclusion of a chapter in "Agenda 21", a plan for action into the 21st century which was endorsed by the heads of state or governments from most of the world's countries. The inclusion of Chapter 13 of "Agenda 21" - "Managing Fragile Ecosystems: Sustainable Mountain Development" – places mountain regions on an equal footing with climate change, tropical deforestation, desertification, and similar issues of global change (Turner et al., 1990) in the global debate on environment and development. Chapter 13 includes two 'programme areas':

A) generating and strengthening knowledge about the ecology and sustainable development of mountain ecosystems;
B) promoting integrated watershed development and alternative livelihood opportunities.

In September 1993, the UN Inter-Agency Committee of Sustainable Development gave the Food and Agriculture Organization of the United Nations (FAO) responsibility for acting as Task Manager for Chapter 13. In this role, FAO has fostered a number of global and regional initiatives; and many countries have also taken steps towards implementing various elements of Chapter 13 (Chipeta and Michaelsen, 1995; Sène and McGuire, 1997; Price, 1999; Sène, 2000). In 1998, the United Nations General Assembly declared that the year 2002 would be the International Year of Mountains, further underlining the global significance of mountain areas. FAO has also been designated as the lead agency for this.

The concept of sustainable mountain development has been defined as "a regionally-specific process of sustainable development that concerns both mountain regions and populations living downstream or otherwise dependent on these regions in various ways" (Price and Kim, 1999). This paper discusses the values of forests in relation to the major areas through which forests are linked to sustainable mountain development, and reviews initiatives that have taken place since 1992.

The Values of Mountain Forests

Chapter 13 begins "Mountains are an important source of water, energy, and biological diversity." Forests play crucial roles in fulfilling all of these functions. Recent work by the World Conservation Monitoring Centre (WCMC), in which mountains were objectively defined according to rules relating to altitude, slope, and relative relief using a global database with a spatial resolution of 1 km, has shown that they cover 24% (35,813,437 sq. km) of the Earth's land surface. This map was then overlain on an existing global database of forests prepared by WCMC. Putting these two databases together, the result is that 28% (5,179,248 sq. km) of the world's forests are mountain forests (Kapos et al., 2000).

In any mountain range, the diversity of ecosystems reflects the range of altitudes, slopes, aspects, geological substrates, and soils; as well as the effects of human activities. All of the centres of greatest vascular plant species diversity are in, or include, mountains: Costa Rica, the tropical eastern Andes, the Atlantic forest of Brazil, the eastern Himalayan-Yunnan region, northern Borneo, and Papua New Guinea. Secondary centres are found in Mediterranean and arid mountains, the Rocky Mountains, and Central Asia (Barthlott et al., 1996). In Europe, a very high proportion of centres of plant diversity is in mountains (Davis et al., 1994). Species diversity typically decreases with altitude; thus, forests generally have greater diversity than the non-forested zones above (Jenik, 1997). An overview of issues relating to the biological diversity of mountain forests has recently been published by Grabherr (2000)..

Mountains are of vital importance to the globe as sources of water, typically having higher rates of precipitation than surrounding lowlands. Forests play a number of important roles in the water cycle (Liniger and Weingartner, 2000). These include the capture of atmospheric moisture, particularly by cloud forests, which are widespread but of particular importance in tropical areas (Hamilton et al., 1994); storage of snow and water in and beneath canopies; and release to watercourses, which is strongly affected by the degree of disturbance by natural and human forces (Hamilton and Bruijnzeel, 1997). In semi-arid and arid regions, over 90 percent of river flow comes from the mountains. Even in temperate Europe, the importance of the Alps is shown by the fact that, while the Alps occupy only 11 percent of the area of the Rhine basin, they supply 31 percent of the annual flow – and more than 50 percent in summer (Mountain Agenda, 1998). Much of the water flowing through and from the mountains is used to produce hydro-electric power. This is largely used on the plains below; though water power has also long been important in mountain economies, especially for grinding grain.

Wood is the primary source of fuel for those living in the mountains of the developing world (Schweizer and Preiser, 1997), and also many industrialised countries, where it has only been supplanted by electricity and fossil fuels in recent decades, if at all. Mountain forests are also the primary sources of fuel for nearby settlements in the foothills and plains, so that the collection of wood for fuel or the production of charcoal is a major factor in deforestation in many regions where mountain and nearby populations – both rural and urban – are increasing. Globally, more than half of estimated wood consumption is for fuelwood and charcoal, largely in developing countries (FAO, 1992). However, there are relatively few regional assessments of the use of wood energy resources; one exception is for the Himalaya-Hindu Kush (Rijal, 2000). The highest rate of deforestation in any biome is for tropical upland forests: 1.1 percent per year. Rates of clearing are particularly high in Central America, East and Central Africa, Southeast Asia, and the Andes (FAO, 1993a).

The second sentence of Chapter 13 notes that mountains are also a source of forest products, agricultural products, and recreation. Mountain forests are important sources of timber in many countries, though the costs of harvesting are typically higher than on low-angle land (Gregersen, 2000; Sekot, 2000). However, in many parts of the world, such land, even if once forested, provides a greater economic yield for agriculture or settlement; a process of conversion that took place centuries ago in Europe and has spread to many tropical countries in recent decades. Thus, the pressures on mountain forests increase. Until recently, the concept of sustained yield from forests focussed primarily on the production of wood for industrial and other uses. New models of sustainable forest management (e.g., FAO, 1993b; Maser, 1994) give greater emphasis to the need to manage forests as ecosystems, rather than 'mines' of exploitable resources. One critical element of this is to ensure sustainable yields of non-wood forest products - valuable for food, nutrition, medicine, construction materials, and household and cultural uses - which contribute to the subsistence and market economies of mountain people; and, in some cases, national economies (Arnold and Perez, 2000; Shrestha and Pokharel, 2000). Such products are vital for many in developing countries, but also provide supplementary sources of food and income in industrialized countries (Hansis, 1996; Richards and Creasy, 1996), and have recently been of increasing importance in the uncertain conditions being experienced in the former communist countries of Central and Eastern Europe.

In many mountain regions of the world, it is inappropriate to speak of 'foresters' and 'farmers' (Price and Thompson, 1997). Agriculture and forestry are inseparable activities within a complex mountain landscape, with forests providing essential resources to ensure the viability of agriculture. These resources depend greatly on local ecological and social conditions. In many parts of the world, grazing animals rely on forage within forests, fodder brought from them, and the shade they provide during hot summer days. The expansion of grazing land by clearing and/or burning at the upper timberline has led to its depression in many mountains, by as much as 300 m in the Alps (Langenegger, 1984). Restoration of forests in this dynamic zone is often difficult or impossible because of changes in microclimate and soil conditions following clearing.

In many tropical countries, slash-and-burn agriculture represents a successful means of utilising forested ecosystems when human population densities are low and government policies do not limit movement. However, settlement and/or high population densities often lead to a level of degradation from which forests cannot recover; and clearance in order to grow illegal crops has affected forests in many less-accessible mountain regions. Agroforestry - through planting, natural regeneration, or controlled use of remnant forests, often combined with intercropping of food crops - can often permit continued use of land by large human populations (Atta-Krah and Tang, 2000). However, this requires that those who make the necessary investments of time and labour have security of tenure and, in many cases, that extension services and other organisations provide new tree or crop species in addition to those of local origin in order to provide the desirable mixture of food security, income generation, and slope stability (McDonald et al., 2000; Singhal et al., 2000).

The longest-established uses of forests for recreation are for hunting and fishing for pleasure: activities that also remain important for subsistence in many regions. The more widespread use of forests for recreation derives from a series of linked factors; particularly, increases in accessibility, leisure time, and income in both industrialised, but also many developing, countries (McCool and LaChapelle, 2000; Pröbstl, 2000; Nepal, 2000). This phenomenon began in the early 19th century in western Europe and spread to the mountains of South Asia, eastern North America, and Latin America over the next century (Price, 1992). However, until after the Second World War, it was limited to relatively few locations. Mass recreation now takes place in mountain forests around the world, with a vast range of activities: both active (e.g., skiing, mountain-biking, hunting, walking) and passive (e.g., bird-watching, painting, sightseeing). A critical issue is how to manage such rapidly-growing activities to minimise environmental and societal impacts, and to maximise benefits to local communities (Price et al., 1997; Godde et al., 2000).

Following the mention of the vital resources provided by mountains - notably, as discussed above, by their forests - the first paragraph of Chapter 13 notes the rapid changes that are taking place in mountains: soil erosion, landslides, and rapid loss of habitat and genetic diversity. The loss of diversity can result from many of the processes discussed above, such as deforestation, excessive harvesting of forest products, hunting, and recreation. The protective function of forests, in stabilizing slopes and limiting damage from extreme events, such as avalanches and floods, has long been known by mountain people with, for instance, local regulation in the Swiss Alps since the 13th century, and national legislation from the late 19th century (Price, 1990). Nevertheless, it should be recognised that this legislation followed major floods after decades of unheeded warnings of the risks of excessive utilisation of the forests. A more recent example is in Thailand, where landslides and floods followed widespread replacement of forests by agriculture and plantations (Hamilton, 1992). The major issue for minimising risks from 'natural hazards' is therefore how to develop and implement policies to ensure stable forest cover (Ottitsch and Weiss, 2000), particularly when this has been lost through human action, extreme events, or a complex mixture of these.

Actions Towards Sustainable Mountain Development

The fact that forests are implicated in the majority of the issues addressed in the introductory paragraph of Chapter 13 underlines their central importance to sustainable mountain development. Forests are also specifically mentioned in a number of the sub-paragraphs describing activities that governments are encouraged to implement within the two programme areas of Chapter 13:

> 13.6(f) "integrate all forest, rangeland and wildlife activities in such a way that specific mountain ecosystems are maintained";
>
> 13.7(b) "build an inventory of different forms of soils, forests, water use, and crop, plant, and animal genetic resources, giving priority to those under threat of extinction. Genetic resources should be protected in situ ...";
>
> 13.10 "Strengthen scientific research and technological development programmes, including diffusion through national and regional institutions, particularly in meteorology, hydrology, forestry, soil sciences and plant sciences";
>
> 13.16(b) "establish task forces or watershed development committees, complementing existing institutions, to coordinate integrated services to support local initiatives in animal husbandry, forestry, horticulture and rural development at all administrative levels".

Under programme area B (paragraphs 13.13-22), there are also a number of sub-paragraphs that propose activities related more generally to various aspects of forests: pilot projects combining environmental protection, development and environmental management practices/systems (13.21a); participatory generation of technology for watershed management (13.21b); technology, training, and dissemination of knowledge relating to agroforestry and other aspects of land and water management (13.21c, 22a); and national centres for watershed management (13.23).

The importance of forests is also underlined in the documents resulting from the regional inter-governmental consultations on sustainable mountain development which have taken place since UNCED, in Africa (ILRI, 1997), Asia (Banskota and Karki, 1995), Europe (Backmeroff et al., 1997), and Latin America (Mujica and Rueda, 1996). All of these documents, endorsed by representatives of a total of 62 countries and the European Union, stress three major issues of direct relevance to forests. First, integrated approaches to land use, involving all stakeholders, are necessary, but require investment. Second, land use practices should be appropriate to land capability and community needs and capabilities. Third, there are strong linkages between land management and the conservation of both water and biodiversity; mechanisms to ensure the security of these important values of forests include the protection of areas with minimum human impacts and the development of ecological corridors and transboundary protected areas.

Many of these cross-cutting issues can be identified in activities which have begun in different countries since UNCED. However, it is rarely possible to say that such activities result directly from Chapter 13. Even when they are specifically in the context of a national plan or strategy for Agenda 21, conservation, or biodiversity (as, for example, in Bulgaria, Japan, Pakistan, Papua New Guinea, or Philippines), such activities may have been planned or underway before 1992

(Price, 1999). The following paragraphs illustrate a few of these activities, recognising that similar examples could probably be cited for other countries. However, few national governments specifically identified such activities in the 'country statements' submitted to the fifth session of the UN Commission on Sustainable Development in April 1997.

In Japan, the Council of Ministers for Global Environmental Conservation approved the National Action Plan for Agenda 21 in December 1993. Chapter 13 of this plan places a very strong emphasis on the management of forests for protection, production, recreation, and conservation. The links between the latter two 'outputs' and economic development is clearly identified in relation to the development of eco-tourism. Nevertheless, while the maintenance and encouragement of mountain economies is a clear goal of the chapter and a law passed in the same year, this is within the constraints imposed by the need to minimise health and environmental impacts. The Basic Plan for Forest Resources, passed in 1996, emphasizes five main functions of forests: 1) conservation of water resources; 2) disaster prevention; 3) environmental conservation; 4) timber production; and 5) health and cultural activities.

One activity that clearly notes its antecedence in Chapter 13 is the Inter-regional Project for Participatory Upland Conservation and Development, which the FAO/Italy Cooperative Programme began in 1992 in Bolivia, Burundi, Nepal, Pakistan, and Tunisia (d'Ostiani, 2000). Its aim is to identify and field test "strategies, methods and techniques for the promotion and consolidation of people's participation in the conservation and development of upland watersheds" (d'Ostiani and Warren, 1996: 11). A number of preliminary conclusions have emerged. First, the inter-regional institutional framework and the flexibility in planning and implementation are both important. Second, participatory methods are necessary but not sufficient; teams must also address technical elements of watershed management and underlying environmental, socio-economic and organisational issues. Third, participatory integrated watershed management involves both process-based activities and physical interventions. Finally, while limited resources can be very valuable for catalysing development investments, most actions take longer than anticipated.

Many of the projects funded by the World Bank and the Global Environment Facility (GEF) in recent years also emphasize participatory approaches and multi-functional economies (Global Environment Facility, 1996; World Bank Environment Department, 1996). Examples of World Bank projects include those in Bhutan, Indonesia, Pakistan, Tunisia, Turkey, and Yemen, which focus on watershed management, improving and restoring forest productivity, and institutional strengthening. Many GEF projects, which focus on conserving biodiversity in national parks and other protected areas, also emphasize cooperative forest management within these areas and in their buffer zones, recognising the importance of ensuring sustainable livelihoods and joint decision-making as necessary elements of biodiversity conservation. These include projects in Bolivia, Cameroon, China, Costa Rica, Ecuador, Indonesia, Mexico, Nepal, and Uganda, as well as Slovakia and Ukraine; thus, such approaches are valid not only in developing but also industrialised countries, as recognised by the Pan-European Biological and Landscape Diversity Strategy, endorsed by Ministers of Environment from 55 European states in 1995 (Council of Europe/UNEP/ECNC, 1996).

In June 1997, the UN General Assembly held a Special Session (UNGASS) to review the implementation of all of "Agenda 21". The final document of this meeting specifically mentions mountains in relation to four issues:

- continued deterioration of mountain ecosystems, resulting in diminishing biological diversity (para. 9);
- the need to formulate and implement policies and programmes for integrated watershed management (para. 34);
- the need for ecosystem approaches to combat or reverse soil degradation, recognising the multiple functions of agriculture (para. 62);

the need for national policy development and implementation to ensure sustainable patterns of consumption and production in tourism (para 68).

These concerns relate very closely to many of the values of mountain regions explored in the first section of this paper. According to the UNGASS final document, all countries are expected to have prepared national strategies for sustainable development by 2002 – since declared as the International Year of Mountains – involving all interested parties and integrating economic, social, and environmental objectives. There is considerable scope, and need, for the large number of countries with mountain forests to consider how these should be considered in such strategies.

The Role of IUFRO

In recent decades and years, there has been a widespread shift in the science and practice of forestry, from emphasis on the production of wood towards management based on recognition that forests serve multiple functions and produce a wide range of outputs (Price and Butt, 2000). This multifunctionality has long been present in most mountain forests, even when they have primarily been managed for sustained harvests of timber, but is now increasingly recognised as the basic concept which should underpin mountain forestry around the world (Buttoud, 1998, 2000).

Recognising the general shifts in forestry, as well as the changing expectations of populations around the world regarding mountain forests, and the rapid rates of change in the cover and uses of forest ecosystems, in 1995 the International Union of Forestry Research Organisations (IUFRO) established a Task Force on Forests in Sustainable Mountain Development for the period 1996-2000. The Task Force has two main purposes with respect to the roles of forests in the sustainable development of mountain areas:

to provide a framework for developing and strengthening linkages within IUFRO and between IUFRO members and other relevant organisations and initiatives;

to prepare an assessment of major issues for mountain forests at the beginning of the 21st century.

It is recognised that trends in the cover and/or density of mountain forests in different parts of the world are different, with two broad types which will often have to be considered separately in the assessment. The first is in the temperate zone (industrialised countries), where cover and/or density are generally stabilised or increasing, from land abandonment and re- or afforestation (e.g., Piussi, 2000). In certain regions, significant impacts of tourism and air pollution occur. The second is in tropical, semi-arid, and arid countries, where there are significant decreases in cover and/or density, especially through clearance for agriculture. Serious erosion and desertification, exacerbated by human activities, are often major problems. However, the causes of change in forest cover interact and in many complex ways (Scherr and Templeton, 2000).

A number of means have been used to fulfil the purposes of the Task Force. An early activity was the creation of a 'mountain forests network' on the IUFRO website, listing active individuals and organisations both within and outside IUFRO. Linkages have been developed with other relevant initiatives at different scales, notably regional (e.g., European Cooperation in the Field of Scientific and Technical Research [COST] Action E3, FAO/European Forestry Commission Working Party on Management of Mountain Watersheds; European Observatory of Mountain Forests; FAO Latin American Technical Cooperation Network) and global (e.g., Inter-governmental Forum on Forests, the Mountain Forum). A side meeting was held at the World Forestry Congress in Antalya, Turkey, in October 1997, in order to begin to define further work. In addition to the issues raised throughout this paper, the participants suggested that the Task Force should work on the following areas:

advocacy of the commonalities of mountain regions, including the promotion of North-South dialogue;

valuation of the benefits of mountain forests, which requires the close involvement of social scientists from diverse disciplines, with a focus on the service-related functions of mountain forests;

contributions of science to awareness-raising and policy-making, through strong linkages between social and natural scientists, practitioners, and decision-makers.

The IUFRO Inter-divisional Conference on Forest Ecosystem and Land Use in Mountainous Areas in Seoul, Korea, October 1998 (Korean Forestry Society, 1998) was a further key event in the activities of the Task Force. Subsequently, its major activity has been the preparation of a state-of-knowledge report on forests in sustainable mountain development, with 90 contributions from 124 authors around the world, to be published in time for the XXI IUFRO Congress (Price and Butt, 2000). The report includes a small number of comprehensive overviews at a global scale, some overviews at regional or country scales, and many case studies illustrating topics at local to national scales. The overall conclusion from the report is that we have many snapshots, but not enough consistent data sets – especially with regard to economic data, for both market and non-market goods and services – or analyses or syntheses which are sufficiently broad in both space and time and bring together insights from a sufficiently diverse range of perspectives. Such broad analyses and syntheses are becoming ever more essential in an era of rapid economic, political, and ecological change and are necessary to provide the foundations of integrated policies which recognise the key roles of mountain forests for many sectors of society.

Around the world, within and outside IUFRO member organisations, research in mountain forests is being undertaken by scientists from a wide range of natural and social scientific as well as technical disciplines; and also by local people who, though they often have little if any training in the 'scientific method', can provide vital complements to the results generated through this 'objective' process. To bring together and integrate these different worldviews, new technologies such as geographic information systems can be of great value; in general, better means of communication, using all appropriate media, are essential (Pandey, 2000). Research is an essential element in defining the future of mountain forests. Yet, for the benefit of both mountain people and all those who depend on and enjoy the environments they manage, the results of research must be effectively disseminated to all those concerned, in mountain villages, forestry companies, government agencies, academic institutions, non-governmental organisations, parliaments, regional policy-making bodies, and global organisations. Such issues will be discussed in the concluding business meeting of the Task Force at the IUFRO Congress, with a view to defining IUFRO's activities to contribute to sustainable mountain development in the period up to, during, and beyond the International Year of Mountains, 2002.

Abstract

Ecological stability properties are attributes characterising the dynamics of an ecosystem. They include the concepts of resistance (staying essentially unchanged despite the presence of disturbance agents) and elasticity (speed of return to reference states or dynamics after a temporary disturbance). In the management of mountain forests that protect against natural hazards such as snow avalanches, resistance and elasticity are already intuitively used. However, traditional silvicultural approaches have focused on stand dynamics and considered the forest as a "stable" system. This is insufficient in the long-term since driving factors, be they external to the forest ecosystem such as atmospheric inputs, or internal such as browsing, have the potential to affect stand dynamics and thus effective protection, especially since they may exhibit long-term trends. Potential changes in, for example, chemical soil properties, need to be considered in forest management, and an ecosystem-based view adopted. Ecological stability properties that are crucial for long-term effective protection need to be identified, monitored with suitable indicators, and integrated into the sustainable management of these forests. The concept of ecological stability properties is so flexible that is not only a promising conceptual tool to sustainably manage protection forests, but also forests delivering other products and services.

Keywords: Sustainable forest management, Natural hazards, Mountain forests, Resilience, Resistance.

Introduction

The concept of "ecological stability" has been appealing to many ecologists for many decades (MacArthur 1955, Lewontin 1969, Holling 1973, Pimm 1984, Rapport 1998 p. 27). However, applications of the concept to specific ecological problems based on real data have been sparse (Larsen 1995, Grimm 1999). One of the problems with "ecological stability" is the fuzziness of the concept. In a comprehensive review, Grimm and Wissel (1997) conclude that the term has caused so much confusion that it should be avoided. They advocate subdividing the concept into several "ecological stability properties", including resistance (staying essentially unchanged despite the presence of disturbance agents) and resilience (returning to the reference state or dynamics after a temporary disturbance). They also provide a rigorous terminological framework that is applicable in a variety of situations, and present a checklist to precisely characterise an ecological situation, which enables meaningful stability statements to be made.

Ecological stability properties have not only been used in a purely ecological context. Some stability properties have also intuitively been used in forest management. In the case of protection forests, i.e., forests on steep slopes that protect people and assets against natural hazards such as snow avalanches and rockfall, resistance and resilience are of particular interest (Brang, submitted). Sustainable management of these forests means containing forest dynamics in a way that unacceptable impact of natural hazards is avoided (Brang et al. 2000). As the occurrence of natural hazards is bound to specific stand structures, the limit between acceptable and unacceptable impact can be described in terms of stand structural variables. For protection forests in the Swiss Alps, such minimum conditions for effective protection have been defined and are now used in silvicultural decision-making (Wasser and Frehner 1996). The rationale for trying to achieve minimum, and not optimum conditions is that most silvicultural operations on these slopes are so costly that expenses exceed revenues. Consequently, subsidies are needed as an incentive for the forest owner to carry out silvicultural operations aimed at ensuring effective protection. Spending subsidies in a cost-effective way means subsidising only operations that are absolutely necessary to achieve acceptable, and thus minimum levels of protection.

In an earlier paper (Brang, submitted), I have explored benefits of applying resistance and elasticity to the sustainable management of protection forests. This contributes to a comprehensive analysis, characterisation, and evaluation of disturbances and slow changes in protection forests. Resistance and elasticity can equally be applied to all dynamic ecosystem processes, e.g., stand dynamics, regeneration dynamics, and changes in soil chemistry (Brang, submitted). Resistance and elasticity can also be quantified using suitable variables. Reference conditions (or dynamics) can be selected based on purely ecological considerations, or on ecological services (Cairns 1995) a forest is expected to provide. The concepts are also linked to the risk analysis framework (Risk Assessment Forum 1996): high resistance to changes can be expressed as low likelihood (and potential damaging impact) of these changes, and high elasticity means short time periods with potential damaging impact.

However, many questions remain to be answered. Managing protection forests, in the face of multiple disturbances, for specific minimum levels of resistance and elasticity of relevant ecosystem properties is challenging in several ways. First, a silvicultural operation itself is usually a disturbance (Geils et al. 1995) with potential side-effects, which may trigger further unplanned disturbances. Second, the disturbance regimes in mountain forests are currently changing. New types of disturbing influences emerge, and old types gain in strength. Mountain forest ecosystems in Switzerland are currently subject to unprecedented impacts of atmospheric pollutants (causing soil acidification, eutrophication, and nutrient imbalances, Flückiger and Braun 1998, Kurz et al. 1998a), global climate change (Price and Barry 1997), and browsing by ungulates (Brändli 1995). These influences have the potential to impair effective protection, and thus to impede the sustainable management of these forests. The question is therefore how silviculture is going to cope with these challenges. Third, there may be trade-offs between resistance and elasticity. If this is the case, forest management should not maximise one at the cost of the other, but find an optimum.

In this paper, I am going to conceptually address these questions. I will illustrate the ideas with examples, and provide scientific evidence where available.

Ecological Stability Properties: an Old Concept Gains Momentum

This section is for the reader who is unfamiliar with the concept of ecological stability properties. Grimm and Wissel (1997) define three basic concepts that are part of ecological stability properties: 1) ”constancy” (= staying essentially unchanged), 2) ”resilience” (= returning to the referential state or dynamics after a disturbance), and 3) ”persistence” (= the persistence through time of an ecosystem). ”Constancy” includes the property ”resistance” (= constancy despite the presence of disturbing agents). ”Resilience” includes the property ”elasticity” (= speed of return to the reference state or dynamics).

A "disturbing agent" is a factor that has the potential to abruptly and substantially change ecosystem characteristics. This change may occur on various temporal and spatial scales. Its effect on an ecosystem is called a "disturbance", as "any relatively discrete event in time that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment" (White and Pickett 1985). In this paper, I subsume "events" caused by continuously acting agents such as acid deposition that lead to slow changes in the ecosystem also under the notion "disturbance" (but see Jax 1998/1999).

Statements about an ecological stability property are only meaningful if the ecological situation is clearly defined (Grimm and Wissel 1997). A stability statement such as ”this forest is more resistant than that one” is so vague to be almost meaningless. Does the statement refer to the resistance of the landscape to changes in forest patch patterns, or to the resistance of an ant to a leaf falling to the ground? Grimm and Wissel (1997) advocate defining the ecological situation using six characteristics which are applied to forests in Table 1. In the context of sustainable management of protection forests, the ecological situation is given by the scale of the natural hazards involved, the nature of the protective effect of the forest, and the disturbances that have the potential to impair effective protection. Stability statements in this paper refer, unless otherwise stated, to the following situation: The level of description is the population level; the variables of interest are variables describing the spatial structure of the stand; the reference values of the variables of interest are values at which the stand offers effective protection against snow avalanches and rockfall (Wasser and Frehner 1996); the disturbances are caused by wind or bark beetles; the spatial scale is the stand scale; and the time scale is 500 years. Examples of meaningful stability statements are "this stand (area 5 ha) will recover from a complete windthrow disturbance to a stem density of 400 ha^{-1} (dbh   8 cm) within 40 years", and "the soil on 50% of this area of 1 ha will resist changes in pH to values below 3.0 in any soil layer within the next 200 years, given annual acidic inputs of 4 keq yr^{-1} ha^{-1}." For managing protection forests of the European Alps, the most relevant stability properties are resistance and elasticity (Brang, submitted). In terms of stand structure, the ideal protection forest is highly resistant to natural disturbances that have the potential to impair effective protection; it has moderate resistance to natural disturbances that do not impair effective protection, but enable renewal of the tree layer, and can easily be replaced with anthropogenic disturbances (silvicultural operations); and it is highly elastic, i.e., regeneration rapidly fills any gaps.

Natural and Anthropogenic Dynamics of Mountain Forest Ecosystems as Related to Natural Hazards

Managing a protection forest is different from managing a forest for timber volume, timber value, aesthetics, recreation, species diversity, or habitat for specific threatened species. Managing a protection forest means primarily managing stand structure because only a specific structure ensures effective protection. The protective effect of a protection forest is mainly the result of an interaction between natural hazards, trees, gaps, soil surface roughness, slope, and weather conditions. Trees prevent, by snow interception and release, and by differential snow melt, a homogeneous snow layer from building up (Imbeck and Ott 1987). Trees' stems, stumps and nurse logs stabilise the snow pack, by providing an anchoring system and a rough surface. In a protection forest, disturbances affecting trees on an area exceeding a certain minimum area have the potential to impair effective protection. Gaps exceeding 30-50 m perpendicular, and 100 m parallel to the contour line should be avoided in order to prevent snow avalanches from releasing (Wasser and Frehner 1996). This means that small-scale disturbance regimes are preferred.

Fortunately, small-scale disturbance regimes, with gap areas below 0.1 ha, prevail in the Swiss Alps (Zukrigl 1991, Brang et al. 2000) although specific data are missing, and quantifying these disturbance regimes (e.g., gap size distribution, disturbance frequency) would be a highly rewarding task. Large-scale disturbances only exceptionally occur, mostly as a result of wind and bark beetles, and rarely from fires and snow break. Moreover, there is evidence that Swiss mountain forests would be more resistant to large-scale disturbances if they were in a more natural condition. Extensive human disturbance that started in the Middle Ages has probably reduced the forests' resistance to such disturbances. As an example, stand structures are currently more homogeneous than they were in old-growth forests (Brang, submitted). This means that improvements of current stand structures to increase a stand's resistance against disturbances are possible. Current management practices in Swiss protection forests are aimed at speeding up this change towards more heterogeneous stand structures. In some cases, managers even try to implement anthropogenic small-scale disturbance regimes in cases where large-scale disturbances would be prominent in natural stand dynamics, e.g., in montane *Picea abies* forests *(Korpel' 1995*). It is unclear, however, to which extent this is possible in the long-term.

Table 1. Checklist for ecological stability properties (Grimm and Wissel 1997), applied to the management of protection forests. The table describes how the ecological situation can be defined to make measingful ecological stability statements.

Characteristics of the ecological situation	Question to be answered	Possible answers in the context of protection forests
Level of description	On which hierarchical level of an ecosystem are we describing stability?	Individual organism to landscape, depending on the desired protective effect. In the frequent cases where this effect directly depends on trees, the population level is used.
Variable of interest	Which (measurable) state variables are we referring to?	Indices of the spatial distribution of trees, distribution of the diameter at breast height, distribution of gap sizes and orientations, volume increment, estimated nutrient cycling rates
Reference state or dynamics of the variable of interest	What is the state variables "acceptable[$]" behavior?	"Acceptable" values of state variables depend on knowledge about the dynamics of protection forests and their relation to effective protection, and on the risk acceptable to the people needing protection.
Disturbing agents and disturbances	Which disturbing agents are affecting systems behaviour, and to what extent?[¶]	Disturbing agents that can cause the unwanted death of trees (storm, snow load, bark beetles), or that have the potential to alter tree species composition, and growth and mortality patterns (pathogenic fungi, extreme climatic events, bad management practices, soil acidification, browsing ungulates); frequency and intensity of the disturbances.
Spatial scale	To which spatial scale does the stability statement refer?	Tree to landscape level (0.001 ha – 100 ha). The spatial scale is given by starting and run-out zones of natural hazards.
Time scale	To which time scale does the stability statement refer?	Years to several centuries.

[$] Grimm and Wissel. (1997) focus on "normal" reference states or dynamics without external influences. This seems inappropriate in the context of an ecosystem managed for specific purposes. The notion of "acceptable" behaviour is more precise.

[¶] Grimm and Wissel. (1997) define disturbance as the result of dynamics exceeding reference dynamics. In the context of forest management, reference dynamics are dynamics where acceptable levels of disturbance are not exceeded. Management usually aims at replacing part of the highly variable natural disturbances by more predictable human disturbances.

Do Current Silvicultural Operations Enhance Forest Resistance and Elasticity?

Many traditional silvicultural operations involve the sudden removal of trees. More smooth changes can be achieved, e.g., by girdling (Guariguata 1999); however, such

methods are not widely practiced. One reason for this is that in *Picea abies* stands, girdling may trigger bark beetle attacks. In protection forests, cuttings are at present restricted to single trees or small stand patches the size of which is limited by the natural hazards involved (Wasser and Frehner 1996). Do these silvicultural operations increase or reduce a stand's resistance in the face of natural disturbing agents such as wind or bark beetles? In the last paragraph, we have already seen that this has not always been the case in the past (Brang, submitted). When addressing this question, we have to take into account that many of the relations mentioned below, although plausible and common knowledge of practicing foresters, remain to be demonstrated using rigorous scientific methods.

The ideal stand in a protection forest consists of trees or tree clusters that are mutually independent and resistant on their own, with their crowns being separated and reaching to the ground (Ott et al. 1997 p. 21, Brang et al. 1998). In such cases, removing a tree or a tree cluster has little influence on the stand's resistance, apart from a certain increase in canopy surface roughness. However, many stands are currently far from this ideal stand structure, with high stem density, the trees being mutually dependent and short-crowned with slender stems, and with internal stand edges being sparse. In these stands, thinnings may reduce inter-tree competition and increase the individual resistance of the trees to wind in the long-term (Slodicák 1995). However, in the short-term, removing a tree often means breaking up a fragile balance, and exposing trees to loads that they are not adapted to. Will they resist storms that, before the operation, hit their neighbour trees? Deciding whether the potential beneficial long-term effect (stabilisation) of such an operation will outweigh its short-term risks (destabilisation) is difficult. The potential destabilising effect can be minimised, by leaving the trees and tree clusters that seem most stable (low coefficient of slenderness, long crowns, no signs of root or stem rot, Wasser and Frehner 1996), and by leaving internal stand edges intact, but it cannot be entirely avoided. An operation that is aimed at stabilising a stand can therefore trigger further unplanned disturbances. The solution is often to concentrate management efforts on other stands with higher chances of success (Ott et al. 1997 p. 82, Brang et al. 2000), especially if the revenues from such an operation do not cover its costs, and if the operation must therefore be seen as an investment with uncertain return. This is frequently the case in Swiss protection forests.

Similar questions as with operations aimed at increasing resistance arise with operations that should enhance elasticity by promoting regeneration. In protection forests, regeneration is supposed to take place in small gaps, or under a light canopy. This is also often the case in old-growth forests on similar sites *(Korpel', 1995).* Elasticity increases with increasing seed rain, increasing share of microsites (Clarke 1992, Chambers and MacMahon 1994) that are favourable for successful seedling emergence and establishment, higher density and better condition of pre-established seedlings and saplings (seedling and sapling bank, Morin and Laprise 1997), and with faster growth that enables the recruitment to offer effective protection against natural hazards sooner. Seedling mortality, e.g., as a result of browsing (Eiberle 1989) should be low. In protection forests of the Swiss Alps, there are no long-term observations of silvicultural operations aimed at promoting elasticity by promoting regeneration, apart from planting which can be successfully done (Schönenberger et al. 1990, Ott et al. 1997 p. 96, Brang et al. 1998). The short-term evidence that is currently available suggests that creating small gaps, shelterwood-type and single-tree selection cuttings can be successful (Imbeck and Ott 1987, Ott et al. 1997, Brang 1998). The obstacles that are often encountered are browsing, unavailability of suitable microsites, and high seedling mortality.

The silvicultural technology to increase a stand's resistance and elasticity is available. The cases where the outcome of silvicultural operations is highly uncertain are identified (Ott et al. 1997 pp. 90, 93). The question remains if, using this traditional technology, protection forests can be successfully managed in the long-term.

Enlarging the Scope of Management of Protection Forests

Traditional silviculture in protection forests has tried to influence stand dynamics by replacing natural disturbance regimes with anthropogenic disturbance regimes (Fig. 1, arrow 1) which are more predictable. Increasing the resistance and elasticity of managed stands has been an implicit goal. This is understandable since stand dynamics determine how effective the protection against natural hazards is (Fig. 1, arrow 2). However, stand dynamics depend on many other dynamic factors and processes (Fig. 1, arrows 3). They depend on populations of browsing, fraying, and seed-dispersing animals that may promote specific tree species, and reduce the share of others. They depend on soil fauna and mycorrhizal fungi, on invasive plant species that have the potential to hinder tree regeneration, on new fungal, bacterial and viral diseases affecting trees and other organisms. They depend on changes in atmospheric inputs (Fig. 1, arrows 4 and 5) which alter soil chemistry, and on climate. They depend on soil physical properties. The dynamics of most of these ecosystem components and external forcing factors have usually been neglected in the management of protection forests. This was possible because these components were usually present in "acceptable" levels, with their variability only exceptionally causing any (recognised) unwanted changes to the tree layer. Action was not primarily taken in a preventive, but rather in a curative manner, after a specific damage such as windfall had occurred. Moreover, silvicultural operations have influenced some of the mentioned crucial ecosystem components (Fig. 1, arrow 6). In some cases, unwanted side-effects of silvicultural operations are known. Examples include the build-up of deep organic layers after replacing broad-leaves with coniferous trees on acidic soils (Fiedler 1980), or nutrient depletion or soil compaction as a result of heavy machinery used for timber harvesting (Zabowski et al. 1994, Jurgensen et al. 1997).

The challenge for silviculture is not only to integrate interactions of various ecosystem components and external environmental factors with stand dynamics and silvicultural operations (Fig. 1), thus enlarging the traditional view of forests as tree assemblies. The challenge is also that forest ecosystems are not systems in balance since some of the forcing factors (especially climate and atmospheric deposition) are not stable, but show trends. These trends are likely to finally exceed the resistance of current stands and thus cause *permanent* changes in stand dynamics (Huntley and Birks 1983, Bauerochse and Katenhusen 1997), be it by influencing tree establishment, growth and mortality directly, or indirectly by changes in ecosystem components that are crucial for trees. Forest ecosystems are slowly moving towards unknown new reference conditions of state variables (or of dynamics), which complicates also the application of ecological stability properties. The development of old stands (e.g., in *Picea abies*, stands exceeding 250 years in age) is particularly uncertain since such stands are very rare today. First evidence for such changes is the increase in tree growth (Spiecker et al. 1996) in central Europe. Other changes can be anticipated; e.g., selective browsing by ungulates is likely to change tree species composition (Eichenseer 1997, Kienast et al. 1999), stand structure (Kienast et al. 1999) and the internal stand climate, and atmospheric deposition is causing soil acidification that can affect fine root dynamics, and eventually tree nutrition (Dettwiler 1986, Kratz et al. 1996).

Is it now necessary to revise traditional silvicultural practices in protection forests in order to take other ecosystem components and states into account, and to adapt to environmental trends? Some of the mentioned ecosystem components (such as browsing animals) and states (such as soil physical properties) can be influenced by silvicultural operations, while other driving factors (such as climate change and atmospheric inputs, Fig. 1) are driven by processes out of reach of a forest manager. I do not see any general principle applicable to enhancing a forest's resistance, although the general diversity (or complexity)-stability relationship as proposed by MacArthur (1955) is increasingly supported by more realistic foodweb models (McCann et al.

1998). However, empirical evidence for this is still sparse (Johnson et al. 1996). It seems more promising to hypothesise a general diversity (or complexity)-elasticity relationship. This would suggest creating or maintaining diverse stand structures and species compositions in a forest ecosystem. In the absence of clear empirical evidence, adopting this approach is an application of the precautionary principle.

Integrating crucial ecosystem components and states into the management of protection forests does not mean rejecting traditional silvicultural systems. Traditional stand variables such as the stand density, the dbh distribution, gap size, shape, and orientation, and the cover and species composition of the regeneration are still relevant for silvicultural decision-making, and need to be assessed. However, other ecosystem components that are crucial for stand dynamics and sensitive to change need also to be monitored, if feasible on site, if not on adjacent intensive monitoring sites. These components need to be identified, and suitable indicators selected for monitoring. Their resistance to change, and their elasticity can equally be described using the framework of ecological stability properties. The selection of indicators needs to be site-specific. An already acidic soil may be sensitive to acidification from atmospheric inputs, while this is no issue on a site with ample nutrient supply.

The primary issues deserving our attention in protection forests in the Swiss Alps are soil acidification by atmospheric inputs that exceed critical loads and levels (Braun et al. 1996, Kurz et al. 1998b), which may cause nutrient imbalances and losses in the composition of the mycorrhizal fungi, browsing (Brändli 1995), dense ground vegetation and lack of nurse logs (Ott et al. 1997 pp. 29, 54), all impeding regeneration, loss of biodiversity at the level of species richness, and diseases of trees and seedlings. Those current silvicultural practices that have unwanted side-effects with respect to these issues need revision.

Do Resistance and Elasticity Compete or Support Each Other?

To explore the relation between resistance and elasticity (Webster et al. 1975), they should be applied to the same ecological situation. The highly resistant and resilient stand is a dream, as in this example: In many cases, a closed stand without gaps will be more resistant to wind than a stand with gaps. On the other hand, a closed stand without gaps will have fewer microsites suitable for regeneration, and thus lower elasticity, than a stand with gaps. I hypothesise that this competition-type relationship holds for populations where adults and juveniles are competing for the same resources. It seems to hold also for the case of browsed seedlings: Species that are not so often browsed, and thus resistant to browsing, like *Picea abies*, have more difficulty to recover from browsing than seedlings of broad-leaves like *Sorbus aucuparia* that are preferably browsed. However, already in this case there are species that show both low resistance and elasticity to browsing, like *Abies alba*. It is therefore not clear in which cases resistance and elasticity are competitive, and in which supportive.

At a stand scale, the silvicultural question whether resistance or elasticity should be promoted is often asked. In which situations and to which extent should a stand’s resistance be sacrificed in favour of its elasticity by promoting regeneration? With ideal stand structures, this question is easy to answer. As individual trees and tree clusters are mutually independent, whole clusters can be removed for promoting regeneration, without impairing the stand's resistance to disturbing agents such as wind. But how do managers decide in homogeneously structured stands? As the current stand's resistance is required for effective protection now and in the near future, while promoting regeneration will ensure effective protection only after several decades, and may even lead to gaps exceeding the maximum size for effective protection, the decision is very often taken in favour of current needs, i.e., resistance. An additional reason to favour resistance over elasticity is that regeneration can be introduced by planting, and is even growing faster than natural regeneration in many cases (Kahls

1973). This suggests proceeding with stabilising thinnings only, with insufficient light conditions for regeneration, and accepting natural disturbances as starting points for stand renewal.

Conclusions

If properly applied, ecological stability properties (Grimm and Wissel 1997) are a rigorous scientific concept to describe ecosystem dynamics. Some of the challenges that the use of this concept in forest management presents have been addressed in this paper and illustrated with the example of forests protecting against natural hazards. In such protection forests, the requirements for a continuous effect of the forest are especially high. Management aims at maintaining or creating specific stand structures which ensure high resistance and elasticity of the forest in the face of multiple disturbing agents.

When striving for a balance between resistance and elasticity in protection forests, a traditional silvicultural approach is insufficient. An ecosystem-based view (Schlaepfer 1997) of the forest needs to be adopted, and trends in driving factors such as climate change and atmospheric inputs recognised and anticipated in forest management.

The concept of ecological stability properties is not yet operational for field applications although some of its facets are already implicitly used in traditional silvicultural approaches towards the management of protection forests. It seems possible, however, to progress in implementing the concept, and first attempts for achieving this have been made (Brang, submitted). Tools for indicator development are available (Fisher 1998, Jackson et al. 1999, Prabhu et al. 1999).

The concept of ecological stability properties seems to be generally applicable to forest management, no matter which management goals are pursued. Integrating ecological stability properties such as resistance and elasticity has the potential to make the outputs of forests more predictable. The concept deserves further attention in sustainable forest management.

Abstract

The traditional agroforestry systems in the Himachal Himalayas have shown that the local farmer is aware of the benefits of mixed cultures and grows at least three to six types of trees in and around his fields. The overall prevalence of trees under traditional agroforestry concept at each farmer's field showed an increase from 47% in the lower hills to 67% in the middle hills. In general, 35-60% of farmers' fields have trees in traditional agroforestry, ranging from 35 to 46 different species from the lower hills to the middle hills. In the lower hills, the focus was on timber and horticulture trees whereas in the middle hills the prime aim was to integrate fuelwood and fodder trees in the system. Keeping in view the indigenous knowledge of the architectural shape of the tree in which the farmer manages a particular type of species, various tree prototype models were developed and tested. These canopy architecture prototype models depict the type of the tree for lopping practice, the extent, and the zone of the canopy management done by the farmers. In this work, the human perception in adoption of a particular prototype of an agroforestry tree in a system was highlighted. The concept of conserving the biodiversity increased from the lower to the middle hills. The indigenous practice of coppicing, lopping, and pollarding the trees for crop compatibility with respect to the size of the field was traditionally adopted by farmers because it both improves the productivity of land in terms of fuel and fodder and reduces the stress on village forests.

Keywords: Agroforesty, Indigenous technology, Prototype, Tree Architecture

Introduction

The Himalayas constitute one of the well-defined phyto-geographical regions of the Indian sub-continent. Farming is by far the most important and widespread occupation in the region. About two-thirds of the rural people follow diversified farming which includes animal husbandry, agriculture and fruit farming as major components. Farming in the Himalayas still continues to be largely at the subsistence level. Adoption of trees in agroforestry is not a new concept in Himachal Himalayas but has been practiced traditionally since time immemorial. Agricultural innovations have concentrated heavily on developing high-yielding crop varieties. As a consequence, the role of trees in meeting subsistence needs and providing conservation and protective functions have been overlooked, as have traditional management practices and technologies. This has resulted in the disappearance of some species traditionally used and maintained by farmers. Though a number of studies on Himalayan agroforestry systems are available (Toky et al., 1989, Punam 1990, Gilmour and Nurse 1991, Nair and Dagar 1991, Ralhan et al., 1991, Atul, et al., 1994, Sundriyal et al., 1994, Atul et. al., 1995, Dagar 1995, Sharma et al.,1995, Thapa et al., 1995, Atul and Punam1996, Semwal and Maikhuri 1996, Singh et. al., 1997), information on the indigenous knowledge and species management by the farmers in the traditional agroforestry system within the ecosystem, which has great diversity in composition, structure and function, is fragmentary. Integration of indigenous knowledge and experience in promoting agroforestry remains a prerequisite to ensure its social acceptability and sustainability. Understanding local tree-use practices, then, is necessary for formulating adoptable agroforestry systems.

This study aimed to analyze the farmers' perception in adoption of a particular prototype of an agroforestry tree and to explore the indigenous knowledge before interaction strategies are formulated for the sustainable development of the Himachal Himalayas.

Materials and Methods

Study area

The study was undertaken in Kangra Valley, which encompasses the sub-montane low hill subtropical and middle-hill sub-humid zones of the Himachal Himalayas. The Shivaliks and Dhauladhar Himalayas traverse the Kangra district from northwest to southeast. It is the most populated and biggest agricultural district of Himachal Pradesh, 5,063 sq. km in area. The pattern of land utilization has largely remained unaltered over the last decade. Forests occupy more than 39% of the area. The net area shown is only 21.1%: a decline of 7.78%. The agricultural economy of the district is predominantly small-holding oriented. About 64% of the total holdings are less than one hectare in size, but these account for only 14.91% of the total cultivated area. The holding size group of 1-2 hectares accounts for 18.17% and 2-5 hectares for 13.18% of the total holdings. Holdings above 5 hectares comprise 4.6% of the total holdings in the district and cover more than 44% of the total cultivation area. Out of the 134,560 holdings enumerated in the valley, 101,160 individual holdings cover 67.67% of the total area of the holdings. More than 84% of the individual holdings have less than 2 hectares of land, occupying nearly 35% of the total area owned by the group, while more than 60% of the joint families have less than 2 hectares of land and occupy less than 25% of the transitional Palampur area. In the Kangra valley, farmers integrate trees, crops and grasses on a small piece of land to meet their basic needs of food, fuel and fodder under the umbrella of agroforestry.

Method of Study

Data was collected on various traditionally prevalent agroforestry practices in the Kangra valley from different zones starting from Kangra (lower-hill: 800m), Palampur (transition between lower and mid-hill), Mandi (mid-hill: 1900m). The average rainfall of Kangra, Palampur and Mandi is 1702, 2515 and 1800 mm annually. The soils of these sites vary from clay to loam or loamy soils. Thirty-six villages in these areas were selected from the revenue record numbers using the random number table with three replicates in each cluster. The method employed for sample selection was as described by Mehl (1990). The data were analyzed statistically using ANOVA (CRD design) (Zar 1974). The number and name of the villages was the same as given by the revenue department. The data encompassed the mapping of the fields in the selected village fields to know the stratified distribution of various prevalent arboreal components in the village ecosystem. For calculating the prevalence of agroforestry, a minimum of 30 fields with trees were selected. Each field was evaluated in terms of the number of trees, type of trees, the existing prototype of the tree, tree position, tree dimensions, practice of the associated agriculture system etc.

In addition to pre-formulated questionnaires (6,475 respondents), group discussions were held to identify farmers' tree objectives. The method followed was that given by Chuntanaparb and Ranganathan (1990), with location-specific modifications. Among the more noteworthy modifications were those related to participatory mapping. A visual image of village layout, shown in a phyto-geographical map mosaic, helped locate specific visual features and identify village land-use patterns, which were physically surveyed during the study. This permitted the project research group to analyze land-use practices and discuss specific issues related to tree management.

After introducing line drawing examples of stem form and canopy shape, local persons were invited to sketch drawings representing their own ideas about the management of agroforestry trees on their fields. The prototypes emerged through iterative changes based on participants' comments (Fig 1) as followed by group discussion on undesirable tree characteristics. Finally, refining the local participants' sketches developed the tree prototypes. The line drawings developed through this process helped not only in identifying the tree (prototype) but also in understanding the management practices (Table 1) that were applied to species selected for different agroforestry systems.

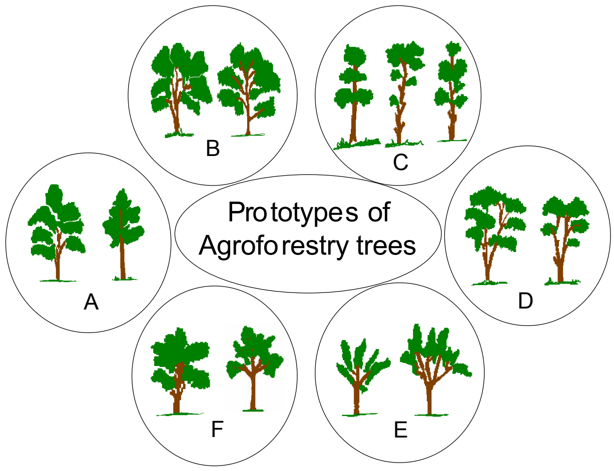

Fig. 1 Different prototypes of agroforestry trees prevalent in the traditional agroforestry systems

Results and Discussion

The study on the traditional agroforestry fields helped to reveal the distribution of various prevalent systems in the village ecosystem. The areas studied were significantly different in the prevalence of the traditional agroforestry systems (Table 2). It was found that the mean prevalence of traditional agroforestry systems in the village fields was lowest (47%) in the lower hills, 52% in the transition zone of the low and mid-hills, and 67% in mid-hills. The range of adoption of agroforestry was quite different from mean values, ranging from 31.96 to 62.97% in the lower hills and from 42.78 to 70.31% in the mid-hills. The mid-hill areas presented a unique picture in that there were pockets with more than 90% prevalence of trees in the farmers' fields; of 36 pockets sampled, the lowest value was 40.9%. Thus, it can be inferred that at the higher altitude, there were trees on almost each farm, which supports the postulate that the farmers have cleared the forests for agriculture and the trees on each field are the remains of those cut forests (Bishop 1983).

The number of species prevalent in different zones presented an inverse relationship with the precentage value of the adoption of agroforestry i.e., there was a significant decrease in the number of species with both increasing altitude and agroforestry adoption. Maximum values of farmers' field length and width did not vary significantly between the zones, whereas the minimum dimensions varied significantly (Table 2). The lowest values were observed in the transition zone. This is because, in the transition zone, the tea gardens and the unused lands were transformed to the agricultural fields through the intervention of the local population. The data analysis unveiled the minor features of the traditional agroforestry system and the prevalence of different prototypes on the farmers' fields. The manner in which farmers grow and maintain trees and perennial shrubs in a single production system with other components, such as agricultural crops and animals, is often determined by a number of external governance and inter-household characteristics. Changes in the overall economy and agriculture have overriding effects in farmers' agroforestry decisions. Household decisions influence species selection also. It was found that, in the lower hills, the farmers' preference was mainly to grow *Dalbergia sisoo* (Tali), followed by *Celtis australis* (Khirk), *Grewia optiva* (Beul) and *Salix* sp. (Beuns). In the mid-hills, the strong dominance of *Grewia optiva* (Beul) was clearly seen and other additional tree species were *Ficus* sp., *Morus alba* (Toot) and *Bauhinia variegata* (Kachnar). In the transitional zone, the farmers' preference was *Pyrus lannata* (Kainth), *Grewia optiva* (Beul), *Salix* sp. (Beuns) and *Albizia stipulata* (Ohi) in descending order of adoption.

.

Table 1: Classification criteria of different prototypes of agroforestry trees

	Criteria	Prototype					
1	**Periodicity of management**	A	B	C	D	E	F
	Lopped every year			+	+	+	
	Lopped with yearly gap period						
	Lopped with gap of two or more years		+				+
	Not lopped at all	+					
2	**Extent of lopping**						
	Heavy lopping			+		+	
	Moderate			+			
	Partial		+		+		+
	No lopping	+					
3	**Purpose of tree management**						
	Fodder		+	+	+	+	+
	Fuel wood		+	+	+	+	+
	Fruit	+					
	Timber	+					+
	Animal bed			+	+	+	+
4	**Objectivity**						
	To increase leaf yield		+	+	+	+	
	To increase branching		+	+		+	
	To increase height of tree						+
	Others	+					+
5	**Canopy management**						
	Top					+	
	Middle		+	+			
	Lower		+	+			
	Mixed			+	+		+
	Nil	+					
6	**Lopping mechanism**						
	Only leaving top			+			
	Only side branches		+		+		+
	Only alternate canopies			+			
	Completely					+	
	Nil	+					
7	**Size of tree**						
	Small					+	
	Medium	+	+		+	+	+
	Tall		+	+	+		+
	Very tall			+			
8	**Managed at what unit**						
	Base	+	+		+		
	Side branching		+	+	+		+
	Top branching					+

The species-specific adoption by the farmers of the Kangra valley showed a different picture when cumulative data were analyzed. *Grewia optiva* emerged as the most adopted species (94.1%) followed by *Dalbergia sisoo (*63.1%) and *Celtis australis (*36.6%). This suggested that most farmers were adopting the silviculture components in traditional agroforestry, whereas when seen in terms of micro-zonal variation, the picture was different. *Grewia optiva* was found to be the main component / tree in the agro-ecosystem of the mid-hills as, of the cumulative figure of 94.1%, 59.5% was in the mid hills. *Grewia optiva* was completely missing in the fields of the lower hills, where it was replaced by *Dalbergia sisoo* as the most important agroforestry tree. Thus, adoption of a particular tree in a specific area can be attributed to micro-environmental variations in the ecological habitat of that species. An interesting finding was that, in general, the preference of farmers changed from cash crops like timber and horticulture in the lower hills to fodder trees in the mid-hills, fodder being the major constraint.

Based on the information gathered on farmers' perceptions, preferred location and disliked characteristics of the trees were identified. Farmers select species for specific locations according to their experience in tending and maintaining trees (Table 3). Prototypes identified by farmers for specific niches express concern over space requirements. Environmental conditions and the farmers' knowledge of crop requirements also influence them. The growth or biomass production of a specific species in a particular area was the result of appropriate environmental parameters including crop-environment interactions. The interactive function of atmospheric energy and soil moisture are key environmental conditions determining potential growth performance (Wickramasinghe 1990). Farmers were unable to grow straight- and long-stemmed species on sloping land with wind exposure. If they do, the stems grow crooked at about 2-3 m above the ground. This emerged to be an important factor for farmers not having single-stemmed species on their farmlands. Thus, for the sustainable development of such areas, it is critical to introduce species capable of withstanding high-velocity wind.

Participatory sketching of tree prototypes helped in understanding farmers' tree-management objectives, and how these objectives differed depending on a tree's ecological niche and the agroforestry production system. Broadly, users' perspectives vary not only with regard to tree products, but also with regard to species characteristics. In maintaining and growing trees within a limited land area, a farm family's decisions are influenced by a number of key issues related to their needs and experience. Thus, tree-use practices vary across regions, agro-ecological zones, and households.

Table 3: Analysis of variance of different parameters (mean values) of the farmers field for agroforestry adoption

Zones	Adoption	Prevalent species	Farmers field dimensions

This research, which gives priority to farmers' expressed needs and views, can facilitate formulating a farmer-oriented approach to promote tree species in agriculture, grasslands and wastelands i.e., agroforestry. Village agroforestry systems in Kangra Valley are associated with age-old tree-use practices that have evolved through farmers' experience to meet survival needs. Tree products - food, fuelwood, fodder, timber and mulch - contribute directly to household survival. Benefits of village agroforestry systems are diverse, but food products are of outstanding importance among them. The ability of *Morus, Grewia* and *Celtis* to ensure fuel and fodder security during the dry season and to provide familiar, traditionally used fodder products throughout the year are reasons why these species are found widely in the studied villages (Table 3). Another important factor is their ability to adapt to a limited space on limited land and still yield fodder during the scarcity period.

For *Grewia optiva*, irrespective of the order of preference and variation in the hill zone, the tree was managed in a specific prototype i.e. F and B (Fig 1) in which only side branches were partially lopped to meet the fodder and fuelwood requirement and to restrict the height of the plant to a medium level with a single or double forked bole structure. In the *Salix* species, the prototype ranged in five different types from B to F i.e., managing and lopping the tree depending upon the fuel, fodder, timber or any other requirement of the farmer (Table 3). In the mid-hills, the *Ficus* species was predominant and its architectural shape was maintained in B type only indicating the indigenous practice of partial lopping of primary and secondary branches, not at regular intervals. The presence and management of the indigenous forest tree species like *Hamiltonia suaveolens* showed that when abandoned tea orchards or unused lands were brought into agricultural use, farmers managed those trees which are secondary fodder and fuel wood sources. It was interesting to note that the multipurpose tree species (nitrogen fixing, source of fodder and fuelwood etc.) like *Bauhinia variegata* were managed under different prototypes, shapes indicating their relationship with their multi functional roles. Thus, it can be concluded that in the traditional systems, the shape or kind of prototype of an agroforestry tree is a direct function of its role in the system as well as the tree management practice adopted by the farmer to meet his purpose.

These findings about the traditional agroforestry systems and the use of indigenous knowledge about their management have to be taken seriously before intervention strategies are formulated. Efforts to promote agroforestry systems among small-scale farmers through introduction of improved varieties must recognize farmers' practices and expressed needs regarding tree products and characteristics. On this basis, priority species in the study area requiring improvement efforts were found to be *Grewia optiva* and *Celtis australis* irrespective of the location of the village, whereas fruit trees like *Mangifera indica*, and *Syzygium cumunii* and fodder tree *Bauhinia verigata* are of second priority. It can be inferred that the proximity of the city might have influenced the farmers towards fruit trees, the immediate source of cash.

Dependence on tree (being grown by their earlier generation) products for food and fruit is high among the people, who are unable to generate an adequate off-farm income to support a family or produce other commodities to meet the family's food needs. Apart from these factors, the culture of tree-use practices and local food habits have important effects on farmers' species decisions.

Conclusions

Traditional agroforestry systems based largely on indigenous knowledge and species are parts of the cultural patterns of the community. The gap between these indigenous systems and modern innovations is wide, despite attempts to replicate traditional systems with external support. While non-scientists have maintained the indigenous agroforestry systems of Himachal Himalayas, scientists can contribute in many ways to promote greater productivity, diversity, and enhanced returns to the family. Scientists can learn many lessons from farmers and, in turn, collaborate with them in developing techniques and new varieties that can be integrated into their farms. Transforming these findings into operational intervention programs will be complex, but is necessary to promote adaptable tree-use practices. This information related to tree-use practices can be interpreted in various ways according to one's objectives, but the major points are as follows:

1. Farmers' priorities for tree species vary according to the primary needs of the farmer's family.
2. Dependence on tree (being grown by their earlier generation) products for food and fruit is high among the people, who are unable to generate an adequate off-farm income to support a family or produce other commodities to meet the family's food needs. Therefore, farmers' needs and choices should be considered when promoting trees.
3. The best-suited tree characteristics cannot be determined by considering either the tree species or its products in isolation.
4. An attempt must be made to obtain the best germplasm from the local gene pools for further improvement. This would enable geneticists to apply genetic improvement to promote important local species. This is also essential in gaining farmers' reliance on the materials promoted by scientists.
5. Tree management practice is an important tool in the successful adoption of any agroforestry system. Ecological compatibility in terms of management has to be worked out before recommending any new innovation in the system.

Thus, though agroforestry is thought to be the best land management system, this is not accepted by all, particularly the smallholders. If by making use of indigenous knowledge gathered from traditional systems, we can make them ecologically as well as economically viable, only then we can think of sustainable Himalayan development.

Abstract

Taiwan, with a total area of 35,915 km^2 and a population of 23 million is rich in forest resources; 58.5% of Taiwan is covered by forest, which plays an important role in soil and water conservation, timber production, and recreation. From 1914 to 1945, mountain development was concentrated on forest exploitation, railway and forest road construction. From 1946 to 1975, timber production, agriculture, and horticultural practices became the main scheme of mountain development. In 1976, the government passed the Forestry Management Innovation Act. Mountain development shifted from timber production to recreation and horticultural production for increasing the income of mountain communities. In 1989, timber harvesting was banned in natural cypress stands of national forests. In 1992, cutting was completely banned in natural forests. Since then, forest management has concentrated on sustainable forest ecosystem management. Culture and recreation have become the main thrust of mountain development. In recent years, the cultivation of crops has caused serious soil erosion disasters. Integrated forest management has great potential to ensure stability and sustainability in timber production and to provide ecological and economic security to mountain development.

Keywords: Forest, Environment, Mountain development, sustainability

Introduction

Taiwan lies off the southeast coast of mainland China. It is mostly mountainous, with an average annual rainfall of 2,510 mm and average annual temperature of 23°C. There are more than 200 important tree species of economic value, and includes species such as Taiwan red cypress, Taiwan yellow cypress, Taiwan red pine, Taiwan spruce, Taiwan hemlock, Chinese fir, camphor tree, machilus, and green bamboo. The forests play important roles in soil and water conservation, timber production, and recreation.

The role of forestry in Taiwan was to stimulate economic growth in the early development of the mountains. With socio-economic and population growth, pressure on forest and mountain development grew unevenly. The competition for land, inadequate management, and pollution have resulted in forest depletion and environmental degradation. Abuse of forest land has created great environmental impacts (Young 1994). The trade-off between economic growth and environmental quality as well as social function is one of the main issues of forest development policies in Taiwan. Forest and mountain development is not an objective per se but rather an instrument in the process of achieving national economic development (Adamowicz et al. 1993).

Forest ecosystems are an important part of the global environment. Forest conservation and sustainable management may be buffers to developmental impacts. As a nation in the global community, Taiwan strives very hard to foster conservation and sustainable forest management in order to ensure economic stability and environmental security. This paper presents an overview of Taiwan's experience in forest and mountain development.

Forest Resources

Taiwan, located in the sub-tropics, with a total area of 35,915 km^2 and a population of 23 million is rich in forest resources. About 58.5% of the land, nearly 2.1 million ha, is covered by forests: 1,120,400 ha (31.2%) of hardwoods; 438,500 ha (12.2%) of softwoods; 391,200 ha (11.0%) of mixed wood forests; and 362,300 ha (10.1%) are bamboo forests and ranges (Yao 1997).

There are six forest types: (1) spruce-fir: distributed at high elevations over 2,500 m mountain areas; (2) hemlock (2,000 to 3,000 m); (3) cypress: composed of red cypress (*Chamaecyparis formosensis*) and yellow cypress (*C. obtusa var. formosana*) (1,500 to

2,800 m); (4) pine and other conifers: composed of Taiwan red pine, Taiwan white pine, Chinese fir and Japanese fir (300 to 2,800 m); (5) mixed conifer-hardwoods (1,500 to 2,000 m); (6) hardwood type (from sea level to 2,000 m).

The total forest growing stock is 358.7 million m^3, of which hardwoods and softwoods account for 176.3 million m^3 (49.1%), and 182.5 million m^3 (50.9%) respectively (Yao 1997). Taiwan also supports very rich bioresources including 4,021 vascular plants, 524 algae, 4,261 species of fungi, 61 mammal species, 402 bird species, 92 reptile species, 30 amphibians, and 17,609 species of insect (Chung et al.1993).

Forest Development

1914 - 1945

From 1914 to 1945, Taiwan forestry was geared to timber production from natural forest exploitation in order to boost the national economy. In 1910, the Japanese government launched the Ali Mountain development plan. Ali Mountain railway was set up in 1912, and large-scale logging was carried out. Timber production was confined mostly to natural forests of Taiwan red cypress and Taiwan yellow cypress in the high mountains. During the 34 years from 1912 to 1945, the total cutting area in Ali Mountain was 9,773 ha, and 3.5 million m^3 were cut. During the 21 years from 1922 to 1942, the island-wide cutting volume amounted to 22.9 million m^3, and 352,889 ha were reforested (Chao 1999). Railways, forest roads, and many new villages were established to meet the needs of forest development and reforestation. During this period, the economy of the mountain communities was booming.

1946 - 1975

From 1946 to 1975, the Taiwan Forestry Policy and Management Guidelines were implemented. Soil conservation and timber production were the major projects. There were 370,000 ha of protection forest in 1958. During this period, 394,339 ha of forestland were reforested (Chao 1999, Yao 1997). However, forestry policy focused on timber production for supporting the nation's economy. The Taiwan government gained a large surplus revenue of US$5.8 million annually from forest development (Chao 1999). Timber production, agricultural and horticultural practices became the main emphases of mountain development.

1976 - 1991

From 1976 to 1991, the forestry policy shifted to support national soil conservation. In 1976, the government passed the Forestry Management Innovation Act, and formulated implementing projects, i.e., expansion of reforestation areas, strengthening forest protection and forest land management, expansion of protection forests, enforcement of hillside stabilization and flood control, forest recreation and natural environment conservation, and application of scientific techniques. The cutting volume decreased sharply. During the first four-year period of 1976 to 1980, annual cutting volume was restricted to 100 million m^3. The Taiwan Forest Bureau encountered serious financial difficulties due to the great deficit in the self-sufficient enterprise budget system. Therefore, in the second four-year period of 1981 to 1984, and the third four-year period of 1985 to 1991, the annual cutting volume was changed to 150 million m^3. From 1977 to 1989, the Taiwan Forestry Bureau accumulated a large deficit. The government started to subsidize the budget for reforestation and soil conservation in 1983. The budget of the Taiwan Forest Bureau was changed from enterprise budget system to official budget system in 1989. In 1989, timber harvesting was banned in natural cypress stands of national forests, and cutting was absolutely prohibited in protection forests, watersheds, ecological conservation areas, national parks, and steep areas. During the period, 69,798 ha were reforested (Chao 1999, Yao 1997).

1992 - 2000

From 1992 to 2000, the forestry policy concentrated on agroforestry, reforestation, windbreaks, as well as soil and water conservation (Lo and Lin 1993), with an emphasis on the establishment of environmental forestry to counterattack forest depletion and environmental degradation. In

1992, timber cutting was completely banned in natural forests. Since then, forest management shifted to sustainable forest ecosystem management. In October 1996, the government launched the All People Reforestation Movement to encourage and subsidize private forestry. During this period, cultural and recreational development, as well as environmental protection have become the main thrust of mountain development. From 1992 to 1996, 23,274 ha were reforested (Chao 1999, Yao 1997).

Mountain Development

1914 - 1945

From 1914 to 1945, great emphasis was given to timber production. Mountains with rich forest resources, such as Ali Mountain, Ba-Sen Mountain, Tai-Pin Mountain, Wan-Shian Mountain, Shiang-San Mountain and Luh-Tsang Mountain, became the target for forest development (Chao 1999). Railway and forest road construction improved transportation to mountain areas, and people migrated to mountain communities to provide the labour force for forest development. The logging enterprises stimulated socio-economic activities, and new towns were established.

In 1914, logging operations were started in Ali Mountain Forest District, which had 60,000 ha of forest. Every year 44,808 m^3 of lumber were transported to Chiayi city for processing and trading (Chao 1999). Thus, Chiayi city became the center of lumber marketing, and remains vigorous in the lumber industry.

Ba-Sen Mountain was developed after Ali Mountain in 1916. Ba-Sen Mountain Tree Farm covered an area of 12,000 ha. Fong-Yuen city was created with an annual timber production of 38,340 m^3, and it continued to prosper for 30 years (Chao 1999).

The development of Tai-Pin Mountain began in 1921. Tai-Pin Mountain Forest District had an area of 26,585 ha and timber stock volume of 13,720,280 m^3. A new town, called Lo-Dong with 10,000 inhabitants, was created as the lumber trade center in northern Taiwan in 1921. By 1945, the population had increased to 30,000, of whom 10,000 worked in forestry-related enterprises (Chao 1999).

In 1933, timber cutting was started on Wan-Shian Mountain with annual timber production of 11,600 m^3. A new mountain village, called Sui-Li with 31,600 inhabitants, was established in 1945 (Chao 1999).

Shiang-San Mountain and Luh-Tsang Mountain was developed in 1940 and 1943 respectively. Chu-Dong, located in Shin-Chu Prefecture, was the center of wood processing and timber marketing (Chao 1999). It remains a city famous for furniture industry.

1946 - 1975

From 1946 to 1975, timber production, agriculture, and horticultural practice became the emphasis of mountain development. Tairoko Mountain, with a forest area of 5,511 ha and stock volume of 1.58 million m^3, was developed for timber production in 1946. Hwa-Lian city became an important timber market. In 1948, the government passed the Mountain Reserve Management Act to protect indigenous people and to develop the mountain economy. In 1950, the provincial government passed the Forest Land Leasing Act to encourage citizens to participate in reforestation. From 1951 to 1958, 55,119 ha of forestland was leased (Chao 1999). These ACTs had led to the inappropriate use of forest land to cultivate fruit trees, teas, and other vegetables. In 1959, the Executive Yuan allocated Chi-Lan Mountain Forest District (48,766 ha of forest) and Ta-Cha-Si Forest District (46,191 ha) to the Forest Development Administration of Vocational Assistance Commission for Veterans (Yao 1997). Forest development was the major part of mountain development during this period. Exportation of high-quality timber supported the national economy. Administration problems such as illegal cutting, abuse of forestland, and forest fire resulted from agricultural and horticultural practices.

1976 - 1991

In 1976, the government passed the Forestry Management Innovation Act. Mountain development shifted from timber production to reforestation, soil and water conservation, recreation, agricultural and horticultural production for strengthening the economy of mountain communities. In 1989, timber harvesting was banned in natural cypress stands of national forests (Chao 1999). Timber production decreased sharply. A large proportion of the forestry budget was invested in reforestation, soil and water conservation, and recreation facilities. Due to the prosperous economy and the development of the transportation infrastructure, the public demanded forests for outdoor recreation. Thus, forest recreation stimulated another change in mountain development. Also, inappropriate use of forest land for the cultivation of high-value crops, such as betel nut palm, tea, and wasabi caused serious problems in forest management. Avalanches, soil erosion, and mudflows caused tremendous damage to villages.

1992 - 2000

In 1992, cutting was completely banned in natural forests, and sustainable forest ecosystem management began. Cultural development and forest recreation became the main emphasis of mountain development (Shuai 1992, 1993a). The government has invested large amounts to strengthen the development of mountain villages, and tried to set up an agroforestry scheme (Huang 1998, Lee et al.1995, Lin 1998, Lo and Lin 1992, 1993, 1995). In recent years, inappropriate use of forest land for cultivation of agricultural and horticultural crops has become more serious. Due to high demand for high-cool land vegetables, mountain development shifted to the inappropriate use of forest abuse for vegetable production (Shuai 1993b). Thousands of hectares of betel nut palm, tea, ginger, wasabi, fruit tree, and vegetables have caused serious soil erosion disasters, and undermined mountain development. Landslides and mudflows have become the nightmare of mountain villagers. Large landslides and mudflows have often occurred during the typhoon and monsoon season. Soil erosion disasters usually destroyed the results of mountain development, such as bridges, roads, railways, houses, farms, livestock, and crops, as well as killing people.

The Future

From 1914 to 1991, the role of forestry in Taiwan was to foster the economic growth of the nation. Intensive forest and mountain development resulted in forest depletion and environmental degradation. It is very important for resource accounting to be an essential ingredient in national policy formulation. Economic and environmental values must be integrated into national accounts (Brundtland 1987, FAO 1994, 1995).

Rapid deforestation and forestland abuse have resulted in forest depletion, which intensifies issues of soil erosion, sedimentation, alluvial water flow and other consequences. Thus, Taiwan forestry has adjusted toward sustainable management and raised concerns about the environmental impacts of the current shift in forest cover from marginal cropland through reforestation. Forest ecosystem management is the main basis of forest and mountain development in Taiwan today.

In the future, Taiwan's forestry policy will focus on sustainable production and environmental protection. Integrated forest management has great potential to ensure stability and sustainability in timber production and to provide ecological and economic security to mountain development, as revealed by Taiwan's experience.

Abstract

Conditions in mountainous regions are distinctive as regards ecological as well as socio-economic aspects. However, while ecological features, which set mountain regions apart from other areas, are quite similar among all mountain regions, socio-economic conditions differ quite highly between different types of mountain areas in Europe. Consequently there also exist different approaches to mountain forest policies. Based on national studies, which were undertaken in the framework of COST action E3 (Forestry in the Context of Rural Development), information on mountain forest policies in 11 mountain regions in Europe has been compiled for analysis. The comparative analysis is performed using a Boolean approach to comparative analysis which allows the comprehensive analysis of qualitative and quantitative information without having to rely on random sampling of cases. From the analysis, the cause of conflicts as being ultimately a result of struggle for scarce resources is revealed. The choice of political instruments, too, reflects power structures in a society as well as its general political culture.

Keywords: Policy analysis, mountain forests, qualitative comparative analysis

Introduction - Mountain Forests and Forest Policies

The Protective Effects of Forests as a Problem of Power and Distribution

Ownership Rights and the Control of Forest Resources

Following a critical theory approach to land use allocation, the distribution of land and land use mirrors the distribution of power within society (Soja 1989). Liberal general equilibrium theory, projected onto the allocation of land uses, suggests that under ideal market conditions, land may be allocated to the most profitable land use, meaning the one which is willing to pay most for purchasing or renting the land. Since, compared to other forms of land use, forestry is a rather low interest activity, forests have remained in areas, which were so far of little interest to other forms of land use (Hyttinen*, et al*. 1998).

Torrents and avalanches have always been a phenomenon of alpine environments; they become a problem only where they endanger the existence of human infrastructure. Thus, as long as there exists enough land for all competing interests to be allocated in areas outside the reach of these phenomena, they are not likely to become an object of policy formulation, since they are not perceived as a problem. Therefore a high population density can be assumed to be one highly relevant factor in the causal complex of conflicts related to torrents and avalanches. This is especially important in comparing different policy approaches to coping with these phenomena.

Actual control over land management regimes, which would include conversion to other forms of land use, was effectively taken away from local tenants in most European countries at some time in the second half of the second millennium. Formal land-ownership might still have remained with the local population through either direct, mostly small-scale, private tenure or community ownership, but strict regulative measures concerning the conversion of forest land to other forms of land use as well as reforestation requirements restrict land-owners' choices quite distinctively. The enforcement of management practices conforming to the aims of forest policies was handed over to forest authorities.

Power Structures and Political Instruments

The choice of political instruments to be implemented can be regarded as a reflection of power structures. Where a strong lobby of agricultural landowners in mountainous areas existed, they may have been capable of mobilising large funds for subsidies. In such conditions a general aim of rural policies to keep farmers on their land and farmland under production usually also may be witnessed. The power of the forest service here then relies strongly on its role as the institution responsible for funnelling public funds.

If, on the other hand, the population of mountain areas had no powerful lobby, the authorities could rely on regulative instruments and later on the acquisition of abandoned farm land to implement forest policies. Under these conditions, the power of forest authorities lies in their ability to impose regulations upon landowners as well as on their role as large landowners able to offer income opportunities.

Thus, under either of the two constellations, forest authorities have become rather powerful institutions in rural and mountainous regions. The theory of institutionalism suggests the existence of a powerful bureaucracy itself to be an explanatory factor for the existence of political programs, which are ultimately in the self-interest of such institutions. However, due to the fact that this factor, the existence of a powerful forest authority, can be observed in all countries or regions considered in this study, its consideration does not offer much explanatory insight.

The Protective Effects of Forests as a Problem of Policy-making

Mountainous areas are rather sensitive ecosystems, due to the harsh climatic, and the hydro-geological and geo-morphological conditions. Therefore, adequate management of mountain forests is crucial for maintaining the resource. Traditionally, mountain forests have been used for agriculture, forestry and hunting. Clear-cuts for the purpose of shipbuilding or fuelling smelting works and farmers' uses of the forests for litter collection or grazing often led to degradation of the forest ecosystem. Some formerly forested areas today are bare karst.

The research described in this paper started with the assumption that people nowhere are so dependent on the forest as in mountainous rural areas. In mountainous regions, forests provide various prominent services for the community: besides their importance for work opportunities and income, they protect the land against erosion and settlements and traffic devices against avalanches, rock-fall, mudflows and landslides. Furthermore, they are also of decisive importance for the climate and watershed management; the maintenance of mountain forests is an important factor to prevent floods in the lowlands. Last but not least, mountainous forests are highly appreciated recreation areas and enclose ecologically unspoiled biosphere reserves[1]. However, the so-called "protection functions" are often identified[2] as the most outstanding services that mountain forests offer to society. These protection effects of the forest are manifold, and for policy considerations their different characteristics have to be recognised. Two main categories of protective effects of mountain forests can be distinguished:

a) protection of the site against soil erosion and degradation
b) protection of settlements and transport facilities against natural hazards

Site Protection

Mountain forests are sensitive ecosystems, which are vulnerable to natural forces. Over-use can result in degradation of the forest ecosystem. If the forest disappears, the production capacity of the site, the good effects of the forest on climate and water budgets, and work opportunities are also lost to society. This view is well illustrated by the

Norwegian definition of mountain forests[3]:"Mountain forests are forests where the climatic conditions, especially temperature and wind, are strongly restricting factors for seed setting, seed ripening, germination and production"; and the Austrian definition of protection forests[4]: "Protection forests are forests found on easily erodible sites which, therefore, need appropriate management". The forests have to be protected against "self-destruction" (Norway), or respectively, against the "erosive forces of wind, water and gravity" (Austria). The forest laws of most countries include specific regulations for the management of mountain forests (Austria, Bavaria, France, Greece, Italy, Norway, Switzerland[5]). Management restrictions typically are the following:

- obligation for the maintenance of the forest,
- official approval of cuttings, and
- restriction of clear-cuts.

The forest areas affected by these regulations are rather extensive. In Switzerland almost 100 % of the forest area in mountainous cantons were regarded as protection forests according to the definition of the former forest law. Today's Swiss forest law no longer distinguishes between protection forests and regular forests. In Austria, protection forests are defined by detailed criteria in the forest law and all forests that meet this definition are to be managed in an appropriate way. Forests that meet this legal definition automatically qualify as protection forests (ex lege) and benefit from a special protection status. No official act is necessary to make this status effective. According to the Austrian national forest inventory, one-fifth of all forests count as protection forests. The meaning of the expression "protection forest" or German "*Shutzwald"*, comprises two aspects: on the one hand, the forest protects the site against erosion; on the other, the forest has to be protected against inadequate management. In some countries, protection forests are depicted in forest function plans (Austria, Bavaria). Contrary to this category, forests with direct protective effects for settlements and infrastructure should logically rather be termed "protective".

Natural hazards protection

In mountainous regions with high population density, forested slopes provide protection against avalanches, rockfall and landslides. Inadequate forest management can produce severe risk to hazard-prone areas beneath the forest. The problem in managing these forests is that the forest area produces timber and deer for the private forest owner, while at the same time owners of properties situated underneath are interested in the protection service. These goods and services are partly compatible and partly competitive with respect to each other (GLÜCK 1998). A certain degree of security will be supplied even if the forest is managed for timber exclusively. No management restrictions are required for the provision of this minimal degree of security if only the forest is preserved. If more protection against hazards is desired, timber production has to be reduced (or, forest management cost rises). The cost of foregone timber production (or game or cattle production,) in order to increase the provision of security is the opportunity cost for provision of the protection service. Protective forests directly protect settlements and infrastructure. As there is higher interest in these protection services, stronger regulations are formulated here than for site protection forests. Rights for property owners situated underneath the forest are formulated (Austria, Slovenia), or the authority has significantly more instruments for forest management intervention in this specific situation. The authority at least is advised to register areas of protective forests (Bavaria, Switzerland). The forests may be declared by an official act as protective forests (Norway), or as "ban forests", as they are called in Austria. Management measures may be prescribed by the authority (France, Austria, Bavaria and Switzerland). If necessary, they may be expropriated (Greece). In Austria the owner of the property benefiting from the protective services of the ban forest may demand special measures to enhance the protective effect of the forest. In Slovenia, the management of these forests is regulated by contracts between the forest owner and the state or the town/village. In both countries, Austria and

Slovenia, the forest owner has a claim for compensation by the beneficiary. The area of protective forests, for which the stricter regulations are effective, is much smaller than the more general prescriptions for site protection forests.

Although legal regulations in most countries clearly distinguish between these two categories, in some countries no lingual differentiation is made. The term "protection forest" (German: "*Schutzwald*") is often unspecifically used for both types (Weber 1998). In colloquial usage, the expression is linked with the "protection functions" of forests, and in most countries a range of such protection functions is attributed to the forest. So, for example, in Bavaria site protection, water protection and protection against avalanches are considered in the forest function plans (Beck/Suda 1998). According to the Bavarian forest law, the following types of protection forests are distinguished:

- absolute protection forests, situated in high-elevation or on easily erodible sites,
- limited permanent protection forests, protecting against natural hazards, and
- limited temporary protection forests, preventing neighbouring stands from storm damage.

In Austria, the forest law defines protective effects of the forest both against natural hazards to protect settlements and infrastructure, and against erosion to maintain the productivity of the soil. So-called welfare effects relate to the positive effects of forests on the climate and the provision of drinking water. The term protection forest, according to the forest law, would be reserved only for site protection, but in practice the word is also connected with protecting settlements against natural hazards. Partly this "sloppy" usage has "political" functions: protection forests according to the forest law are surveyed by the national forest inventory. The resulting figures of this survey are cited as an argument for the importance of mountain forests for protecting human settlements in mountainous regions. Yet, in contrast to the rather extensive acreage of protection forests, the forest area directly protecting human facilities is much smaller.

The consequences of these considerations for forest policy are that different instruments are adequate for regulating the different categories of forests protecting the site or protecting against natural hazards. In each case, the protection is an external effect of the forest and a public good, but the circles of beneficiaries are different. While the effects of avalanche protection clearly can be allocated to a small number of benefiting parties, the effects of the prevention of erosion and preservation of forests are for the benefit of a greater community; e.g., all cities downstream along the rivers benefit from mountain forests through reduced flood peaks.

In fact, different regulations are formulated in most countries for these two types of protection services. For site protection, restrictions of forest management are laid down in the forest laws. For natural hazards protection, further regulations can be set or the authority may take measures. In the latter case, the forest owners regularly have a claim for compensation by the state or the beneficiary.

In practice these strict regulations often are not implemented properly. A common problem for the preservation of mountain forests in most countries is that hunting or grazing uses cause damage to the forests. Most of the countries report that the problem of mountain forests is not a silvicultural problem but a question of the lack of implementation of existing regulations by the authority (GLÜCK 1998).

Besides regulations, subsidies are also granted for forest management. Where forests are damaged by improper use, subsidies instead of prescriptions are often used to restore the forests.

The comparison of mountainous countries in Europe in course of the COST Action E3 has shown that mountain forest policies are quite different in some respects. Although the analysis revealed that most countries have the common problem that protection of mountain forests is severely affected by hunting or grazing, the problem situation varies among the different countries, and instruments applied also vary.

Materials and Methods

Materials Gathered in Case-study Regions

In order to arrive at more general conclusions concerning the mechanisms governing mountain forest policy making, several case studies have been compared.

The regions and countries to be included in this analysis were chosen based on the work done in the framework of Working Group (WG) 3 of COST E3. The information needed for this analysis was derived from country reports submitted for COST E3 and from additional questionnaires sent out in spring 1998. Information was obtained for Bavaria[6] (Germany), Casentino (Italy)[7], the Catalan Pyrenees (Spain)[8], Greece[9], Graubünden (Switzerland)[10], Departement de Savoie (France)[11], Tyrol (Austria)[12], Pratomagno (Italy)[13], Trentino (Italy)[14], Slovenia[15], and Vest-Agder (Norway)[16]. For Greece, Trentino and Vest-Agder, additional information was obtained from data collected for the case study reports for the FORWARD project at the European Forest Institute.[17]

Using a method of qualitative comparison based on Boolean algebra, the combinations of different factors, which occur in these case study regions were studied concerning their relevance for observed outputs of the political administrative system. Two examples of this are presented below.

Methods of Comparative Analysis in Social Sciences

Two main types of strategies can be detected in the approaches toward comparative research in social sciences, the variable-oriented approach and the case-oriented approach.

Quantitative Techniques

The variable oriented approach encompasses quantitative strategies, using statistical methods like regression analysis to test theories against empirical evidence. These methods focus on variables and their relationships, rather than individual cases. While this bias enhances the methods' capability to address abstract theoretical concerns, the strategy is less adaptable to understanding individual cases or categories of cases.

Simply put, the result of any quantitative study is always that the analysed theory or hypothesis may be either rejected or accepted with a certain probability. The variable-oriented approach allows for the analysis of a large number of cases, but it also demands the availability of data from a comparatively large number of cases. The simplified conception of causality embodied in statistical models also enhances the aim of generality of results, but it discourages considerations towards causal complexity and thus fundamentally alters the research dialogue between concept formation and data analysis.

Also it has to be stated that quantitative statistical approaches assume the sample to be taken from a fairly homogenous population, for which general statements may then be deduced from the results. Given the complexity of historical development, this may not be necessarily assumed in development research.

Related to the assumption of a homogenous population from which the sample is drawn is the fact, that the importance of any observed causal relation among the observed cases for the final result is ultimately dependent on the

frequency of this observation within the observed sample. Also the sample is required to be chosen randomly from the homogenous population and to be representative for that population with regard to the distribution of explanatory variables.

Qualitative Approaches

A case-oriented approach allows for the consideration of cases as a whole and is aimed at understanding examined cases in their historical complexity. It is thus based in the tradition of qualitative social scientific research. Research dialogue is centred on intersections of causal conditions. The method allows for the consideration of causal complexity, which is mainly evident in the observation of similar outcomes from different starting conditions or, vice versa, different outcomes from seemingly similar starting conditions.

Admittedly this bias towards understanding of cases in their complexity restricts the number of cases that may be compared with this method. Consequently the potential for the generalisation of results is also diminished. The latter may be countermeasured by the categorisation of data as well as by explicitly stating the contextuality of new theoretical findings.

The different advantages and disadvantages of qualitative and quantitative strategies are not to be taken as final arguments for or against either of these approaches, but are simply to be seen as guidelines towards the applicability of the two approaches to specific scientific problems.

Another possibility is the development of new approaches that try to incorporate the key advantages of both strategies. The application of Boolean methods of qualitative comparison, as suggested by Ragin (1987), is a step in this direction, which incorporates the capability for causal complexity as well as the handling of larger sets of data, which is facilitated by software packages developed for this type of analysis. An essential difference between this approach and statistical methods is, that the frequency of an observation is not methodologically linked to its importance for the final result, even though frequency considerations may be incorporated into the analysis process.

The method requires the researcher to establish hypotheses concerning the relevance of phenomena responsible for a specific outcome. The results from different cases are compared to each other and, using logical minimisation techniques, those conditions which are seen to be most relevant for an outcome can be identified. The QCA method allows for a more detailed and systematic comparison of complex case studies than would be possible without the standardised procedure. For computing, no "quantitative" data in form of real numbers but rather qualitative data coded as Boolean variables (1=presence, 0=absence) are required. Via truth tables "necessary" and "sufficient" conditions for a certain outcome are sorted out. The method has been used in forest policy research by Hellström (1996) and Hellström and Rytilä (1998), a work which investigated forestry-related conflicts throughout Europe, as well as by Hyttinen, Niskanen, and Ottitsch (1999) for investigating the role and opportunities of forestry and the forest sector in the development of remote rural areas in Europe.

Results From Case Studies

Example for a Result of the QCA -approach

The qualitative comparative analysis was performed using Ragin's QCA-approach. An example for this step is provided here for demonstrative purposes since the listing of all the tested hypotheses would strain the available space in this paper.

Existence of Specific Programs Aimed at Restoring Mountain Forest Areas

For the existence of specific "restoration programs" the following set of explanatory variables may be taken into consideration:

> **A high share of (mountain) forest land.** If natural conditions were the main reason for related policies, then a high share of (mountain) forestland would also mean a high likelihood for the existence of related policies.

A high population density, which is an indicator for strong interests competing for an increasingly scarce resource (land).

A history of industrial forest use (i.e., planned use of forest resources for the supply of industries (mining, smelting, timber industries) as opposed to farm-related subsistence use and agroforestry systems (i.e., livestock grazing). For the needs of industries large even-aged stands were established following clear-cuts in the 19th century. These even-aged stands may now be reaching their decomposition-phase. Due to competing land uses, forest regeneration was hindered, requiring restoration measures.

A rising trend in economic development. This would mean also a good situation of public funds. This in turn means that public money is available; following theories of public administrations, one may expect that public institutions will try to find ways to spend it.

A high share of private land-ownership. Since the provision of protective functions is not in the immediate interest of private landowners and so far no markets have existed for these products, it may be assumed, that political instruments have been installed for the procurement of these services.

The truth table shows, that there exists one contradictory configuration, which is represented by the Catalan Pyrenees region in Spain and the canton Graubünden in Switzerland. In both of these cases there is a forest share lower than 50%, a low population density in relation to habitable land, a good economic development, a tradition of industrial forestry and no domination of private ownership. Yet while these conditions coincide with an existing specific mountain forest policy in Graubünden, there is no specific mountain forest policy in the Catalan Pyrenees.

```

Example 2

Which Conditions Result in a Preference for Fnancial Incentives?

For the question of which conditions more likely result in a preference for the implementation of financial incentives, the following factors are assumed to be of relevance:

A rising trend in economic development. This would also mean a good situation of public funds. This in turn means that public money is available; following theories of public administrations, one may expect that groups in society will compete to be considered in the redistribution process.

A high share of private land-ownership. Since the provision of protective services is not in the immediate interest of private landowners and so far no markets have existed for these services, it may be assumed that political instruments have been installed to provide them. For private landowners, subsidies are the most attractive form of instrument. This is also to be seen in context with the next factor:

The presence of corporatistic structures. In the presence of corporatistic structures, in which sector administrations act in the interest of their clientele, it can be assumed that they will prefer subsidies over other political instruments, since they strengthen their influence and power. Under such conditions, landowners may also be expected to have considerable political influence, especially in societies with a significant share of rural population.

Management of public land by the forest authorities, who also provide extension services for private lands (Einheitsforstamt).
This may be seen as an indicator for even stronger corporatistic connections between landowners and the administration. It may also be assumed that, if forest authorities are competing with private landowners in

markets for conventional forest products, it is difficult to impose regulative sanctions for the procurement of infrastructural services. On the other hand, it might also be argued, that the presence of an "Einheitsforstamt"-type of management is an indicator for an even more powerful forest authority, since it has not only political instruments in its hands but may also enact power as an actor on local labour and raw material markets.

<u>Minimisation for result 0 - no strong subsidies:</u>

```
Minimized Truth Table #1
File: SUBHIA08.QDM
Model: SUBHI = ECODEV + PRIVOWN + CORPORAT + EINHFORA
Outputs Minimized: 0
Method: Quine-McCluskey (Minimal)

  ecodev corporat EINHFORA +
  privown corporat EINHFORA
```

<u>Identification of necessary conditions:</u>

The absence of corporatistic structures AND the management of public forest by the forest authorities (i.e., Einheitsforstamt-type of management) are both *necessary* conditions for the absence of strong subsidies, however they are NOT *sufficient.*

Minimisation for result 1 - strong subsidies:

```
Minimized Truth Table #2
File: SUBHIA08.QDM
Model: SUBHI = ECODEV + PRIVOWN + CORPORAT + EINHFORA
Outputs Minimized: 1
Method: Quine-McCluskey (Minimal)

  ECODEV CORPORAT EINHFORA +
  ECODEV PRIVOWN EINHFORA +
  ECODEV PRIVOWN CORPORAT +
  ecodev PRIVOWN corporat einhfora
```

<u>Identification of necessary conditions:</u>

None of the conditions can be regarded necessary, since each is observed either present or absent in the observed configurations. However, the dominance of private ownership is present in three of the observed minimised configurations, this is also true for “high economic development”, yet they coincide only in two configurations.

Discussion

Example 1 – Existence of Programmes Aimed Specifically at Mountain Forest Restoration

Among the factors taken into account for this analysis, a high population density (in mountain areas) seems to be the most distinctive causal factor, although it has to occur together with other factors, especially a rising trend in economic development and a history of industrial forestry. This becomes even more obvious in comparison to the causal combinations identified for the 0-cases. Among these, there also exists a combination of rising trend in economic development and history of industrial forestry (Vest-Agder) but, due to a very low population density, no land use conflicts are observed.

Based on the analysed cases, the question of land tenure seems to be of less importance; especially it cannot be claimed that a dominance of private land ownership is more likely to produce the need for public intervention.

The contradictory cases (Catalan Pyrenees and Graubünden) require further analysis to identify the reasons for this contradiction. First it has to be mentioned that population densities in these two regions, although both being defined as low (i.e., for the purpose of this analysis a threshold value of less than 100 inhabitants/km^2 in relation to inhabitable land was defined), differ significantly. The number of inhabitants/km^2 are 80 for Graubünden and 15 for the Catalan Pyrenees respectively. Also the fact, that the mountain areas which are part of the Pyrenees make up only a comparatively small part of Catalonia, situated along its northern border, whereas Graubünden is more or less completely situated in an Alpine environment, may be of relevance. Other variables additionally to the ones considered in this example might explain the differences: with the status of a canton, Graubünden has considerable political weight in formulating Swiss policy, and furthermore, most of Switzerland can be called rather mountainous. Other variables additionally to the ones considered in this example may explain the difference such as the political power in the national context or the degree to which other regions in a country share specific conditions.

Example 2 – Preference of Financial Incentives

Those cases in which forest authorities can rely on regulative measures to enforce forest policies imply a rather weak position of forest land-owners in the whole process of forest policy formulation and implementation, which is indicated by the absence of corporatistic structures. The strength of forest authorities in addition is indicated by the presence of “Einheitsforstamt”-type of management structures.

The diversity of the observed 1-results makes it a bit more difficult to draw conclusions from this analysis. Were it not for the two cases of dominating community-ownership (Graubünden and Trentino), the dominance of private land-ownership would turn out to be a necessary condition. On the other hand, the two cases of Pratomagno and Casentino are responsible for the fact that “high economic development” is considered to be NOT a necessary condition for the observed outcome “preference for financial tools”. In this context of course it has to be remarked, that in those regions the observed subsidies derive mainly from European Union (EU) funds.

For further analysis it will thus be necessary to consider additional factors, such as the different forms of public ownership (community, province/region, country) as well as the sources of funds and the specific nature of funded projects.

Conclusions

Based on the data used for the two analyses, the dominant role of socio-economic factors in the shaping of forest policies is evident. On one hand, the cause of conflicts as being ultimately a result of struggle for scarce resources becomes apparent in Example 1. Even though this may sound trivial, it has to be kept in mind that many of the observed policy measures[1] have aimed at physical aspects of the observed problems. Another result, worth mentioning again, is that the subjection of forest land to a land use in the interest of industrial regimes has taken place in many European countries since the Medieval Ages. This fact can also be claimed to be a causal factor of high relevance for the emergence of problems in mountain forest areas.

The choice of political instruments, too, reflects power structures in a society as well as its general political culture. More centralised systems tend to favour regulative measures, whereas decentralised structures tend to favour financial incentives. The latter also points to societies, which prefer consensus-seeking processes to more direct ways of conflict solution.

The variety of factor combinations, even if logically reduced, re-emphasises that policy analysis cannot provide *turn-key-solutions* for any given problem, since it is not possible to exactly reproduce every condition in an intended implementation. It is, however, possible to demonstrate causalities under observed conditions, which may then either strengthen or weaken established theories.

Abstract

In this paper we share some of the experiences we have had in integrating science and policy. We have been discussing this topic and developing appropriate roles for scientists and policy makers for several years in IUFRO.

In our paper we focus on the following five points:

1. Science helps policy makers create new visions and new possibilities for forest management.
2. Policy makers have visions too, and science can help convert their visions into reality.
3. Science helps bring organization and logic to debates among policy makers.
4. The role of a scientist and scientific processes are unique and should not be compromised.
5. Science administrators have a distinct role and it is not the same as the role of a scientist.

Keywords: Forest science, Forest policy

Science Can Help Policy Makers Create New Visions and New Possibilities

*) This paper is based on a paper by Robert Lewis, Jr. ("The Role of Science in Natural Resource Policy Development") presented at IUFRO Division 6 Conference, Pretoria, South Africa, January 8, 1999.

Science can help policy makers create a new vision and new possibilities for forest management. Scientists by nature are seekers of truth. Knowledge generated by scientists can spark new ideas among policy makers at various levels of influence, whether local, regional, national or international in scope. The knowledge generated by scientists is most useful when it is clearly understood and aggressively communicated to a broad audience. We will use a few examples to illustrate this point.

In the United States about 80 percent of the population lives in urban and suburban communities. The U.S. Forest Service conducted a major research study to empirically show the value of urban forests in reducing energy consumption by residents and improving overall environmental quality. Knowledge generated by forest scientists documented the annual savings homeowners could realize by strategically planting trees around their homes to reduce heating costs in winter and cooling costs in summer. The secondary benefits were aesthetic improvements to urban communities. Also, the net savings in energy consumption by homeowners could reduce fossil fuel consumption for heating and generation of electricity, thereby improving the air quality. Results also showed that cities could reduce the rate of storm water runoff through careful management of urban forests and well planned developments. Scientists are not policy makers, but clearly developed information or knowledge useful to policy makers.

This knowledge generated by forest scientists was communicated through a network of professionals, such as American Forests, and used by city officials in Chicago, Illinois; Atlanta, Georgia; and other major cities to change city planning practices to incorporate environmental values and long-term cost savings to residents. Clearly, the science helped city officials to see a new vision for urban planning.

The second example of science helping policy makers create a new vision for forest management deals with forest health. Millions of acres of forests in the United States are at risk due to decades of fire suppression and overstocking. Fuel loads are heavy with downed woody debris, underbrush, and too many stumps per acre. Some of the forests are so weakened that they are heavily infested by bark beetles. In most cases, simple prescribed fires alone will not solve the problem, because after the prescribed fires to clear up the underbrush, the stands are still too dense to support healthy growth. If nothing is done and droughts occur, catastrophic fires will eventually result. Consequently, soils will be damaged, streams could be polluted with siltation and/or mud slides and significant wildlife habitat could be deteriorated. Science provided the clear definition of this problem and offers possible solutions to policy makers. Research at The Forest Products Laboratory in Madison, Wisconsin, is providing options for policy makers to consider while dealing with this problem. The excessive stand stocking is composed of small diameter conifers with little or no market value in local communities. The research effort is aimed at taking a non-marketable raw material such as small diameter pine trees, and converting it into a new and marketable product. Policy makers are being presented with new research knowledge and technology to craft a new vision of restoring forest health while providing economic opportunity to rural communities. The research scientist should not provide the policy or select an action for managers, but can and should present knowledge in such as way that policy makers will see new possibilities for better forest management.

Science Can Help Convert Policy Makers Visions into Reality

Policy makers have visions too, and science can help bring their visions into reality. There is an old proverb which states that "they that are without vision shall perish". Clearly, our policy makers have vision. Research scientists and research administrators should recognize and respect the visions of policy makers. Science can and should play a major role in bringing reality to the visions of policy makers. Sometimes the policy maker's visions might be presented as a challenge to science. Science can and should respond to the challenge with the support of the policy makers.

Policy makers in many countries have articulated a very good vision on sustainable forest management. This is a very worthy vision for all nations. In fact, we have criteria and indicators for sustainability. In many countries, these criteria and indicators have received much interest from all sectors, including federal and state governments, industry and environmental groups. We are very proud of the role of the global forest scientific community in developing these criteria and indicators. IUFRO's Task Force on *Sustainable Forestry* has been very successful in this matter.

Policy makers in Denmark have agreed upon a vision of "doubling the forest area in a tree generation". This vision involves many challenges to forest science in trying to find a better decision basis for answering questions like: Which kind of forest should be planted where, for what purpose and how? Forest scientists have helped bringing this vision into reality by i.a. documenting the need for new urban forests within walking distance for recreational purposes, and by finding new better and cheaper methods of afforestation.

Policy makers, leaders of government, and citizens around the world have expressed concern about documented increases in atmospheric carbon dioxide and subsequent global warming. The political impact on the physical and biological assets of the world would be at great risk with significant long-term changes, flooding, extended droughts, species migration and perhaps disappearance, and major disruption of delicate ecosystems could be reality if trends are not stopped and/or reversed. Major policy makers, such as Presidents, Kings, and Prime Ministers have expressed a vision for long-term reductions in atmospheric carbon dioxide. Forests serve as a major sink for carbon dioxide and science can help policy makers realize their vision through development and implementation of new knowledge and climate change technology. The knowledge necessary to manage forests and forest resource utilization for maximum carbon sequestration is a possibility. Options for forest management policy and practices to help stop and reverse the trend is an achievable role for science.

As scientists and science administrators, we should feel obligated and honored to respond to the call for truthful objective and useful knowledge through credible science programs. We can and should always perform our work with the highest ethical standards and never shade the truth emanating from our scientific inquiry.

Science should never taint its credibility by reporting anything less than the well planned, executed, analyses of scientific results following the scientific process. In the long run, policy makers will appreciate the truthfulness of science reports, even if the reports conflict with the policy maker's vision.

Science Can Help Bring Organization and Logic to Debates Among Policy Makers

Science helps bring organization and logic to debates among policy makers. Forest management and public policy development are subject to intense debate at both international and national levels. Policy makers in both the career and elected positions are frequently placed in the middle of heated debates among interest groups and are expected to resolve the contentious issues. In forest management, clearly articulated long-term goals and a sound basis for achieving the goals are essential for problem resolution. Science can bring relevant and unbiased knowledge to the debate and help sharply focus the decision makers attention on the success factors for consideration.

Over the past seven years, the USDA Forest Service has moved toward large-scale ecosystem management and accelerated the involvement and use of science to make policy decisions and land management plans. Large assessments documents, such as, the Sierra Nevada Ecosystem Project and Interior Columbia River Basin assessment, have played a major role in resource management planning. The current state of knowledge is placed in the hands of decision makers with a number of options available for consideration.

A Management Plan for the Tongass National Forest in Alaska was recently completed after years of debate over earlier draft plans. Throughout the process, science played a major role in helping managers decide among several options. A science consistency test was developed and used to ensure adequate consideration of relevant science in the final plan. Consequently, the decision maker was able to present a defensible plan for public review and debate. Clearly, forest scientists played a major role, but they were never placed in the role of decision maker. They simply provided credible and relevant information in a timely manner.

The Role of a Scientist and Scientific Processes

The role of a scientist and scientific processes are unique and should not be compromised. The primary role of a scientist is to develop and communicate new and useful knowledge through the scientific process. The new knowledge is subject to intense peer review and must come across as credible. Hypotheses testing experimental design and statistical analysis are essential skills for good scientific inquiry. However, the greatest attributes of a scientist are imagination, thought process, self discipline, and the ability to communicate findings.

The scientist is not a policy maker nor is the scientist a forest management decision maker. However, the knowledge generated by scientists is the basic foundation for good management and policy decisions. In an ideal situation, scientists should collaborate with forest managers and policy makers. True collaboration includes intellectual dialogue where both parties add value to the ultimate outcome of a research project. Scientists need to acquire a clear understanding of management and policy issues before deciding what problems to solve through scientific research. Scientists must relentlessly seek the truth through experimentation and scientific inquiry. Ultimately, they must also report the truth even when the truth or scientific conclusions conflict with current policy and practices.

Science has the role of analyzing issues and identifying the critical success factors for achieving the desired outcomes in forest management. Science also has the role of bringing order to chaotic discussions/debates.

However, science does not and should not have the role of policeman of forest use and public policy debates. Success can be measured in the final outcome of policy development and, ultimately resource conditions on the ground. Resource conditions are inclusive of physical, biological and social attributes.

The Role of Science Administrators

Science administrators have a distinct role and it is not the same as the role of a scientist. People in purely science administration positions are no longer research scientists and should no longer feel compelled to shy away from policy debates. However, they should be careful to not compromise the objectivity and independent thinking of their scientists. Whenever science administrators enter a public policy debate, he or she should make it clear that views expressed are personal rather than the conclusion of a scientific study, unless such conclusions are quoted.

Science administrators are primarily responsible for enabling scientists to do work. Providing the support and funding for research are two essential function for science administrators. Equally important is the direction given to scientists on program development to address the larger policy issues faced by the nation, region, or state. Science administrators should also organize and enable teams to conduct collaborative research across disciplines and organizations.

We believe science administrators should also serve as a buffer between scientists and policy makers. The science administrators must protect the independent thinking and objectivity of scientists. A scientist without credibility is a liability rather than an asset in policy debates and legal appeals to management plans. Therefore, we place great emphasis on the science administrator's role in buffering scientists from the influence of policy makers.

Conclusion

We have significantly increased our understanding of how to integrate forest science into policy decisions over the past decade. We will continue to learn more in the years to come. There are no set of rules on how this process should work, but we have tried to present a set of general guidelines which are useful in any country. We encourage us to continue to share experiences from around the world in IUFRO. We believe we all have a common goal of helping better inform our policy makers and forest managers of the great benefits of science in resolving difficult forest management and policy problems.

Using Scientific Uncertainty to Shape Environmental Policy

Abstract

Environmental management and policy formulation are increasingly characterized by conflict. Issues concerning natural resources, land-use practices, and global climate change have been fraught with debate and indecision. Some argue that the required information and levels of certainty fall short of scientific standards for decision making; others argue that science is not the issue and indecisiveness merely reflects a lack of sufficient political willpower. In the case of global climate change, even such unprecedented efforts as the IPCC appear to provide insufficient scientific guidance to formulate decisive environmental policy. Nonetheless, science remains the foundation for informing, evaluating, and shaping policy. Yet perhaps more than ever, science is subjected to keen scrutiny; scientists are required not only to report but also infer and substantiate this inference in a range of decision-making contexts. One of the most difficult and confusing aspects of translating science to policy is the interpretation of scientific uncertainty as embodied in statistics, model output, and opposing scientific opinions. Whereas scientists are familiar with uncertainty and complexity, the public and policy makers often seek certainty and deterministic solutions. We assert that environmental policy is most effective if scientific uncertainty is incorporated into a rigorous decision-theoretic framework as *knowledge*, not ignorance. Policies that best utilize scientific findings are defined here as those that accommodate the full scope of scientifically-based predictions.

Keywords: Environmental policy, Global climate change, Uncertainty, Risk, Decision making

Introduction

The rate at which humans are altering the biosphere has increased dramatically in the past century (see Reischauer and Fairbank 1960, Vitousek et al. 1997, United Nations 1997). For scientists, policy makers, and the public at large, the inferences drawn from scientific findings concerning these alterations differ greatly. Even unprecedented efforts such as the Intergovernmental Panel on Climate Change (IPCC, 1990, 1996) appear to provide insufficient scientific guidance to formulate decisive environmental policy. Although the latest report from the IPCC was heralded as an unprecedented international scientific consensus, considerable scrutiny and debate concerning the validity and implications of its findings followed (see Shackley and Wynne 1996, Raynor and Malone 1997). This now-familiar pattern wherein policy lags behind science has been characterized as either a cautious response to uncertain predictive capabilities or as dangerous procrastination fueled by political and economic exigencies (New York Times 1997, The Oregonian 1998). Critics argue that scientists know too little about global change to warrant anticipatory policy formulation and assert that current information and their levels of certainty fall short of scientific standards for decision making. Others maintain that science is not the issue, and that the indecisiveness of policy makers reflects a shortfall of political willpower (Gelbspan 1997). In either case, science, policy, and politics are intertwined in the climate change issue as commentary on the recent withdrawal of Ford Motor Company from the fossil fuel-related Global Climate Coalition suggests (see Los Angeles Times 1999).

We discuss the means by which some dysfunctional aspects of the science-policy interface, herein referred to as the *science-policy gap,* can be ameliorated. Specifically, we suggest that inaccurate translations from science to policy derive in large part from an improper inference of scientific uncertainty (Funtowicz and Ravetz 1990). Generally speaking, whereas scientists may be familiar with the conditions of scientific uncertainty, the public and policy makers often seek certainty and deterministic solutions. In some cases, the social and cultural standards superimposed onto those of science may become critical constraints to effective decision-making (Table 1; Gunderson *et al.* 1995). This discussion underscores the need for adaptive management principles and a rigorous decision-theoretic framework as a foundation for robust policy formulation (Lee 1999, Walters 1986, 1997, Dovers *et al.* 1996).

Sources Of The Science-Policy Gap

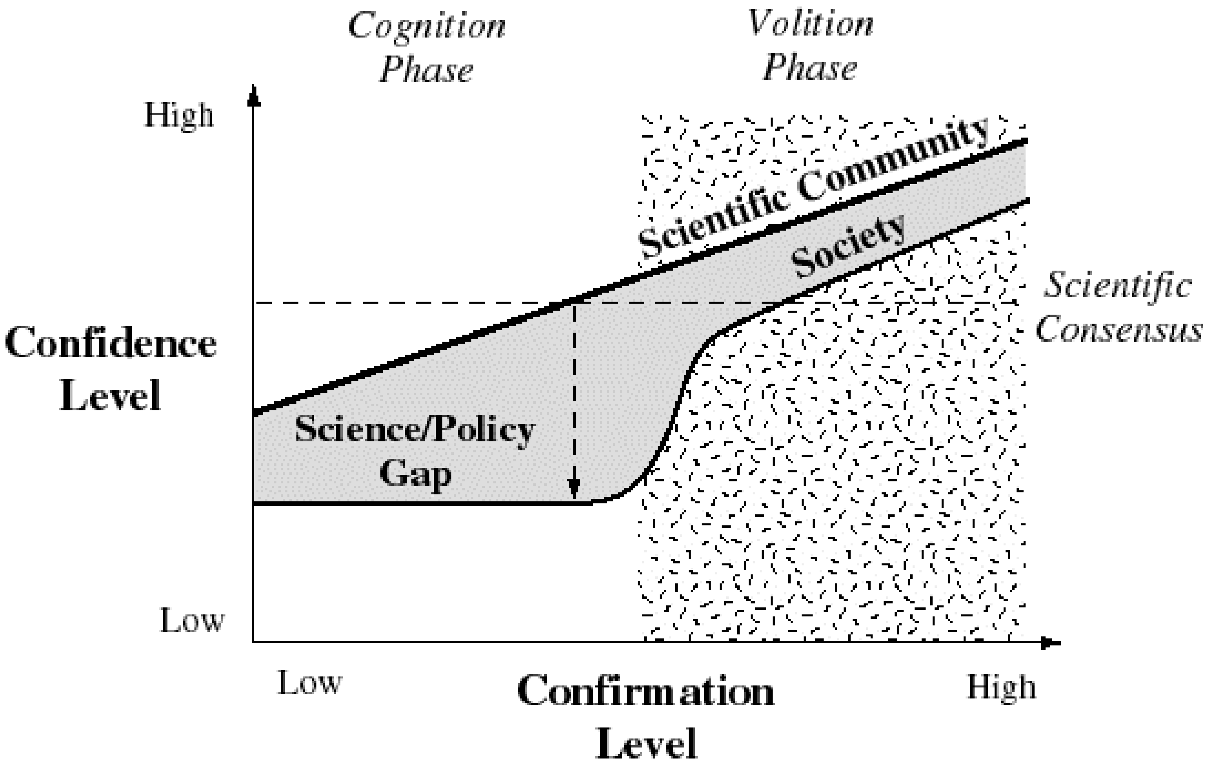
To better articulate the nature of the science-policy gap, it is useful to outline the life history of a scientific model from the perspective of Kuhn's (1962) paradigm shifts: the level of *confidence* in the model by the scientific community increases with the level of *scientific confirmation* (i.e., scientific activities that cumulatively corroborate the theory's hypotheses; Figure 1). As evidence accumulates to support the underlying hypotheses of a model, confidence in its representations increases (e.g., weather prediction models). In time, a model achieves greater standing as inferences concerning its representations are disseminated and debated in scientific literature and other fora.

Publication, citations, and merit awards, such as competitive grants, mark acceptance. At some threshold of accord within the scientific community, consensus emerges. However, the emergence of a so-called scientific consensus does not necessarily guarantee the level of certainty demanded by most policy makers (see Lemons 1996).

Table1: Characteristics of science and government (after Crerar 1987, cited in Manning 1988). The institutions of science and government are generally marked by very distinct behaviors and attributes. These differences contribute to some of the difficulties associated with transmitting and translating scientific information into policy and decisions.

Characteristics of Science and Government	
SCIENCE	**GOVERNMENT**
Probability accepted	*Certainty desired*
Inequality is a fact	*Equality desired*
Anticipatory	*Time ends at next election*
Flexibility	*Rigidity*
Problem oriented	*Service oriented*
Discovery oriented	*Mission oriented*
Failure and risk accepted	*Failure and risk intolerable*
Innovation prized	*Innovation suspect*
Replication essential for belief	*Beliefs are situational*
Clientele diffuse, diverse, or not present	*Clientele specific, immediate, and insistent*

Figure 1: Schematically, the science-policy gap is defined as the difference in levels of confidence for a given scientific finding expressed by the scientific community and society. Generally speaking, as confirmation of a model or scientific finding increases, the level of confidence in the finding increases. This relationship is portrayed as linear for the scientific community where the confidence level tracks the rate of confirmation. In contrast, the degree and rate at which social confidence and consensus develops for a given scientific finding may lag that of the science community due to a complex of social factors. In reality, the shape of this function will vary with individual scientific findings.



Even the constants of physics and chemistry are recognized as potentially inaccurate or imprecise, and subject to continual revision (Peterman and Peters 1997). In the case of large-scale simulation models, constants and parameters contain assumptions and uncertainties that propagate in uncertain ways to produce uncertain output. For scientists, this is business as usual (Raynor and Malone 1998, Morgan and Henrion 1990). For society and its decision-makers, however, such uncertainty may cast a shadow upon science itself (Shackley and Wynne 1996).

In contrast to the relatively formal process characterizing the scientific community, the acceptance of scientific results by a diverse public sector may differ markedly. We define the science-policy gap as the difference in levels of confidence for a given scientific finding expressed by the scientific community and society (Figure 1). In actuality, the broad categories of "public" and "scientific" comprise a vast array of individuals and groups having distinct histories, cultures, and belief systems that influence perceptions of non-human and human nature (Nader 1996). For example, because of their position within government, agency scientists may hold very different attitudes toward scientific uncertainty relative to their academic counterparts. An agency scientist has fealty not only to the scientific community, but also to a sometimes highly-politicized leadership that may be directly involved in defending policy. Paradoxically, the reluctance by scientists in such agencies to reveal ambiguities and uncertainties to the public out of fear of diminishing their credibility serves only to engender greater mistrust in the public (Walters 1997).

The science-policy lag is evidenced by the length of time required for a given scientific finding to assimilate into society. In part, the lag can be attributed to the rate of information dissemination. During this *cognition* phase, scientific information (e.g., effects of greenhouse gases) is disseminated by various media (e.g., Internet, science magazines, television). Realistically, the science-policy gap is more than an information gap; the extent to which society's level of confidence in a theory or model lags that of the scientific community depends on other significant factors.

The Role Of Cognitive Dissonance And Volition

Individuals and groups exhibit varied responses when faced with new information. If such information is consistent with extant behaviors and beliefs, it can be readily accepted and integrated. However, if the new information conflicts with behavior and belief, the resulting state is described as *cognitive dissonance* (Festinger 1957, Adams 1973). According to the theory, the inconsistency and psychological discomfort of cognitive dissonance can be reduced by changing one's beliefs, values, or behavior. Dissonance can be avoided by rejecting or avoiding information that challenge belief systems, or by interpreting dissonant information in a biased way.

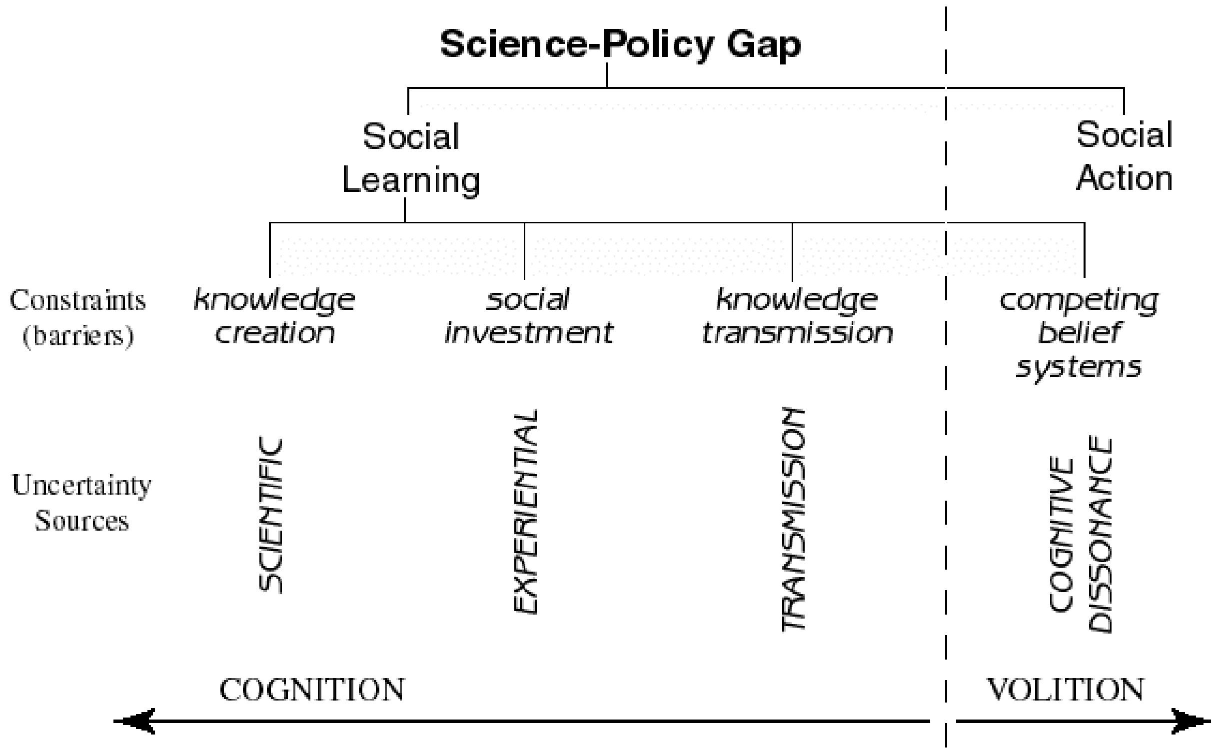
The role of cognitive dissonance can be observed in numerous contexts. One highly publicized case concerning public land use dramatically exemplifies the collision of differing world-views. As early as 1976, a landmark report was published forecasting future shortfalls of mature, harvestable timber independent of any consideration for the northern spotted owl (*Stryx occidentalis*; Beuter et al. 1976, Yaffee 1994)

In ensuing years, this shortfall, combined with improved technologies in harvesting and processing, and a vigorous raw materials export market, resulted in significant job declines. Yet despite this information, the issue continued to be misrepresented as an "owls-versus-jobs" issue, one that failed to acknowledge trends within the timber industry (Yaffee 1994). This type of oversimplification of complex issues and denial of "dissonant" information continues to embroil science in acrimonious public debates (USDA and USDI 1994, USDA 1996).

Dissonance between existing beliefs and new information may be shaped by a host of factors, all of which inhibit the rate at which scientific findings are assimilated into policy. In what we have called the *volition* phase of the science-policy gap, public debate around an emerging scientific consensus may derive from a combination of cultural, psychological, and economic interests threatened by the policy inferences of dissonant scientific findings. One obvious example is the tobacco industry, which is undergoing an onslaught of litigation decades after research confirmed the health risks of smoking tobacco. The volition phase of the science-policy gap may be described in many cases as social inertia borne not of a paucity of information, but of a complex, deep-seated resistance to change derived from numerous social, religious, and cultural sources (see Figure 2; Jasanoff and Wynne 1998, Lee 1993).

By definition, science is a provider of new information, and has always been cast in the dual role of both defending and attacking reigning paradigms (Schick 1997, Yearley 1996). For this reason, science will frequently produce cognitive dissonance, uncomfortable levels of uncertainty, and resistance in the body politic. Acceptance of its findings will be contingent upon attitudes and perceptions toward uncertainty and risk (Dorner 1996). In the case of global climate change, the challenge is to delineate appropriate responses to highly uncertain predictions of ecological and social crises in the absence of reliable estimates of risk (IPCC 1996).

Figure 2: The science-policy gap consists of related sets of constraints and sources of uncertainty.



The Role Of Scientific Uncertainty

Scientific uncertainty is typically characterized by statistical analysis (e.g., statistical confidence intervals, model output). Decision making in the sciences, such as that accomplished by hypothesis testing based on frequentist statistics, is usually performed according to consistent, though arbitrary standards (e.g., Type I error probability levels of 0.05). In less controlled situations, scientific uncertainty must be ascertained by other means, such as model prediction errors. Although a familiar companion to most scientists, there is little tolerance in the policy arena, as in most organized human activity, for the uncertainty and "ignorance" typically associated with complex systems (Briskin 1998). In contrast to the society that utilizes science to reduce uncertainty, "[d]oubt is clearly a value in the sciences" (Feynman 1998). Hence, the culture of science ends up in competition with the demanding exigencies of economics and politics, except when its findings are possessed of sufficiently high levels of certainty (Sims and Baumann 1974).

Nowhere is this truer than in the case of global climate change. The large-scale simulations presented in the IPCC reports portray a set of highly uncertain outcomes for various boundary conditions (e.g., global patterns of temperature extremes under fixed scenarios for CO_2 emission controls; IPCC 1996), which are themselves based on uncertain estimates of model parameters (Shackley et al. 1998). The IPCC reports represent both a wealth of accumulated knowledge *and* uncertainty. Unlike more tractable, data-rich scientific problems that readily yield understanding from statistical analyses, science in the IPCC report appears to confound policy makers who prefer more "certain", contained estimates of risks. The presence of uncertainty associated with climate change science has been interpreted as an undermining of scientific authority and as a hindrance to policy (Shackley and Wynne 1996, Martin and Richards 1995).

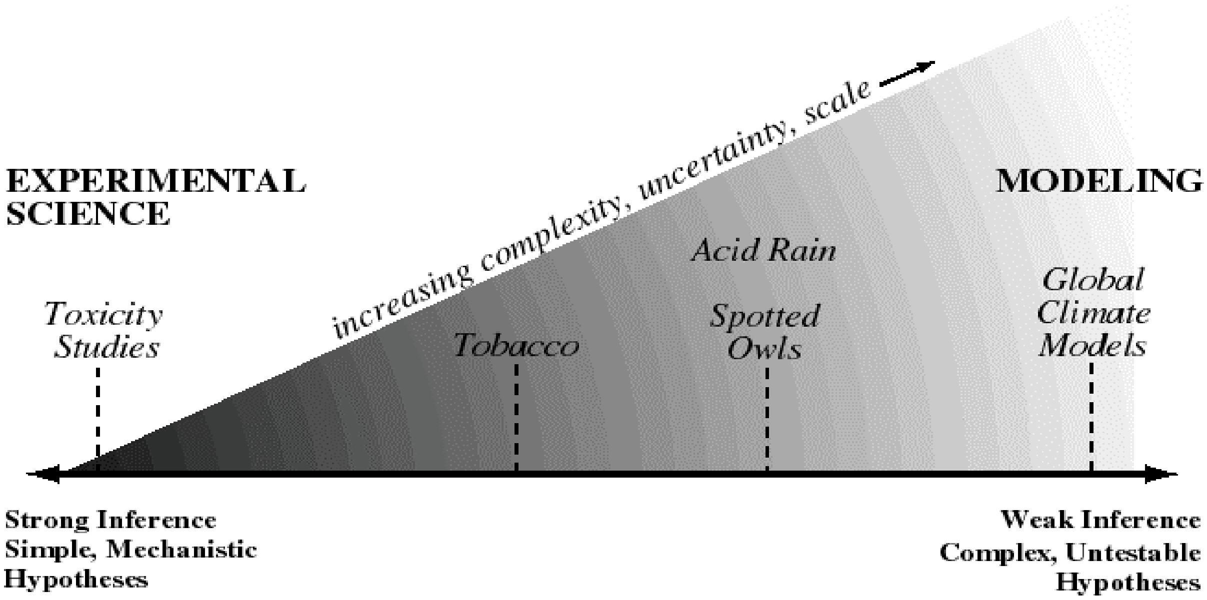
The uncertainty (or the lack of confidence in scientific findings) perceived by the public and policy makers can be grouped into two categories. First, there is uncertainty about the uncertainty. The public is puzzled by debate within the scientific community when it surfaces in the media (e.g., compare Schlesinger and Jiang 1991 and Risbey et al. 1991, Martin and Richards 1995). For example, in a recent Congressional hearing on global change, when asked about an immediate, "act now" versus a "wait and see" policy, one scientist stated that "[m]any would argue that we know more than enough…to include it at the top of the list of issues deserving serious consideration by policy-makers" (United States 1995; pp. 1127). However, a second scientist in the same hearing wrote of his concern about the continuing increase of CO_2 in the atmosphere, claiming that "[w]e have demonstrated no acceptable scientific basis for predicting catastrophic or near catastrophic effects that would council against a wait, think and see pattern" (United States 1995; pp. 1135). Such diversity in opinion may signal confusion and ignorance, thereby supporting a rationale for inaction. As one major petroleum corporation states, "Let's face it: The science of climate change is too uncertain to mandate a plan of action..." (New York Times 1997).

Uncertainty also plagues the interpretation of science in second way. For many, the significance of scientific findings is irrelevant or incomprehensible to the exigencies of everyday life. A lack of familiarity with scientific methods hinders a ready translation of science into personal choices (Smith 1996, Joyce 1995). Underlying this phenomenon are profound differences in perceptions of space and time of the type that characterize different cultures (Deloria 1995, Abram 1997). For individuals in post-industrial societies, the vast spatial and temporal concerns of science lie far outside their experiential domain of short-term, local events (Catton 1980; see Figure 3). Not surprisingly, these differences in are reflected in the relatively short cycles of funding and elections that drive policy formulation and decision making and preclude effective treatment of long-term crises in the natural world (Gunderson et al. 1997). The problem is exacerbated by the intricacies and inaccessibility of numeric models, the primary tool for investigating large-scale, complex systems (Oreskes et al. 1994). In contrast, traditional experimental science generally retains credibility, because it is conducted at scales familiar to most individuals, or at levels of complexity where scientific inference is rarely disputed (e.g., the role of micro-organisms in disease, tidal predictions; Figure 3).

Conclusions: Bridging The Science-Policy Gap

We have asserted that the normative discontinuity, or gap, between the scientific community and policy making institutions becomes increasingly dysfunctional over high risk issues characterized by large uncertainties which derive from complex, unfamiliar spatio-temporal domains. Increasingly, these conditions describe more and more environmental issues. The present attitude that "faster and better" science is sufficient ignores the source of the science-policy gap. The idea that greater certainty can be obtained and allow for more "certain" conditions for decision making with better and faster science is based on the erroneous supposition that uncertainty is finite. This attitude is in direct contradiction with the nature of scientific inquiry (Feynmann 1998). Whether or not, they continue to be science-based, environmental policy formulation and decision making will be accomplished under conditions of uncertainty.

We propose three general approaches for bridging the science-policy gap. Under the assumption that shared understanding of science and its implications will attenuate the polarity between science and society, the first, and most familiar approach is to directly enhance public confidence by increasing communication (Dovers *et al*. 1996).



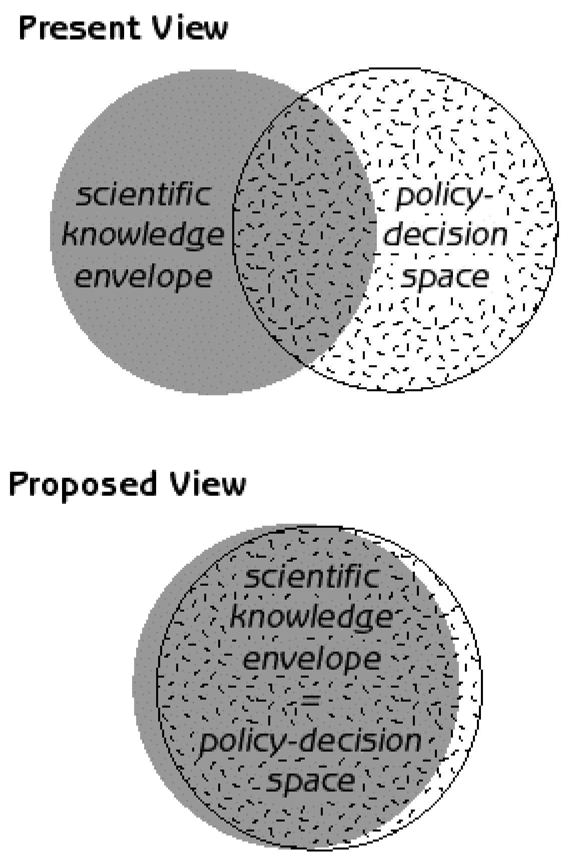
. Figure 3: Science uses a combination of data, theory, and models depending on the particular problem at hand. Increasingly, models are employed to address multivariate and large-scale environmental questions such as global climate change. The strength of inference for various scientific activities will differ; generally speaking, there is less confidence in understanding large-scale, complex systems than confined experimental systems described by simple mechanistic hypotheses. Issues such as global change, involving large-scale, complex systems, are intrinsically more uncertain

There are innumerable examples of the effects of science education and communication on changes in policy via the public. For example, many policy makers and legislators rely upon the views of concerned citizens, scientists, and lobbyists to formulate scientifically-valid law and policy (Wynne 1995). Since the 1960's, most national environmental legislation has been prompted, and to a great extent, shaped, by increasing public awareness of the scientific aspects of environmental degradation. Citizen groups are increasingly organized and well-versed in the scientific complexities of environmental issues (Dunlap 1992, Steel and Lovrich 1997). As such, they have become increasingly litigious in challenging the practices of government agencies. With the resulting judicial standoff, there are calls for broader participation and collaboration in environmental policy and decision making (e.g., Committee of Scientists 1999, USDA 1999, Shindler and Cheek 1999). When scientists and managers inform and involve their public constituencies in meaningful collaborations, the policy outcome is more likely to be consensus-based and less prone to legal challenge from disaffected stakeholders (Spinos, pers. comm., Johnson and Campbell 1999).

A second possible approach is to increase confidence by increasing the rate of scientific confirmation. This approach reflects the attitude that scientists can decrease uncertainty sufficiently to allow more precise estimations of risk for policy makers. However, in the case of global climate change, the IPCC (1996) report states that perhaps the greatest weakness in trying to formulate policy derives from a demonstrated inability to predict advances in science and technology. This may doom "wait and see" policy options; science, with its large, complex simulation models of possibly chaotic systems may never produce the needed levels of certainty (Oreskes *et al.* 1994, Casti and Karlquist 1991, Abel 1998).

To account for these seemingly inescapable uncertainties, we propose a third alternative to bridge the science-policy gap: realign the definition of scientific uncertainty as perceived by the public and policy makers with that of the science community. This means that scientific uncertainty must be regarded in the policy arena as it is in scientific circles --- as information for hypothesis building, experimentation, and decision making. In effect, the conflicting models and statistical confidence levels that represent the bounds of scientific knowledge would delimit the scope of a flexible science-based policy (Figure 4). This strategy would recognize that: (1) science and knowledge are intrinsically uncertain, with new information continually altering our perceptions and beliefs; (2) decisions based on scientific information must be made in a context of uncertainty; and (3) faster and better science as an adequate basis for policy formulation is inconsistent with the nature of scientific inquiry and resilient policy formulation.

Figure 4: Scientific information is best represented by policy if the entire envelope of relevant scientific knowledge (including uncertainty) is encompassed. This translates to formulating a policy that spans the range of scientific opinion that has undergone the process of peer review.



This perceptual shift requires policy makers to adopt a rigorous decision-theoretic framework and learning approach to policy formulation in accordance with tenets of adaptive management (e.g., see Lee 1999, Walters 1986, 1997, Gunderson et al. 1995). While there are significant obstacles to achieving such a rapprochement between science and policy (see Walters 1997, Lee 1999, Shindler and Cheek 1999, Johnson and Campbell 1999), new technologies and approaches to improve environmental planning and decision making are emerging (e.g., Lee and Bradshaw 1998, Borchers et al. in review, Reynolds et al. 1996, Berg et al. 1999). They will be most effective when utilized to enhance social learning that is linked with social action (Walters 1986, Gunderson et al. 1995). A corollary implies that scientists need to effectively articulate the true nature of science to the public and policy makers. Moreover, activities such as monitoring, designed and performed in partnership with citizens, science, and managers, can enhance public and institutional learning, especially if integrated into a statistically-sound framework for decision making (Lee and Bradshaw 1998).

Finally, as demands for more predictability have increased, the science community has become risk-averse. The charged atmosphere surrounding environmental issues threatens to obfuscate and undermine valid scientific inference (Ludwig et al. 1993). Without the freedom to engage in self-examination and self-doubt, scientific quality and integrity are diminished. This freedom, and uncertainty, is the essence of scientific inquiry.

Abstract

Despite the great social, economic and environmental diversity in countries of Africa South of Sahara (SSA), forestry research issues and advances are quite similar. This is partly influenced by historical facts relating to forest resource ownership and management. In most countries, governments own and manage forest resources. Forestry research institutes are in many countries very tiny departments or units tucked under huge ministries or agricultural research organizations. Their visibility, much less their effectiveness in that position is barely significant, because they are also poorly staffed and financed.

The little available forestry research capacity is poorly managed. The few competent researchers are increasingly getting involved in administrative functions and also looking out for greener pastures. Economic policies imposed by global financial institutions constrain the recruitment of young scientists to take up forestry research now and in the future. Although universities are by far better resourced, their efforts are rarely linked with national research issues. They seem to operate independently, far removed from real world issues.

Through the intervention of some global stakeholders, some research institutes have developed their research agendas, but these have largely remained on the shelf for lack of resources to implement them. Most on going work is largely donor–driven. There is a serious gap between forestry research and development. Research institutes do not have the capacity to extend their findings. At the same time, they are not properly linked with agricultural extension services or NGOs in order to get their messages to stakeholders, especially farmers. This delimits the usefulness of the little that could trickle from forestry research.

In this paper, we have briefly discussed the above-mentioned issues, and made some recommendations. It is clear thats SA countries and the global community have a role to play to redress the situation. We think that unless affirmative action is taken SSA and the world stand to loose the opportunity to benefit from SSA forestry resources.

Keywords: Forestry research, Sub-Sahara Africa.

Introduction

To talk or write about Africa South of Sahara (SSA) as a region is very challenging because it is practically impossible to capture the region's great diversity, as demonstrated in the different cultural backgrounds of its people, ecology, economic development and socio-economic policies, among many other attributes. Many statements made in this presentation are of a very general nature and do not refer to specific individual countries or sub-regions. In this presentation we reflect on the growth of research in SSA as well as the potential for its future growth in a forestry sector which is rapidly becoming unbounded.

In SSA, formal forestry practice was for a long time a tree and forest focussed mission, largely serving the timber-based industry. Soldierly foresters kept the local people away from the forests taken from them, initially by colonial governments and later by post-independence governments. The gazzetement of forest resources as government property represented some of the first policies on 'nationalization' of assets Africa had ever experienced. Even today, practically all-independent African states endowed with significant natural forest resources have large tracts of such 'nationalized' forests under their control. The policies that guided the development and use of such resources largely shaped the development of forestry research in Africa. Some African countries have not managed to effectively disentangle themselves from the shortcomings of such policies in re-orienting their focus and emphasis on forest research.

The reality for all time has been that forestry in many SSA countries is inextricably linked to agriculture and therefore to food security. Local communities interact heavily with forest resources, primarily for life sustenance (food, water, medicines, fodder, and wood fuel), but also for cultural and religious purposes. There are also those who extract products for sale to generate income. Arnold and Townson (1998) estimate the number of persons in SSA that generate income from natural forest based products at about 15 million. Products such as fruits, honey, medicines, cane, bamboo, building poles and thatch grass are commonly extracted for this purpose. Previously known as 'minor forest products', these products in fact support the livelihoods of far more people than do products based on industrial timber. However, as they generated little revenue for state coffers, virtually no resources were committed to sustaining their supply.

Until recently, and most probably due to threats arising from desertification and deforestation, as well as concerns from environmentalists and the international community, SSA research revolved mainly around industrial forestry production both at primary and secondary levels. Very little research has been directed at meeting the needs of local communities.

The main shortcoming of this approach to development was to ignore the potential to improve the welfare the majority of the forest stakeholders using these resources. For example, critical areas where information continues to be scarce include, but are not limited to:

- The mutual relationship between the local communities and tree and forest resources.
- Enterprise development at local community level based on tree and forest products.
- Linking forestry with other land based activities like agriculture, livestock, and wildlife, in household production.
- Understanding and managing ecological systems with low forest/tree cover, e.g. semi-arid regions and heavily populated areas.
- Potential for indigenous knowledge in forest management.
- Steering the production of international public goods and services to also benefit local communities

Certainly understanding and incorporating these and other issues in forestry would have required a drastic departure from the traditional forestry practices, because these issues bring to the forefront the welfare of the local people, acknowledging them as stakeholders and partners in managing the resource. While the definition and content of forestry have been changing very rapidly in the recent past, traditional forestry management practices have moved very slowly in response. With the rapidly increasing number of stakeholders and diverse demands, it is now difficult to know where forestry begins and ends. There is increasing recognition that we are dealing with a very porous and unbounded sector. Forestry is increasingly being viewed as integrated natural resource management. The range and interests of stakeholders and 'players' in the 'new' forestry game is therefore orders of magnitude larger than previously. The knowledge requirements for managing such a vast sector are immense. While there are very many players and of different professional backgrounds, what professionally goes wrong in forestry is almost always ascribed to foresters. Paradoxically there is no other sector that in recent times has been so accommodative of others. This has been demonstrated by the level of consultation characteristic of the 1980s and 1990s when many of these countries formulated their National Forestry Action Plans/Programs, also known by other names like Forestry Master Plans.

So if the sector has opened its doors to so many 'new' stakeholders, why is forestry research lagging so far behind? Is it possible that the new stakeholders have either an extractive mentality or a conservationist and protectionist view of forestry with an unwillingness to invest in generating new knowledge for improving management of these resources? In this paper we highlight some key factors that have shaped and continue to shape forestry research in Africa, and how forestry research institutions can position themselves to address an ever-changing research agenda. The issues selected for this presentation are:

- Set up, growth and stability of institutions and research programs
- Managing national forestry research capacity
- Forestry research, development and extension continuum
- Collaboration between national, regional and international institutions.

Some national governments and donors have supported the revision and reformulation of research agendas, both at national and sub-regional levels. These efforts continue to be reinforced by new and emerging events in forestry like the Forestry Action Plans/Programs and several international agreements and conventions to which these countries are signatories. Forestry departments/services in many SSA countries are in a continuous state of planning and revising plans. Some of the key areas under consideration include:

- Understanding the local communities and how they relate to tree and forest resources
- Methods to conserve tree forest genetic resources
- Marketing forest products and services (other than timber)
- Integrating forestry with agriculture, for instance, understanding problems and opportunities of agricultural expansion at forest margins
- Wildlife management and user rights in forest areas
- Dry season fodder for livestock, especially for pastoral nomads
- Role of trees and forests in agricultural production, agroforestry
- Catchment forestry and water management
- Wood energy development
- Improving quality and life of timber in rural housing
- Understanding and managing ecological systems where trees are scarce, e.g. semi-arid regions

There is no doubt that forestry researchers are re-awakening, to focus some of their work on local community needs. In the discussion, we have not separated internal from external factors that affect forestry research. Shortcomings in research funding are mentioned at various stages, although we acknowledge that this topic deserves a more comprehensive treatise.

Set Up, Growth and Stability of Institutions and Research Programmes

Centralized forestry administration emerged during the colonial period and has largely been adopted by independent governments. A number of legislations were then put into place to guide selected forestry activities and the functioning of the forestry administrative units which are still operational today. For example, in Malawi a forestry unit was established in 1891 as part of a broader Scientific Department and the unit was to focus on planting Mlanje cedar, with field experimental work (research) on this species carried out in Zomba (Kowero et al 2000). The initial forest policies in Kenya were dictated by the demand for firewood for the Kenya-Uganda railway at the beginning of the last century, while in the Sahel region forest practices between 1930 and 1960 were guided by the desire to protect land where groundnuts (an important crop) were grown (Goumandakoye, 1996). Forestry institutions have for a long time been managed as small sections in ministries responsible for agriculture, natural resources or environment. As a result, not only is forestry research marginalized but the forestry profession as a whole is poorly staffed and financed.

Efforts to restructure the sector and also allow for growth of some of its sections saw research and development become some of the components of government forestry sectors. Forestry researchers as well as their colleagues in forestry development continue to be on government payrolls irrespective of the amount and quality of their output and demand for the same. With time, these two sub-sectors have become so autonomous in some countries to the extent that many related institutions, like universities, rarely link their plans effectively with one another or with forestry developments. This is confirmed by the observations made by Kowero and Spilsbury (1996) and Spilsbury et al (1999).

Some forestry research in SSA has been demand driven. Unfortunately such demand has been largely localized within the industry. For example in East Africa, considerable plantation research precluded the establishment of industrial forest plantations, because such plantations were seen profitable. This is also true for South Africa. In many other SSA countries with good and reasonable supplies of natural forests for industry, research focussed on properties of tree species for the industry. In countries like Ghana, Nigeria, Cameroon and Cote d'Ivore research in the lowland rain forests aimed at improving the silviculture and management practices in such forests, largely with the industry in mind.

So the industry created a direct demand for research for its products and exerted an indirect demand for research on its raw materials. The volume of forestry research done in SSA and for specific academic interests during the colonial period was scanty, largely because there were few advanced academic institutions like universities. Hence development of research took off on a small scale and at a very slow pace.

The independence period was marked with the advent of advanced institutions of learning, an increasing volume of forestry related demands, and problems related to desertification and deforestation. The portfolio of forest departments therefore increased, from an almost exclusive focus on forest harvesting and protection to inclusion of some social, economic and environmental aspects. Increased donor support also made it possible for national governments to address a broader spectrum of forestry and related issues, especially reformulation of national forestry policies, and strengthening and initiating new institutions to deal with forestry. Faculties and departments of forestry were established at universities and a few autonomous forestry research institutions have emerged.

As the mandate of the forestry sector expands, and with increased resources, forestry could have the potential to address a myriad of demands and problems from a larger pool of stakeholders. The demand for information is increasing. National governments and the international community have put up infrastructures to address the increased information needs, and this is leading to some growth in forestry research and training in Africa. However, this infrastructure continues to be severely weakened by ongoing economic reforms in practically all SSA countries. Generally speaking, the effects of the reforms include stagnation or decline of research in some countries. The sustainability of long-term research in some institutions is increasingly becoming questionable. Preference appears to be given to short duration type of projects, which are preferred by many funding agencies. Engagement in consultancies is increasingly becoming a coping mechanism, not only to the institutions but to individual researchers as well. Research therefore risks being driven largely by choices made by the funding institutions and not national research priorities. Availability of funding alters priority in implementing national research agendas. For example, if no donor funding is forthcoming for critical/high priority research issues, institutions might tend to continue to survive by working on low priority issues that have funding available.

The degree to which these institutions have been affected by these economic reforms varies greatly within and between countries in the region. Those that have strong links with the industry (like some in South Africa) are still managing fairly well. The forestry faculties and departments at universities are still operational, albeit with reduced real government funding in some countries.

Added to this predicament is the fact that in many SSA countries research institutes are structurally and operationally separated from universities. Their mandates are quite clearly distinguished as research and education/training respectively. This dichotomy tends to deter the universities from undertaking serious problem-oriented research. Instead, the vast majority of graduate student research is for academic ends. The net result is that few forestry problems are addressed or solved, and policy makers find no incentive to put more funds into forestry research in these institutions.

Further, the rather small size of institutions in many African countries does not allow for the development of the critical mass of scientists in many fields. For example, in North Africa, forestry research is conducted mainly by non-forestry departments at universities and research institutes. In Egypt, the Desert Development Centre of the American University of Cairo conducts forestry research. The Centre has done much work on dry forestry, but the research agenda is limited (El-Lakany 1994).

The industrial side of forestry in many of these countries is still weakly developed. In some countries the industry is in the process of changing hands from government to the private sector. It will take time before a firmly established private sector can create sufficient demands on forestry research and allocate significant resources for that. The present societal and environmental concerns that require research are gradually shifting from the domain of governments to the local communities, NGOs and the international community. A clear picture has yet to emerge as to how these stakeholders can be mobilized for effective research funding. Forestry research institutions should therefore realign themselves with the evolving forestry scenario. This means developing new capacities to address emerging problems and retraining their staff on the same. Closer collaboration among relevant national institutions and even mergers do not only increase capacity to address research problems, but increase diversity of skills within institutions, as well as their potential to attract resources. An institution that continues with a strong tree-forest focus will find it difficult to operate in this increasingly people-environment forestry world, and is likely to become irrelevant.

Managing National Research Capacity

Africa's investment in forestry education is the lowest in the world. In a continent with a forest cover estimated at 520,237 thousand hectares of forest in 1995 (FAO, 1999) and a population of 730 million people, there are only 15 professional level schools of forestry that have an annual output of at most 400 forestry professionals (guesstimate). Training outside the continent is expensive and is increasingly becoming limited. National governments and donors have largely supported these institutions. In many countries governments have also been the major employers, largely because the private sector remains small and the forest estate is largely under government. However, on-going economic reforms are forcing governments to decentralize many of their responsibilities in forestry to the private sector, NGOs, local communities, and whenever possible to the international community. Consequently the legitimacy for governments as major financiers of these institutions continues to decline, as well as the capacity for governments to employ forestry professionals.

Forestry research institutions need to strategize quickly, taking these changes into consideration. There are continuing changes on the research agenda and clients for research results also keep changing. This calls for retraining of research staff and new ones to address new and emerging issues. According to Kowero and Spilsbury (1997) about half of the forestry and related research manpower in the Southern African Development Community (SADC) need postgraduate training to equip them with requisite research skills. Spilsbury et al (1999) report that such training is required for about one third of the research manpower in West and Central Africa. Some SSA countries have very small pools of young forestry scientists. Those with adequately trained scientists (MSc. and PhD. levels) and reasonable research experience (at least 4 years) form the majority (about two thirds in West and Central Africa and half of the total in SADC). There are also problems of capacity mobilization. Measures to reduce government spending as a means in economic reforms have led to reduced or complete halting of staff employment in many government departments. In forestry research institutions the reforms have and continue to constrain recruiting young researchers. Consequently SSA is experiencing a serious imbalance between young and less experienced (but trainable researchers) on one hand, and well-trained and experienced researchers on the other. As the latter group gradually retires from forestry, moves to greener pastures or assumes more administrative responsibilities in and outside the sub-sector, there will be no adequate and suitable replacements. There is therefore, an impending vacuum of forestry expertise.

The capacity to address present day forestry and related research problems is dispersed in several institutions in these countries, and does not always reside in the traditional forestry research institutions and university forestry faculties and departments. These countries have to come up with strategies to consolidate and mobilize this capacity. At present the forestry institutions have demonstrated increased ability to interact with relevant national institutions, but the level of interaction between them and universities, where most of this capacity (human and equipment) resides, is low (Kowero and Spilsbury 1997). Such interaction is mostly in terms of training and thesis research. The 15 universities offering professional and postgraduate education in forestry have at least 250 qualified educators/researchers. Due to various reasons, including lack of funds and institutional policies, less than 20% of these highly qualified forestry experts are engaged in any research.

Forestry Research, Development and Extension Continuum

Many countries in SSA have the core forestry activities, namely research, development and extension under the direction government. Under this arrangement, development activities tend to take the lion's share of resources. Extension is given minimum emphasis, and is at times undertaken as part of other rural extension services, and by other sectors. Forestry extension is a very recent challenge, and has quite limited resources. Most resources are in the hands of NGOs. Therefore, the few research innovations in forestry continue to lack reliable outlet channels. The public is therefore often unaware of what is going on in forestry research. Even at universities where such results could complement teaching material, the packaging of such information into documents for use by students is very problematic.

Recently, governments and NGOs have gradually given considerable weight to forestry extension. Many NGOs have created awareness of key forestry issues in local communities, in addition to equipping the communities to embark on forestry and related projects. NGOs, and especially the local/national ones, are largely missing in forestry research.

With the advent of more decentralized government structures operating in a market economy, many countries fail to bring together the various stakeholders and direct their efforts towards shared goals. Governments have, and are continuing to decentralize forestry development to the private sector, local communities and other stakeholders. They therefore become increasingly less of clients for some types of research output, and therefore lack the incentive to support such research from a cost/benefit perspective. The stakeholders who take over some of the government responsibilities are scattered and lack the cohesion to make them stand as a unit and with one voice. In such a manner their collective demand for research and extension information is not usually felt strongly enough, let alone their ability to collectively finance research and extension services. The rural communities stand out very prominently in this respect.

Research, development and extension remain compartmentalized in many countries, and rarely does research feed into development and vice versa. Kowero and Spilsbury (1997) report that forestry research institutions in Central and West Africa allocate less than 10% of their budgets on interactions with user groups of their research results. In a parallel study Kowero and Spilsbury (1997) report that in the SADC countries about 17% and 28% of the institutions they surveyed allocate more than 20% of their budgets and staff time, respectively, to extension activities. The universities were found weaker in this respect as compared with other institutions. And yet the universities have the bulk of qualified researchers. The low interaction with users of research results raises questions on the relevance of research undertaken by many research institutions in SSA, as well as how they formulate their research priorities and programs.

With an ever-growing number of stakeholders, the challenge to many African institutions is how to effectively harmonize all research relevant to forestry within their individual countries and establish mechanisms for its coordination. In a market economy environment, research will largely be demand driven. The government and the private sectors have the capacity to pay for some of this research. Presently private sector research in forestry is missing in many of these countries. However, as governments continue to put more forestry responsibilities on the poor local communities, their research and extension demands must be planned for. Who shall do this and how? Further, the international community has to be mobilized for funding research that shall sustain the availability of international public goods and services. Again who shall do this and how?

Another research-development dilemma is uptake of research results, and especially in new fields. Often many institutions come up with results worth experimenting with. But then who should mobilize investment for such ventures? One case in point is that of adding value, through processing, packaging, and marketing, on some non-wood products that research has established their properties and markets, among other attributes. The absence of this linkage continues to rob those dependent on these resources of additional incomes and creates disincentives to care for such resources. The usual explanation in such cases is that research institutions have no mandate for production, while on the government side the common reason is that forest departments cannot go into business. The development of an enterprise capacity at the local community level will give more credit to research on some of the 'minor forest products'. However, how to create such capacity still eludes Africa.

The forestry sector is expanding very rapidly, overlapping with other sectors and creating new areas and disciplines like agroforestry. In many countries, demarcation of responsibilities for the emerging aspects the sector has not been done. While there is a huge potential for forestry to contribute to rural livelihood and development, the poorly equipped forestry departments are not able to cope with the challenges and responsibilities of bringing this about. Rural development planners and especially agriculturists have to step in and create conditions for alternative livelihood support systems that also have the potential for reducing pressure on dwindling forest resources. The roles of various sectors in rural development need to be clarified. In the absence of such a strategy, even with excellent forestry research the contribution of forestry to development is doomed to remain diffused and weak.

Collaboration Between National, Regional And International Institutions

The case for collaboration between national institutions has already been made. This section examines briefly collaboration between national institutions on one hand, and regional and international institutions on the other.

The world scene is changing very rapidly, and approaches to economic development and security have led to the upsurge of a number of groupings in many parts of the world. In SSA we have the Economic Community of West African States (ECOWAS), the East African Community (EAC), and the Southern African Development Community (SADC), as major economic groupings. Some of these groupings are moving very rapidly in integrating the economies of the constituent member countries. Also within them some sectors of the economy, like trade, security, and communications have moved faster than others have. The forestry sector lags very much behind in this respect.

Consonant with regional economic integration, research has also followed suit and SSA has three main sub-regional research organizations (SROs) namely Association for Strengthening Agricultural Research in Eastern and Central

Africa (ASARECA), Conference des Responsables de Recherche Agronomique en Afrique de l'Ouest et du Centre (CORAF), and Southern African Centre for Cooperation in Agricultural and Natural Resources Research and Training (SACCAR). There is an apex research body known as Special Program for African Agricultural Research (SPAAR) that is presently transforming itself into Forum for Agricultural Research in Africa (FARA). The change has arisen mainly because SPAAR is a World Bank supported organization and with its head office in Washington, whereas FARA is an indigenous organization, a brainchild of the SROs, and is to be housed within Africa. That notwithstanding, the agendas of the SROs and the apex organizations have very little to do with forestry research. All these organizations have a component of natural resources research, but this is largely restricted to soil and water issues. Very little trickles into agroforestry and practically nothing to forestry. SSA cannot continue to be represented by such organizations in matters of forestry research as long as this focus prevails. In fact SACCAR has shed off the little link it has had with forestry research in SADC, denying the SADC countries effective forestry representation at sub-regional, regional and continental levels. Either SPAAR/FARA and the SROs give significant weight to forestry and acquire forestry manpower and other resources at their establishments to address forestry research issues, or Africa has to establish other mechanisms for making its forestry case at sub-regional, regional and continental levels. The apex body and the SROs do not have forestry manpower in their establishments, and this makes their agendas hinge on food and cash crops.

Recently we have seen efforts to establish sub-regional networks on specific forestry research themes and tasks. Two such networks are the Forestry Research Network for Sub-Saharan Africa (FORNESSA) coordinated by FAO, with EC funding, and the African Forestry Research NETwork (AFORNET), coordinated by the African Academy of Sciences in collaboration with International Foundation for Science, and with Sida funding. FORNESSA is geared at strengthening forestry research institutions while AFORNET builds the capacity of individual scientists. The networks are still in their infancy and with some teething problems. They are struggling to secure support and identity so it is too early to judge their performance. SSA countries and their regional groupings should be mobilized for resources to support these networks. IUFRO as an international network with vast experience should also continue to strengthen these young networks with resources and expertise.

Many international institutions, including the CGIAR centers, work in collaboration with the SROs in identifying areas for research collaboration and support. The SROs being largely agricultural have not managed to promote the forestry side with such institutions, hence the little or scanty resource mobilization, by the SROs, for forestry over the years. Forestry oriented institutions like CIFOR, ICRAF and some northern institutions, have largely gone into partnerships with individual country institutions at their own initiative or that of the individual country NARS, and not necessarily through their mobilization by the SROs. The national forestry institutions collaborate with international institutions much more in matters of training their staff and less so in forestry research. With the forestry issues continuing to be scanty or absent on the agendas of meetings between the SROs and the international institutions, forestry research will remain marginalized at both sub-regional and regional levels. Some of the international institutions and donors have chosen to work with the SROs in taking up or funding regional activities, forestry included.

There is therefore an urgent need to educate the international community on the inability of the existing SROs to represent any sub-region in SSA in matters of forestry research. At the same time SSA should promote new and emerging forestry regional units to take the lead in negotiating with the international community on forestry research. For example, the SADC-FSTCU can assume such responsibility in SADC and not SACCAR, a SRO that has already abandoned such a mandate. In December 1999, the Association of Forestry Research Institutions in Eastern Africa (AFREA) was formed. This brings together forestry research institutes in Burundi, Djibouti, Eritrea, Ethiopia, Kenya, Rwanda, Sudan and Tanzania. This body can now take on ASARECA's role to promote research in forestry. The SADC-FSTCU, AFREA and similar units should as a matter of principle be represented at all SRO regional meetings to present the forestry case, as long as the present SROs continue to gain mileage on the basis of their natural resource mandate. Such units could pioneer efforts to form independent SROs in forestry research in SSA. These units should work with AFORNET and FORNESSA.

The complexity of natural resources management, and forestry in particular, and the role played by forests in the lives of the SSA peoples and their environment, justify giving much more prominence to forestry and forestry research at sub-regional and regional levels. Such prominence has been and continues to be undermined by the focus and glaring shortcomings in supporting forestry research. It is high time that SSA countries realized that forestry research could make a major contribution towards the conservation and sustenance of agricultural productivity. This can only be achieved if sufficient resources are invested in forestry and related research. The first step is for these countries to evaluate how best to handle forestry and forestry research in particular at country and sub-regional levels. Africa has already positioned itself to move in tandem with the rest of the world in handling economic development through regional groupings. Forestry and forestry research cannot remain the exclusive domain of weak national institutions and housed in inappropriate SROs, especially considering the stakes in terms of international public goods and services that forestry can offer, particularly to agriculture and environment

Conclusions and Recommendations

Existing institutional arrangements at country and sub-regional levels in SSA are inadequate for engendering forestry research. Emerging networks are a step in the right direction, but enormous support is needed to make them operational.

The structure and development of forestry research manpower is of major concern in practically all SSA countries. An aging but well trained and experienced cadre is not only poorly managed, but also insufficiently supported by young scientists who can take over research in the future. Policy makers should consider the consequences of decisions on economic reforms that constrain staff recruitment in forestry. University research capacity should be better managed to support national forestry research units and work in tandem with them to solve real forestry problems.

The re-alignment of African nations away from centrally planned economies and with the state holding a major stake in forestry, to market economies with many government functions decentralized to the private sector and local communities creates another major challenge to forestry research institutions in SSA. The hitherto guaranteed funding of forestry research by government as well as employment of research professionals is fast disappearing. New stakeholders in forestry as well as new clients for research are emerging. There is a need to work out mechanisms to capture research demand and assign responsibilities to the various organizations involved. Participation of the private sector must be given space.

On the global front we see increased re-alignment of the world economic system into economic groupings. SSA is involved in these developments, its limited capacity notwithstanding. Forestry is increasingly attracting regional and global attention, and SSA is fully participating in this. The challenge in SSA is how to position the forestry research sub-sector in a regional setting so that it can effectively respond to challenges these global and regional changes create. We recommend the establishment of a strong forestry research capacity at sub regional level.

Ministries responsible for agriculture together with NGOs form a strong capacity for the extension of forestry innovations. There is a need establish mechanisms by which these institutions can carry forestry extension messages to stakeholders, especially farmers.

Training new and re-training old forestry staff is another important area. Given the recent expansion of forestry mandates, it is necessary to improve forestry curricula and open up the scope of serving foresters. National and regional networks, in collaboration with universities and international organizations should conduct short training courses that address key forestry research issues.

It is clear that a good policy on forestry research is necessary but not enough. Practical steps must be taken to make SSA better able to deliver quality forestry research for the betterment of human welfare and the environment.

Abstract

Issues and problems relating to forests have become increasingly interdisciplinary and global. Subsequently, there is increased recognition that many problems related to forestry cannot be resolved by the forest sector in any country or any region alone. Instead, dialogue and co-operation between various sectors of society, and various regions is needed. Indeed, the forest sector has lately been concerned about the sufficient incorporation of various interests in its policymaking. However, an equally important question is whether the forest sector is itself sufficiently involved in decision-making in issues that are taking place outside the forest sector but which still have major importance to the sector. Moreover, while participatory policies are gaining increasing support within forest policy, the participation of scientists in policymaking is typically regarded as undesirable, or at least limited to science policy administrations. In this paper, both these challenges are discussed through the examination discussion forums as modern forest policy means. Ass all illustration, experiences from a new type of discussion-forum known as the Forest Forum for Decision-Makers in Finland (FFDM) are presented. During only a few years of action, FFDM has succeeded not only in improving the interface between science and policymaking, but also in increasing dialogue between decision-maker in forestry and other sectors of society. Finally, the question of the applicability of this new concept internationally is discussed.

Keywords: Forest, Research, Practice, Policymaking

Introduction

Issues and problems relating to forests have become increasingly interdisciplinary and global. The struggle for sustainable forest management, against deforestation, the loss of biodiversity and climate change have forced policymakers from different fields into more intense co-operation than ever. Such co-operation takes place in an international policy system which has transformed from a system of sovereign states into a mixed system consisting multiple stakeholders (e.g. states, international corporations and organisations, NGOs, media) that have many different types of means and strategies in their hands when pursuing their interests. Many new stakeholder groups demand that information about policy options and their consequences are made available for everyone. They also have valuable knowledge and skills that are needed to supplement the actions of sovereign states. In recognising the complexity of issues and the variety of interests relating to sustainable forest management, the international forestry community has expressed a particular need to improve the interface between the forest sector and other actors who have an interest in forests. This international strive for participatory and consensus-based decision-making is visible in most international forest policy processes since the UNCED conference.

The amount of information available for policymakers has exploded. Simultaneously as knowledge on forest ecosystems, forest management and society has grown, the understanding of the full complexity of most forest issues has become increasingly demanding. Accordingly, there is increasing recognition of the importance of sound scientific information as a foundation for policy positions (Mills & Solberg 1998). As part of the international dialogue on forests, the improvement of the interface between science, practice and policymaking has become a crucial issue for forestry policy development. Especially the need to improve the use of forestry research in support of policy decisions is frequently expressed among forest policy makers. For example, this issue was raised in Austria where the International Consultation on Research and Information

Systems in Forestry (ICRIS 1998) convened in 1998 for seeking ways and means to implement research support and provide background information for international forestry initiatives. Following the recommendations of ICRIS, the International Union of Forestry Research Organisations (IUFRO) has lately established a task force for the very purpose of strengthening the interface of science and policymaking in forestry globally.

Accordingly, the forest sector has lately been concerned about the sufficient incorporation of various forest-related interests in its policymaking. An equally important question is whether the forest sector is itself sufficiently involved in decision-making on issues that are taking place outside the forest sector but which still have major importance to the sector. Important decision-makers in forestry issues not only include top-level representatives of forest-related interests but also top-level decision-makers in banking and insurance, trade, other industrial sectors, education, labour unions, politicians, the media, etc. Moreover, while participatory policies are gaining increasing support within forest policy, the participation of scientists in policymaking is typically regarded as undesirable, or at least limited to science policy administrators (Mills & Solberg 1998, Lewis & Koch 1999). In this paper, both these challenges are discussed through the examination of discussion forums as modern forest policy means. For illustration, experiences from a new type of discussion-forum, the Forest Forum for Decision-Makers in Finland (FFDM) are presented. During only a few years of action, FFDM has succeeded not only in improving the interface between science and policymaking, but also in increasing dialogue between decision-maker in forestry and other sectors of society. Finally, the question of the applicability of this new concept internationally is also discussed.

Science and Policymaking

Utilisation of Science

Not only the production but also the effective and proper utilisation of scientific knowledge in support of policymaking is a profound goal of the scientific community. Below, three different types of utilisation of scientific knowledge in decision-making are presented, as identified by Lampinen (1985).

Instrumental utilisation has direct influence in decision-making. From a supply point of view, instrumental utilisation of science involves the well known chain of basic research – applied research – development – application. This type of approach is most typical for the innovative processes related to natural sciences and technological solutions. From a demand point of view, instrumental utilisation of scientific knowledge is best described as problem solving. This process may be described through the following chain: analysis of decision-making situation – identification of information needs – production or gathering of scientific information – interpretation of the research results within the framework of the decision-making situation – choice of solution. In short, the decision-maker uses scientific evidence consciously in order to fill in gaps of knowledge that are strategic to his decision-making. At large, the instrumental utilisation of science in decision-making is open to many types of criticism. Even in its best applications describe the utilisation of scientific knowledge only partly.

In ***conceptual*** utilisation of science, research does not provide direct answers to predefined questions but has a more indirect influence on decision-making. Research helps to conceptualise the problem in question. Most often, research has more impact on problem formulation than problem resolution. In this approach, science has no monopoly to "correct" information. Decision-making is also based on previous experiences, and other non-scientific communication.

Political utilisation is another form of indirect influence of science to decision-making. Instead of using research to search for the best possible solution, science is used to support a specific policy. Often, in political utilisation, research results are harnessed to serve purposes for which they were not produced. However, researchers may also themselves offer decision-makers such results that they are themselves comfortable with. Their motivation may be increased research funding of willingness to influence decision-making towards the researchers own views. Concern for political utilisation of science has also been expressed by many forest research administrators, emphasising that the importance of scientists in support of policymaking is based on credibility which should not be compromised (Mills & Solberg 1998, Lewis & Koch 1999).

Basically, all three approaches deal with what type of information to produce and what to do with the produced information. Indeed, the most typical forms of the science-policy interface are production-oriented; they are related to the identification of information and research needs, or to the dissemination of research results (e.g. extension, education). These two form an important feed back system where at best, the scientific community and decision-makers are in constant interaction. In order to bring valuable information to the policy table, and help focus subsequent research studies on policy-relevant topics, Mills and Solberg (1998) emphasise the need to build a collaborative infrastructure and relations between science and policymaking. This can be accomplished, for example, through proactively conducting research on anticipated policy issues, regular conferences, joint research studies, adaptive management, and boundary spanners.

Knowledge Generation

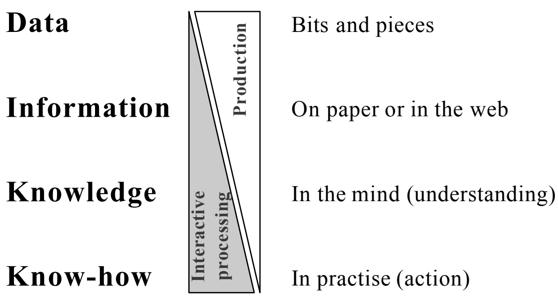
According to Seppälä (1998), the generation of know-how begins from basic or raw data; bits and pieces of unorganised information. The processing of data into time series etc. results in information. Only when such information is processed through, for example, methods of scientific research, and only when we learn to understand connections between different aspects, may we talk about knowledge. Knowledge involves synergy where the whole is more than the sum of pieces. The difference between information and knowledge can be illustrated as information being on paper or in the web, whereas knowledge is in the mind. When knowledge is supplemented with skills and readiness gained from, for example, education or learning in practice may we speak about know-how. In addition to being able to answer to the question "what", know-how implies an ability to answer to the question "how". Not even know-how is sufficient to guarantee application.

Accordingly, know-how generation is not only about what information to produce and what to do with it; it also involves the question of how to process information into knowledge and know-how. As Figure 1 illustrates, the further we proceed from data towards know-how, the stronger demand there is for interactive processing of information than for producing it.

A particular need to broaden our understanding of the role of the science community in the processing of information into knowledge and know-how arises from information overpopulation. Towards the end of the millennium, the world has been increasingly fascinated by the information revolution that is said to have been brought about by modern information technology. According to Drucker (1999), although the new electronic distribution channels will change the printed book, it will nevertheless remain a printed product, with the main task of providing information. Owing to new efficient distribution technology, the amount of printed information easily available increases at immense speed. Today, we live in a confusing situation of information overpopulation (Koski 1998).

Owing to the increasing complexity of forestry issues and information overpopulation, it has become increasingly difficult to build up knowledge from pieces of information and apply it into practice through know-how generation. A strategic key issue for future information management is to learn how to organise and increase the value added sate of information as a key resource. The processing of information into knowledge and know-how is essentially based on high quality processors. Despite modern technology, the role of key individuals and interactive dialogue in the processing of information is irreplaceable. This type of interactive and joint processing of information is based on an essentially closer connection between the scientific community and decision-makers, which may raise questions and concern related to the use of science in lobbying.

Figure 1. The roles of information processing and production within the process of generating know-how.



Science and Lobbying

Jaatinen (1999:22) defines lobbying as influencing political decision-making in the interest of a group by communicating with publics relevant to the political process in a certain issue. These publics are the political decision-makers and officials, competitors, the mass media, citizens, and the constituents of the lobbyist. Accordingly, central aspects of lobbying include communication, influence and interest. The science community is not exempt from these aspects. In fact, the science community is expected to disseminate and communicate the information provided by scientific methods in an open manner. Inevitably, one important motivation for communication is to influence decision-making. Moreover, it is in the interest of the science community that decision-making is based on sound scientific information as a foundation for reasonable and accepted decisions. This overall goal of the scientific community should be separated from the types of interests involved in political utilisation of science. From this point of view, the science community cannot be viewed as an external actor to lobbying and policymaking. This argument is also supported by another angle on lobbying.

Typically, lobbying is understood as attempts to try to influence the environmental conditions of the organisation through communication. It implies that the lobbyist knows what decisions are in line with his long term interests. This, again, implies that the lobbyist is well aware of the political, economic, social and cultural environment in which decisions are made. This is no longer self evident in modern society. In fact, the assumption that communication is interactive contains the notion of two-way communication also in relation to lobbying (Jaatinen 1999:46). As one form of lobbying, environmental scanning helps the organisation to note external and internal changes important for the functioning of the organisation early, and to take these into account in decision-making. Communication with the scientific community is an essential part of scanning the environment in which the organisation operates, and thus, an integral part of the lobbying of any organisation.

In circumstances of substantial uncertainties, instead of communicating on behalf of achieving predefined goals, communication to test and reformulate the goals of the organisations involved, so that they are better aligned with overall social, economic, and political development, is of uttermost importance. Such communication is essentially based on listening and learning more than on informing or persuading. This form of lobbying actually involves joint and interactive processing of information into common knowledge and know-how in an open manner. Moreover, lobbying does not necessarily need to be understood as a linear process of one group influencing another. It can also be viewed as a series of linear influence efforts by alternating parties in striving for an agreement (Jaatinen 1999). Discussion forums offer one important arena for such communication, and a natural arena for the involvement of the science community in policymaking.

Discussion Forums as Means of Forest Policy

According to motive, discussion forums can be divided into three main groups. Discussion forums aimed at information dissemination (left in Figure 2) largely follow the logic of typical seminars: selected information is presented and ”tested” through questioning and discussion. Such forums typically include a group of selected speakers who present their views on requested themes. The following discussion mostly takes place between individual participants of the forum and the speakers. In other words, most communication is two-sided, usually involving the speaker as one of the two communicators.

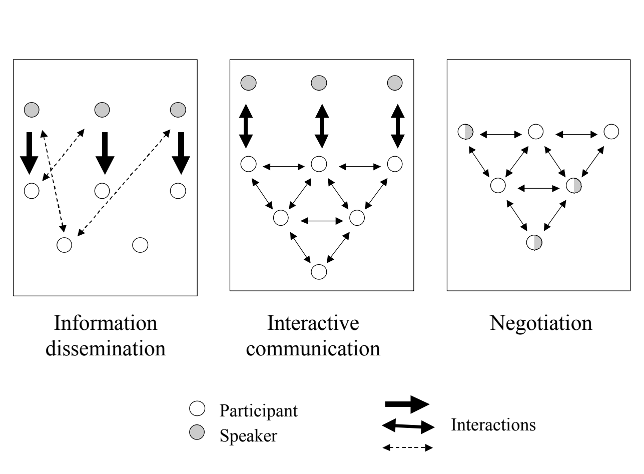
The second type of approach to discussion forums is based on interactive communication between the participants of the forum (in the middle in Figure 2). The main purposes of such forums are to a) increase the knowledge of the participants on selected themes and b) broaden the views of the participants by learning from each other through discussion or groups work involving the whole group. In such forums, outcomes are measured in the learning experiences of the group as a whole, which is more than the sum of the learning experiences of the individuals. Although it is not necessary for a successful forum of this type, they may, at best, result in joint commitment or mutually accepted strategies.

The third type of discussion forum (right in Figure 2) makes no difference between speakers and participants. Each participant shares his knowledge with others in order to achieve a common goal which is usually set by the organiser of the forum in the form of a specific task. Typically, the task is to find common ground and commitment to joint strategies through negotiation. This type of forum largely resembles working groups.

Although these three types of discussion forums are, or course, only stereotypes, a survey of discussion forums in Europe (Hamunen & Hellström 1998) indicates that this typology is applicable to most situations. Furthermore, forest discussion forums may be classified according to several organisational or operational features, such as the organiser(s), duration and regularity, size of the forum, working methods, openness, selection of participants and speakers, and the themes discussed.

The variety of motives and goals of discussions forums raise the question whether they still represent the same type of forest policy means. In forest policy text books, policy means are typically divided into the following groups:

Figure 2. Forms of interaction within forest discussion forums



Regulatory (juridical-administrative) control:
: laws and statutes, administrative guidelines, announcements, registrations, orders and prohibitions

Economic incentives:
: subsidies, subventions, loans, taxes, tax concessions, payments, material support

Public ownership, planning and budgeting:
: state owned forest industry and forests

Information means:
: research activities, education, advising, information services, communication.

Obviously, when using the above mentioned categories, discussion forums may at best be classified as information tools. Information policies include a variety of ways to produce information about forestry for the purposes of information dissemination, campaigning, education, research and development, environmental and social impact assessments, and inventories. Information policies may focus on a variety of different groups, from the industry to special interests groups or consumers. Through information policies, the society aims at advising the citizens of what is right and wrong, or what is good or bad; how citizens should act and what is permitted. Accordingly, in addition to information dissemination, information policy includes views and recommendations for behaviour. (Sairinen 1996.) Most discussion forums deal with information in many ways. They present latest research results, they try to motivate, persuade or appeal the participants of the forum and they may even search for model solutions. However, the understanding of discussion forums as policy tools does not need to be restricted to information tools.

Particularly the internationalisation of the forestry debate has highlighted the inability of traditional forest policy means in securing sustainable forest management. Simultaneously, conflict management has become an important field of forest policy at national and local levels. Problem solving in either field cannot be forced upon any of these actors through any of the policy means mentioned above. The latest approaches in policy research identify one further group of policy means, namely negotiation (e.g. Sairinen 1996). This groups comprises a variety of instruments of different nature. Yet, common denominators for means within this group are interaction, negotiating, problem solving and joint commitment by different parties to commonly agreed goals or actions. Negotiation is a communicative policy tool which also involves some elements of information exchange. Thus, it has features in common with information policy but enlarges it and adds a wholly new perspective to it.

Typical examples where negotiation-based forest policy instruments have been used are negotiations preceding international agreements, and conflict management through mediation. In international forest policy, no other policy instrument is even successful, owing to the sovereignty of nations. At national levels, negotiation-based policy tools have been used in committees and working groups of different kinds. Later, the recommendations of such committees may have been enforced through regulatory-administrative decision-making. Negotiation processes are voluntary, and not even a unanimous results guarantee that the administrations are willing to make the final decisions. Although lacking decision-making power, negotiation instruments are important tools in creating channels of communication between a large variety of interests groups, publicity and open discussion. Accordingly, the result of negotiation is not decision-making but a joint agreement which is based on common interest and which is, thus, acceptable for everyone involved. (Sairinen 1996.)

Viewed from this new perspective, discussion forums most often include features of both information policies and negotiation instruments but with different emphasis. For example, discussion forums operating as more or less in the manner of working groups may largely resemble negotiation instruments, whereas discussion forums operating as more or less in the manner of seminars may resemble information policy approach the most. Obviously, the closer we proceed from information dissemination-oriented forums to negotiation-based forums, the more concerns may be expressed in regard to the extent and depth of involvement of the scientific community.

Forest Forum for Decision-Makers in Finland

Concept and Activities

The establishment of a discussion forum on forestry issues, directed at top-level decision-makers throughout the Finnish society was considered in forest sector organisations already in the early 1990s, since a recognition of the fact that the increasingly inter-disciplinary and international forest issues cannot be resolved by the forest sector alone. Instead, cross-sectoral co-operation is needed. Finally, after careful preparation, the first Forest Forum for Decision-Makers (FFDM) was opened in September 1996.

The communication strategy of FFDM can be viewed from two aspects: forest and society (Figure 3). In the 1990s, the Finnish forest sector has readily adopted the global goal of sustainable development, and vigorously aimed at defining sustainable development in relation to forest management. In its communication strategies, the acceptability of present sustainable forest management in the eyes of decision-makers and the public ("social license to operate") has become a major concern. Typical examples of attempts to increase the social acceptability of sustainable forest management include criteria and indicator processes, image campaigning and forest certification initiatives. The forest-society relationship can be viewed from the society's point of view, too. For many decision-makers outside the forest sector, the use of forests is only one "tool" among many others that can be used to fulfil various societal goals. The key to influence decision-making that takes place outside the forest sector but which still has important implications to the sector, is largely based on creating social demand for the use of forests. Such demand has to originate from broader societal concerns and it cannot be forced upon the decision-makers by the forest sector. Instead, it requires a communication strategy that is essentially based on close interaction between the forest sector and society, and where the forest sector is ready to open up for mutual learning. These two views on the forest-society relationship are aligned with the understanding of lobbying as two-way communication, as discussed earlier.

According to these principles, FFDM is directed at top-level decision-makers of society, with main focus on participants from outside the forest sector. One third of the participants represent forestry or forest based industries, whereas two thirds represent other sectors of society (non-forest based administration, interest groups, political parties, businesses, media, NGOs). The forums have 25-30 participants in each, and each forum is participated by different individuals. FFDM aims that bringing a new proactive mode to forest sector communication by aiming to:

motivating and improving the ability of the participants to address increasingly global and complex forest issues in sustainable ways (social acceptability), and

discovering new ways for the forest sector to support the resolution of societal problems of general importance (raising social demand).

In the beginning of each forum, the participants have been asked about how the forum can help to improve their abilities in decision-making related to forestry? The answers can be divided into three main groups, with similar emphasis given to each:

Information (e.g. high quality and multiple aspect information about the present state and future economic, ecological and social challenges of forests and the forest sector in global development)

Interaction (e.g. new personal and over sectoral contacts, broadening of ones understanding of forest issues through open dialogue, and immemorial experiences in a relaxed atmosphere).

Integrated views (e.g. new ideas, integrated visions and strategies, and seeds for over-sectoral co-operation).

On the basis of the needs of the participants, the following operational concept was created for the forum. (Figure 4).

Figure 3. The communication strategy of the Forest Forum for Decision-Makers in Finland (FFDM).

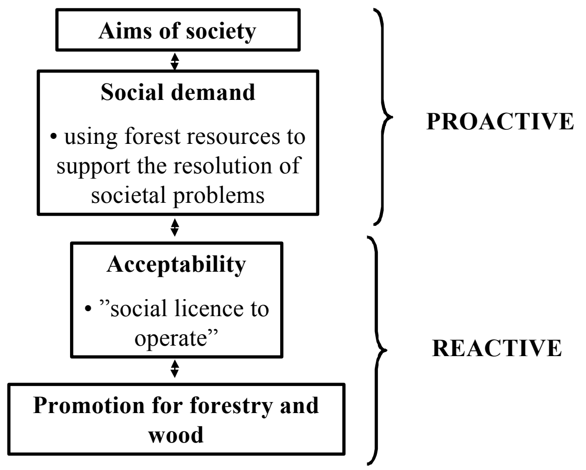


Figure 4. The operational concept of the Forest Forum for Decision-Makers in Finland (FFDM).

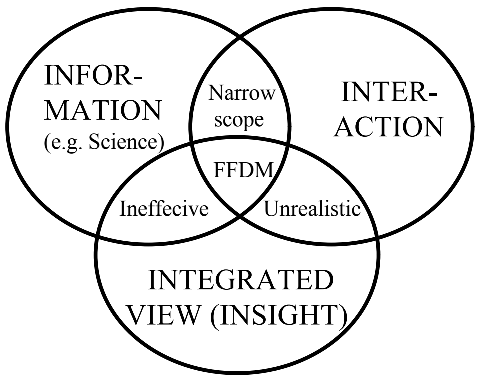


The most interesting part in Figure 4 are the intersections of the three elements. In a situation where interaction takes place on the basis of high quality information but without the involvement of multiple parties, resembles a situation where traditional lobbying takes place. Discussions tend to be narrow in scope and are leaned towards individual interests (not seeing the forest from the trees). On the other hand, if interaction takes place among multiple parties, without the involvement of high quality information, there is a danger that strategies may be unrealistic (roots firmly in the air). Finally, in a situation where decisions are made on the basis of high quality information and multiple parties, but personal interaction is lacking, there is still a danger that decision-making is ineffective (the forest does not answer when called at). This highlights the importance of all three aspects in discussion forums that aim at building knowledge and know-how in support of decision-making.

The forums last for a total of four days, including a seminar session arranged in the Helsinki region, and an excursion to other parts of Finland. In addition to these forums, seminars and other gatherings are regularly arranged jointly for all those who have participated one of the forums. Essentially, the

Forest Forum is not only about single courses or forums, it is about networking and “keeping in touch” with decision-makers throughout the society. Each forest forum aims at providing a general understanding of the whole branch, the so called forest cluster. It focuses on e.g. global forest development, national forest, environmental and industrial policy, rural development, family forestry, silviculture, forest ecology and protection, recreation, wood procurement, bioenergy, pulp and paper industries, wood working industries, packaging, and forest related machine industries. The forums contain short lectures that act as impulses for a number of group discussions, group work and joint strategy discussions. The speakers of the forums include e.g. cabinet ministers, administrators, leading scientists, interest group leaders, and practitioners. The participants themselves are also an important group of lecturers. In the FFDM, no one is an expert in everything, and every one has something to share. (For further information on the forum, see Hyttinen & Hellström 1997, Hellström 1999, http:www.smy.fi/pma/engl).

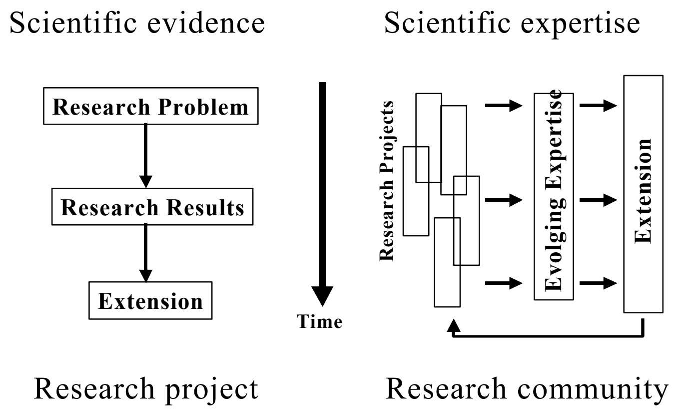
In the typology of forest discussion forums discussed above, FFDM could be classified as a discussion forum aimed at joint and interactive knowledge building (middle in Figure 2). Accordingly, FFDM is not a decision-making body, but a knowledge generation body arranged in active support of decision-making both within and outside the forest sector. If the categorisation of forest policy means is applied, FFDM can be associated with category 4 (information tools) because one of its basic elements is the aspiration to increase the forest and environmental knowledge of decision-makers. However, FFDM is much more. Although FFDM does not aim, say, at decision-making or any activities that are binding to all parties concerned, it underlines the interactive way of communication, problem solving and increased personal commitment to joint ideas. Accordingly, the Forest Forum involves many of the features that characterises negotiation oriented policy means.

The Role of Science

In relation to the science-policy interface, a relevant question is, what is the role of science in FFDM. The role of scientists and the scientific community in FFDM is two-fold. The traditional production-oriented approach to the science-policy interface is presented at the top in Figure 5. In this traditional approach, science is involved in a linear feed-back system with political decision-makers. Top-level scientists present findings of their research results and engage themselves in discussion with decision-makers on the impacts of policy options and further research needs. This approach corresponds to instrumental utilisation of science presented earlier under science and policymaking.

In FFDM, key persons within the scientific community (e.g. science administrators) are also actively involved as participants. Together with other decision-makers they involve themselves in joint processing of information into knowledge and know-how. Accordingly, they are not involved only as experts of their own research field but as participants with broad-based expertise in forest related issues, and with equal status with the other decision-makers of the forum. In FFDM, the generation of knowledge and know-how is essentially based on personal interaction. An important feature of FFDM is that scientists and policymakers interact at an individual level. Moreover, such personal interaction takes place between scientists and policymakers representing very different types of disciplines and interests. This multitude of aspects is the core of generating new, integrated knowledge. This approach is particularly applicable in dealing with issues where uncertainties related to scientific information tend to deepen the science-policy gap (see Bradshaw & Borchers 1999), and where there is need to combine information of various types in order to raise the level of understanding (e.g. scanning the decision-making situation and alternative future developments, facilitated problem solving). This approach is very close to conceptual utilisation of science, as presented earlier under science and policy making.

Figure 5. The roles of science in the FFDM.



Outcomes

By the beginning of the new Millennium, FFDM has been active for over three years, during which a total of eight individual forums have been arranged. They have been participated by a total of 205 top-level decision-makers throughout the Finnish society. This gives a good basis for evaluating its results.

Although it is, of course, difficult to point out that a certain decision in forest or other policy has been induced by FFDM, the forest sector has been convinced that the substantial results (e.g. new trends in decisions taken outside the forest sector, and increased interest and receptiveness to forest-related information) have been worthy of the input.

This is illustrated in the numerous official and unofficial recognition received from the Finnish forest sector (e.g. "Forest Action of the Year" prize by the Finnish Association of Professional Foresters). However, rather than promoting individual substantial issues of interest to the forest sector, the main substantial output of FFDM has been increased integration of the views of the forest sector and joint strategies that are better aligned with overall social development. This has been made possible through mutual learning and joint interactive processing of information into knowledge and know-how. The individual forums of FFDM form a continuum where knowledge processed in one session forms the basis for knowledge-building in the following session. Thus, FFDM has within a short period of time become a respected independent "knowledge generator" in Finnish forest policy. This is also reflected in the active involvement of FFDM in dialogue relating to the Finnish National Forest Programme, as well as co-operation during its preparation in 1998 and later implementation.

In aiming at "opening up", FFDM has been an effective means of public relations, too. Among decision-makers outside the forest sector, FFDM has succeeded to increase both knowledge and interest in forest issues – factors which are necessary for making good decisions. In particular, the participants have acknowledged the openness of communication and the way in which forest issues have been dealt with from a variety of angles, leaving the conclusions to the participants to make. This type of opening up has created increased trust and credibility of the forest sector, and reduced conflict potential among participants representing very different types of interests. The improved overall image of the forest sector helps open up new opportunities for increased involvement and integration of the forest sector in society. Moreover, the network of personal contacts created at FFDM has opened up channels for traditional ways of influence for all people and organisations involved. This also means increased influence in issues of interest to the forest sector. In relation to the science-policy interface, FFDM has succeeded in activating scientists to reach out to policymakers for communication about research needs and findings.

Although both elements of strategic goals – public relations and substantial issues – are of importance *per se*, they are very much interrelated. One would not work without the other. This is one important background for the success of the Forum.

Discussion

The example of the Forest Forum for Decision-Makers in Finland (FFDM) represents a rather untypical form of discussion forums. By actively focusing on knowledge generation, it offers more support for policy decisions than typical seminars. Yet, it lacks the decision-making power which is typical to negotiation forums, or the issue-specificity which is typical of working groups. Owing to its special role in comprehensive knowledge building, it offers an effective arena for strengthening the science-policy interface in a way that does not compromise the integrity or credibility of the science community. Moreover, FFDM illustrates one possible way to address the challenges related to participatory policymaking, communication with other sectors of society, and decision-making under information overpopulation.

Considering the success of FFDM, is there any reason why – with slight modifications - the concept would not work in other conditions, even internationally? Plans to establish similar types of new, knowledge building forums at the national level are already being made in a few European countries. In 1999, the FAO/ECE Team of Public Relations Specialists in the Forest and Forest Industries Sector launched the idea of establishing a new type of discussion forum at the Pan-European level, the European Forums for Forest and Society. Strategically, it would largely follow the logic of the Forest Forum for Decision-Makers in Finland, but with some practical modifications in implementation (http://www.unece.org/trade/timber/pr/effs).

In the global forest policy sphere, it is also evident for the need to reach out from the forestry community towards other parts of society, and strengthening the science-policy interface. Reaching out in an open manner is only possible as a joint effort of the international forest community. The scientific community can play an important role in identifying such needs and promoting action.

This paper only scratches the surface in trying to understand the role of discussion forums as modern forest policy means though the examination of a specific example. Even this example illustrates the difficulties involved with trying to understand modern discussion forums in the framework of traditional forest policy means. Rather than providing scientific analysis, this paper raises abundant questions. One of the most important questions for the future is the potentials of this type of forums in the prevention and management of conflicts within major policy processes. Considering the growing amount and importance of discussion forums in forestry, there is urgent need to address the role and effectiveness of forest discussion forums as policy means, through the use of formal means of policy analysis.

Abstract

The main potential advantages of networking, for agricultural, agroforestry and forestry development in Tropical Latin America, are: 1) synergy and complementarity among national research institutions; 2) improvement of the bargaining position of producers; 3) support for biotechnology development; 4) protection of germplasm and intellectual property rights; 5) upgrading postgraduate education; 6) recognition of institutional capabilities; and 7) exchanging and managing information.

The main limitations to networking in the region are: 1) weak national information transfer structures; 2) slow development/adoption of electronic media, 3) inappropriate choice of network activities; 4) low network sustainability due to weak commitments from members; 5) inflexibility of networks; 6) dispersal of participants (larger countries); and 7) insufficient donor coordination. Eight research/development priorities are suggested for the region: 1) accelerated recovery of degraded pastures (e.g., using agroforestry and forestry technologies); 2) policy issues, regulations and practices that affect land use (e.g., impact of reforestation incentives); 3) increased quality of products (e.g., "organic" markets/"green" labelling and certification criteria); 4) development and massification of biotechnology and biocontrol techniques (e.g., coffee or cocoa shade systems); 5) demand and quality requirements (i.e., market intelligence and prospection) along with the development, valuation and marketing of new products, goods or services (e.g., certified tradeable offsets [CTO´s], water, recreation); 6) diversified sustainable use of natural resources in flexible production systems that can adapt to changing market prices and other demands (e.g., timber-coffee combinations, annual crops and fruit trees); 7) silviculture of secondary forests (bio-physical and socio-economic analyses); and 8) protection of improved and natural germplasm, and intellectual property rights.

Keywords: Agroforestry, Extension, Information transfer, Institutional development, Planning

Introduction

There has been a gradual shift in the priorities of the national and regional organizations involved in agricultural, agroforestry and forestry research in Tropical America towards specialized areas such as: genetic exploration and improvement; bio-technology; integrated pest control; and in the case of some institutions, such as CATIE, to a systems rather than a commodity focus (i.e., farming systems). Forestry research has increased slowly over the past 25 years, but research and development projects focusing on the tree component of natural and managed ecosystems have become much more common (Box 1).

The breadth of topics has widened, taking into account issues of current interest in the region, such as the use of geographical information system (GIS), biodiversity prospection, conservation, sequestering Carbon, gender analysis, as well as the traditional emphasis given to productivity and socio-economic analyses. As the degree of specialization of individuals and organizations increases, there is an increased need for horizontal collaboration (e.g., networking) to resolve complex land use problems.

There has been also a gradual change in the nature of international collaboration over the last three decades, from large regional "donor-driven projects", which carried out all of their activities with their own resources (very little counterpart contribution), to small multiple-funded projects, that depend on local/national collaboration, including financial and human resources from all the participating institutions. In the process, the Latin American countries have gained more power over priority setting, which is now carried out in consultation with target groups and international collaborators rather than as a direct response to each funding opportunity. Simultaneously, the main approach to agricultural, agroforestry and forestry development problems has changed from an on-station, bio-physical emphasis to on-farm, participatory research in which socio-economic aspects are given increasing priority (Prins et al. 1999). Most agricultural, agroforestry and forestry research is now carried out by graduate students and national collaborators, sometimes advised by international staff. At the same time, international donors have become more focused on promoting institutional development (e.g., SIDA-Sweden, NORAD-Norway, DANIDA-Denmark, COSUDE-Switzerland and USAID-USA).

Most of this research is now designed to solve specific problems identified nationally and regionally, involving strategic or applied approaches. Within this continuum, applied research is usually carried out by or with national institutions while the international partners, such as the European universities, are more involved in strategic and basic research. It is hoped that this mixture of different levels of collaboration and complementarity will continue in the future, since it allows all partners to participate to varying degrees at all stages in the process of identifying, researching and solving high priority problems in the region. Collaboration at all stages, including different forms of networking, is essential to increase the information flow between the different actors with the goal of increasing the efficient use of ever scarce research resources, and hence the impact of the research community on the priority problems of the region. Nevertheless, although there are many potential advantages from networking, there are also many limitations to increasing cooperation between institutions working in Tropical America.

Advantages of Networking and Global Cooperation in Tropical America:

Compensating for Weak National Research Departments

The small countries of Central America cannot support independent forestry research units and even agriculture research is severely limited by scarce resources. A fundamental change has occurred in their national agricultural and forestry institutes. Services have been privatized (e.g., extension activities given to producers or NGO's) and research departments have been cut back and de-centralized. The clients for agricultural research and development results are increasingly in the private and less in the public sector. Trade barriers are reduced, competition to sell products increased, and quality becomes more and more important. Since many of the bio-physical problems faced by these countries are similar, and even some of the socio-economic limitations, it is clearly beneficial to promote regional research programmes and data bases that can support national technical assistance and training activities.

Improving the Bargaining Position of Producers

The increasing demand for standardized quality products in ever greater quantities, in order to attract buyers/processors, and the need to improve efficiency for both producers and clients, suggests that the forestry or agricultural organizations of a country, and even for a whole region like Central America, will need to increase cooperation and coordination. An example is coffee production and sales. The competing countries are in agreement that the Central American region as a whole must cooperate to produce and market high quality products which are recognized as being produced in an environmentally friendly and sustainable way (IICA/PROMECAFE 1997). Market share in the recently developed "green" labelled timber and "organic" agricultural product segments, where costly certification is required and actual production volumes are very small, will be improved (and costs reduced) by cooperation between organizations who could otherwise be seen as competitors.

Biotechnology Development.

In addition to medicine, biotechnology is revolutionizing agriculture, agroforestry and forestry throughout the world. The ability to compete in future markets, especially where quality requirements are strict, will partially depend on adopting these modern technologies, but costs are high and requirements for professional staff exacting. Once again, networking/cooperation between countries in Tropical Latin America will be needed to be able to access these costly new technologies. An example is the joint programme of CIRAD (France), the national coffee institutes in eight countries, and CATIE, which is aimed at reproducing improved coffee germplasm. However, in many cases, these technologies are better developed by the private sector, particularly large corporations, where horizontal cooperation is more difficult because of the proprietary nature of the discoveries.

Protection of Germplasm and Intellectual Property Rights

As one of the foundation stones for sustainable research and development programmes, regional and national research organizations need to ensure mass adoption and commercial return from their products. The issues involved in protecting improved or natural germplasm and intellectual property rights are complex and require world wide cooperation to develop and implement a common strategy. IUFRO could play a valuable role here, leading the dialogue and accords taken in this strategic matter

Upgrading Postgraduate Education.

The increasing demand for specialists within the general fields of agriculture and forestry has provoked many Latin American universities to offer higher level degrees. However, the quality of such advanced degree programmes depends on the availability of highly specialized Professors, sophisticated laboratory equipment, research funding and well equipped/funded experimental stations, as well as access to real life conditions; e.g., on-farm research. When the quality of the education is world-class, costs per student are high. Cooperation, not only between Latin American institutes, but also with Universities in Europe and North America, is required to develop joint degree programmes which will offer comparative advantages over existing degrees, not only to Latin American students but also to students from temperate countries who wish to specialize in tropical subjects. Access to funding and to existing networks of Institutes in developed countries (e.g., NATURA in Europe) is an attractive option for advanced Latin American degree programmes because it is too expensive for any one Latin American or European University to offer all of the specialized courses which one or more students may require.

Recognition of Institutional Capabilities

As a result of access, language and historical priorities, Latin America is still the "New World" for most scientists (and some institutions!) in other continents. For example, despite increased attention to divulgation of its programmes and results, CATIE is still an unknown institution to many European decision makers. On the one side, CATIE has seen many bilateral funding/resource opportunities limited because it has been perceived as an "International Institute", while on the other, it has not been considered when the distribution of international research funds is discussed! In order to apply for EU or bilateral funds, CATIE often has had *to work through* a European lead institute. On one occasion, CATIE was advised that it could not be accepted as the coordinator of a European Union INCO research project; however, a later proposal, modified to comply with this requirement, was rejected because "It is not clear why CATIE needs the European lead institute to carry out the proposed plan of work"! Networking helps an institute like CATIE to become recognized and helps to resolve these contradictory instructions/perceptions about its status for regional and bilateral cooperation and support.

Box 1. Principal Agroforestry Systems in Latin America [@]

Agro-silvicultural systems (trees with crops)

- *Trees in perennial crop plantations such as coffee or cocoa* (Beer et al. 1998, Muschler 1999). Includes timber trees, multiple-purpose trees and service trees (N fixation, shade management, mulch producers). Service trees are managed only for the benefit of the crop; i.e., they produce no or only low value products (e.g., *Erythrina* spp. in coffee or cacao).
- ***Taungya*** (Schlönvoigt 1998). Crop planting in tree plantations during the establishment phase of the trees.
- ***Slash and burn*** ("Barbechos"). Traditional agricultural system using natural plant regeneration to recover soil fertility and control weeds (Nye and Greenland 1960).
- ***Line planting around crop fields*** (Méndez et al. 1998). Includes living fence posts, hedges, boundary line tree planting (often timber species) and windbreaks.

Silvo-pastoral systems (trees with pastures and/or animals only) (Pezo and Ibrahim 1999).

- ***Grazing in secondary forests and plantations.*** More common in recently regenerated/planted forests.
- ***Fodder trees/shrubs.*** A traditional but underutilized practice, with especially high potential for seasonally dry areas.
- ***Line planting around pastures*** (see above for details).

Agro-silvo-pastoral systems.

- ***Homegardens*** (Lok 1998). Very complex multi-strata mixtures of trees, shrubs, vines, perennial and annual crops, that usually include small animals, especially chickens and pigs. Home gardens generate a wide range of products for family use or sale.
- ***Grazing in agro-silvicultural systems*** (Pezo and Ibrahim 1999). Very common during the dry season, after crop harvest, to utilize crop residues (stubble) as well as the only green fodder available (tree foliage).

@For a general reference to the range of agroforestry systems, including those named above, see Nair (1989).

Improved diffusion of information about the particular interests of individuals and research groups, and a small amount of seed funding, would facilitate student/professor interchanges leading to new collaboration and hopefully, in the medium-long term, new joint research projects. This could provide the foundation for a successful application to some collaborative research programmes such as INCO of the EU. Distance, time and financial constraints severely limit the ability of Latin American institutes to follow-up promising initiatives and obtain opportune, precise information from donors, which often requires personal contact. They need partners who will represent them and defend an equitable share of resources for all collaborators, and hence contribute to establishing sustainable research programmes in Latin America (for the benefit of all concerned).

Exchange and Dissemination of Information and Results

Latin American research and development institutes need feed-back from all of their clients and collaborators as an essential input to dynamic planning and institutional development. The environmental and economical context within which they operate is changing rapidly and they need a close and constant interaction with international organizations in order to be able to take into account political/scientific trends and developments that will influence their programmes. They can also make a reciprocal contribution to non-Latin American organizations, by presenting the priorities and developments in the region (e.g., at this symposium) as well as the results, technologies and methods (including scientific) they have developed.

Limitations to Networking and Global Cooperation in Tropical America:

Weak Information Transfer Structures

Most Latin American countries do not have a clearly defined political structure to support and promote the transfer of research and development results and other extension activities. National extension services, if they exist, are poorly structured and seriously limited by a lack of operational resources. Transfer of information to groups outside of the research community, ranging from farmers to politicians, also has been limited because the format, language and content of most dissemination materials were choosen by the authors and not by the target group. There is a clear need for researchers to collaborate more closely with NGO and other organizations dedicated to technical assistance and training to ensure the use of the information they generate and that they are focusing on the priority topics of their target groups. In many cases, continued funding for research activities will depend on demonstrating compliance with these aspects.

Two examples of how CATIE has adapted to satisfy these requirements are: 1) the integration of its research, postgraduate and outreach programmes, with staff having principal responsabilities in one programme but being required to participate in all three; and 2) the formation and support of commodity, theme or system networks (e.g., coffee, educational and agroforestry networks) in the Central American countries that, amongst other activities, hold annual planning meetings to agree on their research, technical assistance and training priorities and mechanisms. The activities of these networks has brought the researchers and their clients into closer contact with benefits for all involved. However, additional specific projects are needed to synthesize research results, and to develop and test dissemination materials and other methods of divulgation to ensure appropriate packaging of forestry, agroforestry and agricultural information in a form which target groups can assimilate. There is also the need to promote contact between the different professional groups involved in agricultural, agroforestry and forestry research and development. IUFRO, the biggest forestry research network in the world, makes major contributions in this respect, especially during its international meetings where joint or parallel sessions of different groups are encouraged. Another example is NATURA, which promotes horizontal cooperation of the principal agricultural research institutions in Europe. However, full membership of NATURA is only available to European institutions and not to the “associated” members from tropical countries such as CATIE.

Slow Adoption of Electronic Media

In Tropical America, access and familiarity of agricultural, agroforestry and forestry extension-technical staff with electronic media is still very limited. For example, an internal evaluation of the use of a diskette containing an annotated bibliography of all of CATIE´s agroforestry publications (1950-1996), that was distributed principally to the members of agroforestry networks in Central America, concluded that, even when access to a computer was not a limitation, very few of the recipients ever consulted this data base. Another concern is that these same national staff rarely publish their valuable experiences with agroforestry technologies, hampering dissemination and massification of the best results.

Following the example of many international and national organizations (e.g., CORPOICA 1999), CATIE may produce an extended and improved version of its agroforestry annotated bibliography on CD ROM, but for a different class of clients (e.g., Universities within and outside of the region). The revised agroforestry bibliography has also been printed as a book (CATIE 2000) and distributed, especially to national field staff in order to encourage the application and adaptation of some of the technologies described in the over 700 publications that are included.

In order to promote the use of electronic media, it is not enough that the research/development community produce attractively packaged products (e.g., CD ROM´s) of their results, which may serve the purpose of promotion of the institution but are not effective in transfering information. Priority should be given to equipping/training national staff in the use of these media; e.g., producing self-training forestry and/or agricultural modules where the need for and the benefits of using electronic media are more obvious, and hence recipients will be motivated to learn and become accustomed to the new media.

If well managed, Web pages can be a very important source of information, a medium to market services and products, and a powerful tool to position an institution in the ever more competitive international environment. However, Web pages can create a negative impression if not constantly updated and if there isn´t a rapid reply to the enquiries they generate. It is recommended to keep Web pages simple and always assign responsability to a person to carry out permanent monitoring/updates from the moment of their establishment.

Inappropriate Choice of Network Activities

It´s important to carry out internal reviews with network members to identify the activities where the programme/network has been most useful for them. For example, for training and information transfer, the Central American agroforestry networks promoted by CATIE have been effective mechanisms but they have not been successful to date as a means to promote certain research topics or the adoption of standardized research methodologies. An additional mechanism, run with the networks and which offers some seed money conditional upon acceptance of standarized methodologies, is however showing promise.

Low Network Sustainability

The sustainability of national networks depends upon having one or more national institutions providing medium-long term support to one or more persons who have a genuine interest in the continuation of the network. There also needs to be some minimal independent resources available to support the logistics of the network. Some of the most successful examples of research networks have been the series of international provenance trials organized by the Oxford Forestry Institute (Box 2).

Inflexibility of Networks

If they are to be sustained, network programmes have to be flexible to allow for changing priorities of the members; e.g., there should be flexibility when deciding what kinds of annual meetings, which range from planning workshops, courses or symposia, can be supported. Conformity of national networks to a standard model to provide a basis for a regional/international network is not necessarily a desirable goal. Indeed the interest of an international organization to achieve its predetermined goals *via* networks may bias activities away from national priorities. On the other hand, it is important to avoid that one member directs activities of a national network to serve his/her particular interests only.

Costs and Dispersal of Participants

Face-to-face meetings are necessary to sustain networks because electronic media are poorly developed and little used by network members (see above). At least one General Assembly per year, involving all network participants, is recommended for reporting, planning and exchanging information. In some cases, a national network is facilitated by proximity of members and their institutions, and relatively easy logistics; e.g., El Salvador. In other cases, it may be desirable to form regional networks within a country (e.g., North coast of Honduras;Petén of Guatemala) because of cost and time limitations to attending events in a central location such as the capital city. Obviously this is an even greater limitation in the larger countries of South America.

Box 2. Oxford Forestry Institute provenance trials: examples of successful research networks

The Oxford Forestry Institute´s international provenance trials (e.g., *Pinus caribaea, Gliricidia sepium, Leucaena* spp.; *Calliandra* spp.) (Pottinger 1992) are examples of successful forestry research networks that involved many collaborators in diferent countries, who collected information on their own particular trials and additionally made this available to a central coordinating group. These networks succeeded because they offered rewards to all involved: e.g., 1) quality certified seed from many provenances of one or more forestry species (each country or collaborator had the opportunity to identify the best provenance for their own situation); 2) research support (e.g., short courses and statistical support was provided and sometimes analyses were run free of charge for collaborators); 3) standard designs and evaluation methodologies, which were carefully prepared and clearly explained; 4) recognition of all contributions was provided and in many cases collaborators were encouraged/helped to publish scientific articles; and 5) technical assistance was provided in collaborating countries *via* visits of coordinating scientists and on request (e.g., *via* e-mail). It is noteworthy that individual trials were supported by local resources in almost every case; i.e., the network did not offer financial support. In reality, many networks were established, one for each set of provenance trials, and the networks ceased to exist once the experimental programme (or project) terminated. These networks were carefully designed, planned and monitored for specific clearly defined and agreed purposes. Another key element of this success story was the selection of strong, stable, reliable national partners.

Insufficient Donor Coordination.

Despite the emphasis given by many donors to networking and efficiency, networking and coordination between donors, for the management of international research and development programmes, needs improvement; e.g., review/evaluation missions are rarely combined (ASDI-DANIDA-NORAD are a notable exception in the case of CATIE). The cyclical support of donors for research is an example showing that most donors follow the current trend rather than agreeing on a division of support for all the steps involved in the Generation and Transfer of new technologies. Again, some notable attempts have been made by the Nordic countries to improve this situation. In CATIE, attempts to establish a single system to coordinate monitoring, evaluation and financial reporting, of all European donors, have been unsuccessful. This happens because the donor organizations also have limited resources available for coordination activities and they are subject to inflexible and slowly responding government frameworks.

Future Agricultural, Agroforestry and Forestry Research Priorities in Tropical America

In addition to the three priority topics of product quality, use of biotechnology, and protection of germplasm and intellectual property rights, which have been discussed above, five other priority themes for agricultural, agroforestry and forestry development in Latin America have been identified by CATIE staff and collaborators (Box 3).

Accelerated Recovery of Degraded Land

One of the most serious land use problems in Tropical America, and possibly the most obvious, is the conversion of forests to pastures on inappropriate sites and inadequate pasture management, leading to low productivity and unnecessary damage to nature resources, especially water and soil. Although the problem is widely recognized (Kaimovitz 1996) hard statistics on the extent, kind and degree of the damage are needed. Some potential solutions are known (e.g., establishment of improved pasture systems and/or silvo-pastoral systems [Bouman et al. 1999, Pezo et al. 1999] but their application is limited, apparently because of socio-economic limitations (see next section). In order to remedy the problem, pilot scale participative research with rural communities, that is flexible enough to focus on limiting factors, be they bio-physical or socio-economic, is recommended. Basic research on, for example, soil processes, or further on-station applied research on, for example, management regimes for fodder trees, should not be the priority.

Box 3. Priority themes in Tropical America for agricultural, agroforestry and forestry development*

1. Accelerated recovery of degraded land, in particular of the degraded pastures that occupy large areas of land previously under forest cover, using agroforestry and forestry systems.

2. Policy issues, regulations and traditions that negatively affect land use (technical solutions exist for many of the problems but are often not applied).

3. Increased quality of products produced with less or even no agrochemical inputs; e.g., develop "organic" technologies, markets, "green" labelling and certification criteria.

4. Development and massification of biotechnology and biocontrol techniques for tropical crops and timber trees.

5. Improved links to markets, which are increasingly international, and immediate access to information on actual and predicted prices, demand and quality requirements (market intelligence), including the development, valuation and marketing of new products, goods or services: e.g., Carbon credits; market niches, such as tropical fruits; water; eco-tourism; bio-diversity; and reduced off-site contamination.

6. Diversified sustainable use of natural resources in flexible production systems that can adapt to changing demands: e.g., improved silviculture of timber trees as shade in coffee plantations as an alternative to high input unshaded coffee monocultures.

7. Silviculture of secondary forests (bio-physical, socio-economic and ecological analyses).

8. Protection of improved and natural germplasm, and intellectual property rights, by patents or other means.

*Adapted from Beer and Guevara (1998)

Socio-political Limitations

Whilst it is obvious that market opportunities can have a strong positive or negative effect on land use, there are many other framework conditions that affect the application of known improved technologies. Laws regulations and Government incentives have stimulated conversion of forests to pastures (Kaimovitz 1996) and *vice-versa* (Giovanni 1999). Poor and sometimes corrupt application of regulations can influence farmer's perceptions, and hence acceptance of new technologies, for many years after that limitation has disappeared (personal observations). On the other hand, cultural perceptions can be changed when conditions are favourable; e.g., the rapid adoption by Ngöbe indigenous people of Panama of a timber tree planting technology, in abandoned cacao plantations, once they accepted that timber trees are just another crop (Neri et al. 2000). In view of the interdisciplinary nature of research on this and the preceeding topic (degraded lands), the importance of collaboration between individuals and organizations with different expertise is obvious.

Marketing Products and Services.

Markets are becoming increasingly complex, demanding quality, diversity and attention to many factors which were previously ignored in economic calculations. The market for organic agricultural products is expanding rapidly and has recently become an important new opportunity for tropical farmers; e.g., for coffee producers (Boyce et al. 1994). Many tropical fruits offer interesting alternatives (Leakey et al. 1996) but the lack of market development is a major limitation to their promotion. Financial compensation for service functions, such as Carbon credits, water, eco-tourism, bio-diversity and reduced off-site contamination, is beginning to affect land use in some areas (Giovanni 1999) but there are few concrete experiences to date, and even fewer studies of their positive and negative aspects. Hard facts on both the bio-physical, and especially the economic results of promoting tree planting in pure plantations and agroforestry systems, are still inadequate to convince many decision makers to promote wide scale changes in land use.

While there have been huge steps forward in the development and study of sustainable forest management and certification (e.g., criteria for "green" labelling) there are still doubts about the true potential and mark-up premium which can be sustained. Markets are becoming increasingly internationalized and immediate access to information on actual and predicted prices, as well as demand and quality requirements (market intelligence), has become a necessity in order to compete successfully.

Diversified Production Systems

The trend to change traditional diversified land use systems, such as the agroforestry systems found in Latin America (Box 1), to high external input monocultures, has slowed, and even reversed in the case of Latin American coffee culture (IICA/PROMECAFE 1997). As in the case of degraded pasture lands, socio-economic research on these positive developments will provide more dividends than further bio-physical studies that contrast alternative land uses. In addition to the service functions, such as reduced contamination and preservation of biodiversity, which are increasingly recognized and demanded by consumers, these systems can be more flexible and reduce financial risk (Ramirez et al. 2000). An example is the potential of timber tree planting on both small and large private farms, which is now recognized by farmers, scientists and decision markers (Beer et al 2000). Nevertheless, due to limited experience, new participatory on-farm research on the management of these plantations and quantification of all the benefits which they can provide, as well as detailed evaluations of the success of initial attempts to promote such positive changes, are needed to avoid repeating mistakes (Viera et al. 1999).

Silviculture of Secondary Forests

While it is now widely recognized that secondary forests can replace primary forests (at least partially) as a source of wood and non-wood products in Tropical Latin America (TCA et al. 1997), the wide range of conditions and tree species associations require a much greater research effort to develop practical management protocols for each situation and to be able to generalize the lessons learnt. As is the case throughout the examples discussed in this paper, socio-economic research to determine real potentials has lagged behind bio-physical research which has already provided silvicultural recommendations for many forest types (Dawkins and Philip 1998). Also in parallel to the need for research on the impact of laws, regulations and traditions on the actual and potential use of degraded pasture lands, there is an urgent need to evaluate how these framework conditions can promote or hinder adoption of new technologies to manage secondary forests in economically and ecologically sustainable ways.

Conclusions

The rapid changes in the international context within which Latin American forestry, agroforestry and agricultural research must develop, have lead to the need for increased information flow between countries and institutions, and hence have increased the potential importance of networking. Nevertheless many structural and planning weaknesses reduce the effectiveness of networks and, like all tools, they should be constantly modified taking into account the specific limitations in the region: i.e., inadequate information transfer structures; slow adoption of electronic media; inappropriate choice of network activities; low network sustainability and flexibility; cost and distance limitations; and inflexibility of donor institutions. Reduced resources, increasing competition for all institutes (including universities) and the need for rapid responses to both mitigate natural disasters (e.g., flooding in

Central America and Venezuela) and to take advantage of new technologies and market opportunities, are all factors which are forcing Latin American forestry and agricultural organizations, and their overseas partners, to increase cooperation and efficiency. There is also a clear need to truly integrate bio-physical and socio-economic research at different levels (e.g., organism, plantation, farm, eco-region, national, international) if the research and development community wishes to have any impact in terms of improving land use and on the socio-economic situation of rural communities. It is recommended that the Latin American agricultural and forestry research and development community focus on the following eight priority themes: accelerated recovery of degraded land; policy issues; product quality; biotechnology; market intelligence on products and service functions (carbon, water, biodiversity); farm diversification; management of secondary forests; and germplasm/intellectual property rights.

Abstract

The Ongoing processes of deforestation are rapidly diminishing primary tropical forests in Central America. Tropical forest conservation requires that these forests be integrated into the local economies of rural communities and indigenous groups. The achievement of this integration is a complex endeavor involving diverse technical, sociological, cultural, biological, economic and political concerns. To better address the complexities involved, over 75 entities with interests in tropical forest management and conservation have joined together in three operational networks in Honduras and Nicaragua. Network members include public sector entities, NGO, communities and producer groups, universities and technical schools, projects and private companies. Networks collaborate in technical aspects of forest management, in research, in training and higher education, in industry and commerce, in community development, in information dissemination and recently in policy dialogue. This paper discusses progress to date, initiatives to achieve network sustainability, problems and future directions.

Keywords: Tropical forest management, Operational networks.

Introduction

In Central America, primary tropical forests are rapidly being diminished by ongoing processes of deforestation (Current et al. 1995, FAO 1995). The causes of deforestation are diverse: conversion of forest land to agriculture, ineffective control of illegal logging, limited institutional capacity to monitor forest management, problems in the marketing of timber and non-timber products, the lack of tradition in sustainable, tropical forest management, the existence of governmental policies that discourage attempts at forest management, among others. Taken together, these problems limit the long-term integration of tropical forests into the local economies of communities and indigenous groups.

The value of tropical forests (environmental services, source of wood and non-wood products, biodiversity, etc.) is widely appreciated. This appreciation has led to important investments in forest management within community development projects, research initiatives, university programs, and in the formulation of public policies to protect this important resource. Unfortunately, these initiatives are often quite limited in scope and tend to be implemented in an isolated fashion. As a consequence, their influence on forest management and conservation has usually been limited to local, temporary improvements.

In an effort to have a larger, more sustained impact on tropical forest conservation and management, over 75 entities involved in activities related to these forests have joined together since 1997 in three operational networks in Honduras and Nicaragua. This paper discusses the formation of these networks of horizontal cooperation, their expanding role in tropical forest management and initiatives aimed at achieving their sustainability. Problems that reduce the effectiveness of the networks and future directions are also covered.

Formation of Operational Networks in Honduras and Nicaragua

The first experiences in operational networking in Central America took place during the third and final phase (1991-1995) of CATIE's Madeleña Project (madera=wood, leña=fuelwood), an initiative aimed at expanding the incorporation of multiple-use trees into small and medium sized farms in Guatemala, Honduras, El Salvador, Nicaragua, Costa Rica and Panama. Initially, Madeleña was mainly a research project carried out in conjunction with national counterpart institutions in each of the aforementioned countries. After eight years of silvicultural and socioeconomic research, the emphasis was shifted from research to the dissemination of promising research results. This shift was facilitated by the decision to involve other organizations dedicated to forestry extension in the dissemination process including public institutions, nongovernmental organizations and reforestation projects. In this way, the regional Madeleña Network was formed encompassing over thirty entities cooperating in training, extension and research activities (Cannon and Galloway 1995).

The success of the Madeleña Network suggested that a similar approach could be utilized to promote the sustainable management of humid, lowland tropical forests. During the past 20 years CATIE, in collaboration with diverse entities, has generated substantial experience and knowledge on the management of humid, lowland tropical forests. Thus, the decision was made in 1996 to develop an outreach project with Swiss financing to promote tropical forest management in Honduras and Nicaragua. The resultant TRANSFORMA project established as one of its strategies the formation and consolidation of operational networks in each of the regions where the project would be implemented. After several workshops, in which the potential advantages of cooperating within regional networks were discussed, over 40 entities embraced the proposal and formed three operational networks: REMBLAH in Honduras and REMAB-RAAN and REMARIO in northeastern and southeastern Nicaragua respectively (fig. 1). Participating organizations include national forest services and other public sector entities, community and producer groups, universities and technical schools, non government organisation, projects and private companies.

In the 2.5 years since their formation, membership in the three operational networks has increased to over 75 entities. Each member organization designates a representative (and substitute) to participate in network meetings and planning workshops. The term "operational" refers to the fact that member organizations establish shared goals and responsibilities; cooperative activities are carried out and evaluated in a participatory manner. It is precisely this characteristic of the networks that contributes to their effectiveness and viability.

The Role of the Operational Networks

The conservation and management of tropical forest is a complex endeavor involving a wide range of activities of diverse nature. Once initial enthusiasm that led to the founding of the networks had waned, many members felt that cooperative efforts required more direction. In response to this concern, representatives of REMBLAH took the initiative of forming "Working Groups" within the network in order to insure that adequate attention would be given to specific crucial areas. The Working Groups include 1) technical aspects of natural forest management; 2) research and technology transfer; 3) training and higher education; 4) industry and commerce; and 5) community development. REMAB-RAAN and REMARIO in Nicaragua followed suit adding an additional Working Group dedicated to the dissemination of information. In all three networks, each member organization became part of the Working Group(s) that most related to their area(s) of interest and expertise. In this way, the contributions of each member could be channeled more effectively

To provide further direction to network endeavors and to improve the chances for long-term success, each network underwent a preliminary process of strategic planning. Shared long-term visions and prioritized strategic objectives were established for each of the aforementioned Working Groups. Within each strategic objective, prioritized indicators have been proposed to help each network monitor success and advances towards shared long-term visions of the future. Since late 1998, strategic plans have been used as platforms for operational planning. Although the process is only 2.5 years old, some progress has been made, examples of which are now provided (by Working Group).

.

Figure 1. Geographical regions in Honduras y Nicaragua that participate in the operational networks REMBLAH, REMAB-RAAN, REMARIO

In Technical Aspects of Forest Management

Network members have collaborated in standardizing inventory procedures and data processing, in improving the structure and content of management plans and in prescribing silvicultural operations. Successful efforts have also been made in disseminating techniques of low-impact harvesting including directional felling and processing of timber. Through the establishment of Operational Management Areas (OMA), pilot communities and industrial operators are participating in achieving a multiplier effect of these efforts.

In Research and Technology Transfer

Organizations in each region are participating in the installation of standardized, permanent plots for monitoring natural regeneration and growth and yield of tropical forests under management. Installation and monitoring costs are shared, as are generated results. This effort, which forms part of CATIE's regional network of long-term research sites, provides an important opportunity for university professors and students to participate in field research in tropical forest management. Undergraduate and graduate thesis research is being carried out in the aforementioned OMA in biophysical and socioeconomic aspects of tropical forest management.

In Training and Higher Education

Over 40 training activities are being carried out each year on diverse topics related to tropical forest management. Costs are shared as are technical concepts leading to a gradual standardization of forest management methodologies among network members.

In a parallel effort in higher education, eight universities from five Central American countries are participating in a shared, systematic production of teaching materials to be used in courses related to tropical forest management. To date, five regional workshops have been carried out yielding teaching manuals on tropical silviculture, inventories and timber harvesting.

In Industry and Commerce

Network members have jointly financed market studies in Honduras and Nicaragua. In addition, support is being provided to participating community and producer groups and private companies in their efforts to achieve certification and eventually improve access to international markets. Where certification has been attained costs of annual audits are shared.

Efforts have also been made to expand markets for wood of non traditional species and to improve local wood processing.

In Community Development

Improving technical aspects of forest management and increasing income from harvested wood do not necessarily enhance community development. Participating communities have solicited and participated in workshops related to community organization, administration and accounting to ensure that increased benefits from forest management contribute to community well-being. A decision was made in 1998 to seek out increased membership of producer groups (including indigenous communities) and private companies in each operational network; an initiative that has been successful. Network success will largely hinge on a gradual increase in the successful participation of rural communities in forest management and conservation activities.

In Information Dissemination

Documentation centers have been established in each region to provide a place to deposit and access information related to tropical forestry development. Network members are encouraged to contribute “gray literature” to these centers, since this invaluable source of information is frequently lost when projects terminate or when officials change in public institutions. REMARIO publishes a periodic bulletin to inform the public about ongoing activities and future plans.

In Policy Dialogue

As REMBLAH, REMAB-RAAN and REMARIO gain credibility through successful cooperation, opportunities increase for participation in policy dialogue and in influencing laws and regulations. REMAB-RAAN and REMARIO have been instrumental in organizing large, regional forum on the conservation and management of tropical forests. A representation of REMBLAH has participated in an ongoing national dialogue in Honduras on problems threatening the future of broadleaf tropical forests and on opportunities to improve their conservation and management. A recent decision was made to designate REMBLAH as the technical arm of the Honduran National Forestry Agenda in aspects related to tropical broadleaf forests. In the Rio San Juan region, REMARIO has taken a similar advisory role to the Regional Sustainable Development Council. Finally, REMAB-RAAN provides consultation services to the regional government and to public institutions in the RAAN.

Initiatives to Achieve Sustainability of the Networks

CATIE’s TRANSFORMA project initially financed a large proportion of the costs incurred during network meetings. Increasingly, these costs are being distributed among network members. Nonetheless, there exists a general consensus that the networks should not be wholly dependent on contributions from projects and other network members. Efforts are being made to establish the legal status of the networks and to develop proposals to finance their day to day operations. The idea is not to create another local NGO that competes for limited financial resources, but to provide adequate funds for network meetings and planning workshops, for participation in policy dialogue, for internal communication and for dissemination of experiences. Funds may be sought to remunerate the post of coordinator in each network; at present this position is voluntary.

Problems that Reduce the Effectiveness of the Networks

A few of the problems reducing the effectiveness of the networks are briefly discussed in this section. Although some are beyond the control of the networks, it is important to mention them here.

In both Honduras and Nicaragua, the forest services have passed through a period of crisis and restructuring in the last year or two. Field presence has been greatly reduced diminishing the follow-up of management plans and leading to an almost total lack of control of illegal logging. Communities that make attempts to manage forests responsibly are required to invest in management plans, acquire permits and pay national and municipal taxes. Illegal loggers face none of these bureaucratic hurdles or costs. What’s more, they often flood local markets with illegal timber at reduced prices, making it impossible for responsible communities to compete. In policy dialogue, illegality is one of the key issues the networks currently address.

A second problem relates to the persons delegated by participating organizations to take part in network activities. At times, the delegates lack authority to make decisions and/or commit resources. This problem has, at times, led to planning difficulties and the perception that member organizations fail to take seriously their participation in cooperative activities. As the networks gain credibility, this problem has tended to wane.

The regions where the networks operate tend to be isolated from the major spheres of political influence concentrated in Tegucigalpa and Managua. As a consequence, the networks have not always taken part in policy debates relating to lowland humid tropical forests. Again, as networks gain credibility, their participation in policy dialogue is increasingly sought out.

The policy of the networks has been to allow membership to any entity interested in tropical forest management and conservation. At times, this policy has resulted in the presence of environmentally oriented NGO and wood harvesting companies at the same table. In most cases, the networks have served to help resolve conflicts of interest and have provided a forum to discuss steps taken to mitigate impacts of logging through the application of responsible harvesting techniques.

Finally, Hurricane Mitch dealt a huge setback to tropical forest management in northern Honduras. Downed timber flooded local markets, bridges and roads were destroyed and crops had to be replaced. Network members did collaborate to aid communities during the emergency and in the reconstruction phase.

Future Directions

In both Honduras and Nicaragua, there is a move towards decentralization of functions traditionally carried out by national institutions. In this light, municipalities are expected to play an increasing role in the conservation and management of natural resources. Unfortunately, most municipalities have little or no technical capacity and lack resources (human and financial) to sustain field presence. Increased participation of municipalities will be sought out in the coming years to bring networks' technical capabilities to bear on shared objectives.

The incorporation of a growing number of producer groups (representing communities and indigenous groups) and private companies into the networks is a trend that will continue. Network members recognize that forest conservation and management requires that the activity be viable from economic, social, cultural and biological perspectives. Thus, network efforts to improve the markets for forest products will be strengthened through cooperative efforts of participating organizations. Increasing attention will also be given to the social and cultural dimensions of sustainable forest management. Network members will collaborate with participating communities to enhance community organization and to improve administrative and accounting skills. Long-term success will require attention to improved agricultural practices as well, especially when crop production is carried out on steep slopes (i.e. northern mountains of Honduras). Each of these future directions were identified as priorities in the strategic planning process. Since 1999, activities in these areas have been included in operational plans and have been and are being implemented.

Finally, it is not realistic to expect that all network members collaborate together to the same degree in all activities. Some organizations and projects share substantial overlap in objectives and operational strategies and are encouraged to cooperate bilaterally when possible. To provide more structure and formality to cooperative ties, organizations and projects have begun forming "strategic alliances" through the cosigning of "letters of understanding". These non binding documents outline areas of cooperation, indicate individual and shared responsibilities and specify resources each entity will contribute. Since these letters are signed by the director or coordinator of each organization, they insure that good intentions are included in annual operating plans.

Final Comments

The consolidation of the operational networks discussed in this paper is an ongoing process. The importance of the process becomes clear in the following table which contrasts the situation prior to network formation with the present one.

As has been pointed out, results to date are promising. Without doubt, the major impetus for continued participation in the networks will be tangible, shared success and gradual progress towards strategic objectives.

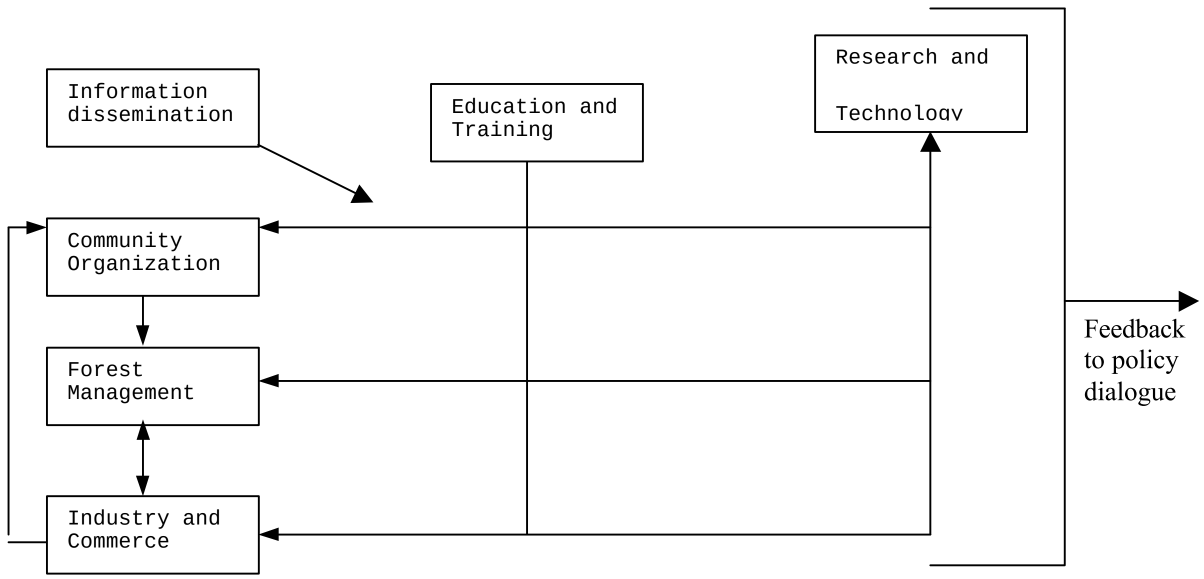
The formation of working groups within each network has enhanced understanding of the multiple dimensions of tropical forest conservation and management (fig. 2). Community organization is required to successfully carry out planning and operational activities and to put to good use generated income. The strengthening of community organization depends, in part, on access to favorable markets and fair prices. Interest in products from tropical forests hinges on the production of reliable volumes of timber of acceptable quality. Determination of allowable annual cut, minimum diameter for harvesting, the need for silvicultural treatments, etc. requires good information from inventories and permanent research plots.

Every aspect of this multifaceted endeavor can only improve over time through the implementation of appropriate training and technical assistance programs. Mid level technicians and professionals are key players in the process, which emphasizes the need for strengthened educational programs. Finally, a favorable political and legal environment is essential to encourage a growing participation in tropical forest conservation and management. Thus, regional efforts must provide feedback to policy makers so that regulations actually favor and not discourage forest development initiatives.

Situation prior to network formation[1]	Current situation
Isolated efforts to promote tropical forest management and conservation	Existence of regional networks that promote cooperation and sharing of experiences
Lack of long-term vision and objectives related to natural forest conservation and management	Public sector institutions, NGO, producer groups, universities and private companies cooperating in strategic planning
Disparate efforts to improve forest management	Cooperative training in all technical aspects of forest management favoring the application of uniform criteria
Weak local technical capacity	Strengthened local technical capacity – formation of trainers for planning and operational aspects of forest management
Little to no local research	Shared local research agenda, cooperative efforts in the establishment and monitoring of permanent plots, undergraduate and graduate research
Few opportunities for communities and companies involved in forest management to access technical assistance	Opportunities to request assistance from network members and/or become part of the local network
Weak links between universities and field activities	Growing participation of university students and professors in training and outreach activities in operational management areas
No entity to represent regional interests in policy debates	Growing participation of networks in policy dialogue

[1] In some aspects, this table is a generalization. Important advances had been made by the PDBL project (ACDI/COHDEFOR) in promoting tropical broadleaf forest management in the mountainous region of northern Honduras prior to the formation of REMBLAH.

Figure 2. Interrelations among "Working Groups" within operational networks in Honduras and Nicaragua. Shared experiences generate important feedback to policy dialogue.



The conservation and sustainable management of lowland humid tropical forests will require a large concerted effort of numerous, diverse organizations. The flow and exchange of information among these diverse entities is essential if progress is to made. Just as the internet requires physical networks for its functioning, the operational networks described in this paper provide the framework for information sharing to enhance success in tropical forest management initiatives. Added to this important function, members in the operational networks jointly implement training, research and operational activities contributing to a shared vision of the complexities involved in attaining the sustainable management of these vitally important ecosystems.

Abstract

Recent information technology has opened up fascinating new visions for global networking, cooperation, and exploiting expert services and education through the use of the Internet. Web-based learning environments and distance learning offer one of the most promising areas for taking advantage of the new technology. As the new technology shifts from pilot projects to every-day use it is likely to cause remarkable structural changes in the education markets, changes which will lead toward new expertise and globalization.

Keywords : Expert Networks, Distance learning, Website

New Internet Technology Points Toward the Virtual School

The idea of the ”Virtual School” is not a new one. The challenge of creating net-based environments for efficient and on-time delivery of study materials, communications, personal feedback and cooperation between students and teachers has puzzled thousands of pedagogics and programmers since the 1980s. Crucial technological steps were taken in the late 1990s when the new programming tools permitted the development of pure browser-based applications. These innovative applications can be used on a standard Internet browser without the necessity of extra installations on students' or teachers' PC. The learning environment (database and user interface) can simply be placed in a given URL on a university's or service providers' server and the users' rights to use the learning environment are controlled by means of usernames and passwords.

Over the same period, the number of Internet connections has exploded, and in developed countries most university students now have access to the Internet. The costs involved in using the Internet have declined, while the quality of the various connections has improved. Most of the net-based distance learning is arranged in an asynchronous environment, but some of the learning environments also support synchronous (online) interaction: chat, shared documents, blackboard, video meetings and video lectures, etc. (Fig. 1). Although it is possible to arrange pure distance learning courses, the new methods are in most cases used in combination with traditional face-to-face teaching. (Pulkkinen & Peltonen 1998).

Tools for Better Education

The freedom to choose the time and place for teaching and learning is a basic advantage in the use of distance learning. This kind of freedom is useful in all education, but it can be especially valuable in further education and in training busy working people with their tight schedules. Distance learning can offer individual and flexible learning experiences and thereby improve motivation, especially amongst adult students. (Linder 1999).

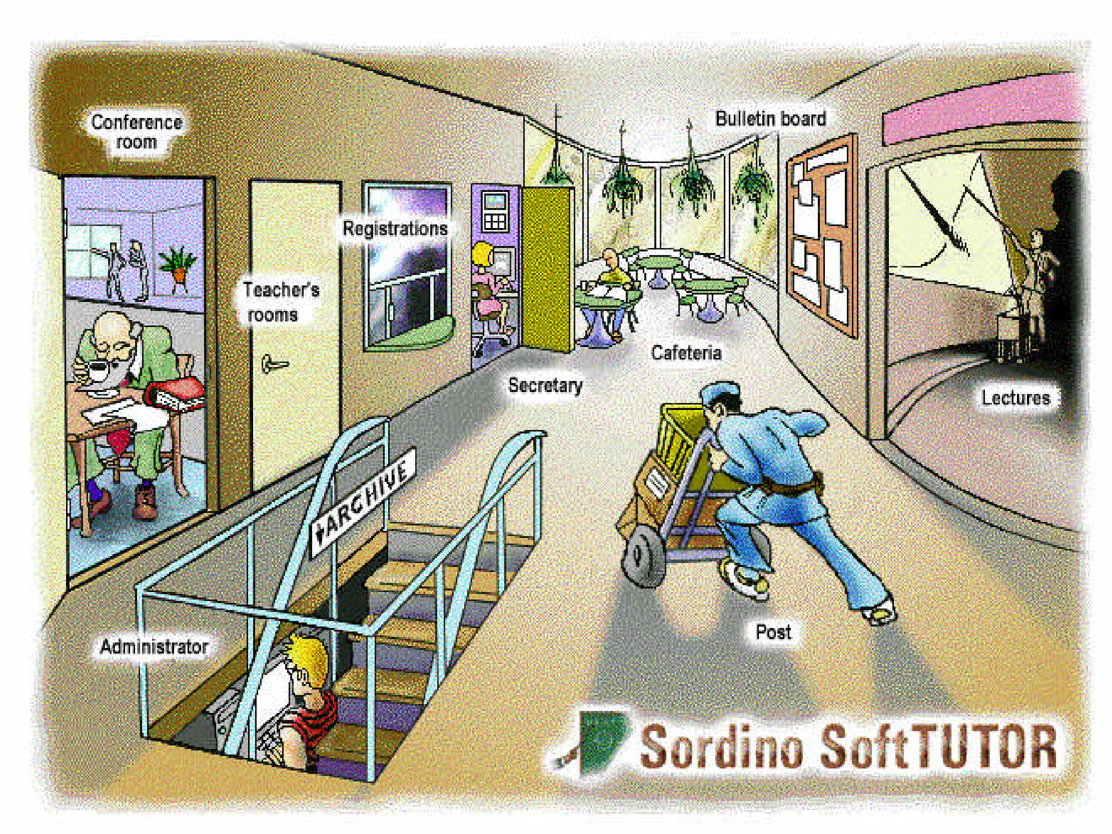
Moving information from place to place is much easier, faster and less expensive than moving people. For example, for a course using video or face-to-face lectures the teaching can include preliminary tasks and exercises through which the students can prepare questions intended for the lecturer. The virtual learning environment is efficient in spreading material, tutoring, giving feedback and evaluating assignments. For many people it is easier to express themselves in writing than by speaking in a crowded classroom - for people like this, distance learning can provide better facilities for communication both with their fellow-students and with their teachers or moderators, and thus can lead to improved learning results. Hence, a net-based learning environment can also provide the tools necessary for improving the quality of learning (In 1999).

From an expert's point of view, net-based distance learning offers new opportunities for marketing one's expertise as a form of educational service. Well-planned and -produced study modules at a moderate cost will be received with delight by many educational organisations whose own resources for both teaching and preparing materials are restricted. Flexibility in the use that can be made of the material can provide an expert with the means to prepare good, up-to-date materials, and the use of distance learning makes it possible to offer services over a wider geographical area and involving a moderate amount of time actually spent in teaching.
[Fig. 1]

A Networked World

Developments in North America indicate that the expansion of Internet and distance learning is rapidly changing markets and placing familiar educational organisations in a new position. Some private universities in the USA have started offering well-produced educational services and curricula that make use of totally net-based learning. Thus, it can now be assumed that in some areas where the contents of education can be standardized they will soon be competing globally (Wagner 1999).

Figure 1. The user-interface of a virtual school often makes use of the metaphora of a real school



Another sign of change is in the globalization of the forest industries. As the companies become larger and spread from their national and continental markets to global markets, so too the sphere of operations of each individual professional undergoes expansion. This, in turn, means that there are new demands for personal skills and expertise. National expertise is no longer enough - students and professionals must prepare themselves for new international tasks by developing their skills in:

- learning about the facts and practices in other countries
- combining different items and curricula to develop an individual curriculum
- acquiring the skills to learn more and to adapt to new environments

In globalization there is often a need for speedy standardisation in different practises. New methods that have been successfully used in other parts of a company can be swiftly spread to new units once the company has acknowledged their value. Inside large companies, new concepts such as forest certification or new technologies such as the cut-to-length method in forest haulage can sometimes cross traditional geographical and traditional barriers with very little delay. Whatever the case, the new situation involved in transferring new technology and practises creates a need for large-scale education programs and efforts. For experts in a company's more traditional areas or for technology-providers the new situation means adaptation to a new environment. Both situations pose considerable pedagogical challenges which could be tackled successfully by means of web-based distance learning. And since enterprises have a tendency to minimize their own educational units, outside services will be needed.

Experiments in the SILVA Network

The newly networked world with its global markets emphasises the need for expertise and ability in organizing, finding consumers, and marketing. The individual or organization which can offer the best expertise in a tempting package will win the client. Hence, the opportunities for the older education organisations lie both in their good reputation and in their wider cooperation in creating new contents and also in marketing.

These trends have been recognised in the SILVA Network, which consists of 32 European universities offering higher education in forestry. The universities involved in the SILVA Network are producing joint European teaching modules and digital materials related primarily to this field. The first module, "Forestry in Changing Societies in Europe", will also be developed for use in an EU-Canada exchange program. The European network has increased bilateral cooperation between the participating universities for example by means of visiting lectures for special courses. Distance learning has proved to be useful in the arrangement of these courses and in enhancing contact between students and foreign experts. During the winter 1999-2000 the Web-based learning environment SoftTUTOR was piloted in the form of two visiting courses: ”Growth Trends in European Forests”, at the University of Joensuu (Finland), presented by Prof. Spiecker, of the University of Freiburg, and ”The Production and Energy Use of Wood Biomass", at the Agricultural University (BOKU) of Vienna, presented by Prof. Pelkonen, of the University of Joensuu. For the coming semester there are also plans to increase cooperation in particular by means of special courses. At the University of Joensuu a number of new courses will be prepared for a web-based learning environment. In combination with video lectures and video conferences these courses are to be offered to other Universities so that some of the students will be taking the same course solely through distance learning. These pilot courses are likely to provide valuable insight into the nature of communication and interactivity in an international ”virtual classroom”.

Difficulties

In practice, there are still both technical and other barriers that continue to reduce the effective implementation of distance learning: inadequate or expensive Internet connections, the actual cost of technical equipment, and a lack of basic ADP and Internet skills amongst both students and teachers. Nevertheless, technology is no longer a major obstacle in developed countries to the adoption of web-based distance learning. Several commercial software products are already available that offer very similar basic properties for net-based distance learning, and the situation is improving year by year. The main impact of low capacity in Internet connections is that there may be some reduction in the use of synchronous activities such as video-conferencing in a large scale.

One of the main problems involved in spreading the use of distance learning is probably a shortage of the pedagogical skills needed for converting teaching to the new format and new learning environments. To make successful use of distance learning the teacher or expert preparing the study materials must already possess reasonably good basic skills in terms of using computers and software. Thus, in addition to his or her professional competence and pedagogical knowledge the teacher should also understand something about the interactive nature of network environments. (Bacsich & Ash 1999)

Producing good-quality study materials and building up a complete distance learning course is also quite time-consuming, especially when it is being done for the first time. Also the costs of copyrights can reduce the use of digital materials. In general, monetary savings in shifting education to the net can only be achieved if the same materials are to be used several times with different groups or where recycling the same digital materials for various different purposes is possible. Part of the costs involved can be avoided by cooperation - jointly preparing materials for wider use - and by using specialised services in converting old materials for use in a new digital environment. (Bacsich & Ash 1999, Peters 1999). Unfortunately, the benefits of using distance learning are hard to prove because there is still a lack of scientific evidence about the results of this method in comparison with traditional educational methods. Comparable test conditions are difficult to arrange and the technology is also still developing very fast. The most valuable advantages attached to the use of distance learning are probably connected with better quality or will emerge in the long run through the development of enhanced methods of updating and revising materials.

Concluding Remarks

The advantages of net-based distance learning are so inevitable that only one (two-sided) question remains in our minds: how fast are the new technologies developing and how can these challenging opportunities be used in everyday teaching and learning situations? These changes are likely to provide new opportunities and wider markets for both organisations and individual experts, and the key factors for success are specialization, international cooperation and networking, and the ability to take advantage of new technologies.

Perhaps, in the not too distant future, every student will be carrying a virtual school in his or her pocket!

Abstract

The development of IUFRO's communication to utilize Internet based technologies is reviewed. During the past quinquennial a WWW based information system was built for IUFRO and its working units. A task force (IUFRO Task Force on Internet Resources) was established to coordinate and facilitate this work. The information system now covers most of IUFRO's activities and a user study helps to plan future development.

Keywords: Research communication, Information system, Internet

Introduction

The utility from scientific research depends on both the properties and the availability of the new knowledge. As noted by Harold Mooney, the Secretary General of ICSU, a relatively small amount of resources spent on enhancing communication and interactions among scientists and with 'the outside world' has a very high value added to the costs of scientific work (Mooney 1999). With the modern communications technologies this enhancement is even more pronounced.

During the 1990's, internet technologies have revolutionalized communication also within forestry sciences. Computer based person-to-person communication (e-mail) and information supply (WWW) are becoming more and more popular (Fig.1). It is both natural and inevitable that these developments deeply affect the functions of an international science organization such as IUFRO. This was also emphasized during the 20th IUFRO World Congress in 1995. The Congress Resolutions "encourage the use of innovative technology to increase data sharing and research efficiency, and to optimise timely delivery of research information to the widest array of users" (Declaration 1995).

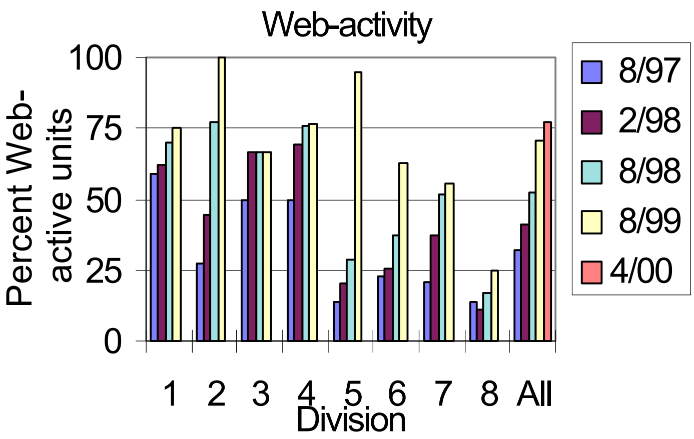
Added to the development of electronic communication, the degree of internationalization has markedly increased in many issues of forestry sciences. The activities related to biodiversity conservation, forest certification, climate change and the Kyoto Agreement have made many forestry issues international. This increases the importance of international communication.

IUFRO Networking Development Plan

To be effective and important, the communication requires both content and infrastructure. Supporting the latter was adopted as an important IUFRO activity: Following a period of exchange of ideas, a common view among IUFRO Secretariat and a group of "activist" scientists was formed and it led to the development of IUFRO Networking Development Plan (Valsta *et al*. 1996a).

The plan was largely developed during a group activity in November, 1995, in Vienna, hosted by IUFRO Secretariat and sponsored by the Finnish Forest Research Institute, the Swiss Federal Research Institute WSL, the Oxford Forestry Institute, the USDA Forest Service, and the University of Agriculture, Vienna. The process was based on sharing experts' views about:

Figure 1. The development of activity in providing information for the WWW system of IUFRO.



- the groups/kinds of users of IUFRO networking services
- the needs of the different user groups
- the services that respond to these needs
- the services that should or could be provided by IUFRO organization

The group performed a rating that produced a list of the most important services at the time (in the order of importance):

- Research Group information on the WWW
- IUFRO organisation information
- Electronic mailing lists
- Proceedings and newsletters on-line service
- Electronic research news
- Translation of documents between different electronic forms
- Person database
- Member organisation information service
- Literature databases
- Terminology database
- World Congress information

In a perspective of about 4 years, we can see what the emphases turned out to be in the realization of this plan. Research Group (now, Working Unit) and IUFRO organization information have become the core of the WWW information. Some of the specified services, such as Proceedings and Newsletters, and Person database have become part of the core area. The three last items on the list have been managed by specialized people as independent projects, but they importantly complement the other services. Translation of documents between different electronic forms was never realized in large scale as a service. Rather, that task is being handled mostly by information providers, themselves.

The IUFRO Task Force on Internet Resources

To bring forward this plan, the Executive Board of IUFRO established a task force in February 1996 (Valsta 1996a, b). The objectives of the IUFRO Task Force on Internet Resources have been to

- enhance international communication among forest scientists and with other parties having an interest in forest research,
- support the goal of decentralising IUFRO and strengthening regional activities,
- coordinate the development and use of internet services so that efforts in the area yield greater benefit, and
- share expertise and services so that the technological advances in computer networking are put in use globally in forest research and among member organisations.

The task force had to be organized so that it brought together a large number of people within IUFRO, working with various tasks. The two main groups of persons in the TF are the *core group members* and IUFRO unit *contact persons*. In addition, members of the secretariat work in close cooperation with the

TF. Additionally, the persons maintaining the regional servers have an important position. About 20 persons made up the core group and at least one person in most IUFRO units has been involved.

The Development

Two major information flows can be identified in IUFRO's internet activities. The first one concerns IUFRO organization information, meetings and publications, SPDC as well as literature and terminology projects, and this is principally managed by IUFRO Secretariat. This is also the more comprehensive and up-to-date part. The second kind of information deals with IUFRO's working units. Although here basic information is generated by the Secretariat, the unit coordinators are responsible for producing information about the mandate and activities of the units. This task is facilitated by Division Webmoderators who help the unit coordinators and division coordinators in producing and updating information concerning the units.

A major strategic step was taken here, supported by IUFRO's Executive Board, as every unit became visible in the Internet by the unit's home page. Not only are the names of the unit officers known to people who have worked around IUFRO in their field but to any person who browses the WWW pages or searches their contents. Needless to say, this situation creates expectations about each unit's activity and accomplishments.

The new communication atmosphere and increased visibility was new and partly unexpected to many of the officers in IUFRO units, especially as this change has been realized after the time when the officers had given their consent. Among other things, this situation shows in the rather unequal speed, at which the units have been giving out information that has been placed on their pages. It is expected that the proportion of units that are active in the WWW has reached its maximum with the current officers: 77 % of units were classified as being Web-active. It can be anticipated that officers selected for the next quinquennial will take the WWW information as a standard procedure.

To enable efficient global reach to IUFRO's WWW information, a set of regional servers was created. It includes locations on different parts of the world: Austria (University of Agricultural Sciences, Vienna, Austria; the main server), USA (University of Minnesota, St. Paul, Minnesota), Costa Rica (CATIE), Chile (CONAF), South Africa (CSIR), Australia (CSIRO), Japan (Mie University) and Finland (METLA) (Fig. 2). This setup reflects the strength of IUFRO being able to rely on support from member institutions.

A User Study

Following a plan of the Task Force, a questionnaire for the users of IUFRO's Internet resources was performed in June-August, 1999. This survey was targeted to IUFRO officers with e-mail addresses, the group obviously representing only a certain proportion of the users, albeit an increasingly common one.

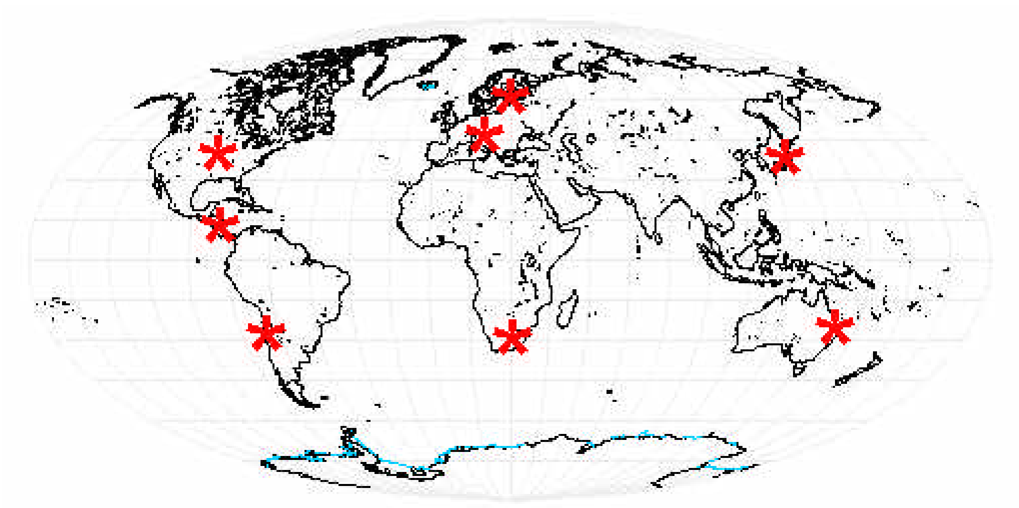
The purposes of the study were to obtain basic information about the views of IUFRO officers on IUFRO's Internet services. Primarily, the present services were evaluated, but the respondents were also asked to suggest improvements and changes.

The response rate following a reminder in July amounted to 63 %, excluding the non-functional email addresses. Those included, the rate drops to 56 %, which can still be considered acceptable.

IUFRO News had been the most important source of knowledge about the existence of web activities. About half of the units of the officers had been active in IUFRO web; notably, 25 % did not answer the activity question.

One third of those persons who had checked their personal information had found it not correct. Much of this number is due to the failure of people in submitting their notice of address change. The questionnaire did not distinguish between people who actually had sent an update on their personal information from those who had not.

Figure 2. The sites of IUFRO's WWW servers.



The strongest features of the web system were meeting announcements, ease of use, and layout of information. Problems were seen in the timeliness of information and data entry overall.

E-mail was, by far, the most popular way of communication. However, hardcopy still was considered indispensable, especially keeping in mind the situation of officers without an e-mail facility. Most of the respondents had used both e-mail and WWW but the circumstances among officers outside this questionnaire were also important.

Future Directions

The expectations on rapid global communication are ever increasing. It is expected that the Internet based services of IUFRO will be central to the organization.

One to One Communication

The database of contact information of the more than 800 IUFRO people is a vital source of basic information. The value of this information is crucially dependent on persons themselves in that they keep the contact information up-to-date. Both the commitment of persons themselves and the technical help provided by IUFRO will help updating.

One to Many Communication

Sharing information is naturally a core function of research. In the global context, WWW is seen to increase in importance for research. Locating the useful information is a key problem with the ever-increasing amount. IUFRO has a great potential in collecting information of a very large number of experts in the field of forestry research. The present WWW system of IUFRO has several strong areas that are likely to retain their value.

The diversity of IUFRO people in their ways of retrieving and supplying information is a challenge for the organization. How to combine simplicity and manageability while maintaining flexibility and alternatives? The solutions to this must include some rigid administration but also approaches that enable the full utilization of grass root activity in IUFRO units and of the contributions of IUFRO people to information sharing. Pilot projects like those of SPDC in the GFIS vision can broaden the geographical outreach.

The Strengths of IUFRO Communication

Although the main form of scientific communication takes place through research reports, one can ask whether that it enough. Do international users of forestry research information also need to interact with a large number of people? The network of forestry scientists that IUFRO represents is a unique phenomenon.

Much of the communication through IUFRO's internet services connects to publications, meetings and individuals. It was very early realized within IUFRO that providing personal information is a sensitive issue and is threatened by misuse. That is why the present system is designed so that only one person's data can be retrieved at a time. On the other hand, combining traces of information from IUFRO's thematic structure and its reference data can provide insight to a valuable knowledge base with respect to forest sciences.

In the Internet context, forecasting is a difficult business. However, community building will continuously be a main activity independent of the specific technology in use. As the availability of computer-mediated communication and web services will increase, the toolbox for international cooperation in forestry research will gain in variety.

The member organizations have not yet had a prominent role in producing their own information to be connected to the IUFRO WWW system. This area has a large potential: how to design data and searches to yield information about the activities and specialties each member institution has. Combining individuals and institutions will bring IUFRO's information system to its greatest value.

Abstract

This paper begins with a discussion of the term 'network'. In the context of this paper, it is taken to mean the flow of information between individuals, institutions and nations. The International Tropical Timber Organization (ITTO) has been developing networks since it commenced operation in 1987. Not all such networks have not been created from 'scratch'; ITTO has been able to tap into existing networks and in many cases strengthened them. These networks extend in all directions – from the international arena to the field level and back again.

ITTO's networks extend to the field level primarily through its project program. In its 13 years, ITTO has distributed funds to about 400 projects in its member countries, predominantly those in the tropics. This creates a natural flow of information: projects consistent with ITTO objectives are proposed by member countries and vetted by an international team of experts. They are then submitted to the International Tropical Timber Council; if approved they may attract funding, which is provided in the form of grants rather than loans. Once a project is implemented, information exchange continues between ITTO and the implementing agencies, and between the ITTO Secretariat and field staff associated with the project. Thus, networks are established or maintained that link the international arena (at the Council level), through national governments, to national and sub-national agencies and non-government organisations, and to field staff.

Complementing this approach are two projects aimed at developing a more structured information network: one produces a newsletter, the Tropical Forest Update, and the other a tropical timber market information bulletin. The newsletter has evolved considerably since its beginnings in 1991, but its aim has remained constant: to promote the exchange of information on the conservation and sustainable development of tropical forests. It has a circulation of about 7,000 and is distributed in English, French and Spanish. It publishes basic information such as the availability of short courses and scholarships and information on recent publications, meetings and other events. But it also provides analyses of the tropical timber trade and sustains a global-level dialogue on the role of forestry in conservation and development. It also feeds back into the ITTO project program by publishing reports about such projects, usually co-written by project field staff and members of the ITTO Secretariat. This affords project personnel the chance to articulate and communicate the outcomes of their work and to learn about the activities of their counterparts in other countries and regions.

The Tropical Timber Market Information Service is aimed specifically at tropical timber traders and trade analysts and operates principally via the internet. It carries price data on over 300 tropical timber items and has developed a price database to service specific trade inquiries and for the production of price trend data. These data are also provided to other international agencies for their own reports on the tropical timber trade.

ITTO has never seen itself as the sole institution with responsibilities in the field of tropical forest conservation and sustainable development. It currently contributes around $20 million a year to field projects; these, on their own, will not solve the tropical forests crisis. But other institutions – global, regional, national and local and the individuals within them can learn from our experiences and we can learn from theirs. This is the value of networks.

FAO Initiatives for Networking in Forestry

by
Oudara Souvannavong and C.T.S. Nair
Forestry Department, Food and Agriculture Organization of the UN (FAO)

E-mail: Oudara.Souvannavong@fao.org
and CTS.Nair@fao.org

Abstract

The paper reviews examples of networking efforts by FAO in forestry, within different regional or global framework, and with broad or more specific objectives. Factors of success and issues in operating the networks are presented. Relatively less complex to operate, theme-specific networks generally achieved good results although inadequate capacity of some collaborating institutions can be a constraint. A stepwise approach was successfully applied for some more complex networks with broader objectives. Generally, regional technical cooperation networks, established to common regional issues, well fulfilled their role in exchange of information and experience. They have created, over the years, competent resource groups, which however need external support to be maintained. Efforts in support to regional networks of forestry research institutions, to enhance national and regional capacities to prioritise and undertake research in an effective way, are presented. Cooperation with other regional or international programmes and institutions has constantly been an important factor of success in all the networking efforts facilitated by FAO.

Keywords : FAO, Networking, Forestry.

Introduction

Networking refers to formal and informal ways in which individuals and organizations establish contacts with one another and develop working relationships to exchange information and cooperate and coordinate activities. Networking is a tool commonly used by FAO in fulfilling its mandate of information gathering and dissemination, technical assistance, and facilitation of international cooperation, across the whole spectrum of frameworks, objectives and activities of the Organization, from broad areas of interest and global networks to topic specific and local networks. The present paper reviews the experience on networking and other collaborative efforts by FAO in forestry, based on representative examples of different kinds of networks. The topics considered are (i) theme-specific networks, (ii) networking under FAO statutory bodies and regional commissions, and (iii) the support to regional networks of forestry research institutions. Factors for success and problems encountered will be analysed.

Theme-specific Networks

International Species and Provenance Trials

The Forestry Department of FAO has been facilitating and coordinating a number of international species and provenance trials, which can be considered as networking activities with well defined objectives, outputs, and time frame.

International provenance trials of teak (*Tectona grandis*) were established in the early 1970s under the coordination of FAO and the Danish International Development Agency (DANIDA) Forest Seed Centre (DFSC). Seventy-five provenances, both from within the natural range of the species and from areas of introduction, were collected and exchanged for trial establishment at over 50 sites in 16 countries. Coordinated evaluations undertaken from 1981 to 1984 and from 1991 to 1992 showed important differences among provenances for growth and stem quality traits. These evaluations resulted in recommendations concerning provenances to be used in different regions.

In 1979 FAO, with financial assistance from UNEP and IPGRI, started a project entitled Genetic Resources of Arid and Semi-arid Zone Arboreal Species for the Improvement of Rural Living (1979-1987) which represented, at the time, the first internationally coordinated, systematic effort for the exploration and evaluation of genetic resources of dry zone multipurpose woody species. Eleven countries in the arid and semi-arid regions of the world participated in the systematic collection of seeds of some 281 provenances of 43 species (mainly of the genera *Acacia* and *Prosopis*) and established field trials. A global evaluation of selected field trials was initiated in 1989 by FAO and DFSC in collaboration with national institutes in the countries concerned. During 1990-1994, 26 trials in 6 countries were assessed. Assessment reports of the individual trials have been prepared. A global synthesis is under preparation as a joint effort between national institutes involved, DFSC and FAO.

Well defined, specific objectives and activities were an important factor of success of these "networks" with relatively limited set life-time. Cooperation among international agencies and programmes was also essential. FAO's role was to provide technical assistance, facilitate global coordination and technical cooperation among countries and regions. A main difficulty was the inadequate capacity of some of the network collaborators, which did not allow them to fully participate in, and benefit from the common research efforts. The number and geographic distribution of adequately maintained trials allowed the achievement of the global objectives to identify species and provenances which are adapted in different conditions and regions. However, a number of collaborating institutions could not maintain the trials over the years because of the deteriorating of budget situation and/or because of changes in priorities.

International Neem Network

Neem, *Azadirachta indica* A. Juss. (Meliaceae), is an evergreen multipurpose tree. Neem is native to the Indian subcontinent and South-east Asia, where it has been traditionally used for centuries. The species adaptation to hot and dry climates has made it one of the most commonly planted species in arid and semi-arid areas both within its natural range and outside. In the African Sahel, neem is mainly planted as shade tree and in windbreaks, although production of firewood by pruning and use of neem in local pharmacopoeia are important. In its natural range, particularly in India, products derived from neem have traditionally been widely used for centuries for many medicinal and pest management purposes. Extracts of oil and chemicals compounds from neem for industrial uses are gaining more and more attention worldwide.

Despite the widespread use of neem, programmes for the evaluation and improvement of genetic resources of neem were not initiated, mainly because of seed viability and handling problems, which placed a serious constraint on seed collection and transfer. As a result, the genetic material presently used in plantations is generally thought to have been originally collected on few stands or trees, and its genetic base is frequently likely to be very narrow, particularly in countries outside the natural range of the species. Neem decline is periodically affecting many Sahelian countries and is alleged to be caused by a number of interacting environmental and genetic factors, possibly aggravated by pathogens.

The International Neem Network was established in 1994, following the recommendations and agreements of the First and Second International Consultations on Neem Improvement in Thailand 1993 and India 1994. The following working principles were agreed upon by network collaborators representing 22 countries from within and outside of the natural range of the species:

- Free availability of seed for research purposes on exchange basis and mutually agreed terms;
- Standardised trial designs and standardised evaluation procedures (common guidelines);
- Free availability of results of trials and research to Network collaborators;
- Provenance seed collection/ handling/ despatch for trials included in the programme to be done by collaborators, with technical support - and limited financial contribution - from the Network;
- Establishment and maintenance of trials to fall under the responsibility of Network collaborators with technical support by the Network;
- Complementary studies (phenology, genetic diversity/reproductive biology,

seed physiology) to be undertaken through specific research projects discussed and approved. Each project has a coordinator and can be presented for funding to potentially interested agencies;

Each Network collaborator can be involved in the various activities according to his interest and capability;

Each participating country has a national focal institute which coordinates the Network activities at national level;

The Network is coordinated by an informal panel formed by representatives of national focal institutes from at least three participating countries, DFSC, CIRAD-Forêt, IPGRI, FORTIP and FAO. Global coordination is entrusted to FAO.

During 1993 and 1994, seed sources were surveyed and documented throughout the natural range of the species and in areas of introduction. Pilot seed collection and exchange were undertaken to improve the procedures used in these difficult operations in view that, neem seed has a recalcitrant or intermediate behaviour. A training course was organised in 1994 in India to familiarise network collaborators with the improved procedures. A total of 25 seed sources from 11 countries, representing the entire eco-geographical variation in the range of distribution of the species were described and collected using agreed common guidelines. The 25 seedlots were exchanged among 21 countries. Field trials were established in 1996-1997 and their assessment started. The next very important step will consist of their evaluation and this will provide information on the extent of the genetic variation of neem. Provenance recommendations for planting at different sites will become available based upon the results of the assessments. This information will be valuable, in particular, to broaden the genetic base of the species outside of its natural range with well adapted and good quality material.

Achievements by the International Neem Network include the establishment of more than 30 provenance trials with a common set of provenances representing the full range of the distribution of the species, and successful exchange of seed and of information, experiences and knowledge between more than 20 countries. This constitutes a basic pool of materials, knowledge and know-how that can pave the way to further developments in conservation, tree selection and improvement, and plantation establishment. Capturing the potential offered by neem is a contribution to the overall development and to meeting the requirements of rural people.

Factors for success include:

Problems and requirements are identified and shared by all collaborators, allowing the finalisation of common, realistic, agreed upon objectives.

The enthusiasm and dedication of individual collaborators have never diminished.

The principles have been agreed among collaborators as one of the first steps taken by the network.

All partners have been identified properly (e.g. relevant national institutes, research institutes, regional and national organisations).

Many personal contacts and very good collaboration between institutes, regional projects, national and international organisations, NGOs have helped the network function in harmony.

Frequent meetings have been held (approx. one each year) to get an overview of the status and progress of work in each country, to exchange information and experience, to discuss and eventually agree upon the next operations to be undertaken.

This stepwise, pragmatic and realistic approach has been recognised and appreciated by many collaborators.

The many booklets and practical guidelines have streamlined the procedures; few serious problems have been recorded during implementation of very delicate operations such as the large scale collection, handling and international exchange of recalcitrant seed.

All data and information have been thoroughly documented. This is extremely important as provenance testing is a long term task which results rely on precise and accurate records of operations and activities.

Many international partners and programmes contributed to different stages of preparation and implementation of the Network's programme: the Forest and Fuel wood Research and Development Project (F/FRED) funded by USAID, DANIDA through DFSC, the French Cooperation through CIRAD-Forêt, IPGRI, and projects executed by FAO such as the project on Improved productivity of man-made forest through technological applications in tree breeding and propagation (FORTIP) and the Forestry research support programme for Asia and the Pacific (FORSPA).

FAO has provided a neutral forum for the exchange of information, experience and know-how; the framework of the international organisation has contributed to smoothen initial difficulties, and facilitated the coordinated participation of other international partners and programmes.

The following key constraints were identified:

Although its programme and activities are well defined, there is no specific budget to support the Network. Activities have been achieved to date thanks to very active contacts and cooperation among national, regional and international partners. However, it has been difficult to get financial support for all activities that collaborators were keen to undertake.

Travel costs for participants in meetings, training courses etc. are high when the Network is operating at a global scale.

The end uses and also the importance of neem differ from country to country. Therefore, the Network needs to be flexible in order to accommodate all collaborators with different interests and capacities. Flexibility is also needed to accommodate new members, and to take new requirements and needs into consideration.

The International Neem Network is entering its seventh year. After a promising and successful start, it now faces new challenges such as the conservation of genetic resources and the selection, improvement and breeding of neem. Considering the under-utilised potential offered by the multipurpose tree, further work could be realised within the framework of the International Neem Network. All information, knowledge, methods and skills are now assets of the collaborators who will decide the next steps. The guiding principle in the activities of the International Neem Network is that full responsibility rest with the Network collaborators. The majority of the activities is undertaken using the collaborators own funds and the activities are to a large extent integrated into the work programme of the organisation. This guiding principle is thought to be a key factor in the long term sustainability of the Network.

TEAKNET (Asia-Pacific Region)

Teak is one of the most important hardwood species planted extensively in several countries in the Asia-Pacific. Being indigenous to the Region, substantial experience bas been gained in the management of natural and man-made stands of teak. Notwithstanding the large scale introduction of fast growing exotics like Eucalyptus and Acacia species, teak continues to lie an important species, especially on account of the high quality of wood, the increasing demand, and the ease of cultivation and management. Growing private investment in teak plantations is a clear indication of the perceived potential of the species, although deforestation and unscientific management have substantially reduced the area of natural stands.

While problems in the countries in the Region are similar and considerable experience exists in dealing with them, there is no effective mechanism to share this and to facilitate the improvement of techniques for conservation, management and utilization of teak plantations and forests. The need for developing a suitable mechanism to facilitate exchange of information was discussed during the China/ESCAP/FAO Regional Seminar on Research and Development of Teak held at Guangzhou, China during March 1991. There was a general consensus to the proposal for establishing an "Asia-Pacific Network on Research and Development of Teak", TEAKNET. It was proposed that ESCAP and FAO should jointly develop a detailed plan for the network mechanism.

A proposal for establishment of the "Asia-Pacific Network on Research and

Development of Teak", TEAKNET (Asia-Pacific Region) was discussed and agreed upon at the Second Regional Seminar on Teak organised, in Yangon in 1995, by the Ministry of Forestry of Myanmar in collaboration with FAO.

The objectives of the network are: (i) exchange of technology and information on sustainable management, silviculture, processing and promotion of teak; (ii) exchange of genetic materials, plants, soils and timber samples together with standardisation of trials to facilitate international comparison; and (iii) collaborative studies on critical areas that are of common interest to member countries.

To fulfil the above objectives, TEAKNET will undertake the following activities: (i) review major developments in the conservation, management and utilization of teak (through a seminar organized once in three years); (ii) information dissemination through: publication of (a) a newsletter (quarterly or half yearly) and (b) case studies and reports on problems of wider interest; maintaining and providing access to data bases on area, production, productivity and trade, individuals and institutions involved in research and development of teak trade and marketing; (iii) support and catalyse collaborative research on problems of common interest; (iv) facilitate the exchange of genetic materials, plants, soils and timber samples for research purpose; (v) facilitate the exchange of expertise and training among the countries/institutions who are part of the network; and (vi) any other activity that are relevant to the main objective of the network.

Considering its broad objective, TEAKNET aims at a diversified membership: (i) institutions, agencies, departments, from both the public and the private sector involved in managing plantations and forests, undertaking research and studies, processing and marketing teak products; (ii) consumer associations; and (iii) individuals with demonstrated and sustained interest in various aspects concerning growing, managing and processing of teak.

A Steering Committee was formed with representatives from member countries and FAO. Efforts to secure specific funding to support activities proposed in the work-plan of the network have been unsuccessful to date. TEAKNET has been able to maintain the information link among its members. It organised a regional seminar on Site, Technology and Productivity of Teak Plantations, 26-29 January 1999, Chiang Mai, Thailand, in collaboration with the Chiang Mai University and FORSPA. The seminar was attended by experts from all teak growing regions of the World, and provided a good review of the state of knowledge and practice, which is very timely during this period when teak plantations are developing at a very high rate, following new short rotation, high-intensity silviculture regimes and based on very high yield projections.

One reason why it has been difficult to find specific financial support to the full set of activities of TEAKNET is probably the width of its scope, covering all aspects from tree improvement to marketing. While keeping its holistic approach, the network might identify areas of focus to be covered by projects with more specific outputs of interest to the members from the public and the private sector.

Networking under FAO Statutory Bodies and Regional Commissions

Networks and networking are part of activities undertaken in the framework of Statutory Bodies and other commissions of FAO, which often include exchange of information and technology in their programmes.

Silva Mediterranea

Mediterranean forests share many common features, which argue strongly for regional cooperation. In 1911 the idea of Mediterranean forestry cooperation was launched and, in 1922, a Mediterranean Forestry League was established under the name of "*Silva Mediterranea*". In 1948, *Silva Mediterranea* evolved into a statutory body of FAO as a Committee on Mediterranean Forestry Questions where the Mediterranean countries members of the FAO European Forestry Commission, Near East Forestry Commission and African Forestry and Wildlife Commission could meet, share their experiences and establish cooperative programmes.

The purpose of *Silva Mediterranea* is:

- to periodically review the trends in the use of forest land in the Mediterranean area and to assess the impact of changes implemented in the agricultural, industrial and urban sectors, and to advise Member Governments accordingly on reorientation or improvements necessary to meet changed situations or newly-emerging needs; conversely, to periodically examine progress in forestry technology within regional and ecological contexts in order to better assess present forest land utilization methods;
- to identify forestry research priorities in the Mediterranean area, determine forestry research projects of common interest to Member Governments in the region and recommend to the Director-General of FAO and Member Governments the adoption of measures necessary to coordinate the concerted execution of these projects by the forestry research institutes in the Region;
- to determine and carry out, in collaboration with Member Nations and with the support of the appropriate national forestry agencies, the technical studies and surveys which are deemed necessary to assist governments of the region formulate national forest policies or facilitate their implementation.

Silva Mediterranea holds its Session every two years, to discuss and address common problems. Where research is needed, the Committee establishes cooperative research networks on subjects identified during sessions. Presently six research networks are operating: a) Forest fire management; b) Selection of multi-purpose species for arid and semi-arid zones; c) Silviculture of species: *Cedrus sp.*; d) Silviculture of species: *Pinus pinea*; e) Selection of stands of Mediterranean conifers for the production of seed to be used in reforestation programmes; and f) Silviculture of species: *Quercus suber*. Each of these networks designates a coordinator and has a focal points in each interested country. Activities are conducted within normal research programmes of national research institutions, and no special funding is allocated to the networks. Nevertheless, these networks can be supported by international organisations such as IUFRO, UNESCO, the International Center for Advanced Mediterranean Agronomic Studies (CIHEAM) or FAO, mainly for meeting organisation and publication of research results. Some donor countries may also support a given network through trust fund projects.

Silva Mediterranea research networks have had variable performances, depending on funding at country level and from external sources. Recently, a regional trust fund project on "Co-operative information on prevention and control of forest fires in the Mediterranean Region", funded by France, was implemented in the framework of the network on "Forest Fire Management". Regional workshops were held in Tunisia and Morocco on the design demonstration of the newly established computerized databases on forest fires in selected countries of the Region and on their effective use in forest fire management. The workshops achieved excellent results in particular in training of national staff and capacity buiding, and awareness raising of issues related to forest fire information generation and management. The research network on "Silviculture of species: *Quercus suber*" looked for ways and means to support the sustainability of the cork oak agro-silvo-pastoral systems through promoting the trade and the use of cork products. This activity was supported by the private sector including producers, manufacturers and users. The cork oak network also developed activities on genetic resources conservation and improvement, in cooperation with the "Mediterranean Oak Network" of the European Forest Genetic Resources Programme (EUFORGEN) coordinated by IPGRI in collaboration with FAO.

Regional Networks in Latin America and the Caribbean

Technical cooperation networks, sponsored by the FAO Regional Office for Latin America and the Caribbean, were established with the following objectives: (i) promote cooperation among the countries of the region through joint efforts and the exchange of knowledge and experiences; (ii) promote the countries' self confidence in their own resources, knowledge and abilities; (iii) strengthen the technical capacities of national institutions above all to identify problems and formulate adequate solutions; (iv) promote capacities and human resources training at all levels; and (v) accelerate development through a more effective use of human, physical and financial resources available in the region.

Technical cooperation networks are integrated by national institutions sharing the common technical interest of the network. These generally are public or semi-public institutions, but may also be non-governmental organizations. Normally, a country is represented by only one institution in each network. This institution coordinates the network's activities at the national level, and must ensure the adequate participation of other institutions interested in the network's activities and cooperate with them.

The technical cooperation networks include (i) the Latin American Technical Cooperation Network (LATCN) on National Parks, other Protected Areas and Wildlife (established in 1983); (ii) LATCN on Watershed Management (1980); (iii) LATCN on Agroforestry Systems (1986); (iv) LATCN on Dendroenergy (1986); and (v) the Caribbean Technical Cooperation Network on Forestry and Related Environmental Matters (1992).

The networks resort to various methods and mechanisms to exchange information and experiences and implement their programmes of activity. They include the following: (i) round tables, workshops and expert consultations to analyze technical matters and coordinate programmes of work of common interest; (ii) training activities through courses and seminars; (iii) study visits and technical exchange; (iv) exchange of research findings, publications and audiovisual materials; (v) periodical communications by means of circular letters and informative notes, (vi) preparation of technical documents and manuals to disseminate appropriate technologies; (vii) cooperation in the execution of national, bi-national, sub-regional, regional and interregional activities such as technical cooperation projects, studies, technical documents or specific programmes.

The FAO Regional Office for Latin America and the Caribbean provides the networks with a Secretariat to coordinates them, both technically and logistically. The Secretariats collaborate in identifying activities of common interest to the countries, as well as their technical and institutional capacities. The Secretariat, jointly with the regional coordinators, proposes a programme of activities for the networks and coordinates FAO's financial and administrative support. It also helps regional and national coordinators in the implementation of network activities and coordinates the edition and publication of technical documents. To ensure the effective dissemination of network activities and achievements at national level, the establishment of national networks was promoted. However, it has been possible to implement national networks only in some of the participating countries. In general FAO support has been fundamental in obtaining the necessary funds to carry out the network's activities. These funds are generally provided by FAO's Regular Programme, in ever decreasing amounts, and by other regional and inter-regional institutions such as UNEP, IUCN, the Inter-American Development Bank, Unesco and the Amazon Cooperation Treaty (ATC). In addition, some regional projects executed by FAO have contributed to finance network activities.

Achievements of the networks have been satisfactory over the years, through activities mentioned earlier. It has however become more and more difficult to sustain them without external funding, although active collaboration with other regional and international initiatives and programmes have produced important outputs. Following consultations with the networks' members, and considering other related ongoing programmes or initiatives under development in the region, decisions will be taken as to the future of the networks.

At national level, two important elements for the satisfactory operation of the networks are: an adequate national coordinating institution and the respective national coordinator. Good results have been obtained in some countries in both aspects, while in others results have been weak. Some important problems are: lack of dissemination of the results of the network's activities at the national level, which is more apparent when there are no national networks, scarce or no communication between the national coordinator and forestry authorities and frequent changes of national coordinators.

Support to Regional Networks of Forestry Research Institutions

The recognition of the need to strengthen the global forestry research system has been concretised in recent years by the establishment of CIFOR and ICRAF as International Research Centres of the CGIAR system, and the broadening of the programme of IPGRI, an other Centre of the CGIAR, to cover forest species. By mandate, the Centres of the CGIAR focus on strategic research and applied research at global level.

National Research Systems, including institutions from both the public and the private sectors, are an essential component of the global research system, to undertake applied and adaptive research, capitalise and transfer research results to local development. International research programmes will have limited impact without appropriate participation and complementary research by national institutions. Most developing countries do not have the adequate capacity to participate in international research projects and to capitalise, adapt results and transfer them at local development level. This essential function of national research systems, including governmental and non-governmental institutions, is reinforced by a new trend of increased involvement of non-governmental actors in forestry and agroforestry development activities, and the need to adapt research to better serve a broader array of users, and get closer to their needs. Thus, strengthening of national research systems is of highest importance.

A regional approach is privileged, as shared and coordinated support at regional level is an efficient means for strengthening of national forestry research systems, while developing adequate co-operation among them.

The Forestry Research Support Programme (FORSPA) and the Asia-Pacific Association of Forestry Research Institutions (APAFRI)

Forestry Research Support Programme for Asia and the Pacific (FORSPA)

FORSPA was launched in 1991 to formalise the informal networking of forestry research institutions that existed earlier in the Region. During Phase 1 (1991-94), funded by the Asian Development Bank and UNDP, research capacity building was attempted through (a) funding field research projects in regional priority areas, (b) strengthening access to information including the provision of hardware and software to national institutions and development of supporting data bases, (c) organizing and supporting meetings and seminars on topics relevant to research, and (d) training researchers and research managers.

Among these activities, funding field research projects was considered to be the more important. Based on inputs from a pre-implementation seminar, five regional priority areas were identified: (a) upland watershed management, (b) improving sustainability of plantation forestry, (c) reforestation of degraded lands and problem soils, (d) ecosystem conservation and maintenance of biological diversity, and (e) promoting community participation in forestry development. Over time, problems inherent in implementing a regional support mechanism emerged. Some of the projects took much more time than anticipated. Partly this was due to the artificial time frame imposed by FORSPA's limited project duration, and partly it resulted from poor project designs. It was also noted that participants in the projects did not take advantage of the networking opportunities provided by the commonality of the themes. Further, it became evident that many institutions participated in the programme to take advantage of the funding opportunities, rather than because of any importance attached to the research theme. Also, much of the support went to countries with already well developed research systems.
The lessons learned from Phase I resulted in a shift in strategy during the bridging phase (1995-96) supported by the Asian

Development Bank and the follow-up Phase Il (1996-2000) funded by the Netherlands Government. To sustain long-term research networking, FORSPA facilitated the establishment of the Asia Pacific Association of Forestry Research Institutions (APAFRI). Funding for small-scale field research projects was discontinued, and instead, support is being provided to networks focused on priority topics and collaborative arrangements like twinning. Country capacity building, especially focused on those where national research systems are inadequately developed, is a major thrust of FORSPA Phase II. Such support includes (a) development of research strategies and plans for research, (b) human resource development to improve research proposal formulation and implementation capabilities and to address specific technical constraints through on-the-job training. (c) improving access to information and (d) promoting collaboration through twinning arrangements.

The lessons learned from FORSPA since its beginning in 1991 suggest that networking and collaborative research at the regional level require:

- a highly flexible approach to address the specific needs at the countries;
- a commitment for long-term support by donors;
- some minimum capacity at the country level to take advantage of the regional support mechanism;
- clear and concise strategies at the national and institutional levels so that network-based research becomes an integral part of the ongoing research and not an additional item that will strain already limited resources.

Asia Pacific Association of Forestry Research Institutions (APAPRI)

As indicated earlier. APAFRI was established as regional non-governmental organization to sustain FORSPA's regional research networking functions. A meeting of the Heads of Forestry Research in the Asia Pacific convened in Bogor, Indonesia in February 1995 approved the constitution of the Association and elected an Executive Committee to initiate its establishment. APAFRI's long-term objective of fostering development of forestry research for sustainable forest management in the Asia Pacific Region is to be achieved by:

- promoting exchange of scientific and technical know-how and information;
- promoting cooperative research and training programmes; and
- strengthening linkages among national, regional and international research organizations.

Until early 1997 APAFRI was managed by FORSPA. During this period the main emphasis was on nurturing the organization, canvassing the membership and providing necessary visibility to APAFRI so that it would be seen as a viable networking mechanism. It became evident that the organization's long-term sustainability would require member institutions to assume managerial responsibility and widen the resource base. Accordingly the APAFRI General Assembly decided to relocate the Secretariat to the Faculty of Forestry, Universiti Putra Malaysia.

APAFRI has developed a strategic plan and has been able to increase the membership to 47 institutions, including private enterprises and NGOs in addition to most of the leading national forestry research institutions and several international organizations. Each member institution pays an annual fee based on the economic status of the country to which the institute belongs. APAFRI has recently been recognised as the first Regional Chapter of IUFRO. FORSPA continues to support APAFRI in its main activities, and facilitated a CIDA-funded project, TREELINK, which is expected to enhance APAFRI's information and research support for ASEAN members.

Since APAFRI is in the initial stages of development, it is too early to judge it's long-term viability. While all research institutions in the region agree on the need for a regional networking mechanism, several have not yet joined APAFRI and there is an attitude of "wait and see". The network's success will depend on its ability to provide high-quality, unique services to its members, develop strategic alliances with international organizations, ensure that core funding is available to sustain key networking functions. and attract external funding for collaborative activities.

Forestry Research Network for sub-Saharan Africa (FORNESSA)

In 1993 IUFRO and FAO convened in Ouagadougou (Burkina Faso) a workshop between representatives of forestry research institutions of the region to look into the urgent needs of the forestry research in Africa. The workshop issued a number of recommendations which, among others, requested FAO to take the lead in facilitating measures and initiatives to support development and funding of forestry research, training of staff and institution building.

In 1994, to follow up with these recommendations FAO took several initiatives among which: i) the participation to a meeting convened in Nairobi (Kenya) in July 1994 by the International Foundation of Sciences, the African Academy of Sciences (AAS) and IUFRO which dealt with support to Forestry Research in Africa; FAO presented then a concept paper on strengthening and networking forestry research in Sub-Saharan Africa; the initiative was unanimously supported and FAO encouraged to follow up; ii) the support for the convening and holding of a technical meeting attended by a group of forestry research experts in November 1994 in Accra to further develop the recommendations of the Nairobi meeting; four research institutions of Côte d'Ivoire, Kenya, Malawi, Senegal and the African Academy of Sciences decided to create a nucleus of a Forestry Research Network for Sub-Saharan Africa (FORNESSA) to promote cooperation among them; Senegal, Kenya and Côte d'Ivoire subsequently approached FAO for support.

In reply to the expressed needs and to the requests received from countries, the FAO and the Special Programme for Developing Countries (SPDC) of IUFRO undertook to formulate a regional project proposal involving interested countries and sub-regions of Sub-Saharan Africa. The project aims at capacity building, development of collaborative research activities and networking; the ultimate result of the project would be the creation of a network of forestry research institutions in Sub-Saharan Africa, a federating mechanism across language boundaries, which will strengthen and build on sub-regional networks already active such as the Forestry Network of WECARD, in Central and West Africa, and the SADC-FSTCU Research Sub-committee in Southern Africa. A draft proposal was discussed and its objectives, outputs and activities were approved in the Expert Consultation on Forestry Research convened by FAO and IUFRO/SPDC, in October 1997, at the FAO Regional Office for Africa, in Accra.

Since June 1998, the Deputy Coordinator for Africa of IUFRO-SPDC has been hosted by the Forestry Group of the FAO Regional Office for Africa to facilitate cooperation in activities in support to forestry research, and in particular in support to FORNESSA.

Following recommendations made by the Accra consultation, the original "FORNESSA" proposal was reorganised into components, which can be supported by different donors. Activities in strengthening of sub-regional forestry research networks or groups, such as the SADC-FSTCU Research Sub-committee, the Forestry Network of CORAF in West and Central Africa and the recently established Association of Forestry Research Institutions in Eastern Africa (AFREA), and in linking them together were included as a component of an FAO-European Commission partnership project on "Sustainable forest management in African ACP countries", which started in January 2000. Activities include:

1. Assist with the establishment and management of databases on institutions, human resources and activities. Databases are tools useful to avoid undesirable duplications of activities and to identify and contact potential research partners. Existing sub-regional databases will be surveyed and reviewed in order to identify those which can be developed into coherent sub-regional and, later on, regional databases. This activity will then update and expand these databases to make them more comprehensive and start to

establish networks of researchers working on common research topics.

2. Support the preparation of thematic sub-regional and regional syntheses and research working groups. Some national institutions have been working in isolation on themes of common sub-regional or regional interest, but not disseminating their results. This component will gather, synthesise and publish such results and, from these, develop a process for collaboration in research areas of common interest to network members. Thematic working groups will be established to prepare and undertake common research projects in these areas.
3. Support greater information exchange and communication on forestry research issues.

A meeting of AFREA, the SADC-FSTCU Sub-committee on Research, and WECARD Forestry Network is planned to be held in July 2000 to formally federate themselves and form FORNESSA.

Activities in sub-Saharan Africa will continue to be undertaken in collaboration with concerned institutions and networks such as IUFRO-SPDC, CIFOR, ICRAF, IPGRI and the African Forestry Research Network (AFORNET), a network of individual scientists supported by the AAS.

The emergence and strengthening of associations and networks of institutions to represent forestry research and facilitate priority setting and cooperation at regional level are a necessity, and very timely, considering the ongoing international initiatives in agricultural research, in particular the Global Forum on Agricultural Research. The Global Forum on Agricultural Research (GFAR) was established in October 1996 by a group of representatives of the developing-country national agricultural research systems (NARS), advanced research institutions, regional and sub-regional organizations, universities, non-governmental organizations, farmers' organizations, the private sector, international agricultural research centres and the donor community, "to mobilize the various stakeholders that constitute the global agricultural research community in their efforts to alleviate poverty, increase food security, and promote the sustainable use of natural resources."

NARS are represented in the GFAR by a steering committee composed of the chairpersons of the five NARS regional fora on agricultural research (i.e., Asia and the Pacific, Central Asia and the Caucasus, Latin America and the Caribbean, sub-Saharan Africa, and west Asia and north Africa). Although covering forest and environment issues in principle, these regional fora are dominated by agricultural concerns in the narrow sense.

"Natural resources management and agro-ecology" is one of the five high priority areas identified by GFAR in its program of work. To appropriately cover this priority area, GFAR will need to open develop a real forestry dimension at all levels (NARS, regional and sub-regional for a, global). Regional networks and associations of forestry research institutions, including APAFRI (now a Regional Chapter of IUFRO) and FORNESSA, should play an important role in this process.

Concluding Remarks

Networking is an approach and a tool, which is widely used in FAO programmes. Networking efforts have concerned all the spectrum of activities: theme-specific projects, regional programmes and global initiatives.

This brief review showed that, although generally successful because of their well defined and specific objectives, outputs and time-frame, theme-specific networks also have constraints. The main one is the inadequate or unsustained capacity of some collaborating institutions to fully participate in the network's activities and benefit from them.

The International Neem Network and TEAKNET are two species networks with broad objectives. The stepwise approach taken by the neem network allowed it to go beyond symposiums and planning meetings, and successfully undertake activities in its first area of focus: coordinated international collection, exchange and assessment of genetic resources of the species. The challenge for the neem network will now be to successfully develop activities to achieve its other objectives (steps), either by involving new collaborators with the required expertise or through collaboration with other concerned initiatives.

Technical and research cooperation networks to address common regional issues have generally fulfilled their role in exchange of information and expertise. These networks require external support to maintain contacts and remain competent resource groups able to provide valuable support to projects and initiatives in their field of expertise. One necessity for these networks, which were established a long time ago, is to periodically critically review and update their objectives and work plans.

Support to the networking of forestry research institutions has been a main thrust in recent years, to enhance national and regional capacities to prioritise and undertake research. FAO will continue to cooperate with IUFRO and other partners in these efforts.

Finally, it should be stressed that, in all the networking efforts facilitated by FAO reported here, a constant factor of success is the active, and often creative, cooperation with other regional or international programmes and institutions.

Abstract

Over the last decade clear trends have emerged with the management of forest resources in Southeast Asia. Some countries have ceased timber production from natural forests, and are now net importers. Others are beginning to perceive declines in production. While these have serious economic implications to many countries in the region, concern for the rapid degradation and loss of some of the world's greatest species diverse forests has been turned into international issues. A number of international initiatives were made to bring about improvement in the management of these ecosystems and to ensure they are not totally degraded. Forest management has ceased to be mere pursuit of yield increments. It now has to address an array of issues collectively described under the principles of sustainable forest management. They encompass socio-economic considerations, environmental issues, and biodiversity conservation matters. Currently, there are approaches to enforce such measures by introducing certified "green" timber only to be traded in the international markets. There are calls to have independent assessment of the forest management as well. Since natural forest management is undergoing heavy scrutiny and greater controls, there are now moves to overcome the decrease in production by investing heavily in timber plantations. As a consequence, the private sector is beginning to participate in an industry that was once the domain of the public sector. Overall, forestry in Southeast Asia is facing considerable challenges ahead. Some future directions for achieving sustainable forest management in the region are discussed.

Introduction

A cursory glance at the timber trade worldwide would reveal some important clues. The area of closed forest in North America and Europe does not come close to that found in the Third World Countries of Africa, South America and Asia, yet the former have higher sector production and exports (Table 1) (FAO 1999). This could mean that the wealth of forests in the third world countries, which are mainly in the tropics, has not been truly realized as the case is with developed nations.

It is also apparent that among the third world countries, Asia and the Pacific region, while not in possession of the largest forest area, is yet enjoying a bigger production and export level. The Asia-Pacific region exports about 33,000 m^3 of industrial roundwood, against about 17,000 m^3 from Africa and South America. Likewise, the export value of forest products from the Asia-Pacific region in 1988 was over US$10 billion while that from the other two regions wass a dismal US$4 billion (FAO 1989).

What are the specific factors behind the strength in the Asia-Pacific region for the high productivity? A glance at the forest production and export values from Asian countries would provide the explanation (Table 2). Aside from the developed Asia-Pacific nations, the Southeast Asian countries are unusually productive, particularly Indonesia and Malaysia. The Asia-Pacific countries export over US$10 billion worth of forest products annually, of which half of it is coming from the two Southeast Asian countries.

Table 1. Total Forest Cover and Exports, 1995 (FAO 1999).

Region	Total Forest Area (x 1000 ha)	Industrial Roundwood Export (mil. cu. m)	Sawnwood Export (m. cu. m)
Africa	530273	7439	1351
Asia	503000	14336	6666
Ocenia	90695	18347	1067
S. America	870594	10066	3493
Central N. & America	536529	23701	58185
Europe	933326	46074	41865

With such a background, the management of forest resources in the Southeast Asian region deserves a further examination. There are numerous questions behind this review:

What circumstances have led to this apparent success?

Can the productivity be maintained?

Are there threats to the resources?

What are the strategies for long term sustainability and growth?

Forest Resource Base of Southeast Asia:

The Southeast Asian countries can be subdivided into the continental and insular Asian countries (Table 3). With the exception of Thailand and Vietnam, all the countries have between 30 and 66% of the land covered with closed forests. In general, the insular region is still well covered with forests, whereas the continental Southeast Asia appears to have lost some considerable areas. In terms of economic importance, forestry is critical for many of these countries. But for Thailand, Brunei and the Philippines, all the rest appear to derive around 10% of their GDP from forest products. Of them, the biggest money earners are Indonesia and Malaysia.

The forests in the continental region are tropical seasonal forests, and those in the insular areas are the rainforests (Whitmore 1974). The rainforests are the major source of hardwoods from the region. For example, of the 25 million m^3 of tropical hardwood logs traded at the world level in 1986, 21 million m^3 came from Southeast Asia and the Pacific region (Nectoux *et al*. 1991). Of that, 19 million m^3 came from Malaysia. It is the same case with sawn hardwood – a total of 6.7 million m3, which is 70% of the world's tropical sawnwood trade, originated from Southeast Asia. This is repeated with plywood as well – Indonesia is now the world's biggest tropical plywood producer, with an export of 5.5 million m^3 in 1987. The strength of Indonesia and Malaysia in the hardwood export market is mainly due to the presence of dipterocarps which dominate the rainforests of the region. These forests are particularly rich in timber as a result.

Forest Management or Forest Degradation

Considering the huge volumes of timber extracted from the natural forests in the region, naturally there is tremendous concern over the consequences:

Will the resource last into the long term?

What about environmental problems?

What are the economic consequences of forest loss?

Table 2. Summary of Forestry Statistics for Asia-Pacific countries (Only countries with >5 mil. ha of closed forest included) (ca. 1988) (FAO 1989)

Countries	Closed Forest Area (x 1000 ha)	Forest Sector Production (mil. US$)	Forest Products Exports (mil. US$)	Round-wood Exports (1000 m^3)	Mechanical wood (1000 m^3)
Australia	41,658	2,549	352	8,497	4,416
China	97,847	17,007	772	10	29,908
India	51,841	10,691	16	76	17,902
Indonesia	113,895	8,450	2,873	1,131	16,807
Japan	24,158	17,566	1,031	16	39,507
Kampuchea	7,548	154	0	0	45
Lao, PDR	8,410	101	10	34	21
Malaysia	20,996	3,922	2,572	20,853	7,706
Mongolia	9,528	128	0	0	474
Myanmar	31,941	599	87	206	498
New Zealand	7,200	1,485	439	1,728	2,445
Papua New Guinea	34,230	265	109	1,383	136
Philippines	9,510	1,349	279	603	1,573
Thailand	9,235	1,403	130	152	1,295
Turkey	8,856	1,629	37	23	5,704
Vietnam	8,770	756	0	0	394

Table 3. Forest resources of Southeast Asian countries (000 ha) (ca. 1985)

Countries	Land area	All forests	Closed forests (% land covered)	Timber Plantations	% GDP
Continental:					
Kampuchea	17,550	12,648	7,548 (43.0)	6	14.0
Lao PDR	23,080	13,625	8,410 (36.4)	11	12.9
Myanmar	65,770	31,941	31,941 (48.5)	15	7.5
Thailand	51,180	15,675	9,235 (18.0)	129	2.4
Vietnam	32,540	10,110	8,770 (26.9)	204	8.1
Insular:

Deforestation

The Asia/Pacific region has for more than three decades been experiencing an exceptionally high rate of tropical hardwood removals (Table 4) (Grainger 1986). As noted earlier, most of it, over 60% comes from just two countries. This appears to result from forest conversion to other land use, mainly agriculture, logging activities.

A step back to the past would provide future scenarios. Not too long ago, countries like Thailand and the Philippines, well endowed with forests, were important exporters of hardwoods. Their rate of deforestation was in excess of 2%, and by the mid-1990s they ceased to be exporters, and are now net importers (Table 5) (WRI 1990).

Table 4. Trends in tropical hardwood removals (1965 – 1995)(in millions of m3)

	1965	1975	1985
All Tropics	77.746	113.747	134.418
Africa	11.666	14.296	17.370
Asia/Pacific	51.348	77.647	85.955
Latin America	14.732	21.804	31.084

Table 5. Area of natural forest and deforestation rates (ca. 1980) (area x 1000 ha)

Countries	Land area	% as cropland	% as forest land	Annual Deforestation rate
Continental:				
Kampuchea	17,550	17	76	0.3
Lao PDR	23,080	4	57	1.3
Myanmar	65,770	15	49	0.3
Thailand	51,180	39	29	2.8
Vietnam	32,540	20	40	0.6
Insular:				
Brunei	590	n.a.	79	0.3
Indonesia	181,160	12	67	0.9
Malaysia	32,850	13	60	1.2
Philippines	29,850	27	37	2.7

Indonesia and Malaysia, although still in possession of over 60% of their forests, are currently losing about 1% of their forests annually. If this trend is not arrested, these timber-rich countries would see the same fate of several other countries in the region.

Causes of Deforestation

Deforestation and the causes behind it are numerous and complex. The following are the leading factors behind deforestation (Panayotou & Ashton 1992):

a) Conversion to Other Economic Uses:

Large tracts of easily accessible natural forests have been converted to other forms of land use such as agriculture, mining, timber plantations, pasture land, urban development, hydroelectric dams, etc. Conversion of natural forest to perennial tree-crop agriculture such as rubber, oil palm, cacao, fruit trees, spices, coffee, sugar cane, etc. have been important economic developments in the region. The pressure to convert more forested land for such development has not ceased, considering the apparently high profits from such activities. These activities result in definite loss of tree cover from the area.

In several countries, governments sponsored settlement programs whereby people were relocated. This has been done in Indonesia, Malaysia and Vietnam. They are called the FELDA scheme in Malaysia and the Transmigration or resettlement scheme in Indonesia (Whitten et al. 1991). The schemes were a means to raise the economic standards of the settlers. Under the schemes, in excess of 10 million ha of natural forests were converted in the region to oil palm and other tree crops for the settlers to work on.

b) Uncontrolled Exploitation:

Although statistics are not available, effects of over-harvesting, overgrazing and fire damage, all of which lead to forest degradation must also be taken into account. The incidences of fire are increasing in the region, with three major episodes of fires in the region in the last two decades. In each instance, about 1 million ha, mainly the peat swamps were burned (e.g. Leighton & Wirawan 1986).

c) Shifting Agriculture:

The problem of shifting agriculture has been highlighted extensively. Easily more than half of deforestation in the region can be attributed to unsustainable shifting agricultural practices (Spencer 1966). The rapid growth of the populations and shrinking of the existing forested areas are the main reasons behind the failure of this age-old system of agriculture. Besides shifting agriculturists, encroachment by landless populations into newly logged forests is also taking its toll.

d) Logging:

Commercial extraction of timber in Southeast Asia has been shown to be largely destructive. An ITTO study concluded that very small percentage (less than 1%) of the natural forests in the region are managed on a sustainable basis (Poore et al. 1989). In all cases, over-harvesting has been the usual practice. The growth figures obtained from more recent studies rarely support the rate of harvesting, and the cutting cycles of 25-40 years are believed to be on the short side. The harvesting using heavy skidder-tractor machinery usually results in damage of over 60% to the residual vegetation (Appanah & Weinland 1990). The loss of potential tree crops as a result of logging damage has not been clearly recognized, but it is showing up to be considerable, and extensively depletes the stock left behind for the second cut (Appanah & Harun 1999). Logging is carried out with maximum speed, and rarely skidding tracks are pre-planned and controlled, very little road maintenance is carried out, directional fellings are rarely employed, pre-felling climber cuttings are not conducted, and little silvicultural tendings are done to improve the commercial regeneration. Besides damage to vegetation, the poor construction of roads, low maintenance, and the use of heavy machinery result in excessive soil erosion.

The overall conclusion is that in the long term, there will be less and less commercially valuable timber left behind. While total destruction of forests is not likely in every country, many of the logged forests would be poorly stocked, and natural regeneration would be scarce

Environmental and Economic Problems:

While deforestation is required in order to develop sustained agriculture and viable cash crop plantations, beyond certain limits such forest openings would cease to be economically beneficial. Some of the countries are already beginning to reach such threshold levels. But agriculture on poor or ill-suited soils has proven to be disastrous and wasteful. The harvests have declined, and farmers have become impoverished as a consequence.

Deforestation, besides loss of valuable wood which was often burned, has resulted in other serious problems. Heavy and unplanned encroachments have resulted in loss of major watersheds, which are facing severe devegetation and erosion (Hamilton & King 1983). This disrupts the water cycle, rivers and lakes become sedimented, and they finally affect agricultural development, hydro-electric dams, and silt up ports. In many cases, the economic gains from logging are heavily offset by costs to society from the environmental damage ensuing. The cost of repairing flood damage has not been estimated in the region, but in the example of the Himalayas, it was estimated at US$250 million per year (Spears 1982).

Logging often comes at the loss of environmental services whose values may even exceed the gains from timber (Repetto & Gillis 1988). Forests are the major source of potable water for large segments of the populations in the tropics. Many countries in recent times have experienced acute water shortages during unusual drought periods. The impact was most severe in areas which have lost their forests. It is indeed ironic that Southeast Asian countries which are some of the wettest in the world suffer from water shortages. A whole lot of other economic activities can be disrupted as a result of deforestation. They include river transport and ecotourism benefits. Climatic changes are also beginning to become apparent as a result of large scale logging activities (Sagan et al. 1979). Scientists speculate that large scale clearing of tropical forests may affect the reflectivity of the surface of the earth, which could alter global climatic patterns and shift rainfall distribution. Another deep concern is the release of carbon into the atmosphere as a result of burning of tropical forests. This additional carbon dioxide in the atmosphere can cause global warming as a result of the green house effect.

The loss of forests has been considered to have affected the livelihood of the indigenous and forest-dependent populations. Large-scale logging has resulted in loss of non-timber goods and environmental services, impoverishing the local people dependent on them. People who subsist on hunting, gathering fruits, nuts, cane, bamboo, medicinal plants, etc. have been affected (Caldecott 1987). Increasingly, non-governmental organizations have been vociferously campaigning against large-scale commercial loggings.

An additional facet to deforestation and forest degradation is the loss of biodiversity (Myers 1984). The rainforests of insular Southeast Asia fall among the richest zones for plant and animal biodiversity known in terrestrial ecosystems (Whitmore 1974). The loss has not been quantified, but considering some countries have already lost about 60% of the forest, the loss in biodiversity should have been substantial. Since not all the countries have done adequate surveys of the plants and animals, the losses may never be even recognized. The loss of biodiversity is not one of scientific curiosity. Biodiversity is necessary for: i) to sustain and improve agriculture and animal husbandry; ii) to provide opportunities for medical discoveries and industrial innovations; and iii) to preserve the choices for future generations (OTA 1987). The rare discovery of an important drug can revolutionize medicine, and that option should not be lost to future generations which may face new and unknown life-threatening diseases. Well-known drugs derived from tropical forests include the rosy periwinkle (*Cantharanthus roseus*), steroids from Mexican yams (*Dioscorea composita*), and antihypertensive drugs from serpent-wood (*Rauwolfia serpentina*). Next, the discovery of rubber tree in the Amazon should trenchantly state the point. Within this century, the crop has grown into a US$4 billion industry, and many countries are quite dependent on rubber exports for their foreign exchange. We are certain there still are economically important plants in tropical forests waiting to be discovered.

A Future for Southeast Asian Forests:

The overall situation for the remaining forests in the region appears gloomy. The once abundant and majestic moist forests have been reduced to half the original extent. If the deforestation and degradation trends persist, these forests will remain as small and isolated pockets in a landscape dominated by agriculture, scrubland, bamboo and grassland. This, however, need not be the case, and neither would the solution lie with locking these forests away for total preservation forever. Indeed this may prove to be disastrous in the end.

The rapid loss of tropical rain forests is easily explained. The populations are growing explosively in the region, and more people are forced to open up forests for a livelihood. Governments are also forced to open up more lands for cash crop plantations to create a cash economy for the rural poor. Besides the growth in populations, the region's economies are growing rapidly as well, creating a high demand for goods and services. Next, many governments, starved for funds, are treating forestry as a major source of foreign exchange. The result is liquidation of forests, and the funds are channeled to other sectors believed to have more growth potential. In all these cases, they do not recognize that forests can yield a perpetual flow of benefits from non-timber goods and services as well as timber. Neither are the costs of compensating for lost services taken into consideration. The result is heavy deforestation and under-investment into forest protection and management. Therefore, the future of tropical forests will depend on realizing their real economic value, and making economics work in their favour. Some of the steps towards making that possible are outlined below.

a. Reclassification and Gazettement of Forests:

In all these countries, forests have already been classified into totally protected, production, and conversion forests for economic development. With the exception of Burma, Laos, and Kampuchea, protection areas covering much of the biologically rich forests have been gazetted (Green et al. 1991). But problems still abound, and the governments' good intentions are often not matched with their capacity to manage them.

What is needed is a mechanism to implement the good policies which have been developed. In addition, many of these countries need to take a second look at their forest classification for production, protection and conversion. There are still large tracts of land which may be unsuitable for production or conversion to other uses. They are best as are, protection forests. On a positive note, in the last two decades, more areas have been classified into protected forests (Table 6).

b. Under-valuation of Forest Resources and Services:

Governments, as typical owners of forests, have consistently undervalued their resources (Repetto & Gillis 1988). They only capture a small fraction of the stumpage value or rent of the timber resource. This and the overvaluation of forest conversion have led to excessive deforestation and under-investment into forest management. The tax system is based on trees removed, with little consideration for the condition of the forest left behind. The additional costs of future silvicultural tendings are not captured. Neither are the economic losses resulting from logging taken into consideration – like the losses of minor forest produce, biodiversity, and fisheries. Similarly, the siltation and flooding problems downstream, additional costs incurred in treating water that is heavily sedimented, weather damage, and loss of recreational benefits and aesthetic values are never accounted for.

c. Multiple-use Management:

If forests are managed, it is usually for a single product, viz. timber. Although this pattern is beginning to change, nature reserves are being policed, and recreation is gaining importance, it is minimal compared to the logging industry.

Table 6. Forest areas devoted for protection in Southeast Asian countries (000 ha) (ca. 1985)

Countries	Land area	Closed forests (% land covered)	Existing Protection Areas	Proposed Protection areas
Continental:				
Kampuchea	17,550	7,548 (43.0)	2,035	467
Lao PDR	23,080	8,410 (36.4)	-	4,721
Myanmar	65,770	31,941 (48.5)	564	739
Thailand	51,180	9,235 (18.0)	4,479	1,185
Vietnam	32,540	8,770 (26.9)	625	-
Insular:				
Brunei	590	393 (66.6)	107	10
Indonesia	181,160	113,895 (62.9)	13,787	12,810
Malaysia	32,850	20,996 (63.9)	1,326	1,438
Philippines	29,850	9,510 (31.9)	177	62

Table 7. Minor forest produce from Peninsular Malaysia (1957 & 1981) (Appanah 2000)

Produce	1957	1981
Timber	2.2 million m^3 = $364 million	10.2 million m^3 = $1.02 billion
Minor Forest Produce:		
Rattan	$74,769	$179,374
Bamboo	$26,193	$101,232
Damar	$10,528	$616
Jelutong latex	$33,911	$938
Gutta-percha	$192	-
Nipah	$84,805	$7,311
Wood oil	$122	$703
Total for MFP	$230,520	$290,174

With the conflict between the various benefits from forests, multiple-use management will become necessary so as to balance the social and environmental benefits along with ecological sustainability (Panayotou & Ashton 1992). Multiple-use management requires a full evaluation of all the forest goods and services, and this is weighed in the selection of the optimal use or combination of uses the area can be put under. The result would be, certain areas may be designated as timber forest in which non-timber goods are collected, while other areas may be managed for watershed protection with limited logging.

d. Minor Forest Produce:

The role of minor forest produce has been misplaced nowadays. In the past, many people were engaged in the collection of rattan, bamboo, damar, jelutong latex, resins, wild game, fruits and nuts. They were undervalued, never entered the cash economy, and were treated as unimportant. However, these products support a large number of people, who either collect the material for personal consumption, or sell it in the local markets for small returns. The loss of such products can upset the economic lifestyles of a large number of people in the region. In Table 7, the value of timber and minor forest produce for two different periods are given (Appanah 2000). It is obvious that in the past, minor forest produce was a valuable resource, which has been on the decline compared to timber harvesting. The figures suggest that the forest dwellers dependent on such produce cannot rely on them any more.

e. Silviculture and Logging:

Current harvesting practices using skidder-tractor methods are extremely damaging to the soils, residual vegetation, and young regeneration (Wyatt-Smith 1987, Appanah & Weinland 1990). The result is heavy siltation of waterways, and high damage to the future crop. Studies in Malaysia have shown that the damage to the future crop is not tolerable, as quite a large number of them succumb to the damage, and ultimately die (Appanah & Harun 1999). The second crop is therefore depauperate of high value commercial timbers of sufficient volume. With unplanned and excessive skidder trails, large areas of the forest become compacted and the young regeneration is destroyed. Not only are the compacted sites unable to support vegetation growth for several decades, the regeneration for the third cut is mostly lost. Several low impact methods have been tried out successfully, which include helicopter logging, mobile skyline cable system, and the long haulage ground cable system (Sasaki et al. 1999, Shamsudin et al. 1999). All of them are very promising, and should be adopted as the suitable harvesting methods. Otherwise, the future productivity of many of these forests is questionable.

In the same manner, a number of management and silvicultural practices have often been abandoned or never implemented. These include constructing of good roads, pre-felling woody climber cutting to reduce damage, protecting buffer strips of streams, and enrichment planting of degraded sites. The technologies are well developed and can be implemented with very low costs.

The estimation of growth for calculating the cutting cycles are far too optimistic, and national averages are used. This leads to very short and unsustainable cutting cycles. Appropriate local growth data are needed for ascertaining the cutting cycles.

f. Plantation Forestry:

In view of the rapid loss of natural forests, plantations have often been promoted as a better alternative to enhance timber production in the region. This has been considered the best option for countries like Malaysia, Thailand, Indonesia and Philippines where the downstream industrial capacity has far exceeded the production from natural forests. The rationale is that natural forests at the most produce about 2.5 m^3 /ha/yr of commercial timber, whereas plantations can produce annually from 10 m^3 /ha of hardwoods to 30 m^3/ha of softwoods. If the plantations are well developed, they will indeed lift the pressure off the natural forests. However, the benefit of natural forests which includes the ecological services and biodiversity may not be fully realized in plantations.

The success of eucalypts, pines and teak in the sub-tropics and dry tropics is used as evidence for their viability in the wetter regions of Southeast Asia. However, the history of plantations in the region does not appear easy and straightforward. There are numerous difficulties whether they are indigenous or exotics, and whether they are monocultures or mixed species. In Table 8, the plantation areas in the region are shown. It is obvious that hardly any of the countries have even reached 1% in area compared to the natural forest areas found in their countries. Indonesia is the only one that has so far gone aggressively into developing their plantations.

The majority of the plantations are monocultures with exotic species originating from subtropical parts of the world. In the 1970s fast growing hardwood species such as *Acacia, Eucalyptus, Paraserianthes, Gmelina*, and *Leucaena*, and the pine species such as *Pinus* and *Araucaria* were planted (Appanah & Weinland 1993). All of them have short rotations, simple stand structure, uniform timber and can be harvested at one felling. Monocultures are not without problems either.

At present, more species are being tested, particularly the indigenous species and those with longer rotations. With appropriate silviculture and hygiene, the plantations are beginning to look more promising than the initial experiences indicated. With more research, particularly in production of planting material and tree selection and improvement, the plantations would meet their initial expectations and may produce more of the industrial timber by the end of the next two decades

Table 8. Forest resources of Southeast Asian countries (000 ha) (ca. 1985)

Countries	Land area	Closed forests	Timber Plantations
Continental:			
Kampuchea	17,550	7,548	6
Lao PDR	23,080	8,410	11
Myanmar	65,770	31,941	15
Thailand	51,180 32,540	9,235	129
Vietnam		8,770	204
Insular:			
Brunei	590	393	0.5
Indonesia	181,160	113,895	1,918
Malaysia	32,850	20,996	120
Philippines	29,850	9,510	300

But most countries will still be dependent on natural forests until the plantations reach maturity. Big planting programs have to start now if that success is going to be realized. In the interim, other sources of timber have to be sought. Agroforestry programmes too offer some hope there. Agricultural wastewood, such as rubberwood and fibre from oil palm fruit bunches and trunks are important sources of wood material for countries with such extensive rubber and oil palm plantations. Already, a US$1 billion furniture industry using rubberwood exists in Malaysia.

Conclusions

The rapid loss of moist forests and their inherent biodiversity have become international issues in the last two decades. People are now arguing that the future of the planet will depend on what happens to the remaining moist tropical forests. With that concern, many international initiatives were begun. The most prominent of them is the issue of sustainable development, and therein the need to manage the world's forests on a sustainable basis. Guidelines, referred as Criteria and Indicators, have been drawn by international agencies (e.g. ITTO's Objective Year 2000) which promulgate sustainable forest management. These guidelines promote holistic forest management, and pay attention to the issues of resource security, continuity of timber flow, conservation of flora and fauna, environmental impact, and socio-economic benefits of forestry. Many countries have developed their own Criteria and Indicators (e.g. the Malaysian Criteria and Indicators: Thang 1997), and are seriously looking at using these tools for managing the forests.

In addition to that, independent market initiatives have also taken place. Nowadays, consumers in developed countries are insisting that the products originate from sustainably managed forests. This has to be ascertained by independent agencies using Certification Schemes. A number of independent organizations (e.g. the Forest Stewardship Council) are overseeing the Certification of Forest Management. Local agencies such as LEI of Indonesia (Lembaga Ekolabel Indonesia) and NTCC of Malaysia (National Timber Certification Council) are organizing the forest certification activities within their countries. Likewise, Assessment Systems to test the quality of forest management have already been developed (Appanah et al. 2000). All these movements are in their primary stage, but with proper coordination and effort, the pursuit of sustainable forest management should be achievable in the next 5 – 10 years.

Besides the above two, there are also international initiatives that are looking into global environment and biodiversity. The Global Environment Fund has been set up to assist programs in tropical countries which are aimed at saving biodiversity and the environment. Although no significant work has yet to come out of this Fund, the world is awaiting for success from such efforts. One recent move that is beginning to take off is the Carbon Bond trading. Industries that are polluting the environment, such as fossil fuel burning power generation companies, are initiating projects for planting trees and managing forests in the tropics. That is a beginning for tropical forestry certainly. It brings forth one basic message – if indeed we belong to one global village, we must invest in the common goods, and must look after it.

Regional Scenarios in Management of Forest Resources: Latin America

by
Ronnie de Camino V.
Department of Natural Resources and Peace,
University for Peace. San José. Costa Rica

Abstract

The paper presents some general figures of the forest resources and its dynamics: amount and evolution of resources, deforestation and its causes, the general forest management situation. The paper will also emphasies on natural tropical forests.

Through selected examples like forest management by the Chiquitanos communities in Bolivia, the extractive reserves in Brazil, forest management by farmers associations in Costa Rica, forest management together by a company and a Mayagna tribe in Nicaragua, the community forest management in the Atlantic coast of Honduras, the community concessions in Guatemala and the ejidos management in southern Mexico, and the impacts of forest management oriented to the markets over indigenous peoples and local communities, are analyse. Lessons will be also extracted on the potential of forest management through local communities. The paper also give a perspective of forest management by private companies in some examples like Mil Madereira Itacoatiara in Brazil, private companies in Santa Cruz with the Bolfor Project in Bolivia, forest management by PORTICO in Costa Rica, etc. The paper will analyse some of the most important changes in the communities and in business as a consequence of forest management.

The paper analyses also the general perspectives of forest management in Latin America and will projects different scenarios and assumes the different consequences that some global initiatives and policies may have, like the Intergovernmental Panel on Forestry and the Intergovernmental Forum on Forestry, the World Commission on Forestry and Sustainable Development, the Global Forestry Programme of UNDP, the forest policy of the World Bank, the Forest for Life Initiative of the WWF/WB, international certification and the Convention on Climate Change. The paper will states the basic assumptions about conditions needed to radically improve the situation of management of forest resources.

Keywords: Forest resources, Management, Latin America.

Sustainable Forest Management In Africa : The Challenges And Issues At Stake

Abstract

Africa has about 1084 million hectares of forests and woodlands, which for decades have been a reservoir of genetic diversity providing on a continuous basis, the needed supplies of forest products , non-timber forest products, ecological benefits and a wide range of services required by the people inhabiting the region. The regional total of forest plantations raised in Africa towards the end of the last century was about 3.64 million hectares; a figure much lower than those recorded for Asia (15.86 million hectares), and South America (6.9 million hectares). With the current rate of forest depletion at 4.0 million hectares per annum, and increasing demographic pressures and human impacts; an era of chronic wood famine is imminent in Africa before the end of the 21st century. The sustainable management of the natural forest resources in Africa can be achieved through well structured research and development programmes. Potential areas of research studies demanding attention include: studies on natural ecosystem; forest resources assessment; harvesting and utilisation of wood and non-wood forest products; and management of watershed and mangrove forests. Proper execution of the research programmes highlighted above, would ensure continuous provision of the economic and social benefits of the natural forests in the region for the present and future generations.

Keywords: Africa, Sustainable forest management, Challenges and issues.

Introduction

The tropical forest resources in Africa cover about 1084 million hectares including forests and woodlands .Throughout the last century, the forests provided a strong economic base for most countries in the continent. In addition, they have been a reservoir of genetic diversity that provide on a continuos basis the needed supplies of forest products required by the people inhabiting the region, as well as help to protect the soil from erosion, floods, siltation and a natural buffer to unexpected climate changes , as well as provide avenues for recreation and tourism .

Sustainable management and development of the natural forest resources in Africa requires urgent attention .This is because of the great influence of demographic pressures and other human impacts which have caused massive degradation and deforestation of the forest resources .

From the miombo woodlands of southern/eastern Africa through the tropical high forests of western/central Africa to the dry forest of northern Africa, it is evident that men and the environment are in a race against time , as the rate of depletion currently placed at 4 million hectares per annum (Chamshama, 1998), far outweighs man-induced regrowth or reforestation efforts. The implication is that an era of chronic wood famine is imminent in Africa before the end of the 21st century.

Considering all the above problems, it is evident that there is an urgent need for a carefully monitored programme of sustainable management, conservation and development of natural forest resources in African region This goal can only be achieved through input from active forestry research activities, improved linkages between education, training, research and policy and research capacity building .

The Need for International Action for Solving Forest Resources Management Problems in Africa

The solution to the forest resources management problems in Africa requires the need to harness appropriate relevant research and development efforts within and outside the African continent. This is because, in as much as the nations in the region are resolved and are willing to face the challenges, the handicaps in terms of increasing rate of forest deforestation and degradation, inadequate research personnel, and/or poorly equipped laboratories, low funding for scientific research and development projects, as well as unfavourable government policies do compound the problems.

The Forest Deforestation and Degradation Issues

Shifting cultivation is responsible for 70 percent of deforestation in Africa (FAO 1982). Other causes are due to unsustainable use of forest resources to meet energy, construction, cash and food needs of the rural communities.

Perhaps, a recently discovered major actor responsible for forest deforestation and degradation in Africa is industrial exploitation of oil and gas resources. Although it is not yet given recognition, it has caused extensive damage to forest lands and resources especially in the oil producing nations in Africa. (ANWORD,1999)

Although the extent of forest damage due to industrial oil exploitation in Africa is yet to be fully quantified, reports have shown that forest degradation due to oil spills and fires in Niger delta region of Nigeria can be responsible for almost 35 percent of deforestation (Dada 1999) .

WRI (1994) provided data on the status of forestry resource base for all the countries in Africa over the last decades . On the average, most of the countries have forests and woodlands occupying about up to 50 percent of the total land area, with Democratic Republic of Congo (DRC); having the largest area of land under tropical high forests . With the current depletion rate of 4.0 hectares per annum, an era of wood famine is imminent in Africa in the 21st century, if the problems of increasing deforestation and degradation of forests are not checked.

In the last century, efforts were made by various countries in Africa to boost their forest resources through the establishment of man-made plantations. Evans (1982), reported the status of plantation forestry in the tropics . Towards the end of the 20th century, Sudan and Nigeria were estimated to have raised 480,000 hectares and 370.000 hectares, plantations respectively; while Botswana and Egypt have each raised about 800 hectares. The regional total of forest plantations raised in Africa during the same period was about 3.64 million hectares. This figure was much lower than those recorded for Asia (15.86 million hectares) and South America (6.9 million hectares) within the same period. The implication of the above figures point to the fact that more forests are being cleared in Africa than established (Evan 1982) . A situation requiring urgent international attention.

The Forestry Research Issues

Sustainable management of the forest resources in Africa requires major input from forestry research. Unfortunately, the present state of forestry research is incapable of meeting this challenge. Plumptre, Dada, and Foudjet (1992), and Chamshama (1998) in separate publications reported that forestry research and development efforts have failed to make the desired impact on improving the natural forest resources in the region due to limited nature of the research and development programmes carried out in solving the problems.

The reasons that may be advanced for the above are as follows :

i. Most of the R and D studies being carried out on forestry-related problems by various stakeholders such as Universities, Research Laboratories and Institutions within the region are limited in their scope, orientations, goals and objectives ; thereby resulting in overlapping, repetition and wastage of funds, which might have been applied or used for up-grading other related programmes that can promote or support the goal of sustainable management of the natural forests in the region.

ii. The flow of information on R and D between the various stakeholders within and outside the region is rather poor.

iii. The dearth of research personnel, poorly equipped laboratories, low funding for scientific research and development projects; and government policies.

Owino (1996) in an attempt to address these weaknesses, highlighted the merits and demerits of the following models and proposed them as being suitable for improved forestry research activities and capacity building.

i. Regional models
ii. IUFRO model
iii. Centers of excellence / postgraduate institutions model
iv. International research centers model
v. Models of developed country research institutions and competitive research grant models.

The African Academy of Sciences (AAS) in response to the need for improved and coordinated research and development activities in forestry, especially in the African continent , implemented the capacity building in the forestry research programme (CBFR). as an outlet of the AAS capacity building in science and technology (AAS,1997).

Initiatives for Sustainable Forestry Management in Africa

Realising the urgent need for sustainable management of the African forests and the need to reduce the problem of deforestation , IUFRO set up a special programme for developing countries with the main goal for improving the living conditions of the rural and urban poor population. In line with the above programme, FAO , CIFOR and ICRIS group in 1998 , also recommended the need to establish a global forum or other appropriate body to bring

together forest research agencies, policy makers , funding agencies and other stakeholders that can aid sustainable management of the forest in Africa. In response to the above, a regional forum- The African Forest Forum (AFF); was initiated with the objectives for;

i. Charting and evaluating the research and the development efforts on forestry management practices in Africa.
ii. Providing guidance and initiatives aimed at enhancing sustainable development of the forests and environment .
iii. Strengthening of policy- science linkages ,and
iv. Actualising the vision for sound environmental and sustainable human development programmes for Africa, and spring board for international cooperation.

Along with the AFF initiative is the proposed African Forest Institute(AFI) which in effect would serve as a monitoring and coordinating body for AFF programmes in Africa and a linking bridge between Africa and other similar international bodies and global fora . However, the initiatives would require strong support by the international community to make the vision of sustainable forestry management in Africa realisable.

Challenges to Effective Natural Forestry Management Research in Africa

A sound forest research base is required for the sustainable management of natural forest resources in Africa. The development of such a base requires the consideration of the underlying factors which should be given more attention in the quest for developing a sustainable management programme for the forests in Africa .

Improved Linkage Between Research Needs and Formulation

There is currently a wide gap between users of research results and researchers. The consequence of this is that most of the research results have not only been sparsely used, they have largely failed to meet emerging challenges facing sustainable management of the natural forest resources in the region. The wide gap between researchers, users and policy makers have made difficult adequate considerations for research especially, when it comes to funding. Research and development efforts that are based on systematic interaction between users of research results, and researchers are those that can provide effective solutions and which can closely fit the user's need.

Research Priortization

This is an important challenge to effective natural forest research management in the region. Priority setting mechanisms at the regional and national levels are often weak or non-existence. In cases where they exist, the mechanisms are often controlled by those with little or no knowledge of forest related sciences and policy relevance.

As a result, current research activities within this region have failed to resolve pressing issues from the various stakeholders. Priority setting mechanisms that would be simple enough to be administered at the regional and national levels, and which would bear relevance to the socio-economic needs of the rural people in the region are urgently required.

Forestry Research Networking

Sustainable management of the natural forest in the region may not be realisable except the various activities and resources geared towards achieving the goals are properly harnessed through a viable cooperative R and D network.

Chamshama (1998), outlined some factors as being necessary for successful networking as follows:

(1) Structures, rules and procedures should avoid conflicts of interest.
(2) Governance should attempt to achieve a healthy balance among conflicting interests to avoid incapture of activities by a particular group.
(3) Governance should devise appropriate response to the "free rider" problem, investment in management, personnel and systems necessary in operating successful network and need to maintain accountability.

Networking would permit sharing of knowledge and skills between stakeholders within and outside the region. It can be an important option for many countries and institutions within the region to overcome resource constraints and to enable the transfer and adaptation of technology found appropriate elsewhere.

It should also have a potential of helping to build research capacity and promote sustainable use of the forest resources by the people, most especially the rural communities whose impact on the forests and environment can be devastating.

Capacity Building for Forest Research

The performance and effectiveness of a forest research institution at solving forest related problems determines the ability for undertaking research by that institution, either in cooperation with stakeholders at national or international levels.

It is only by improving current efforts in forest research capacity building in the region that sustainable development of the natural forest can be achieved. Since research capacity of most countries in Africa are under-developed; the need for improved capacity building to aid the current programme already initiated by the AAS (African Academy of Sciences), would be required to assist in the transfer of research results; to enhance the use of available knowledge; to improve networking; and to facilitate science-based decision-making at all levels. It is however expected that support provided to achieve this goal would be consistent, flexible, and output oriented.

Key Issues in Research and Development of Natural Forest Resources in Africa

The natural forest resources in Africa provide a rich variety of goods useful to the affluent industrial and poor rural communities. The range of goods and services provided by the natural forests include sawn timber and panels for construction, walls, doors and furniture; mining timbers and railway track slippers;

fuelwood as well as other non-wood forest products such as fruits, game-meat, honey, pharmaceuticals, fibers, gums, skins, waxes and oils; amenities and recreation, and soil protection.
The above forest products, and non-wood forest products provide annual earnings from export for most of the countries in the region Some important areas of research necessary for promoting sustainable development of the natural forest in the region are discussed below:

Studies on Natural Forest Ecosystem

There is need for more information on the ecological features and functions of the natural forest eco-system. In certain countries of Africa, certain tree species and eco-systems have been so heavily exploited that they have declined to a level from which it may take some time to recover. For example, certain wood species labeled "Lesser Used Species" (LUS) in Ghana (Oteng-Amoako, Ebanyenle, and Awuku,1998), have virtually disappeared in the forests of Nigeria and Cote D'Ivoire. In effect, studies would be required to determine the productive capacities of the exploited species as well as the eco-systems, and also to provide guidelines that will ensure that the level of utilization does not exceed those capacities. Currently the production capacities of most of the species in the natural forest are unknown, in some countries. Detailed evaluation of the functions of the natural forest ecosystem is necessary in order to assess the characteristics of the eco-systems and match them with the most appropriate uses.

There is the need for research on eco-system dynamics and their relationships; the effects of human activities on ecological processes baseline monitoring; and other basic eco-system species. There is also an urgent need for population studies based on the natural forest eco-system that would provide the much needed information on the ecology and functions of the natural formations. Finally, there is an urgent need to step up the current level of applied research on the natural forest ecosystem in the eco-region. This is important, if policy makers are to be given better advice on matters as to the extent the coastal wet lands can be modified.

Studies on Forest Resources Assessment and Valuation of Forest Products and Services

Many of countries within Africa, lack adequate information on their natural resources due to weak data gathering capacities, poor data retrieval and data distribution systems. The effect is that the countries lack the information base necessary for rational resources planning and management. For example, there is need for information on the extent of forest cover, the area under de-reservation or reserved protection, and the rate of its removal; as well as species inventories for the areas. Also important are information on the degraded forest areas as well as the reserved protected areas. There is need for research on the distribution of ecosystems and species in each country within the region, as well as studies on standards, technologies and techniques that will improve the planning and management of the forest resources use.

The implications of the above studies are that they would provide and aid decisions on the optimum distribution and management objectives for protected/reserved areas, and give insight on where particular conservation measures are needed and aid other aspects of planning and management. Important studies that will be required to achieve above objectives include field studies, mapping of the locations showing extent of severity of erosion, mapping of the relationship between the distribution of important, rare or threatened species in the ecosystems and potentially damaging human activities.

Studies on Forest Harvesting and Utilization of Wood and Non-Wood Forest Products

Industrial forest harvesting is responsible for most of the high rates of deforestation and forest degradation in many parts of the region. Harvesting primarily involves forest land clearing, and poor harvesting practices can deplete forest stand and site resources, resulting in forest degradation . Reliable estimates and projections of the rate of forest degradation and destruction in the region are currently not available. For more sustainable forest practices in the region, it is important to

develop studies to identify the location and severity of the problem. This can be done by initiating and coordinating reliable and comparable forest impact data on forest harvesting operations carried out in the natural forests of the region.
For sustainable use of the natural forest resources, it is important to develop experimental research and management studies aimed at promoting the lesser used wood species, development of more efficient processes and machinery/equipment for processing wood and non wood forest products, to reduce waste and incidental destruction during exploitation.

In the region, there is a great need to develop programmes aimed at promoting rural development based on production systems that enable high proportion of forest cover to be retained (Dada, 1998) and to develop systems of commercial exploitation that utilise other non-wood forest products such as drugs, gums and resins, dyes , and natural silk.

Other research areas that would require urgent attention are assessment of logging residues and their utilization potentials. Development of harvesting models for evaluating flow of logs from the forest to the mill. Such models would permit simulation of certain field actions and studies of their effects on the forest stands without damaging the ecosystem (Dada, 1998).

Equally important are studies to evaluate the annual demands by the forest products industries as well as an assessment of their annual tree removal and/or planting rates. There should also be studies on densification of forest residues and industrial wood wastes for domestic fuel .

Study on Watershed and Mangrove Forests Management

Inadequate management of the watershed due to excessive deforestation and other demographic pressures in the catchment areas of most countries in Africa have resulted in very harmful effects in most of the rural communities downstream. The flooding and gullying emanating from the above have destroyed many of the rural communities and their life-support systems as well as caused siltation of irrigation systems and reservoirs which have reduce flow rate during the dry season, causing loss of water supply and low hydroelectric power generating capacity. The above situation is a major problem currently confronting several nations in the region.

An important watershed is the Lake Chad Basin, which adjoins about four countries (Nigeria, Cameroon, Niger and Chad) within the region. As a result of decades of uncontrolled and excessive dredging and irrigation practices within and around the basin, the watershed has completely dried up. In fact on a recent Map of Nigeria, Lake Chad no longer exists.

Still worth mentioning is the on-going dredging programme of the River Niger from the Delta on the southern coast of Nigeria and along its natural course in Niger Republic. These projects have caused untold hardships and displacement of the rural inhabitants living on the banks of the river as well as massive disruption of the mangrove swamps and coastal wetlands critical to the aquatic habitat of the marine species.

The sustainable management of watershed and mangrove forests are further complicated by many competing uses. In most of the countries, decisions on their uses by policy makers are taken without due regard to the grave consequences of such actions. The major reason for this is the absence of appropriate criteria and indicators that might provide guidelines for policy makers and forests managers in their decisions amongst competing users.

Research studies on development of models for predicting use patterns and effects on the watershed and mangrove ecosystems are urgently needed. These would provide the much needed guidelines for sustainable management of the fragile ecosystems. In countries within the region where watershed forests have been severely reduced and siltation and flooding have increased; studies should be carried out to determine methods of restoring the ecosystem through selection of appropriate species to be used for reforestation. Other relevant studies that would promote conservation of this fragile ecosystem should be encouraged .

Studies on Policy, Socio-Economics, Community Forestry and Poverty Alleviation

Policy and socio-economic research for forest resources management in Africa have generally received limited attention. Hitherto, policy and economic issues were seen as being relevant only as far as production of timber from mainly forest plantations was concerned.

It is now widely recognised that the forests provide a range of non-timber forest products and ecological services to a wide range of people. There is a link between forestry and food availability. The food items include fruits, nuts, leaves, and other examples of large number of edible foods can be obtained from trees and shrubs. In fact, studies have shown in Asia, that community involvement has resulted not only in sustainable forest resource management but has also aided poverty alleviation in rural communities. Studies are therefore needed in Africa on community involvement in forest resources management, both in the protected and reserved areas.

INDEX

INTRODUCTION

This volume of Congress proceedings includes summaries of oral presentations in Group Sessions and Poster/Panel Sessions received by 31 May 2000. Minor changes may have occurred since that date. The Session moderator will mention them when opening the Session.

The following Sessions include posters:

Tuesday 8 August :

* 8.05.00. Forest fires (I). Southeast Asia
* 8.05.00. Forest fire (II). South-east Asia and other tropical regions

Wednesday 9 August

* 1.09.00. Short-rotation forestry for biomass production (II)
* 1.17.03. Tropical forest restoration (I) and (II)
* 6.03.02. Forest terminology
* 8.00.00. Environment forest science in the 21st Century
* 8.05.00. Forest fire (III). Temperate and boreal forests

If provided to the CSC in due time, corresponding poster summaries are included once in this volume, in the Session where they are presented first and additionally in the second section of the poster summary volume of the proceedings.

Special thanks to the authors for their contributions to the scientific programme of this Congress. Enjoy your stay in Malaysia.

Eric Teissier du Cros, Chairman of the CSC

Note: The summaries have been published as received by the authors and reviewers, respectively, who have sole responsibility for their content.

Forest Destruction in Brazil and Cameroon, a Comparative Analysis of the Actors of the Deforestation Process

Herwig Cleuren
Leiden University, Centre of Environmental Studies (CML) Programme Environment and Development, Post Box # 9518, 2300 RA Leiden, Netherlands
Tel: +31 71 527 74 69, FAX: +31 71 527 74 96, Email: cleuren@rulcml.leidenuniv.nl

To understand why forest destruction continues in the Amazon every year with a dazzling rate and why the Congo Basin is seriously threatened, the paper analyses the local context of forest dwellers and the interactions with the regional and national level. in Brazil field data from South-Para show the link between small farmers, loggers and large-estate owners at the forest frontier and their relationship with the urban centre and the different governmental levels. This context tries to describe the influence of powerful actors and their interests, which decide why the Amazon forest burns every year again. in the East Province of Cameroon, selective logging by foreign companies is the main industrial activity, provoking serious confrontations with the traditional farming and gathering practices of local people. The rent-seeking behaviour of the central government with its opaque concession policy is the main player and its links with loggers and local elites is decisive to understand the fate of the Cameroonian forest. This research uses an actors' view to show that local actors choose mostly the option of forest destruction as a result of activities of other actors at regional or national levels. This view explains why this is, from their point of view, the best and most efficient way of using their resources. The practical use of an actors' perspective is that it identifies the obstacles that local actors are confronted with and which cause the bottlenecks for the sustainable options of forest conservation, agroforestry and NTFPs. It should help policy-makers and international donors to combine more adequately their forces resulting in a sound forest management policy, and to develop instruments for forest protection adapted to the local context.

The comparative perspective enables to anticipate and to compare trends, *e.g.* the presence of Asian timber companies in both countries. It also helped to discern the different cultural and policy context and its consequences for the future of the forest. On the one hand, the booming logging industry, which is already established in Cameroon is something many Brazilian state governments want to promote. On the other hand, the empowerment of Indians and landless farmers in Brazil has already resulted in the acquirement of land for local people, while this is still the largest challenge for forest dwellers in Cameroon. Especially for international donors and policy-makers, a comparative analysis gives grips and indications to decide for new projects and which measures are strategically the most accurate in a specific context at a certain time.

Tools for a sustainable management of African closed rain forest

Bernard Dupuy
CIRAD-Forêt, Campus international de Baillarguet. BP 5035, 34032 Montpellier Cedex 1, France
FAX: (33) 4 67 59 37 33, Email: dupuy@hpbaill.cirad.fr

African production forests are being exposed to ever-increasing pressure from logging. It should be possible to make logging compatible with sustainable management. Logging must become a real silvicultural tool followed by thinning. They represent two basic silvicultural operations designed to improve natural forest productivity. The intention is to take advantage of the growth dynamics of the trees by means of thinning operations affecting non-commercial species to balance the logging of commercial species.

Mean volume increment of 75 commercial species, whose diameter is superior to 50 cm, is included between 0,5 and 1,5 cu.m/ha/an. An optimum loggable diameter must be set for each species on technical, economic and ecological criteria. This diameter will be decided upon after analysis of the diameter structure. The loggable volume per hectare must be limited to 25-30 cu.m/ha. Beyond this threshold logging damage becomes considerable. This maximum loggable volume must take into account the growth of the stand during the chosen rotation. The regeneration shoots damaged by logging must be coppiced. After logging, recruitment of commercial species, reaching 10 cm of diameter, is about 3-5 stems/ha/an. Modeling growth, of semi-deciduous forests, shows that waiting periods of 30 years are necessary to reconstitute a stock of 2 or 3 commercial stems (diameter > 60 cm). 30 to 50 years are necessary to restore the initial stock of logged stems.

By means of a thinning operation in non-commercial species it is possible to speed up the restoration of the loggable commercial species stock and to reduce the period between two successive logging operations to around 20 years with partial restoration of initial commercial stock. in forests previously logged, logging rotation of 30-50 years is recommended, depending on the richness of commercial species stock. Systematic thinning must be banned. Selective thinning will be carried out within a radius of about 10 metres around selected future trees (diameter < 50 cm).

Some recommendations can be made for natural regeneration. For commercial species, it is important to keep seed-bearing trees evenly distributed for all species. Non logged clumps, for example, may be kept within logged plots, as can large trees. Opening up the cover should be done carefully in order to limit the spread of creepers and other undesirable adventitious plants in the holes made. Large holes in the cover often give rise to a mediocre regeneration of commercial species (except for *Okoum*, *Ayous* and *Limba*). Main damage in the regeneration occurs during hauling which must be carefully carried out and monitored.

The Sustainability of Short-Rotation Plantation Forests in Indonesia

Eko B. Hardiyanto
Gadjah Mada University, Faculty of Forestry, 55281 Yogyakarta, Indonesia
Tel: 62-274-901400, FAX: 62-274-902220, Email: ekobhak@indosat.net.id

Short-rotation plantation forests for pulp production has increased significantly in the last few years in Indonesia. More than 800 000 ha plantations have been established and 13 pulp plantation projects have been approved. While many of the recently developed pulp mills have been using mixed tropical hardwood for their raw materials, woods from plantations are becoming available. The bulk of recent plantation forest is established mostly on soil relatively having inherent poor fertility and high acidity. *Acacia mangium* is the principal species to be planted due to its fast growth, high adaptability to existing site conditions and suitability of its wood for pulp and paper making. Current development of plantation forest and plantation management is discussed in great detail. This paper also presents the preliminary results of site management and productivity studies and discusses the long-term sustainability of short-rotation plantation forests in Indonesia. It is believed that the sustainability can be attained through the adoption of improved silvicultural practices including organic matter retention, attention to weed control, amelioration of soil nutrition, genetically improved planting stock and improved harvesting practices that minimise physical damage to site and that conserve organic matter, while in the mean time taking into account the social and economic conditions of local people in the management of plantation. Dispute on land ownership of the plantation must also be resolved properly.

Keywords: short-rotation plantation, productivity, sustainability, second rotation, Indonesia.

Silvicultural Principles: Synthesizing Temperate and Tropical Forestry Research

Susan Stevens Hummel
USDA Portland Forestry Sciences Lab, Post Box # 3890, OR 97208 Portland, USA
Tel: (503) 808-2084, FAX: (503) 808-2020, Email: shummel@fs.fed.us

Silviculture focuses on understanding and managing forests for human values and should, therefore, be central to any discussion of forests and society. This paper considers how silvicultural principles could be used to generate focus within the discipline, communicate with specialists from other disciplines, guide research investment decisions, and speed development of management systems for lesser known species. The paper focuses on the silvicultural principle of size-density relations and how it has been investigated in temperate and tropical forests. A review of key studies emphasizes the consistencies and contradictions of experimental results, as well as gaps in research. Applied techniques, such as density management diagrams are based on size-density relations. The extent to which these and other techniques can be adapted to different species and latitudes depends on the generality of underlying principles.

Keywords: size-density relations, competition density, self-thinning

Growth of plantation-grown *Azadirachta excelsa* (Jacobs.) three years after planting

Ahmad Zuhaidi Yahya, Rosdi Koster & Ab Rasip Ab Ghani
Forest Research Institute Malaysia, Forest Plantation Division, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 03-6302101, FAX: 03-6302105

The growth performance of plantation grown *Azadirachta excelsa* four years after planting is discussed. The site is located in Sime Darby Plantation, Malacca, South of Peninsular Malaysia. The soil is derived from granitic rock and is classified as Rengam series (Typic Palaeudults), with sandy clay, slightly firm and compact. Formerly, the area consists of an old rubber plantation, which was manually cut and burned. The slope gradient ranges from 2 - 6 percent. The seedlings were collected from three different seed

sources: Field 2D1, Bukit Lagong Forest Reserve, Forest Research Institute Malaysia, Selangor, Central Kedah and South Thailand. Two hundred seedlings from each location were monitored. The overall growth results from Field 2D1, Bukit Lagong Forest Reserve, Forest Research Institute Malaysia, Selangor, show the best performance in terms of average diameter at breast height and total height of 11.0 cm and 11.45 m and survival rate at 78 % followed by Central Kedah; average diameter at breast height and total height of 10.2 cm and 11.20 m and survival rate at 87 %, South Thailand; average diameter at breast height and total height of 9.9 cm and 10.85 m and survival rate was 71 % respectively. There was no distinct different in term of average height from each location. An average annual diameter increment of more than 3.0 cm for the PCT was achieved for each plot.

Keywords: Growth performance-*Azadirachta excelsa*- average diameter at breast height-average height-survival rate

The broadleaved lowland rain forests (LRF) of Central America are of considerable social, economic and environmental importance to the region, and an ecoregional overview of biophysical aspects of their management for production is now both possible and timely. This review draws heavily on research carried out by CATIE during the last 15 years, concentrating on the most extensive LRF ecoregion in Central America, the Central American Atlantic Moist Forest (Dinerstein et al., 1995), which stretches from central Panama to Belize and Guatemala. Bioregionally outstanding and vulnerable from the conservation standpoint, this ecoregion is also the main source of timber in countries such as Costa Rica and Nicaragua. Frequent hurricane impacts in the centre and northwest of the ecoregion contribute to the diversity of forest types within it, as forest structure and composition in the "hurricane belt" show evidence of long-term adjustment to hurricane disturbance. Work on the north coast of Honduras indicates that the regeneration of certain particularly important commercial tree species may be dependent on such disturbance, though hurricane-impacted forests are compositionally very distinct from true secondary forest (SF) regenerating on abandoned agricultural land. Throughout the ecoregion, SF is characterised by a well-defined group of long-lived pioneer species, most with useable wood. The low elevation forests of the sector from southern Nicaragua through Costa Rica to western Panama are quite well-documented regarding local differentiation of forest types, stand dynamics and silviculture. Primary forest of well-drained soils on undulating or hilly terrain is usually dominated by *Pentaclethra macroloba*, though in northern Costa Rica, this species is infrequent in forests near the western boundary of the ecoregion. The characteristic canopy species associated with *Pentaclethra* on soils developed on old alluvial terrace are different from those of residual soils on ancient lava flows. *Pentaclethra* is also present in wetland (mainly floodplain) forests, which nevertheless show their own characteristic suite of dominant canopy trees. On both well-drained and wetland sites, forest may show marked compositional variation over short distances in relation to substrate factors. The use of existing information on forest types could greatly facilitate planning for forest management and conservation in the ecoregion.

Pentaclethra forests appear to be among the world's most dynamic tropical forests, and monitoring of stands managed for timber production indicates they are both resilient and productive. Liberation thinning produces marked increases in commercial diameter increments and under this treatment, many common commercial species show median increments in the range 0.5 - 1.5 cm yr^{-1}. Mortality rates may increase following such treatment, however; in addition, non-commercial species strongly impacted by silvicultural treatment also tend to be slow-growing, factors which may contribute to long-term decline of their populations. Mortality rates in wetland stands appear similar to those of *Pentaclethra* forest. The commercially important wetland dominant *Carapa guianensis* is nevertheless slow-growing, though it may grow faster in wetlands than on well-drained sites. *Vochysia spp.*, *Inga spp.* and *Goethalsia meiantha* are among the characteristic long-lived pioneers of SF in this sector of the ecoregion. SF in small patches on undegraded sites, with adequate seed sources, is highly productive even on Ultisols, primary forest basal area being reached in < 30 yr, and tree species of this guild may reach harvestable dbh in 15-30 yr; patterns of stand dynamics and tree growth indicate that monocyclic silviculture is particularly appropriate in such situations. Larger

SF patches, on sites degraded by activities such as cattle ranching, exhibit more complex stand dynamic patterns, however, and significant within-patch variations of site quality may become evident. SF will probably maintain a species composition completely different from that of primary forest for >100 yr.

Research-based Approaches to Sustainable Tropical Forest Management in Bolivia

Todd S. Fredericksen, Bonifacio Mostacedo Catalyud
Proyecto BOLFOR, Casilla 6204, Santa Cruz, Bolivia
Tel: 591-3-480766, FAX: 591-3-480854, Email: bolfor@bibosi.scz.entelnet.bo

Tropical lowland forests occupy more than half of Bolivia and represent some of the largest remaining tracts of South American tropical forest outside of the Brazilian Amazon. Where access has been available, many of these forests have been subjected to highly selective logging of mahogany (*Swietenia macrophylla* King.) and a few other highly valuable species. Almost uniformly, this logging has been unplanned with little thought for future harvests. Now, Bolivia is embarking on the implementation of a new forestry law that, if successful, will bring the national forests closer to sustainable forest management. It will be important that forest management plans are based on forest research conducted in Bolivia or in adjacent countries with similar forest types to achieve sustainability. For the past six years, research in ecology and silviculture has been carried out by Proyecto BOLFOR, a sustainable forest management project located in the lowlands of Bolivia. Research during this period has been conducted in many areas, but most studies have had some common themes. These include basic research on the silvics of forest tree species to determine appropriate silvicultural treatments, testing silvicultural systems that provide for profitable and efficient harvesting while promoting regeneration, and reducing the impacts of forest harvesting and other silvicultural treatments on biodiversity. This research has provided information on the phenology, environmental preferences, growth rates and regeneration ecology of a large number of lesser-known species that may increase options for forest management and increase the value of Bolivian forests. Without this information, forest managers have conducted forest harvesting that has been inappropriate for securing the regeneration of the timber species. For example, highly selective logging has almost uniformly been applied in Bolivia, regardless of the fact that the majority of most valuable timber species have low densities in mature forests and require large disturbances for regeneration. Furthermore, pre- or post-harvesting cultural treatments, such as vine cutting, prescribed fire or release treatments, have not been applied to promote regeneration and growth of timber species. The result has been a gradual trend towards the commercial extinction of the most valuable forest tree species. Deforestation in Bolivia has occurred when forests have been degraded of their economic or ecological value through unplanned logging or the application of inappropriate silvicultural systems. Subsequently, forests have then been converted for other uses, such as agriculture, cattle-grazing, or community settlements. To prevent forest conversion, research must provide information on how to profitably harvest forests while promoting regeneration and protecting the ecological integrity of forests. An important challenge will be to disseminate the results of research successfully and promote the use of appropriate silvicultural systems in a country with little experience in forestry other than unplanned logging.

Forecasting sustainable cutting cycles in a Venezuelan lowland forest with the process-based model FORMIND2.0

Ludwig Kammesheidt, Peter Köhler, Andreas Huth
University of Göttingen, Institute of Tropical Silviculture, Büsgenweg 1, 37077 Göttingen, Germany
FAX: +49 551 39 4019, Email: lkammes@ufobi6.uni-forst.gwdg.de

1. We simulated growth and yield of logged-over forest under different logging scenarios over a period of 240 years and compared results with an unlogged stand using the process-based model FORMIND2.0.
2. Stability and sensitivity analysis showed that the stand dynamic was simulated in a realistic range.
3. In the absence of further logging, the logged-over stand approached the stand structure of mature forest in terms of bole volume and basal area after about 50-100 years.
4. Thirty year cutting cycles with conventional logging methods and net extraction volumes of 45 and 60 m^3 ha did not provide sustainable yields under both minimum felling diameter (MFD; 35 and 50 cm, respectively) applied.
5. Only 60 year cutting cycle showed sustainable yields under both logging methods (conventional and reduced-impact logging) with the different MFDs and the whole range of net volumes extracted (30 - 60 m^3 ha^{-1}).

6. Scenarios with reduced-impact logging provided a significantly higher timber volume than under conventional logging.
7. With the longest cutting cycle (60 years), bole volume recovered to levels similar to the mature unlogged stand, while species composition differed significantly.

Keywords: functional groups, logging scenarios, simulation, sustainable timber harvest, tropical forest

Development of Preliminary Stand Growth Scenarios Based on the Relationship Among the Crown Composition, the Crown Structure and the Productivity of *Tectona grandis* and *Bombacopsis quinata* Plantations in Costa Rica

Luis D. Pérez Cordero, Luis A. Ugalde Arias and Markku Kanninen
CATIE, 7170 Turrialba, Costa Rica
Tel: (506)556-0026, FAX: (506)556-2427, Email: lugalde@catie.ac.cr

Projects and private companies in Central America urgently need relevant information on the growth and productivity of priority species used in reforestation, such as *Tectona grandis* (teak) and *Bombacopsis quinata* (pochote). Determining production at the end of the rotation is particularly necessary in the case of advanced aged trees (over 20 years). Spatial competition among plantation trees is one of the decisive factors for adequate growth. One means of evaluating the effect of reduced competition is to monitor tree development. Research was carried out on forest plantation dynamics (study of tree development through time), identifying the composition of crown biomass as an important indicator of competition within a stand, and the effect of this competition on other growth variables. The main objective of this study is to develop preliminary forest management proposals for *Tectona grandis* and *Bombacopsis quinata* plantations to ensure high stand productivity. Models were developed for different relationships among the variables, crown composition, crown structure, growth and productivity, using information from advanced aged teak and pochote plantations in Costa Rica. The basis for the stand growth simulation models included growth and productivity information obtained from the plots measured in the field, results from stem analysis, the relationships among composition and crown structure, growth and productivity. Eight scenarios are presented for each species, using intensive management criteria of a maximum basal area of 18, 20, 22 and 24 m^2/ha, and two initial plantation densities: 1111 and 816 trees/ha. in the preliminary growth scenarios for teak, rotations periods between 25 and 28 years were evaluated, with final densities of 97 to 125 trees/ha, average diameters of 45 to 50 cm, and total average heights of 30 to 34 m. The productivity at the end of the rotation varies between 10.2 and 13.3 m^3/ha/year, yielding a total volume of 270 to 380 m^3/ha. For pochote plantations, scenarios were developed for rotation periods between 24 and 29 years, using final densities between 110 and 130 trees/ha. Expected results include trees with average diameters of 45 to 52 cm, and total average heights of 30 to 35 m, equivalent to a total volume of 220 to 331 m^3/ha, and an annual productivity rate of 9.0 to 11.3 m^3/ha/year. Cost comparisons for intensive versus traditional management practices indicate that the former requires a 25 to 33% higher investment than traditional management. The Pipe Model Theory was tested for *Tectona grandis*, confirming its use for advanced age trees of up to 46 years, evaluating the relationship between the sapwood area at the base of the tree (cm^2) and at the crown base (cm^2), with the foliage weight (kg). in the case of pochote, there is a relationship between the sapwood basal area at the tree base and the crown base with the foliage weight. in addition, for 10 to 23 year old trees, the next to last growth ring of the tree base is strongly correlated with dry foliage weight. For teak plantations, it was possible to carry out stem analysis on trees from dry zone plantations, using the clearly formed rings resulting from a marked seasonality in the area. However, for pochote it was more difficult to identify growth rings in many cases, despite the marked seasonality in the areas such as Jicaral and Samara in Guanacaste. The evaluation of growth scenarios, based on reliable data for plantation growth in the country, was a useful tool to make predictions for plantation management over time. The scenarios allow for the anticipation of future productivity and yields, based on current and potential growth in terms of basal area in the site. *Tectona grandis* and *Bombacopsis quinata* are species with medium to rapid growth, but require intensive management. The present study seeks to contribute to management strategies for these species. Recommendations include reinforcing the results obtained with more data from advanced age plantations, particularly for those older than 20 years.

Silviculture in humid lowland forests of tropical America: assessment of current practices and recommendations for future improvement

César Sabogal, Gonzalo de las Salas, J. Natalino M. Silva
Center for International Forestry Research (CIFOR),
Conveno EMBRAPA, 66095-780 Belém Brazil
Tel: +55 91 276-0041, FAX: +55 91 276-0041, Email: ciforbra@interconect.com.br

The paper reviews and synthesizes past and current silvicultural research and practice for the management of humid primary and secondary forests as well as degraded forest lands in tropical America. This is used to derive some practical lessons to be learned and to identify successful cases and contributing factors. The analysis then focuses on the current application of common silvicultural practices in the region to assess their merits and constraints. A set of guiding principles and "best silvicultural practices" is proposed for two broad management scenarios for silvicultural work (i.e. primary logged-over forests and secondary forests). The last part addresses some ways to improve the adoption of best silvicultural practices in the region. The discussion considers, among other aspects, the potential of on-farm (participatory) silvicultural research, the market prospects for promising timber species, the incentives for forest management, and the need for revision in policy and legislation.

Tropical silviculture: where should we invest?

Rudi Arno Seitz
Universidade Federal do Parana, Rua Bom Jesus 650, 80.035-010 Curitiba, Brazil
Tel: +55-41-232-9084, FAX: +55-41-253-2332, Email: r.seitz@cce.ufpr.br

Looking at the international literature, the overall perception is that tropical silviculture means plantation forestry. But plantation forestry is not the only alternative for management of forests for wood production in tropical regions. in terms of economic return in short time, no doubt that plantations are the best choice. If other values like biodiversity, environmental conservation or sound utilization of natural resources are aimed, focus should be put on management of natural forests. Very important for tropical silviculture are secondary forests, which may have two origins: overlogged primary forests or a secondary forest succession on former forest lands which were used for agriculture or pastures. Silvicultural treatments are quite distinct for this two types of forests. in the first case, normally biodiversity was not to heavy affected, but wood quality of the trees is poor. in the second case, the forests have a very simple structure, but with the absence of the valuable, slow growing tree species. Silviculture means the manipulation of the forest to achieve objectives, which may be a special product (*e.g.* wood), service (*e.g.* carbon fixation) or other commodity. For correct actions we need knowledge of a lot of relationships, between tree species (like *allelopathy*), between trees and soil organisms (like *mycorrhiza*), and between trees and animals (insects, birds and rodents). Also the growth reactions to interferences in forest structures must be known. and manipulation of the forest needs labor. Mechanization is highly developed for plantation forests, but nearly zero in terms of silvicultural treatments in tropical forests. Therefore, governments, industries and researchers should invest much more efforts in the development of tropical forest knowledge, in terms of research as well as practical applications in forest areas.

If forest certification is aimed, still more knowledge is needed. in the guidelines for certification, expressions like "minimization of changes in structure and species composition", "minimization of damages due logging operations" or "ecological functions are kept intact" are quite common and should be combined with improvement of income, for the forest workers as well as for the forest owner. But how to achieve this was never explained by practical demonstrations on the long run. Again, much expertise is required, for the millions hectares of secondary forests in tropical regions.

1.07.00 / 1.15.00 / 1.17.00 International markets for carbon sequestration from tropical forests

International Markets for Carbon Sequestration from Tropical Forests: Principles and guidelines to Ensure Beneficial Local Development and Environmental Impacts.

Sara J. Scherr, Jeffrey Sayer, Joyotee Smith
University of Maryland, Agricultural and Resource Economics Department,
2200 Symons Hall, 20742 College Park, MD, USA
Tel: (301) 405-3860, FAX: 301) 314-9091, Email: SJScherr@aol.com or SScherr@arec.umd.edu

Decisions taken at Kyoto in 1997 and Buenos Aires in 1998 pave the way for international financial and technological transfers to support forest-based activities that enhance carbon storage and sequestration and thus mitigate the build-up of carbon concentrations in the atmosphere. Carbon-related services of tropical forests may be more

cost-effective than emission reduction in energy projects, and various international market mechanisms being discussed could potentially contribute large financial resources for rural development and forest management in project sites.

However, there is widespread concern among the international forestry community that poorly-designed forest carbon projects could pose a major threat to the welfare of forest-dependent people, non-carbon environmental services, and sustainable management of forest resources for national development, and that successful local implementation may not be feasible.

The University of Maryland and the Center for International Forestry Research are organizing an international policy workshop in spring of 2000 to identify conditions and organizational principles under which trade in carbon sequestration services would have positive local socioeconomic and environmental impacts. Recommendations will address selection of project site, types of carbon projects, integration of management with national and regional forest and environmental strategies, mechanisms for distribution of benefits among local people, and incorporation of local interests in project planning.

A presentation based on workshop recommendations will be presented at the proposed IUFRO Group Session, followed by comments from two expert panelists, and then broader discussion. Possible panelists are Dr. Jagmohan S. Maini, of the UN Secretariat of the Intergovernmental Forum on Forests and Dr. Roger Sedjo of Resources for the Future. The presentation will be revised in the light of this discussion, and submitted for publication in a leading environmental policy journal. A policy brief will also be published and disseminated widely by CIFOR.

1.09.00 Short rotation forestry for biomass production

The Status and Future of Short-Rotation Woody Crops in the U.S.

L.P. Abrahamson, Wright, L.L
State Univ. of New York, College of Environmental Science and Forestry, Syracuse, N.Y., USA
Email: cecxt@syr.edu

Short Rotation Woody Crop production systems, involving rotations of 10 years or less, reached a commercial production level of approximately 55,000 ha in the United States by 1999. Hybrid poplars and cottonwoods dominate, but willows, sycamore and sweetgum are also being planted. This wood is produced almost entirely as fiber for pulp and paper and fibreboard. The majority of the commercial production exists in the Pacific Northwest and Southern portions of the U.S. New activity for fibre and energy crops is occurring in the North Central and Northeastern U.S. Experience shows that early success of commercial ventures depends greatly on the existence of well-integrated research programs incorporating breeding, physiology and silviculture and close partnerships between industry, government and academia. Research on short rotation wood fibre crops is in a very active phase and production levels are anticipated to increase. Recent policy decisions by the U.S. government will provide additional research funding and incentives for production of woody crops for energy in addition to fibre.

Research on short-rotation crops by the authors is sponsored by the U.S. Department of Energy, under contract DE-AC05-96OR22464 with Lockheed Martin Energy Research Corporation, by the Department of Energy's Golden Operations Office, by the New York State Energy Research and Development Agency, and by numerous other pubic and private sector partners.

Productivity and Sustainability of Wastewater Irrigated Tree Plantations

Michael J. Duncan, T. G. Baker, J. D. Morris, P. Hopmans, D.J. Stackpole, G.C. Wall
Protection Silviculturalist, Centre for Forest Tree Technology, Post Box # 137, 3084 Heidelberg, Victoria, Australia
Tel: +613-94508666, FAX: +613-94508644, Email: m.duncan@nre.vic.gov.au

Keywords: Wastewater; Biomass; Sustainability; Short rotation; Nutrient sequestration

The utility of tree plantations for the disposal of wastewater has been well established and continues to be investigated throughout Australia, particularly with respect to: the profitable reuse of wastewater, rather than simple disposal; the sustainability of land use under wastewater irrigation; the silvicultural management of plantations to achieve specific objectives such as the production of high-value sawlogs; and the optimisation of nutrient sequestration and water use.

A major concern with wastewater irrigation is the fate of nitrogen (N) and phosphorus (P) in the environment since these nutrients can cause pollution of surface and groundwaters. Municipal wastewaters treated to primary or secondary level often contain greater amounts of these nutrients than can be sequestered by the trees at the rate of irrigation needed to meet the water requirements of trees, particularly in semi-arid environments. While

P will not usually be a problem in the short to medium term, particularly on soils with high P adsorption capacity, there is always potential for leaching of N (as nitrate) to groundwater.

Fast growing trees initially accumulate significant amounts of N in foliage, but the net N requirement of the plantation declines after canopy closure, and as N is recycled through the decomposition of litter and internal translocation. Therefore removal of N and other nutrients by plantations can be maximised by growing trees in short rotations (*e.g.* <6 years). However, such rotations may compromise water use, and also limit the potential products to biomass fuels rather than higher value wood products.

A second concern with wastewater irrigation arises from the often high concentrations of sodium (Na). Therefore, long-term irrigation has the potential to deleteriously affect soil structure through changes in soil chemistry, and ultimately reduce the productivity of the site and its utility for wastewater disposal.

A wastewater irrigated, short rotation coppice trial was established at the Goulburn Valley Region Water Authority (GVRWA) Shepparton Wastewater Treatment Complex in 1993, with the aim of determining whether the long-term irrigation of tree plantations with wastewater is sustainable within alternative silvicultural treatments, by measuring changes in soil properties, the input of water and nutrients in wastewater, tree growth, sequestration of nutrients and salts in trees and soil, and monitoring groundwater depth. The trial incorporates comparisons of coppice rotation length (3, 6 or 12 years), planting density (1333 or 2667 sph) and tree species (*Eucalyptus globulus* or *E. grandis*).

During the first six years of the planned 12-year experiment, growth rates and biomass production in this trial are amongst the highest reported in Australia with mean annual increments of up to 40 m^3 ha^{-1} yr^{-1}. During this period up to 550 kg ha^{-1} of N was accumulated in the above-ground biomass. However, some marked changes in soil properties were apparent within the first three years, including significant loss of carbon (C) and N, and increases in the sodicity of the surface soil.

A Study on the Pollen Morphology of Six Sections in Subgenus *Salix* L. (Salicaceae)

Kae-Hwan Kim, Louis Zsuffa
Chonbuk National University, Faculty of Forest Science, College of Agriculture, Korea

The pollen morphology of 15 species, 2 varieties and 1 forma belonging to 6 sections of the subgenus *Salix* was investigated by means of light and scanning electron microscopy. From a pollen-morphological point of view, subgenus *Salix* is stenopalynous. Species from six sections have been distinguished on the basis of pollen morphology, and a key for their identification using pollen is presented. Based on pollen morphology, *S. jessoensis* (section Subalbae) is the most distinct of the species studied. Species of section Humboldtianae appear to be the most evolved in this subgenus with a closer relationship to section Amygdalinae than any other section of this subgenus.

Keywords: *Salix*; Salicaceae; pollen morphology

Short Rotation Forestry in Korea

Don Koo Lee, Yong Kwon Lee
Seoul National Univ., Dept. of Forest Resources, 103 Seodun-Dong, Kwonsun-Gu, 441-744 Suwon, Korea R.
Tel: +82-331-290-2337, FAX: +82-331-293-1797, Email: leedk@plaza.snu.ac.kr

Keywords: short rotation forestry, fuelwood, biomass, caloric value, *Robinia pseudoacacia*, hybrid poplars

Short rotation forestry in Korea has started since late 1950s and 1960s when Korean Government initiated establishing fuelwood plantations for rural village dwellers. Most of the planting woody species for fuelwood were fast-growing *Robinia pseudoacacia*, *Pinus rigida*, *Populus sp*ecies and *Lespedeza* species, which show good sprouting and adaptability in various sites.

Started in 1959, the total area of fuelwood plantation to be needed was 1.2million ha, based on a total of 2.4 million households. Of these 1.2 million ha, 400,000 ha from existing forests to be used for fuelwood production and the other 800,000 ha to be established by artificial planting. However, the target for the establishment of fuelwood plantation was revised to be 643,000 ha due to failure in plantations. The total area of 643,000 ha for fuelwood was successfully established in 1977, of which 127,000 ha done by IBRD loan project.

In 1980s, research on short rotation intensive culture has started to examine the biomass production by planting densities and species. Tree species for testing were *Populus alba x P. glandulosa, Populus nigra. X P. maximowiczii*, *Robinia pseudacacia* and *Alnus* species. Planting densities examined ranged form 10,000 trees/ha to 40,000 trees/ha. Caloric values, sugar and ethanol contents were also compared for 27 hardwoods and 3 conifers, of which the highest values were shown by *Populus* and *Morus* species. Among the planting densities at nursery sites, the density of 40,000 trees/ha showed the highest above ground dry matters of 20 tons/ha/year from *Populus alba x P. glandulosa* and *Populus nigra x P. maximowiczii*. However, at hillside sites, the density of 4,000 trees/ha exhibited the highest dry matters of 7.7 tons/ha from *P. alba x P. glandulosa* compared to densities of 1,000, 2,000 and 3,000 trees/ha.

In 1978, *Robinia pseudacacia* was planted at various planting densities of 3,000, 6,000, 9,000 and 12,000 trees/ha in the hillside mountain area to test the biomass production for 18 years. During the period, 6-year, 9-year and 18-year rotations were applied for all of the densities. Under 6-6-6-year rotation, the density of 9,000 trees/ha showed the greatest biomass production (37.5 tons/ha), while that of 12,000 trees/ha did the best (60.9 tons/ha) under 9-9-year rotation. Under 18-year rotation, the density of 3,000 trees/ha exhibited the best production (85.8 tons/ha). The greatest total biomass production (108.4 tons/ha) was shown by the density of 9,000 trees/ha under 9-9-year rotation for 18 years.

A survey of short rotation willow growing in Sweden

Anders Roos, Hakan Rosenqvist
Swedish University of Agricultural Sciences, Department of Forest Management and Products, Post Box # 7054, S-750 07 Uppsala, Sweden
Tel: +46 18 671564, FAX: +46 18 673522, Email: anders.Roos@sh.slu.se

This paper presents an evaluative study of short-rotation willow plantations for energy purposes in southern and central Sweden. The results are presented statistically and in Geographic Information Systems (GIS). Willow growing is described according to owner characteristics, farm type, size, land use, willow area and management. Since the two issues of how to increase the share of renewable energy and how to reduce surplus crop production are relevant in many countries, realistic predictions about potential energy-crop growers are needed. Better knowledge about the adoption patterns of willow production in Sweden during the early 1990s could help policy makers, in Sweden and in other countries where short rotation energy forests are being considered, to design effective energy and agricultural policies and to identify target groups for information campaigns. Commercial willow plantations in Sweden expanded in the early 1990s when two main policy decisions were made. First, the implementation phase of a deregulated food policy between 1991 and 1996 made subsidies available for planting willows and for fencing. Second, environmental and energy taxes on fossil fuels increased considerably in 1991, improving the competitiveness of biofuels in the energy market. Data about the 1000 farms in southern Sweden with a farming area of more than 2 hectares and with more than 0.1 hectares under willow cultivation were obtained from the 1995 Farm Register compiled by Statistics Sweden. For comparison, a stratified sample of 535 non-willow farmers from the same geographical region was also used. A postal survey was also conducted of a sample of the willow-growers. The willow growers in southern and central Sweden, were growing about 13,000 hectares of willows in 1995. in relative terms 2% of the farmers in the region grew willows on 0.5 % of the total area of arable land. Willow growing is most common in regions where biofuel use (*e.g.* of residues from logging and forest industries and imported biofuels) in district heating plants is already high. Willow plantations are generally common on large farms and on crop-producing farms. Willows are less common on small farms and on farms with many animals. The survey questions concern information about the willow growing farmer, motives for planting willows, willow plantation management and harvesting, economic aspects and evaluation.

Turkish Energy Forestry for Sustainable Forest Management and Energy

Nedim Saracoglu
Zonguldak Karaelmas University, Bartm Forestry Faculty, Turkey
FAX: 90 378 2277421

Much of the world today is well on its way towards creating an unsustainable environmental situation. It is still possible to solve some of our environmental problems in a efficient and perhaps even a cost effective way by utilising suitable, located forest land and former agricultural land for energy, fibre and timber production. At the same time, some waste products of the community can be added into the cycle again. Biomass production for energy purposes through the cultivation of fast growing, broad-leaved trees will result in an ecologically sound and economically viable crop in Turkey. in this way, unproductive land can be converted to productive energy plantations where wood is harvested as a crop and used for energy purpose and industry. The importance of biomass in Turkey today is indisputable since the traditional biomass fuel wood, charcoal, crop residues and dung are still a primary cooking fuel for some parts in Turkey. For a variety of reasons like rising prices of oil and growing population, biomass fuel might not longer supply the demanded needs. At the same time the shortage of local biomass are increasing. Therefore, the establishment of fast growing plantations would have multipurpose. There is a need to collect and analyse prior experiences in local wood production and consumption in order to design efficient measures to reach the desired situation of local control, cost and the efficient use of energy from biofuels.

Forest land in Turkey constitutes 26.5% of the country, that is about 20.7 million hectares. 12.8% of Turkey is covered by productive forests and the remaining 13.8% is degraded land. Turkey has about 4 million hectares of land subject to the activities of energy forest establishment. The coppice rehabilitation projects have been commenced especially in east and southeastern Anatolia regions since 1978 to control degradation, to rehabilitate and to make the degraded coppices land reproductive. With the realization of project objectives, new job opportunities will be created as well as supplying animal fodder in the region.

The gap between wood production and demand will reach 3.5 million m^3 in per year. If necessary actions are not taken, the shortage in wood production will be even more serious. Thus, the establishment of industrial plantations with fast growing species such as poplar, willow, *Eucalyptus*, *acacia*, alder and oak species are of great importance. Until 1998, energy forest activities with coppice regeneration was undertaken on an area 517 000 hectares and production of fire wood is used for heating and cooking purposes.

A specific goal is to increase the use of wood and wood based residues for energy generation increased at combined heat and power generation plants being established by private sector in locations where coppices and natural forests are available by 2003.

Sustainable Management of Abandoned Farm Lands for Energy Forestry Using Domestic Nitrogen-fixing Tree Species

Hardi Tullus, Veiko Uri

Estonian Agricultural University, Institute of Silviculture, Faculty of Forestry, Kreutzwaldi 5, EE2400 Tartu, Estonia

Tel: (372) 7 421373, FAX: (372) 7 421053, Email: htullus@.eau.ee

Keywords: Alder species (*Alnus* sp.), biomass production, nutrient cycling, cultivation methods energy forestry, short-rotation forestry

In transition countries the volume of agricultural production has fallen considerably over recent years. in addition to agriculture, a large number of important changes have also occurred in forest management and energetics. A need has arisen for the compilation of new economically and ecologically justified agricultural and silvicultural recommendations and sustainable management systems.

Estonia is situated in an intermediate zone between the boreal coniferous forest and the deciduous, broad-leaved forest. Forests cover more than 47% of the total area, in 1992-1996 some 30% of arable land was left uncultivated. With the exception of oil shale deposits, Estonia does not have any major sources of fossil fuels, and a substantial proportion of such fuels must therefore be imported. To ensure the energy supply and improve the environmental conditions a programme of converting boilers from fossil fuels to domestic biofuels was started. The results will help to optimise land utilisation by choosing soils suitable for the cultivation of alders (particularly grey alder energy stands), thereby in a natural way making such areas fertile with the future objective of returning the areas to agricultural use or of cultivating conifer stands.

Purpose of the work was to create yield tables and to determine the rotation period for alder stands as energy forests depending on forest site types. A second objective was to investigate nutrient cycling in alders and thereby their effect on soil fertility. As alders are in symbiosis with actinomycete Frankia microorganisms, which fixate aerial nitrogen and the nitrogen content of alder leaves is therefore high, it can be presumed that the cultivation of alders will have a positive effect on soil fertility.

Silvicultural, ecological and economical aspects of the management of grey alder (*Alnus incana*), hybrid alder (*Alnus incana* x *Alnus glutinosa*) and black alder (*Alnus glutinosa*) stands are analysed. Different cutting and regeneration systems are examined. For the development of rational methods of afforestation of abandoned agricultural land by alders, the experimental plantations were established where various planting materials were used. in order to find out the influence of alder forest, grown as energy forest, on the surrounding environment, above all on soil, and its ability for uptake of chemical elements, as well as to evaluate the possible loss of nutrients after felling and the removal of trees from the place of growth, the concentration of basic nutrients in different plant fractions was analysed annually.

Short Rotation Forestry in Europe

Theo Verwijst
Department of Short Rotation Forestry, P.O.Box 7016, SE-750 07 Uppsala, Sweden
Tel: +46 18 672550, FAX: +46 18 673440, Email: Theo.Verwijst@lto.slu.se

Short rotation forestry (SRF) in Europe has a long tradition and originally aimed at providing a supply of fuel, fodder and convenience wood, usually by means of coppice systems. The main genera involved are *Populus*, *Salix*, *Eucalyptus*, *Robinia*, *Betula*, *Alnus*, *Castanea* and *Quercus*. Eucalypt is confined to the Mediterranean parts of Europe, whereas willow and birch mainly are found in the northern parts. SRF systems both are employed in forestry and agriculture and have integrated functions in agroforestry, shelterbelt- and environmental applications such as vegetation filter systems. Modern SRF has developed towards an industry which needs large volumes and a continuous supply. Consequently the focus is on species with a high initial growth rate and breeding programmes are directed towards resistance or tolerance against pathogens. With the actual range of final products in mind (biomass for energy purposes, paper pulp, particle board, veneer, construction wood) a wide range of growing systems has been developed, ranging from densely planted willow coppice (2x104 stools ha^{-1} and harvested each 2 to 4 years) to widely spaced single-stem poplars (100 stems ha^{-1} and harvested after 25 years). Major developments of European SRF during this century are envisaged in the fields of specialised high quality products and in the field of bioremediation. The increasing amounts of sewage sludge, slurry and other organic waste products from the society form an excellent resource for biomass production by means of SRF.

Comprehensive silviculture and development strategies for pulpwood plantation in China

Shougong Zhang, Sun xiaomei
Chinese Academy of Forestry, Forintek Canada Corp, 319 rue Franquet, Sainte-Foy, G1P 4R4 Quebec, Canada
Tel: 86-10-62884229, FAX: (418)-659 2922, Email: tony.zhang@qc.forintek.ca

In pace with the growing economy and population, and improvement of the living standard in China, the demand for paper and paper products will increase continuously, while wood as the main raw material in the pulp industry is decreasing gradually. Development of fast-growing, short rotation plantations for pulpwood production, which are highly productive through adopting sustainable forest management in relatively small areas of forest land, can make a significant contribution to wood supply. This will replace wood supplies from natural forests in response both to economic development and environmental problems. The status of the silviculture for pulpwood plantation in China is reviewed and its development strategies are discussed as follows:

1) According to the selection of appropriate afforestation species, and the estimation of productivity for pulpwood purposes, the pulpwood bases will be properly planned.

2) Under the guidance of the principle for sustainable forest management and forest ecosystem management, plantation establishment is focused on specific goals of industrial use, i.e. fast growth, high productivity, superior quality, stability, and high profit. Based on systematic research of tree improvement (careful selection of tree species and genetically improved materials with superior vigour, fibre property, and pest and disease resistance), site control (suitable site quality and the maintenance of high soil fertility), stand density control (rational initial density and thinning technology) and economic considerations, the intensive silvicultural technologies will be promoted.

3) Based on clonal selection and vegetative propagation with commercial utilization, optimal combination of the site and clones, the ecological stability and adaptability and genetic variation of pulpwood properties are studied, and the comprehensive cultivation system for clonal plantation will be perfected for development of large-scale clonal forestry.

4) The development avenues towards integration of forest management and the pulp industry will be explored in relation to the Chinese situation, and the pulpwood raw base for a relatively stable supply to

the industry will be established, simultaneously with reasonable development on resource use and finance.

5) Aided by the geo-information system and advanced forest technology, the information management system for pulpwood bases will be set up to serve as the basic tool of planning, management and decision-making, and gradually to make the development of pulpwood plantations sustainable.

1.15.04 Agroforestry

Why Use Agroforestry in European Mountains?

Philippe Balandier, Helene Rapey, Felix Ruchaud
Groupement de Clermont-Ferrand, Division Forêt et Agroforesterie, BP 50085 24, Av. des Landais, F-63172 Aubiere cedex, France

Keywords: Agroforestry, Europe, mountains, silvopastoral systems

As far as agricultural products are concerned, the context of high economic competition in West Europe has led to the abandonment of the less productive plots of land. This has been particularly the case for the mountain areas throughout the region. As agricultural products were the main economic resource for those mountain areas, one important result has been out-migration of population. There is then a trend towards a desertification of mountain areas, as people fail to look after the rural space. Abandoned plots of land are rapidly colonized by a dense shrubby vegetation and afterwards by a closed forest. However, mountain areas are an important tourist attraction, which is not an insignificant income source. However, tourists often give preference to opened landscape and pastures. There is consequently a need to manage the rural space and landscape.

Agroforestry - the association of an agricultural production with tree culture on the same unity - is a possible way to maintain a rural activity, diversify the production and look after the landscape in the mountain areas. in particular, silvopastoral systems - the association of grazing animals with tree culture- are well adapted. Animals maintain extensively the vegetation to a low level, providing an opened landscape. At the same time, the trees provide an additional income to the farmer through timber, fire wood, forage, honey, and other products.

Experiments were undertaken with two silvopastoral systems: the plantation of forest trees in pasture and the opening of dense forests or brushwoods to grazing animals. in both cases, only a low number of trees were planted or kept to allow sufficient grass production to support the flock. Experimental details are presented.

Data were collected for the two kinds of silvopastoral systems for ten years including technical, ecological and economic characteristics and performance. Results of experiments and farmer evaluations are presented. Both silvopastoral systems have proved feasible and interesting from an economic point of view. Grazing animals are really a cheap mean of maintain an opened landscape. On-going research is analysing how those silvopastoral systems can fit into the farmers' exploitations and particularly what are the economic and environmental consequences of introducing trees.

Computer-Based Data-Management Technologies in Agroforestry

James M. Knowles, P.K.R. Nair
University of Florida, School of Forest Resources and Conservation, Post Box # 110410, Gainesville, FL, USA
Tel: (352) 846-0880, FAX: (352) 846-1277, Email: pkn@gnv.ifas.ufl.edu

The past decade has witnessed dramatic progress in the use and deployment of computers for rapid and efficient acquisition, management and analysis of data to support development and dissemination of land-use technologies. This paper will evaluate the developments of computer use within agroforestry, discuss the potentials and suggest future directions in this exciting approach to research.

The major computer-based tools and methods in land-use system research are database management systems (DBMS), decision support systems (DSS), geographic information systems (GIS), and computer modeling. DBMS's are used for the input, storage and retrieval of relational data. With the development of the CD-ROM and the Internet, access to and distribution of large amounts of data have become easier. Databases have been developed containing information related to natural resources such as climate, tree species, and soils. These databases provide information that can be used by planners and managers in making land-use decisions. Decision support systems integrate data (often obtained from a DBMS) with decision criteria or rules to provide users with decision options in planning, implementing, and managing different land-use systems. DSS's have been developed to provide advice in several forestry and other land-use activities; e.g.: timber management of national forests, pesticide application in field-crop cultivation, and management of citrus production. Widespread access to satellite imagery, remote sensing equipment and other sampling equipment has allowed for the development of GIS's to aid in land-use management. GIS's are DBMS's designed to capture, store, analyze, and display data from a spatial point of view. GIS's have been used in evaluating appropriate land uses, the development of precision farming, and in planning agricultural or forestry systems. Computer modeling takes advantage of the computer's ability, often using linear programming techniques, to evaluate many different scenarios (different levels and combinations of inputs to a system) with a minimum of effort. Models have been developed to determine optimum levels of fertilizer required in different agricultural production systems and to understand the growth of trees to more effectively manage production.

Recent developments have seen these technologies applied to problems relating to agroforestry. One of the first such systems was the United Nations University (UNU) Agroforestry Expert System (AES). The UNU-AES is a type of DSS that provides management options for alley cropping under specific conditions in the tropics and subtropics. in response to the need for appropriate information relating to agroforestry tree species, the International Centre for Research in Agroforestry (ICRAF) developed the Multipurpose Tree & Shrub Database (MPTS). This DBMS contains first-hand, site specific information as well as secondary data on over 1000 multipurpose tree species. Other databases have also been developed to provide additional information about potential and current agroforestry tree species. GIS systems have also been developed to aid in the adoption of agroforestry. For example, a GIS-based agroforestry research tool was developed to determine the appropriate agroforestry systems that might be adopted in certain regions in sub-Saharan Africa. One system that models a rubber-cacao agroforestry system in Brazil was developed to bioeconomically simulate a 40-year cycle. The system explores different scenarios to achieve optimum production and profit levels. Modeling efforts in a variety of agroforestry themes have also produced interesting results. As each system is reviewed, its intended audience (farmers, land-use decision-makers, researchers) and end-use (research, development, decision-making) will also be discussed.

Agroforestry in Malaysia

Mohd Abd. Ali Razak, Mahmud A.W. and Najib Lotfy Arshad
Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia

Keywords: Agroforestry, Malaysia, New Agriculture Policy

Agroforestry as a land use, is getting prominent in Malaysia. in 1999, the government launched the New Agriculture Policy with agroforestry identifies as one of two strategic approaches to meet the challenges in the agriculture and forestry sectors. in the New Policy, the agroforestry approach is aimed at addressing the increasingly scarce resources including land and raw material availability with agriculture and forestry viewed as mutually compatible and complementary. The integration of agriculture and forestry is also aimed to create a larger productive base for both sectors. This paper discusses various strategic directions, action plans and recommendations on the agroforestry approach in the New Agriculture Policy.

The Effects of Population Growth and Agricultural Intensification on the Forest Resource of Central Honduras, 1970s-1990s: A Community-Scale Analysis

Sara J. Scherr
University of Maryland, Agricultural and Resource Economics Department, 2200 Symons Hall, 20742 College Park, MD, USA
Tel: (301) 405-3860, FAX: 301) 314-9091, Email: SJScherr@aol.com or SScherr@arec.umd.edu

Keywords: Agricultural intensification, deforestation, hillsides, Honduras, population and environment

The effects of agricultural intensification on forest cover, use and management are of major concern for forest policy and planning, particularly in tropical countries with high rural population growth. International evidence suggests that the relationship of forest cover with population growth and agricultural intensification is not linear. Population growth from low population densities typically leads to forest clearing for extensive agricultural production. But once continuous cultivation becomes the norm, further population increases often result in improved management of remaining forests and on farm tree-planting to meet subsistence needs and new market opportunities, as well as greater action to protect locally important watersheds.

However, our understanding of when and how this process occurs--for different population densities, types of farming systems, physical environments, and policy contexts-is limited. Most insights into these relationships have come from statistical analysis of macro-level changes in agricultural land and forest use. More sophisticated understanding and analysis of the nature, processes and impacts of forest land use and management under various types of agricultural intensification has been lacking. Such analysis is constrained by lack of detailed data that would permit joint analysis of changes over time in agricultural economies at the local level, and associated changes in forest cover and management.

This case study attempts such an analysis, for the Central Hillsides of Honduras, for the period from the mid-1970s to the mid-1990s. By comparing the processes and impacts in 48 communities with varying geographic, demographic, and economic characteristics and varying local governance arrangements, the study sought to identify the impacts of regional economic trends and public policies on forests at the local level. Six pathways of agricultural development in the region (stagnation of basic grains, expansion of basic grains, horticultural intensification, coffee expansion, forestry specialization and non-farm employment) had distinct determinants of economic change, distinct patterns of land and forest product use, and different concerns about local forest resources.

Aggregate tree cover declined only slightly in the coffee, forestry and non-farm employment pathways (which account for three quarters of regional land area), despite rapid population growth, as annual crop production became more intensive and less important to livelihoods. Forest cover declined significantly in the other three pathways, as area in annual crops expanded due to high-value vegetable markets (horticultural pathway), extensive production systems (the basic grains pathways) and cropland degradation (basic grains stagnation pathway).

Findings suggest that the impacts of agricultural intensification on forest resources depend on initial resource conditions and the type of intensification. Resource scarcities relative to population and agricultural development policies have greater impacts on forest conditions than do forest policies. The latter need to be targeted by agricultural pathway. The observed variations in land use dynamics raise concerns about the reliability of macro-scale analysis for predicting forest cover change or informing policy action.

1.17.01 Rehabilitation of mined lands

Reclamation of post-mining landscapes in Eastern Germany - The largest environmental protection project of Europe

Friedrich von Bismarck
Governmental Program for the Rehabilitation and Reclamation for East-German Lignite Mines, Schiffbauerdamm 17, 10117 Berlin, Germany

In East Germany an area of more than 1'000 square kilo-metres was consumed by strip mining and open pits. With the transformation process from a planned economy to market economy in East Germany most of the mines had to close down. The lignite or brown-coal mining had destroyed the landscape: By removing the over-burden the micro-organisms, vegetation, and animals, were lost. Particularly in the 70th and 80th the mining was carried out so intensively, that the reclamation did not keep up with the area devastated by mining. The political leaders had other priorities and so the state run mining companies did not receive the funds for remediation and reclamation.

The remediation is particularly difficult as the overburden consists of sand and gravel and hardly any topsoil. in the dumping areas a new covering soil need to be established and the interrupted nutritional chains have to be build up again to bring back plants and animals. in addition the residual pits are forming dangers to man and nature that appear from the physical properties of the pit slopes. The dump areas are geotechnically not stable. Over long distances the banks tend to slide down suddenly.

The East-German example demonstrates drastically what enormous problems occur, if active mining and land reclamation is not integrated. in order to be able to tackle such a task, a huge amount of various sorts of support was needed. So a first Administrative Agreement for a 5 year action program was signed in December 1992 which was extended in 1997 for another five years until the year 2002. According to this new agreement, now up to 1.2 billion DM is allocated from the Goverment yearly.

The funds are provided for safety-measures in the disused open-cast mines restoration of the water-balance, and rehabilitation and land reclamation.

In early spring of 1999, the program is well established as Europe's largest environmental program, and after more than 8 years of intensive work, progress can be documented in many ways.

Some achievements of the program are shown below. Area of waste-land and dump-areas to be reclaimed (without water-areas) 65.370 ha accomplished in early 1999
- reclamation of forest 27.280 ha
- reclamation of agricultural land 11.590 ha
- natural revegetation and controlled succession 5.760 ha

Total reclaimed area 44.630 ha

New ecosystems are established in order to bring the post-mining landscape on the path leading towards a sustainable development and achieve as well the desired future land use.

In the year 2002 in many areas that looked - for miles and miles - like a lunar landscape at the time of reunification in 1990, you will find many new lakes with water of bathing quality and you will also see thousands of acres of young forests and new agricultural land and areas protected for wildlife, and in some areas it will already be difficult for a laymen to tell that the area once had been mining land.

The impact of industrial pollution on the vegetation of Northern Siberia

Elena Golubeva, Vera Spektor
Moscow State University, Faculty of Geography, 119899 Vorobjovy Gory, Moscow, Russia
FAX: Email: egolub@biogeo.geogr.msu.su

Northern regions of Eurasia and North America are predominantly occupied by forest-tundra ecotones with considerable diversity of landscapes. Along with hydrothermal conditions, their appearance is largely governed by the presence of permafrost and is considered to be "one of the most pronounced boundaries in the landscape regionalization of the Earth". The biological components of forest-tundra ecosystems are extremely vulnerable to climatic changes and anthropogenic pressures. The so-called "land of small sticks", which is the local name for such landscapes, is characterized by larches that are less than 1 m high and branches which grow near the ground, protected by snow cover. 10-meter high trees grow in the valleys, while mosses, lichens, shrubs and dwarf shrubs occupy the concave uplands.

The natural resources of the Russian Lower Arctic, such as polymetal ores, gas, oil and coal, are intensively developed, often without due regard to certain features such as historical sites, as well as consideration of the importance of ecosystems. The Norilsk industrial region demonstrates one of the more serious conflicts between nature and society today. Norilsk is the largest town of the Polar Regions. Nowadays it is the largest center of mining and non-ferrous metallurgy in Russia, which is based on the locally available rich deposits of copper, nickel and coal. in recent decades, the town has also become the largest center of industrially-caused air pollution in the Arctic. Sulphur dioxide and heavy metals are of particular concern. About 2 million tons of sulphur and 60,000 tons of heavy metals enter the atmosphere of this area each year.

Current research is focused on the impact area of the Norilsk mining and Metallurgical Industrial Complex (Arctic part of Eastern Siberia). High emissions of sulphur dioxide and heavy metals, as well as the extreme climatic conditions of high latitudes, have caused large-scale degradation of the surrounding ecosystem.

The results of this investigation are based primarily on field studies of the vegetation cover. Toxic effects are most pronounced at the local level, in the vicinity of plants and industrial centres where pollution accumulates in the ecosystem and enters the biological cycle. It is in such extreme natural conditions, with fragile structural and functional links, that the effects of industrial impact can rapidly be seen in the state of the ecosystem.

Ecology of Post-Mining Landscapes - Fundamental Principles

Reinhard F. Hüttl, Edwin Weber
Brandenburg University of Technology at Cottbus, Post Box # 10 13 44, 03013 Cottbus, Germany
Tel: +49-355-69-2117, FAX: +49-355-69-2323, Email: huettl@tu-cottbus.de

Surface mining has a severe impact on landscape ecology. At many places, reestablishment of ecosystems is impeded by extreme site conditions.

Restoration of sustainable ecosystems resembling the situation before mining or rehabilitation towards designed systems with predefined goal functions requires complex knowledge based on an ecosystem approach, particularly if seminatural systems shall be recreated, *e.g.* by directed succession. Unfavourable physico-chemical site factors often must be actively compensated by rehabilitation measures, displaced target organisms must be brought back onto the sites. Areas designed for agricultural or forestry use must be rehabilitated considering the future perspectives of the users, i.e. interactions with socio-economical questions have to be considered if successful recultivation shall be achieved.

Knowledge can be extracted from mined land rehabilitated during this century, *e.g.* by means of chronosequence studies. Natural succession processes on post-mining sites starting from "point zero" are not only unique events in cultivated landscapes, they help understand natural ecosystem dynamics - far beyond the actual post-mining landscape.

Results from a number of research projects will highlight the various aspects and the scope of development of the ecology of post-mining landscapes using as an example the lignite mining district of Lower Lusatia in eastern Germany. Based on chronosequence approaches and long-term observations, a concept of ecosystem development on minesites was developed integrating various aspects potentially altered on former minesites and compared to ecosystems on natural, undisturbed sites: pedogenesis and organic matter transformation, natural flora and fauna succession, water and element budgets.

However, so far the dynamical aspects of ecosystems on former minesites are still not understood well enough to predict their long-term future development. Novel methodological approaches are needed to extend our knowledge and meet the demands of decision makers and land managers.

Forest Rehabilitation in the Baltic Region - The Oil Shale Study Case

Ülo Mander, Elmar Kaar, Priit Kask and Hardi Tullus
University of Tart, Institute of Geography, u, 46 Vanemuise St, 51014 Tartu, Estonia
Tel: +372 7 375819, FAX: +372 7 375825, Email: mander@ut.ee

The Estonian oil-shale field is the largest commercially exploited oil-shale deposit in the world. It contains over 60% of explored reserves exceeding 6600 million tons. The mining of oil-shale was started in 1916 and its total output exceeds 770 million tons of shale. Presently, 6 underground mines and 4 open pit mines are in operation. All the operating mines are located in north-east Estonia, i.e., in the central and eastern part of the deposit. in this area, the overburden reaches ranges 0-70 m due to gentle southward dipping of Ordovician strata. Mining in pits started to spread intensively in 1959 when excavators with a scoop volume of 15-20 m^3 came into use to remove surface. Pits are used in digging up to depth of 40 m with a total area of 23 thousand hectares. If oil-shale is deeper than 50 m underground mining is used. Nowadays around 50% of oil-shale is mined in pits. Until 1999 around 11700 ha was mined. The reclamation order of exhausted oil-shale pits was determined by the Estonian government as early as 23 November 1923. The planned afforestation of oil-shale pits began in 1960. More than 365 ha of experimental stands are planted on smoothened oil-shale pits to ascertain the most suitable tree species and bushes (all together 52 species have been used), cultivation methods, cultivation times and most suitable planting material sizes. The physical and chemical characteristics, water regime, microclimate and natural vegetation growth on these areas of land have been studied. From 1978 to 1980 128 permanent sample plots were established in experimental and productive stands. The growth and development of different tree species is studied after every 5 to 10 years, as are the initial density of trees depending on the species, the need for thinnings, vegetation and soil formation processes.

As of 1 September 1998 there are 8374 hectares of forest stands planted on smoothened oil-shale pits. 85% of them are pine stands, 7% are birch stands, 4% are spruce stands and 2% are larch stands. Other species make up around 2% of the cultivated area. Fire and insects endanger spread monocultures of *Pinus sylvestris*. Pine stands need thinning at a young age. *Larix europaea*, *L. sibirica*, *L. kurilensis* and *Betula pendula* show quite good growth on calcareous soils. They exceed pine stands of the same age (25-30 years) by 4 to 7 metres in height. Larch stands with an initial density of 1200 - 1800 plants per hectare, and birch stands with an initial density of 3000 - 3500 plants per hectare (2 year old seedlings) do not need thinning at a young age. in very rocky areas (rocks compromise 50-70%) *Alnus* spp. are more suitable to promote the soil formation processes.

Trees and bushes are also suitable for cultivation of oil-shale chemical industry residual formations like ash plateaus and coke-ash heaps with height up to 100 m. Experiments have been carried out there with 28 species. Fertilising with N and P fertilisers is necessary. in alkali conditions *Betula pendula*, *B. pubescens*, *Alnus glutinosa*, *A. incana* and *Populus trichocarpa* showed the best vitality.

Native Tropical Forest Rehabilitation: A Case Study from Brazil

John A. Parrotta
International Institute of Tropical Forestry, USDA Forest Service, Post Box # 25000, 00928-5000 Rio Piedras, Puerto Rico, USA
Tel: +1-787-766-5335, FAX: +1-787-766-6263, Email: j_parrotta@upr1.upr.clu.edu

Keywords: Amazonia, biodiversity, mine reclamation, native species, reforestation, tropics

Restoring productive, self-sustaining tropical forest ecosystems on surface mined sites is a formidable challenge that requires the integration of proven reclamation techniques and reforestation strategies appropriate to specific site conditions, including landscape biodiversity patterns. Restorationists working in most tropical settings are usually hampered by lack of basic information on the wide variety of native tree species that characterize these forests as well as insufficient understanding of the ecology of disturbance and natural recovery that can aid in the design of effective restoration programs. A notable exception to this is the forest restoration program developed since the early 1980s by a Brazilian bauxite mining company operating at Trombetas in Par State in central Amazonia. A systematic nursery and field research strategy was used to develop a reforestation program based on mixed plantings of more than 70 native primary forest tree species. This technique has been used to replant about 100 ha of previously forested minelands each year over the past 15 years. Research in recent years has evaluated this approach and other, generally simpler, techniques used at a smaller scale at this site in terms of post-plantation biodiversity development and other indicators of restoration success or sustainability. The results of these studies have shown the overwhelming importance of careful site preparation and topsoil handling/replacement practices in determining both future productivity and biodiversity of developing forests irrespective of the complexity of the planting design used. Beyond this, study results show that the inclusion of a wide variety of forest species, particularly later successional species, is very important for long-range restoration success due to limitations on natural recovery processes that inhibit seed dispersal and subsequent colonization of many primary forest species. Many of the lessons learned at this site have implications for the design of mineland rehabilitation and forest restoration programs worldwide.

Ecosystem development on post-lignite mining sites: element budgets of false-time series

Wolfgang Schaaf
Brandenburg Technical University of Cottbus, Post Box # 101344, D-03013 Cottbus, Germany
Tel: +49-355-694240, FAX: +49-355-692323, Email: schaaf@tu-cottbus.de

The post-lignite mining landscape in Lusatia is dominated by sandy substrates of tertiary and quaternary sediments. Lignite and pyrite contents of varying amounts can result in extremely phytotoxic site conditions. To establish pine stands on these sites, large amounts of CaO were used for amelioration. These forest ecosystems virtually start very close to the "point zero" of development, especially with regard to soil development, plant-soil interactions, and establishment of biogeochemical cycles. The development of these ecosystems at 2 - 60 years old pine stands on two typical substrates in a "false-time series" approach was studied. Water and element fluxes in different ecosystem compartments along these chronosequences were measured, analyzed with respect to differences between substrates, and compared to pine ecosystems on non-mined sites of the region. Main objectives were to identify the dominating processes and temporal trends in ecosystem development and to use flux budgets as an indicator for ecosystem functioning.

Soil solution compositions indicate very high spatial and temporal dynamics. Over time sharp depth gradients are formed due to amelioration and soil forming processes. Soil solutions are mainly composed of Ca, Al, Fe, and SO4 depending on soil pH and pyrite content. Dynamics in lignite-free sands are much less pronounced and show overall lower concentrations.

The results reveal fundamental differences of element budgets between the two substrate types due to their different geochemistry. The fluxes of almost all elements under investigation at lignite and pyrite free sites are similar or even lower compared to a non-mined site which can be explained by low weathering rates of the dumped material consisting mainly of quartz and low atmogenic input rates. in contrast, the lignite and pyrite containing sites show very high dynamics of initial development induced by substrate composition and are characterized by high element flux rates and intensive transformation processes, i.e. changes and redistribution of element pools.

The following processes could be identified as dominating factors in soil formation at the lignite and pyrite containing sites - Prite oxidation resulting in the release of large amount of acidity, sulfate, and iron, intensive weathering of primary minerals within the substrate releasing considerable amounts of Al, Ca, Mg or K depending on the specific mineral composition of the substrate, and precipitation of secondary salt and mineral phases like gypsum or oxides, hydroxides and sulfates of alumnium and iron.

Since pyrite oxidation can be a rather fast process depending on its control by chemical or microbial oxidation, a pyrite-free zone is developing from the surface to increasing soil depths over time.

- Leaching of easily soluble or labile secondary salt and mineral phases like gypsum, anhydrite or epsom salt. Over time this zone develops down the profile, too, forming a zone free of pyrite and salts.

- Both processes are affected by the amelioration measures taken in recultivation practice. Large amounts of lignite ash are incorporated in the topsoils resulting in an input of high amounts of Ca and Mg, but also to a lower extent sulfur. This of course introduces a large acid neutralization capacity compared to the substrate-internal buffering and also enhances formation of gypsum and other sulfate salts like MgSO4 that is leached very fast in high amounts from the profiles. The raising of soil pH on the other hand induces precipitation of Fe - and Al - oxides/hydroxides.

The chronosequence approach to study "false-time series" of post-mining sites has proven to be a very useful tool to identify dominating processes on the ecosystem level.

Biodiversity and The Role of Arbuscular Mycorrhizal Fungi for Enhancing Tailings Revegetation at PT Freeport Indonesia.

Yadi Setiadi, Yahya Alkatiri, Jemmy Rumainum
IUC-IPB, Forest Biotechnology, Campus IPB Darmaga, 16001 Bogor, Indonesia
Email: amf@indo.net.id

The PT Freeport Indonesia Company mill is presently processing about 150,000 tons of ore (Gold and Cupper) per day of which about 3% becomes ore concentrate. The remaining 97% is discharged into the Ajkwa River watershed in the form of tailings, and settles out in the Ajkwa Deposition Area (ADA), which currently covers an area of approximately 133 km^2.PT Freeport Indonesia has an intensive program to rehabilitate tailing deposition area by establishing vegetation cover. However, the proposed target is difficult to be achieved, due to several major constraints which are related to the unfavorable environmental conditions existing at the tailing sites. The succesful establishment of trees in these unfavorable tailing conditions may be enhanced by introducing the effective and selective AMF by inoculation of the seedling in the nursery. The novel functions of arbuscular mycorrhizal fungi (AMF) as biofertilizer inoculum for improving growth and health of plants and as an agent for bioremediation of heavy-metal contaminated soil are recognized. A limited survey of local arbuscular mycorrhizal fungi species was conducted in ADA areas at the Maurujaya Reclamation Research Center (MRRC), Mile 21, PT Freeport Indonesia. Representative soil and root samples were collected from different rhizosphere plants. Using standard methods, the roots were stained and the AMF spores were extracted from the soil, isolated, and identified. Selected AMF isolates were also cultured using devised test tube methods and mass produced on pot cultures. The local AMF isolates which were obtained in culture, were tested for their ability to increase the early growth of host plant grown on tailings as a substrate.

Among the 43 identified plant species grown on tailings, the root systems of 39 species (90%) are colonized by AMF. These data show that mycorrhizal associations are needed for plants to successfully adapt to growing conditions on tailing deposits. Among the pioneer tree species, the rhizosphere of *Macaranga mappa* contained high AMF species richness. Thus enhancing early establishment of this species by re-cultivation are expected can enhance the improvement population of indigenous AMF. Based on spore propagule counts, twelve spore types included in three genera of *glomalian* fungi (i.e. *Glomus*, *Acaulospora* and *Sclerocystis*) were found in the sites (early sere succession). Three other common genera, *Gigaspora, Scutelospora* and *Enthrophospora*, were not found at the sites. Results from pot experiments shown that among the local AMF isolate tested, Isolate MRRC-4 and MRRC-46 gave the best results. These isolates can significantly (P.05) enhance the biomass of host *S. grandiflora* grown on tailing by 453% and 326%, respectively, compared to the controls. They can also consistently improve the biomass of *S. grandiflora* grown on control ultisol soil by 123% and 95%, respectively. Isolate MRRC-46 and MRRC-4 has yet to be identified, however, both isolates form intensive mycelia around host plant root systems. This mycelial network may be important as a chelating agent and in nutrient absorption, and thus can facilitate plant establishment on tailing sites. This paper will review the novel function of mycorrhizal arbuscula for tailings rehabilitation, and provide a step by step protocol how to develope and used this mycorrhizal inoculant as a clean technology for rehabilitation and bioremediation of contaminated tailings at PT. Freeport Indonesia.

1.17.03 Tropical forest restoration

Restoration of a Sri Lankan rain forest: An eight year review of experimental trials

P. Mark S. Ashton, I.A.U.N. Gunatilleke, and C.V.S. Gunatilleke
Yale University, School of Forestry and Environmental Studies, 360 Prospect St, CT 06511 New Haven, USA
Email: mark.ashton@yale.edu

In the moist tropics much research has demonstrated that many late-seral tree species of the rain forest do not establish well on forestlands that have been cleared for agriculture and subsequently abandoned. This is most acute for the site-specific and shade-tolerant timber trees of mixed-dipterocarp forests in southeast Asia. For the last ten years we have been testing the use of Caribbean pine (*Pinus caribaea*) as a nurse for establishing rain forest timber trees. We selected 9 species of trees and 4 non timber species in two experimental sets of treatments that created microsites for planting seedlings within and adjacent to experimental openings within 20 year old pine plantations. Initial results after two years revealed that planting within the centers of canopy openings (photon flux density of 22 mols m-2 d-1; approximately 50 % of open conditions) that were 8 m wide provided conditions for greatest growth. in these circumstances seedlings grew between 3 and 15 times faster in height, depending upon species shade-tolerance, as compared to conditions beneath the closed canopy of *Pinus* (3 mols m-2 d-1; approximately 7 % of open conditions). Seedling planted in the full open had very high mortality during the first year and exhibited the poorest growth. The more shade-intolerant species showed greater response increases in all measures (dry mass gain, leaf area increase, height growth) than the more shade-tolerant species. Mortality of all species was higher in the *Pinus* understory, but this was most significant for the shade-intolerants. Results after eight years were the same but with greater differences between treatments. Seedlings planted in openings were growing at nearly 2 m yr^{-1} in some of the species, while growth of seedlings beneath the *Pinus* canopy was not more than 25 cm yr^{-1}. For the non timber species, two were lianas (cane, medicinal climber), one was a ground orchid with ornamental value, and one was a herbaceous shrub (cardamom). After two years all four species grew best in the edge microsites of the canopy openings. in these circumstances cardamom yielded 50 g plant-1 yr^{-1}, cane grew over 1 m yr^{-1}, the medicinal liana grew over 50 cm yr^{-1}, and the ground orchid produced the greatest number of flowers (25 per plant yr^{-1}). Results from these experiments have been used to construct planting guidelines for the various species tested along with an economic valuation (using NPV, net present value) of optimum species combinations for restoration on formerly cleared lands that have been reforested with Caribbean pine.

Underlying Causes of Deforestation and Forest Degradation and Constraints against Rehabilitation Efforts in Ghana

Dominic Blay, Adu-Anning Charles
Forestry Research Institute of Ghana, University Box 63, Kumasi, Ghana
FAX: 233-51-60121, Email: forig@africaonline.com.gh

Sustainable development of the forest resources of with the active cooperation of all stakeholders including rural communities is one of the important objectives of the forest and wildlife policy of Ghana. However achieving this objective cannot be possible without addressing the problem of deforestation and degradation. It is estimated that about 32% of forest reserves have been degraded. While there are no records for the areas outside reserves it is assumed that more than 75 % of those areas are also degraded. The major contributors to the deforestation and degradation are the people in the rural communities. While rural communities are blamed for contributing to the problem of deforestation and degradation discussions on these problem focus mainly on the activities which have contributed to the problem. However the rural communities are driven undertake those activities because of certain factors. Therefore to solve problem of deforestation and degradation and thus help in the sustainable development of the forest resources in Ghana these underlying factors and efforts that motivate rural communities need to be identified and remedies found for them. Deforestation and degradation in Ghana have been attributed to fire, unsustainable farming practices, logging and mining. Farming for instance has led to the loss of whole forest reserves. Efforts were therefore made to stop the encroachment of more reserves by farmers. Thus one of the first action that was undertaken was the eviction of the farmers living in the degraded reserves. Unfortunately this met with stiff resistance from the farmers with the result that the action was not successful.

Also in spite of the fact that deforestation is continuing efforts have being made to rehabilitate some of the degraded forests through taungya, enrichment planting and plantation establishment. Taungya and enrichment planting were tried and abolished. Plantation establishment, which is continuing, however involves only the use of mainly exotic species and in the past did not involve the local communities.

This paper therefore takes a look at the problems of deforestation and degradation as well as rehabilitation by discussing the underlying factors that motivate deforestation and degradation. It also discusses the reasons for the resistance put up by the farmers towards their eviction as well as the reasons for abolishing taungya and enrichment practices as well as the use of mainly indigenous species for plantation establishment.

The paper makes suggestions for actions that can provide solutions for the underlying factors that contribute to deforestation and degradation and measures to overcome that will enable the farmers living in the forest reserves contribute to the rehabilitation programme. It also makes suggestions on the appropriate methods for rehabilitating forests degraded through different direct actions.

Forest restoration for biodiversity conservation in Northern Thailand

Stephen Elliott, Vilaiwan Anusarnsunthorn, David Blakesley, Puttipong Navakitbumrung, Cherdsak Kuarak and Sudarat Zangkum
Chiang Mai University, Forest Restoration Research Unit, Biology Department, Science Faculty, 50200, Thailand
FAX: +66 53 892259, Email: scopplrn@chiangmai.ac.th

Restoration of degraded forest ecosystems for the conservation of biodiversity requires development of different methods to those currently used for commercial forestry. Research must cover a much broader range of indigenous trees species, instead of focussing only on those of economic value. Ecological criteria, such as ability to shade out herbaceous weeds and attract seed-dispersing wildlife, must be emphasized when selecting species for planting. Furthermore, processes of natural forest regeneration must receive greater consideration, to develop effective silvicultural strategies.

This paper will present a synthesis of research findings aimed at developing ecologically effective and socially acceptable methods to restore degraded, seasonally dry, tropical forests within conservation areas in northern Thailand, where the primary aims of management are biodiversity conservation and watershed protection. Seasonal drought, fires and heavy human impact present special challenges to the restoration of such forests.

The results of a research program to screen nearly 400 native forest tree species for their potential usefulness in forest restoration programs will be presented. The program included studies of the seasonal cycles of seed production of mature trees in undisturbed forest as well as experiments on seed germination and seedling growth under nursery conditions. The relative importance of various criteria considered for species selection will be discussed, including: seedling performance; ease of propagation; ability to shade out weeds; ability to foster regeneration of other tree species; inhibited natural seed dispersal and rarity. Initial results will be presented of planting trials using mixtures of 30 native forest tree species and testing various silvicultural treatments, such as fertilizer application, weed control and mulching.

A program to test the applicability of new methods developed by the program within a hill tribe community living within a national park has also been initiated. A community tree nursery was constructed within the village and community members have participated in nursery management, tree planting, weeding, fire control and monitoring the success of planted plots. On the basis of the experience gained during this program, the challenges of introducing local communities to new methods of forest restoration will be discussed.

Rehabilitation of degraded Tropical Rain Forest by enrichment planting of endemic species in a forest of Sabah, Malaysia

Jan Falck, Charles Garcia
Swedish University of Agriculture Sciences, S-90187 Umea, Sweden
Tel: +46-90-7865884, FAX: +46-90-7867669, Email: Jan.Falck@ssko.slu.se

The valuable timber from tropical rain forests around the world is an essential resource often used to meet the demand for economic development in the local societies. Most tropical rain forests are able to gradually recover from a selective harvest. But repeated harvest too early in the secondary forest and/or wild fires can call for rehabilitation plantation to speed up the recovery process. The main objective of this effort is to improve biodiversity. Planting and tending tree seedlings of old growth species in the degraded forest is supposed to facilitate migration and reestablishment of fauna and flora belonging to the natural forest. in the current study, located to Sabah, we investigate the feasibility of rehabilitation planting in a secondary tropical rain forest degraded by harvest and the 1983 wild fire. Under the canopy of a Macaranga- dominated pioneer forest more than 30 Dipterocarp species, some non-*Dipterocarps* and fruit trees are planted using two different plantation concepts i.e. line and gap plantation. The study also includes tests of different techniques for seedling and wildling production and different regimes of shade adjustment in the pioneer vegetation overstory. in the first phase, starting in 1998, 4500-5000 ha will be planted in a 5-year period.

The main result so far is that gap plantation is cheaper than line plantation. The reason being that only five compass lines need to be cleared compared to ten for line plantation. Gap plantation appears to give the new Dipterocarp forest a more natural structure since the seedlings are more irregularly spaced than after line plantation. Seedling survival was similar following the two plantation concepts exceeding 85 % after three months.

Funding is mainly provided by a Swedish company and the local counterpart: Innoprise Corporation SDN BND.

Transformation of degraded farmer forests into managed semi-natural forests in Eastern Paraguay

M. Grulke, Albrecht, J.; Monges, E.; Perez de Molas, L.; Quinteros, M.; Campos, D.; Rodriguez, L.
Paraguay
Email: Proyecto Enaprena [enaprena@quanta.com.py]

50 years ago, more than half of Eastern Paraguay (about 160.000 km2), was covered with subtropical lowland rainforests. Today the forest cover is about 10 to 15 %. All residual forests have been exploited selectively once or several times. There are no primary forests left. As a consequence of the rapid deforestation in the last few years the discussion over how to maintain the residual forests has arisen in political circles and in public. The approach "maintaining by managing" is favored.

Nearly half of the paraguayan population assures her economical existence by managing small-scale farms with an extension of 20 ha. or less. These farms are caracterized by a strongly marked mixed production system: Food-crop cultivation, cash-crop cultivation and livestock-breeding. Generally the farms include small forests which are used without any management-plan and later on - when degraded and economically unattractive - converted into agriculture.

Until today there is no systematical investigations available on how to manage these residual small-scale forests and what economical impacts on the farming system a sustainable management might have. The investigation project was initiated in September 1998.

The aim of the investigation is to assess the potential of rising farmer's income by the integration of sustainable forest management in the farming mixed production system.

The investigation is carried out as an integrated On-Farm-Research-Project in the bufferzone of the National Park Ybycu¡, situated 150 km. south-east of Asunción. in all stages of the project, which are described in the following, a high level of active participation of the farmer families is required:

- Development of adjusted forest management concepts. The management concepts should be compatible with

- the target(s) of forest production (fuelwood, construction wood for subsistency, comercial timber, non-wood forest products) determined by the farmers themselves.

- the farmer families personal, technical und financial abilities to carry out a forest management.

- the natural conditions of the residual forests for a sustainable management. To respect these general conditions in the first instance was necessary a socio-economic assessment. Elements of the Participatory Rural Appraisal were used. Afterwards the forest ressources have been inventorized in three case-study farms.

Both, the socio-economic assessment and the forest inventory, showed, that to cover the forest product needs of the families in the long run, on-farm small reforestations are necessary as a complement to the management of the residual forests.

- Implementing the forest management concepts and the reforestations/enrichment By putting into practice the forest management it is possible to recognise and resolve technical problems and to assess the real costs and benefits of the initial silvicultural activities. This project stage will be finalised in the current year.

- First evaluation of the economic impact of the forest management With the cost-benefit assessment of the initial forest activities in combination with a simulation of future forest growth and future cash-flows a first evaluation of the economic impact on the farming-system of sustainable forest manegement should be possible. The economic evaluation will be carried out in the year 2000.

It is expected, that the results of the investigation project give practical assistance to the owners of small-scale forests and to the forest extension agencies. It is also expected, that political decision makers, for the purpose of promoting small-scale forestry, get additional arguments based on scientific results, e.g. in the discussion about subsidies for forest activities.

The Potential Role of Plantations on the Rehabilitation of Native Forest Biodiversity in Degraded Hilly Areas of Bangladesh

Mohammed Kamal Hossain
Chittagong University, Institute of Forestry and Environmental Sciences, 4331 Chittagong, Bangladesh
Tel: 880-31-726310, FAX: 880-31-610004, Email: ifescu@globalctg.net

Keywords: Plantation, Rehabilitation, Biodiversity, Degraded areas, Bangladesh

The natural forest loss and degradation of forest lands in Bangladesh are proceeding at an unprecedented rates eroding the biological diversity and prospects for sustainable economic development of forest resources. About 0.67 million ha hill forests rich in both floral and faunal diversity and another 0.73 million ha Unclassed State Forest (USF) areas alone in the Chittagong Hill Tracts are shrinking and degrading mainly due to agricultural expansion, shifting cultivation, encroachments, land alienation and over exploitation. Considering the magnitude of deforestation and slow growth of the existing natural forests, artificial plantation programs are getting priority day by day and there is an increasing evidence that forest plantations may play a key role in harmonizing long term forest ecosystem rehabilitation. in the past, the poor yielding heterogeneous natural forests were in the gradual process of conversion into plantation forests through clear felling and artificial regeneration with desirable exotic and indigenous tree species. Reforestation activities are also being continued in depleted and barren areas. The catalytic effect of tree plantations on native forest succession under a variety of degraded sites may be obtained and plantation forests can have the same functions as secondary forest stands.

The paper describes the necessity of the gradual conversion of the degraded hilly areas to a prospective plantations of suitable tree species which will ultimately save the natural hill forests of several hundred economically important species of both the plants and animals. The denuded hills of Chittagong, Chittagong Hill Tracts, Coxs Bazar and Sylhet Forest Division areas comprising a vast land resource of the country can neither be kept unproductive barren nor can be allowed to be abused by the peoples. As early as these denuded hills are brought under permanent forest cover by afforestation of suitable tree species, the better benefit will be derive by the local people and the nation. The depleted hilly areas which can sustain only forest crops, have been suggested to be sought under afforestation programs with valuable tree species. To restore the former biodiversity of the forested area, monocultures will be discourage whereas, emphasis should be given to indigenous species. A proper species-site matching mechanism and mixed plantations of diverse end uses should be given priority. Participation of local peoples in plantation establishment, management and protection will also enhance the activities of tree planting programs instead of shifting cultivation or jhum cultivation. Participatory approach and jhumia rehabilitation program will be given emphasis in an aim to rehabilitate the nomadic jhumia families and to improve their economic conditions with the restoration of native biodiversity over the denuded hilly areas.

Restoration of the Native Understorey Vegetation in the Plantation Forest Areas of Chittagong University Experimental Plantation Area

Mohammed Kamal Hossain
Chittagong University, Institute of Forestry and Environmental Sciences, 4331 Chittagong, Bangladesh
Tel: 880-31-726310, FAX: 880-31-610004, Email: ifescu@globalctg.net

Keywords: Restoration, Native species, Understorey vegetation, Plantation forest, Species composition

The degraded natural forest areas of Chittagong University experimental plantation area was in a gradual process of conversion in to a productive plantation forest through clear felling the existing natural vegetation and then followed by artificial regeneration. Both the exotic and indigenous tree species are getting preferences in the plantation programs in an aim to restore the degraded sites to a vegetation cover with valuable timber species. The native vegetation cover also emerged with the growth of the artificial plantations which restore the partial biodiversity of the original ones. The present study was an aim to survey the native understorey vegetation by random quadrat method in different years plantation. Mixed plantations of *Acacia auriculiformis*, *Albizia procera* and *Cassia siamea* of 1982 showed the presence of 36 different species in comparison to 21 species only in *Eucalyptus camaldulensis* plantations. of these, 15 understorey species are common in both the mixed and eucalypt plantations, whereas 21 species are solely present in mixed plantations and 6 species in the eucalypt plantations only. The index of similarity (Is) of ground vegetation in both the plantations is 0.36. The dominant species in both the plantations are *Clerodendrum infortunatum, Eupatorium odoratum, Lantana camara*, *Microcos paniculata* and *Vitis* *assamica*. Similar survey in the 1984 mono-plantations of *Artocarpus chaplasha*, *Swietenia macrophylla*, *Acacia auriculiformis* and *Eucalyptus camaldulensis* showed that the presence of understorey vegetation was 34, 33, 33 and 32 respectively indicating that the mono-plantations of the different species did not significantly influence on the restoration of the native understorey vegetation. *Clerodendrum infortunatum*, *Crotalaria saltiana, Eupatorium odoratum, Ichnocarpus frutescens, Lantana camara*, METLA*stoma malabathricum*, *Microcos paniculata* and *Syzygium fruticosum* are common species found in all the plantations. Similarly 1987 *E. camaldulensis* and *A. auriculiformis* plantations showed the presence of 32 and 26 understorey species respectively. of the species, 18 are common in both the plantations.

The study also revealed the presence of maximum understorey species (36) in the 1982 mixed plantations and lowest (21) in the *E. camaldulensis* plantations. The presence of understorey species in plantations also depends on the initial field preparation practices, even the initial cultural practices. The previous vegetation of the site, planting spacing and also the surface soil conditions determine the intensity and species composition of the plantations. The proper species mixing in suitable sites and the initial silvicultural treatments may restore the native understorey vegetation which will ultimately conserve the valuable native biodiversity in artificial plantation areas of the degraded hilly areas of the country.

Comparative ecological study of natural forest, man-made forests and grass lands for developing sustainable forestry in Sakaerat, Northeastern Thailand

Koichi Kamo, Tosporn Vacharanghura, Sirin Tiyanon, Chingchai Viriyabuncha, Suchat Nimpila, Bunnasart Duantsrisame, Rattana Thaingam
Forestry and Forest Products Research Institute, Division of Forest Environment, Matsunosato, Kukizaki-cho, Inashiki-gun, 305-8687 Ibaraki, Japan
Tel: 0298-73-3211, FAX: 0298-73-1542, Email: kamo@ffpri.affrc.go.jp

Keywords: restoration of forest, man-made forest, biomass, net primary production, plant species diversity

Man-made forests could play a crucial role in the process of restoring forest ecosystem to a region. However, we have not yet clearly evaluated the role and significance of man-made forests in this process. At Sakaerat, in northeastern Thailand, various stands of exotic and indigenous tree species have been established on grass lands during an re-afforestation project conducted jointly by Thailand and Japan (JICA). The goals of the present study were to evaluate the present status of re-afforestation in terms of the role of man-made forests in restoring the forest ecosystem and to develop suitable forest management systems capable of enhancing the forests on a sustainable basis. We studied biomass, productivity, and the plant species diversity of man-made forests composed of exotic species (*Acacia mangium*, *A. auriculiformis*, *Eucalyptus camaldulensis*) and indigenous species (*Xylia kerri, Dalbergia cochinchinensis, Pterocarpus macrocarpus*) and compared with those from neighbouring natural forest (dry evergreen forest) and grass lands (*Imperata cylindrica*, *Neyraudia reynaudiana*) in 1998 and 1999. The results were as follows:

1) By 13 years after planting, exotic man-made forests had accumulated above-ground organic matters levels 20 to 30 times as great as the *Imperata cylindrica* grassland and 1 to 1.8 times as great as the natural forest, whereas indigenous man-made forests accumulated 6 to 17 times as much above-ground organic matter as the grassland and 0.3 to 0.9 times as much as the natural forest. Much larger biomass developed in the exotic stands than in estimated seral forests during secondary succession from *Imperata cylindrica* grassland to dry evergreen forest; these values were approximately equal for indigenous stands and the seral forests.

2) The leaf biomass in the man-made forests ranged from 2 to 5 ton/ha. This range of leaf biomass was the lowest measured thus far in various types of forests.

3) The annual above-ground biomass increments in the man-made forest were 1.4 to 3.7 times as high as the increment measured in *Imperata cylindrica* grassland. The annual net primary production in exotic man-made forests and indigenous man-made forests were, respectively, 1.2 to 1.8 times and 0.6 to 1.1 times as great as the level in natural forest. The low level of leaf biomass, combined with high turn over rates of leaf mass, was found to have enabled exotic species stands to attain high level of net primary production.

4) More plant species with various life forms became established in man-made forests of exotic and indigenous species than in grass lands; the values range from 62 to 82 plant species per stand. Among the plant species established in the stands, seedlings and saplings of forest tree species accounted for 29 to 40% of the total. A noteworthy thing was almost no invasion of *Imperata cylindrica, Neyraudia reynaudiana* in the man-made

forests. in Sakaerat, the occurrence of surface fires decreased greatly after establishment of the forest stands. This could be a result of the disappearance of these shade-intolerant grasses under the stand canopies, since such grasses are a major source of fires. Preventing surface fires could, in turn, have allowed tree seedlings to become established within the man-made forests. in this context, the small leaf biomass in the stands created enough shade to prevent invasion of the two grasses and to provide a suitable light environment for seedling establishment.

From these results, it appears that re-afforestation helped the ecosystem to accumulate large amount of biomass and fix large amount of carbon in a relatively short time because of high net primary productivity, and accelerated the forest succession from grass land to natural forests by increasing the stocking of advance growth of indigenous species in the stands. Based on these results, we discuss suitable management systems for promoting forest succession and for enhancing the quality of forests on a sustainable basis.

Participatory restoration of a degraded landscape in Kerala state, India with indigenous forest tree species of commercial potential

K. K. N. Nair, R.C. Pandalai
Kerala Forest Research Institute, Peechi, 680 653 Kerala, India
FAX: 0487-782247, Email: libkfri@md2.vsnl.net.in

While there is increasing pressure to transform more of unproductive landscapes in India into productive areas by the introduction of exotics like *Eucalypts* and Acacias, a pilot scale experiment was conducted to restore such a wasteland using indigenous forest tree species, the products of which are of commercial demand in the Indian System of Medicine. With the active participation of the rural beneficiaries, ensured by Participatory Rural Appraisal (PRA) method, the land capability, vegetal cover and adverse factors which operate in the ecosystem rendering it degraded and unproductive, were understood and an area of 12 ha was adopted for development under the scheme. Species selection for artificial regeneration was also accomplished through PRAs, where, acceptability to the people and the environment were the priorities and long-term returns on a sustainable basis, the economic doctrine. The tree species, thus selected for the restoration programme, are Aegle marmelos (L.) Correa, *Caesalpinia sappan* L., *Oroxylum indicum* (L.) Vent., *Pterocarpus santalinus* L.f. and *Saraca asoca* (Roxb.) de Wilde, the last three among them very rare or endangered due to over-exploitation of their medicinal products vis-a-vis degradation of their natural habitats. The restoration component of the programme involved procurement of seeds, establishment of nursery, raising seedlings of the six species in sufficient numbers, field planting them and monitoring their survival and growth rates. The data generated during each of the phase were analysed and is presented in the paper to conclude on the success of the rehabilitation programme. in the nursery, Aegle marmelos and *Caesalpinia sappan* recorded maximum germination rates, whereas, in the case of outplanted seedlings, better survival and growth were observed for *Caesalpinia sappan* and Pterocarpus santalinus. The programme also generated direct employment to the beneficiaries during its nursery and planting phases, and created awareness among them on alternate economically potential, indigenous species for restoration of unproductive and degraded sites in the place of exotics - not eco and etho-friendly. Moreover, the strategy evolved for the intervention and transfer of technology pertaining to the nursery and plantation aspects of the species were so designed to facilitate the beneficiaries to undertake such rehabilitation activities in future, in similar areas with same or similar species, ecologically suitable and economically viable.

Development of Wasteland Through Tree Plantation in Chattisgarh Region

Sunil Puri
Indira Gandhi Agricultural University, Department of Forestry, 492 012 (M.P.) Raipur (M.P.), India
Tel: +91 771 420828, FAX: 91-771-424532

Plantation of multipurpose trees (MPT) species play an important role in restoring productivity, ecosystem stability and biological diversity to degraded lands. The choice of Plantation species is likely to influence both the rate and trajectory of rehabilitation process. in chhattisgarth region where entisols (red laterite) and inceptisols dominate which have negligible productivity; there is a need to find ways to increase productivity by including wood perennial. Out of the total geographical area of 144018 sq. km nearly 20 % area is under red laterite soil, commonly known as bhata soil. Due to poor waterholding capacity, available field moisture and very poor nutrient status of these soils, the productivity is extremely low. Beside the low productivity the problem of soil erosion is predominant in the uplands. in order to conserve the soil and increase productivity, the tree plantation programme was undertaken. Both forest tree species and horticulture tree species viz., *Albizia lebbeck, Dalberiga sissoo, Gmelina arborea, Pongamia* *pinnata, Albizia procera, DendroCalamus strictus, Azadirachta indica, Anacardium occidentale, Annona squamosa, Emblica officinalis, Psidium guajava* and *Zizyphus mauritiana* were planted either as block plantation or as energy plantation. The survival and growth performance after 4 to 6 years of plantation revealed that many of the tree species could be planted in red laterite soils of chhattisgarth region. Among the tested species *Eucalyptus tereticornis, hardwickia binata, Leucaena leucocephala* and *Emblica officinalis* out performed in block plantation. Growth and biomass of bole, branches, leaves and fruit after 7 years of plantation were assessed. The highest growth performance and biomass production were in order, *L. leucocephala* > *E. tereticornis* > *A. procera* > *D. Sissoo* > *A. indica* > *H. binata* > *T. arjuna*. The variation in soil properties at different depths of soil under different tree species was also studied. Increased levels of nutrients (N, P and K), moisture content and organic carbon varied in different species and nitrogen fixing trees, in general, showed higher nutrients. Moisture and nutrient, contents decreased with depth. The results are discussed in the light potential of introduction of exotics in comparison to indigenous species.

Seed and seedling demography of an alien tree species Bischofia javanica in a subtropical island forest of western Pacific

Naoko Yamashita, Nobuyuki Tanaka, Koichi Kamo, Hiromichi Kushima
Forestry and Forest Products Research Institute, Tsukuba Norin-Kenkyu-Danchi, Post Box # 16, 305-8687 Ibaraki, Japan
Tel: (+81)-298-73-3211 ext.494, FAX: (+81)-298-73-3796, Email: naokoy@ffpri.affrc.go

Bischofia javanica Blume (*Euphorbiaceae*), indigenous to southeast Asia, was introduced into Bonin Island in early 1900's as a timber tree. On Bonin Island, a small Japanese island in the western Pacific, it became established in the natural forest replacing native tree species and assumed dominance in the local forest as a canopy tree or an emergent at maturity. It is competitively replacing the preferred native species of which 73% are endemics occurring in highly valued conservation areas. These endemic species and the native forest biodiversity are being seriously threatened by *B. javanica*. Conservation measures to control *B. javanica* is being considered. But the ecological behaviour of this species is not well known. The aim of this study is to clarify the ecological traits which confer an advantage in the regeneration of *B. javanica* over native species. We investigated the early establishment of *B. javanica* including seed fall, seedling emergence, and seedling survival both in the field and in greenhouse experiments. Seed fall of *B. javanica* occurs mainly from December to February and shows considerable yearly variations. A large number of seed (about 2400/m^2) was observed in the autumn of 1995 (mast year) but for the next 3 years, very few seed were produced. To evaluate seed longevity in forest soil, we buried seeds in forest soil and checked their viability at regular intervals over 2 years. About 7% of the seeds with pulp and 3% of the seeds without pulp buried in forest soil were still viable after 2 years. This suggests that *B. javanica* forms short-term seed banks that will be exhausted in a few years without the input of newly fallen seeds. Mortality of seed produced in the autumn was quite low resulting in high seed germination in the following rainy season (middle May to June). This initial flush of germination produced a dense carpet of seedlings (mean 210/m^2), but low numbers of seedlings continue to emerge for several years. Many seedlings die after 2 months (in mid-June to July) from wilting, and to a lesser extent, from damping off and herbivory. Compared with *B. javanica*, seedling emergence and persistence of native species were much lower under forest shade. Large numbers of seedlings and saplings of *B. javanica* also dominated most forest gaps indicating a competitive advantage over other species in disturbed sites. This is supported by findings in greenhouse experiments where *B. javanica* seedlings showed capability of high growth rates in both high and low light environments. It appears that *B. javanica* seedlings have the ability to occupy gap openings and reach maturity more quickly than native species. Based on findings of this study, *B. javanica* can be characterized by its high seed output, low seed mortality, a large annual seedling emergence from newly dispersed seed and short-term seed bank. It is also capable of high seedling survival by maintaining high growth rates both in gaps and under canopy shade. It is likely that these regeneration traits contribute to the success of *B. javanica* in the juvenile stage and to the over-abundance of this invasive species on the island. Forest management to control *B. javanica*, therefore, will only be effective by combining the removal of adult trees with reducing the seedling population to a very low level. *B. javanica* can persist in the shaded understorey but can not reach maturity without canopy openings. By eliminating the sapling population in gaps would reduce the further spread of *B. javanica*. Suppressing its natural increase in the juvenile stage is probably the most ecologically and economically effective means of maintaining long-term control over large areas.

2.01.00 Physiology of tropical and temperate trees

Within- and among-provenance variability of *Pinus ponderosa* seedling response to long-term elevated CO_2 exposure

James L.J. Houpis, Paul D. Anderson, David J. Anschel and James C. Pushnik
Southern Illinois University, Department of Biological Sciences, Box 1099, 62026 Edwardsville, Illinois, USA
Email: jpushnik@oavax.csuchico.edu

Among- and within-provenance variability in growth and physiological performance of *Pinus ponderosa* Dougl ex P. Laws seedlings were investigated in response to ambient or elevated atmospheric carbon dioxide (ambient + 175 µL L^{-1} or ambient + 350 µL L^{-1} CO_2) for sixteen months. Among-provenance variability was studied with bulk-collection sources from five different physiographic regions of California. Within-provenance variability was examined with three half-sibling families from a common physiographic locale.

Regardless of source, stem volume increased at ambient + 175 µL L^{-1} CO_2, however, further increases in CO_2 to ambient + 350 µL L^{-1} resulted in a variety of stem volume responses with about equal numbers of sources showing either no change or slight increases. Physiological responses to elevated CO_2, including decreased efficiencies of photochemical transfer (Fv/Fm), no change in stomatal conductance, and increased photosynthetic and water-use efficiencies, were consistent among half-sib families. This limited survey shows little within-provenance variation in CO_2 effects on seedling physiology. The within- and among-provenance variability in growth response to CO_2 indicates differing genetic control of carbon acquisition and allocation mechanisms among sources of *Pinus ponderosa*. Understanding the extent and source of intraspecific variation in growth and physiological responses to elevated CO_2 is a critical need in developing management strategies for future atmospheric environments.

Ecophysiological studies at the Top of a Lowland Rain Forest Canopy in Southern Taiwan

Yau-lun Kuo
National Pingtung University of Science and Technology, Department of Forestry, China-Taipeh
FAX: +886-8-7740346, Email: ylkuo@mail.npust.edu.tw

Diurnal patterns of photosynthesis, transpiration and stomatal conductance of five species were measured in a lowland rain forest of Nanjenshan in southern Taiwan from 1995 to 1997. These physiological measurements were taken at the uppermost canopy of *Ficus benjamina*, *Machilus kusanoi*, and *Michelia compressa*. Those at the middle canopy were monitored only in *Ficus*, and those of understory species were represented by *Psychotria rubra* and *Aglaia elliptifolin*. Under moderate weather conditions seasonal courses of net photosynthesis in the uppermost canopy of the *Ficus* tree showed a positive correlation with leaf temperature. However, when leaf temperature exceeded 33°C and leaf-to-air vapor pressure deficit exceeded 2.5 kPa, net photosynthesis as well as stomatal conductance declined. Low temperatures in winter and high temperatures in summer inhibited net photosynthesis as well.

Photosynthetic photon flux density (PPFD) was found to be the major environmental factor affecting primary photosynthetic productivity of plants in Nanjenshan forest. Usually, diurnal courses of both net photosynthesis and transpiration followed the variation patterns of PPFD. Diurnal mean PPFD and net photosynthesis in the upper canopy of the Ficus tree were 643 µmol photon m-2 s-1 and 6.94 æmol CO_2 m-2 s-1, respectively. Comparatively, measurements at the middle canopy were only 14% and 30% and those of understory species were only 3-6% and 7-11% of the upper canopy values. The photosynthesis productivity of Ficus, Machilus and Michelia were 10.8, 11.2, and 11.7 g CO_2 m-2 day-1, and their transpiration rates were 1.30, 1.51, and 1.53 kg H2O m-2 day-1, respectively. Net photosynthesis at the uppermost canopy measured at 9 am, or mean net photosynthesis measured at 8 am and 10 am, had significant linear correlation with the diurnal carbon gain. This suggests that short-term measurements of photosynthesis, performed at periodic intervals in the morning, can be used to predict the daily leaf carbon gain in a lowland forest tree.

Dependence of biomass formation on carbohydrate content in the leaves of *Populus tremula*

Ülo Tamm, M. MAndreand H. Tullus
Estonian Agricultural University, Forest Research Institute, Kreutzwaldi str. 5, 51014 Tartu, Estonia
FAX: 372-7-421 053, Email: ytamm@eau.ee

Several vegetation models suggest profound changes may occur in the boreal forests with a doubling of atmospheric CO_2 and global temperature rise. These forest responses may result from changing competitive relationships among species (Solomon, Cramer, 1993) and increases in the wood production capacity of deciduous trees (Kellom et al., 1995). Results from FGM calculations indicate that the competitive ability of several deciduous tree species that occur in Estonia could increase significantly with rising temperatures in association with increases in their biomass in the forest ecosystem (Mandre, Klysheiko, 1996). Leaf orientation, display and anatomy and branch type of *Populus tremula* (aspen) have suitability for enhanced CO_2 acquisition with climate change suggesting an increase in the relevance of aspen in Estonian forests.

Knowledge of carbon allocation processes is essential for understanding tree growth; however, such knowledge of the mechanisms and controls of carbon allocation are generally lacking. Carbohydrates are necessary for the growth and biomass formation of a tree, and we have determined the carbohydrate content and nutrient status of aspen leaves in relation to their location in the canopy.

The canopies of aspen trees (n = 12 in each year) were sampled from ten equal horizontal layers. Canopy foliage was obtained from all canopy layers at the end of the leaf growth period in 1987-1994. The specific leaf mass (mg m-2) and the dry matter distribution (%) increased, whereas, the area of leaves in a canopy layer (m^2) decreased with increase in canopy height. On average aspen leaves contained 10.3% soluble sugars and 1.7% starch on a dry mass basis. The lowest content of non-structural carbohydrates was usually found in the lower canopy layers. Beginning from mid-canopy the carbohydrate content showed an upward trend. The content of non-structural carbohydrates varied with position of the leaves in the different canopy layers and with the N, P and K contents in the tissues, reaching a maximum in the upper canopy layers. Leaves of the upper canopy layers had 15-20% more soluble sugars and 30-40% more starch than the lowest canopy layer. The content of hemicelluloses in aspen leaves fluctuated between 40-70 g kg^{-1} and seemed to be higher in mid-canopy. Regression analysis showed a strong relationship between the specific leaf mass, leaf area and the percent carbohydrate content of foliar dry matter.

Biomass and morphological characteristics of aspen were related to the carbohydrate content in leaves. The relatively large differences in carbohydrate concentrations in different canopy layers of *Populus tremula* suggests that leaves have differing abilities to assimilate CO_2 from the atmosphere. Enhanced growth and acclimation of photosynthesis of several *Populus sp*. were also shown by Ceulemans and Isebrands (1996) for elevated CO_2 conditions. These results suggest the possibility for expansion of *Populus tremula* in Estonian forests with projected changes in environmental conditions.

Photosynthetic characteristics of tropical trees and their ecological significance in climate changes

Yanhong Tang, Okuda Toshinori, Manonkara N. and Rahim Nik
National Institute for Environmental Studies, Onogawa 16-21, 305 Tsukuba, Japan
Email: tangyh@nies.go.jp

Tropical forests may contribute a large proportion of the photosynthetic CO_2 uptake by terrestrial ecosystems. However, the CO_2 fixation contribution of tropical forests is still unclear for its quantitative amount. Consequently, it is difficult to predict the ecological role of tropical forests in regional and global CO_2 budgets. Some studies suggest that tropical forests are significant carbon sinks, but others reveal that some tropical forests (Amazon) can be CO_2 sources, especially during dry seasons. Without further detailed understanding of the physiological characteristics of tropical trees, it would be difficult to quantify the contribution of tropical forests in the global carbon budget.

In this study, we evaluated whether tropical tree species show any particular physiological characteristics in CO_2 uptake that differ from the evergreen tree species of temperate forests. We surveyed photosynthetic data for tropical tree species from literature, and measured photosynthetic characteristics for some typical tree species in the Pasoh Forest Reserve, Malaysia. Particular attention was given to seedlings of tree species from South East Asian tropical forests, since knowledge is still rather limited for this region among tropical forests of the world.

We found that tree seedlings from tropical rain forests tend to use light efficiently under low photosynthetic photon flux density conditions, whereas their canopy leaves, exposed to direct sunlight, tend to show a higher resistance to photoinhibition in comparison with the majority of temperate tree species. By examining the effects of various environmental factors on photosynthetic parameters, we found that sunflecks may contribute to a larger proportion of leaf carbon gain for tree seedlings in tropical rain forests than in temperate evergreen forest species. We also note that the high CO_2 concentration in forest floor enhanced leaf carbon gain of tree seedlings.

Our results suggest that we need to account for physiological differences between temperate and tropical trees in model predictions of their contributions to leaf carbon gain. We propose a set of parameters for characterizing the differences in photosynthetic responses between tropical and temperate trees, which may facilitate model prediction of climate change impacts on the global carbon budget.

A Correction Coefficient for Dealing with Variation in Sapflow with Position in Sapwood

Daoqun Zang, C. L. Beadle and D. A. White
Chinese Academy of Forestry, 100091 Beijing, China
FAX: 86-10-62872015, Email: zang@rif.forestry.ac.cn

Sapflow sensors were used to investigate the variation of sapflow velocity in the sapwood of *Eucalyptus globulus*. Sapflow velocity was measured sequentially at 5 mm intervals across the sapwood by moving two probe sets simultaneously on two opposite radii. A second probe set was placed in a fixed position at right angles to the first set. Sapflow velocity ratio was defined as the velocity of each moving sensor divided by that of the static sensor. The ratio at each position was constant but varied across the sapwood. The variation was high and implied a need for large numbers of sensors for accurate determination of sapflux. To overcome this necessity, a correction co-efficient was determined for use in conjunction with a fixed sensor probe set. The coefficient was calculated as a weighted average of the velocity ratios obtained with depth in the sapwood.

2.01.17 Vegetative propagation

Recent Advances in Mass Propagation of *Acacia mangium*, *Acacia mangium* x *A. auriculiformis* hybrid and *Acacia crassicarpa* by Tissue Culture

Antoine Galiana, D.K.S. Goh, O. Monteuuis
CIRAD-Forêt, Plant Biotechnology Laboratory, Post Box # 60793, 91017 Tawau, Sabah, Malaysia
Email: antoi@pc.jaring.my

Keywords: *Acacia mangium*; *Acacia crassicarpa*; *Acacia mangium* x *auriculiformis* hybrid; micropropagation; forest plantations

Acacia species, and more specifically *Acacia mangium*, have become major plantation tree species in South-East Asia during the last two decades, particularly in Indonesia and Sabah. These fast-growing species are mostly used for pulp production but their wood can also be used for general construction, furniture, particle board as well as plywood. During the past few years and in the context of an increasing demand of superior plant materials by local forest companies in Sabah, the Plant Biotechnology Laboratory Project has carried out micropropagation studies on the three major plantation species of Acacias: *A. mangium*, *A. mangium* x auriculiformis hybrid and *A. crassicarpa*. The cloning of superior genotypes is more appropriate in the case of *A. crassicarpa* compared to *A. mangium* since the genetic variability is known and often observed to be much higher within and between progenies in *A. crassicarpa* than in *A. mangium*. in the case of *A. mangium* x *auriculiformis* hybrid - that is known to have a better growth than the *A. mangium* pure parent species - vegetative propagation is currently the only way of propagation since propagation by seeds from bi-specific orchards still remains not feasible at the present time. Although the micropropagation method allows the cloning of superior adult *Acacia* genotypes in a shorter time than conventional methods of propagation, especially in the first stages of the long rejuvenation process, the combination of both in vitro and conventional methods of propagation is the most cost-effective and appropriate strategy to be applied for large-scale afforestation programs.

Micropropagation protocols and appropriate culture media were developed for each of the three *Acacia* species studied. Our tissue-culture experiments were mainly focused on the improvement of the multiplication rate through axillary budding and the in vitro rooting ability of the axillary shoots obtained. The protocols were initially developed from juvenile materials (seedlings) and then adapted to mature genotypes. The in vitro introduction of shoots directly collected from mature trees was shown to be successful since responsive and contaminant-free cultures were obtained on specific introduction media for all species. The next step consisted in defining a suitable methodology for maintaining selected genotypes under intensive micropropagation for long periods of time. The multiplication rates varied strongly between and within each of the three species, except for *A. mangium* in which no genotype effect was found among the clones tested. Conversely, clonal differences were observed for adventitious rooting ability in *A. mangium* and *A. crassicarpa* but not in the *A. mangium* x *A. auriculiformis* clones studied. Overall, *A. mangium* displayed a weaker potential for in vitro root formation from microshoots than *A. mangium* x *A. auriculiformis* and *A. crassicarpa*. Ex vitro acclimatization of in vitro rooted plantlets in nursery was also less successful for *A. mangium* compared to the hybrids (50% and 90% respectively). A very low percentage of recovery (5 to 10%) was obtained in the preliminary acclimatization experiments performed on *A. crassicarpa*.

Prospects of tissue culture for improving teak plantations

Doreen K. S. Goh, Antoine Galiana and Olivier Monteuuis

CIRAD-Forêt, Plant Biotechnology Laboratory, Post Box # 60793, 91017 Tawau, Sabah, Malaysia

Tel: 60-89-775-328, FAX: 60-89-762-314, Email: dorngoh@pc.jaring.my

Keywords: *Tectona grandis*; clonal propagation; tissue culture; teak clones; forest plantations

Teak (*Tectona grandis*) is a high quality timber valued for the attractiveness and durability of its wood. Increasing lack of available natural resources has resulted in a step up of reforestation programs on teak. The conventional means of propagation is through the use of seeds. However, this source is limited by availability and germinability of seed lots and further, by variability in the growth and performance of the derived plants. Methods through vegetative propagation aiming at the production of improved planting materials have been investigated. The propagation of selected clonal materials is of importance owing to the obvious gains that can be derived in terms of growth yield and superior wood characteristics as well as for traits that confer resistant to pests and diseases.

Within the joint project between Innoprise Corporation and CIRAD-Forêt, in addition to the issuance of rooted cuttings at the nursery level, a technique has been developed for the in vitro propagation of teak. Using the tissue culture protocol, it is now possible to select and introduce any outstanding or "Plus" tree for mass multiplication regardless of its age. The technique also allowed the germination and multiplication of seed lots that are hard to come by or show low viability in the nursery. Using a sole multiplication/elongation culture medium with minimal hormone addition, an exponential multiplication rate of 3 to 4 microcuttings per plantlet can be obtained at every six to eight week cycle. Spontaneous rooting occurs in more than 80% of the microcuttings and in the acclimatization phase, more than 90% survival is seen. The protocol incorporates the lowest costs possible, simplicity, and ease of manipulation, thereby making the propagation of selected teak clones highly feasible.

The success of the protocol has so far resulted in the transfer of more than 200,000 micro-shoots to the nurseries and subsequently to the field for further testing. Genetic materials comprising of fourteen different origins used in various trials are being maintained in the laboratory and will be used in future deployments depending upon their field performance. The propagation of clones from such a broad genetic base is definitely compulsory for the the technique to be broadly and effectively applicable.

To date, commercial activity involving the sales of materials to local and overseas planters has been undertaken by the project on a small scale. in view of the successful results obtained from the transfer of plantlets overseas, the use of this technology for setting up superior quality teak clonal plantations in even more distant countries appears to be very promising.

Keywords: Micropropagation; Tissue culture; *Larix, Pinus, Quercus, Prunus, Zelkova*

The forest biotechnology research project was carried out with support from the Forestry Agency of the Ministry of Agriculture, Forestry and Fishery, Japan from 1986 to 1996. The cooperative research group consists of 18 prefectural research institutes (Hokkaido, Akita, Gunma, Saitama, Ishikawa, Aichi, Gifu, Mie, Wakayama, Tottori, Hiroshima, Ehime, Kochi, Fukuoka, Kumamoto, Ohita, Miyazaki, Kagoshima) and 1 national research institute(FFPRI). In this project, proper micropropagation techniques were developed for *Larix* hybrid, *Cryptomeria japonica, Chamaecyparis obtusa, Pinus thunbergii, Pinus densiflora, Diospyros kaki, Quercus acutissima, Quercus serrata, Quercus phyllyraeoides, Castanea crenata, Zelkova serrata, Prunus verecunda, Prunus jamasakura, Prunus spachiana* forma *ascendens, Betula grossa* and *Melia azedarach.*

Mass propagation of *Larix* hybrid using shoot primordium liquid culture system and direct rooting system of *Prunus* are prospective newly developed techniques for practical application of micropropagation for high quality trees. Micropropagation by axillary shoot culture of *Zelkova serrata* has high potential for commercialization because of its high value in the market. Tissue culture system of a 850 years old natural monument *Prunus* tree was developed. Following these successful achievements, new local biotechnology project « Development of preservation and propagation techniques of useful forest resources using biotechnology» has started from 1996. This 8 years long project group consists of 14 prefectural research institutes, 1 private company and 1 national research institute(FFPRI) and is supported financially by the Forestry Agency, Japan.

Private Sector Forestry Research - A Success Story from India

Piare Lal
ITC Bhadrachalam Paperboards Limited, 106, Sardar Patel Road, 500 003 Secunderabad, andhra Pradesh, India

Keywords: *Eucalypts*, Clone, Productivity, *Casuarina*, Genotype

Almost the entire 76 million ha recorded forest area is owned and managed by the State Governments in India. Forestry research, by the State Forest Departments and various Forest Research Institutes, is mostly funded by the Government. Legislation for *sui generis* protection for breeder's rights is still pending, and there is no mechanism for certification of seed of forestry species or registration of clones. There is no wonder, therefore, that there is little incentive for private sector investments in forestry research.

Despite many constraints, ITC Bhadrachalam has been implementing a major research and development project since 1989 with a view to improving the productivity and profitability of plantations and making farm forestry an attractive land use option.

Starting with cloning of 64 candidate plus trees (CPTs) of *Eucalyptus tereticornis* and Mysore Gum during 1989, more than 500 CPTs have been cloned so far. Based on their comparative performance in field trials, 72 promising, fast growing and disease resistant clones, with productivity ranging between 12-44 cum/ha/yr. under rainfed conditions, have been identified. Several hybrids have been developed through controlled pollination between selected best `Bhadrachalam' clones of *E. tereticornis* and other species of *Eucalyptus*. Hybrid seedlings with good heterosis have been cloned. These hybrid clones are under field evaluation.

In vitro propagation, a viable alternative for the continuous supply of planting material for recalcitrant tropical forest trees

Shyamal K. Roy
Department of Botany, Jahangirnagar University, Dhaka, Bangladesh
Tel: 880-2-7708478 436. Fax: 880-2-7708383. E-mail: shkroy@juniv.edu

Key words: tropical trees; in vitro propagation; acclimatisation; plantation.

Natural regeneration of forest trees is poor because of sporadic seed production and most of the species produce recalcitrant seeds that are intolerant to desiccation, so that their genetic diversity can not be preserved in conventional seed banks. Concerted efforts must therefore be made to evolve methods for mass multiplication of forest trees, their conservation and cloning of superior genotypes for use in tree improvement programme. During the last decade, significant progress has been made in the propagation of fruit and forest trees through *in vitro* culture technology. For clonal mass propagation, through *in vitro* culture, from shoot tip and nodal explants of mature trees, we have established protocols for some tropical trees e.g. *Artocarpus heterophyllus*, *Artocarpus chaplasha*, *Azadirachta indica*, *Gmelina arborea* and *Elaeocarpus robustus*. Small twigs were collected in spring season from coppiced branches of selected trees and protocols have been established for their mass clonal propagation. The techniques consisted of four major steps. 1. Establishment of *in vitro* cultures from rejuvenated tissues, 2. Induction of multiple shoots from individual explants, 3. Rooting and 4. Acclimatisation. For culture establishment, multiplication and rooting Murashige and Skoog's (MS) nutrient medium was used. Explants of different species showed different responses when cultured on MS medium supplemented with various concentrations and combinations of cytokinin, auxins, casein hydrolysate and coconut milk. Polyvinylpyrrolidone (PVP) was required to overcome the effects of phenolic compounds secreted from the explants. Depending on species, 65-85% cultures produced shoots. For multiplication newly formed shoots were subcultured to fresh medium designed for each plant species, and 15-20 shoots per subculture were obtained through several subcultures. Well developed shoots were rooted by implanting them on root induction medium. For acclimatisation four to six-week-old regenerants were transplanted into sterilized soil and compost (1:1) and covered with transparent polyethylene sheets misted three times per day. After 3-4 weeks the plantlets were transplanted singly in polyethylene bags containing sand, soil and compost (1:1:1) and kept under indirect sunlight. After 8-10 months they were transplanted in the open field where 70-85% plants survived. The technique is feasible as viable alternative for the continuous supply of planting material for recalcitrant trees as well as for the conservation of forest gene resources.

2.02.00 / 2.08.00 Future of breeding and plantations in a sustainability-oriented world

Dynamics of nutrient budgets during coniferous plantation development: Interest for sustainable management recommendations

Etienne Dambrine, Jacques Ranger, Marie-Pierre Turpault, D. Gelhaye, B. Pollier
INRA Nancy, Seichamps, 54280 Seichamps, France
Tel: 00 33 3 83 39 40 71, FAX: 00 33 3 83 39 40 69, Email: dambrine@nancy.inra.fr

This paper aims at (1) showing the nead of chronosequence studies in forest ecosystems; (2) presenting contrasted situations of nutrient budgets calculated for representative coniferous plantations from France, semi-extensively managed, where risks of soil nutrient depletion linked to silviculture is high; (3) discuss the causes for contrasting results; (4) Evaluate the sustainability of different forest management scenarios.

Material and methods

Two chronosequences of three stands were used to study the dynamics of nutrient budgets. Input-output nutrient budgets were calculated as: Total atmospherical deposition + Release of nutrients from soil mineral weathering- Biomass removal - Deep drainage.

The sites: i) Aubure (Vosges) is a chronosequence of three stands of Norway spruce (*Picea abies* Karst.) 20-, 40- and 90-year old, planted on acid sandy soils developped from a leuco-granite. The elevation is 1100 m, rainfall 1500 mm and mean annual temperature 6-C. Stands are Mg and Ca deficient. ii) Vauxrenard (Beaujolais) is a chronosquence of three stands of Douglas-fir (*PseudoTsuga menziesii* Franco), 25-, 45- and 65-year old, planted on an acidic and desaturated soil, previously cultivated, developped from a rather rich volcanic tuff. The site elevation is about 750 m, mean annual rainfall 1000 mm and mean annual temperature 7-C. The stand mineral supply is correct.

Results and discussion

Aubure: The mean annual nutrient budget is negative for all elements, and the nutrient budgets calculated for the three development stages (three stands) are also always negative. in the young stands, the budget deficits are link to the high biomass incorporation and drainage losses are low. in the older stand, the deficit is similar but mainly linked to drainage as biomass incorporation is low in this declining stand. Norway spruce planted on a very poor soil, acidified by atmospheric deposition take advantage of soil nutrients during the young stages of stand development, but its nutrient status progressively decrease in relation to the its shallow rooting, and drainage losses increase.

Vauxrenard: The mean annual nutrient budget is strongly negative for all elements, but the deficits of the budgets decrease with stand-age to become more or less nil in the older stand (apart for Ca which is always few negative in the 60-year old stand). The deficit is strongly link to drainage losses which were attributed to two factors: i) the Douglas-fir is not the native vegetation for the site and a new organic matter equilibrium is going on and ii) the previous land occupation by agriculture induced a high nitrifying activity which cannot be compensated by nitrate uptake by Douglas-fir. The over-loading of NO_3-N induced a strong excedent of protons leading to cation losses associated with the mobile nitrate. Atmospherical deposits increase the phenomenon but is not the main driving force.

Sylvicultural consequences of these contrasting situations are: at Aubure, the nutrient budget is always negative, indicating that there is no management possibility other than liming and fertilization to restore the soil quality. At Vauxrenard, the nutrient budget tend to be equilibrate for rotation length longer than 60 years and a biomass harvest limited to stem (with bark), indicating that the soil fertility would stabilize for a rotation time longer than 80 yrs.

Conclusion

Nutrient budgets are dynamic, therefore chronosequences studies are needed to evaluate forest sustainability. Soil fertility may or may not stabilize when increase the rotation length, depending on soil type, pollution climate, previous land use and stand adaptation to site conditions.

Tree breeding and Plantations in Europe: a regional situation report

Jochen Kleinschmit
Niedersächsische Forstliche Versuchsanstalt, Abt. C - Forstpflanzenzüchtung/Waldgenressourcen, Forstamtstr. 6, D-34355 Staufenberg OT Escherode, Germany
Tel: +49 5543 9408 0/ 9408 10, FAX: +49 5543 9408 61, Email: nfv-abtc@t-online.de

As a reaction to the more and more artificial environment of humans and some bad experiences with human impact on nature there exists an increasing scepticism against manipulation of nature in the European society. This scepticism is not restricted to the public but can be found in the forestry society as well. Often non reflected comments like: “natural regeneration is always better than plantation” or “tree breeding is against nature” can be heard. As soon as such ideas and feelings become more general, they have implications on funding.

With the assistance of colleges from 25 European countries the situation of tree breeding and tree plantations in Europe was evaluated. The results are presented in the first part oft the paper.

Tree breeding is regarded as important in nearly all European countries. The main emphasis of tree breeding is on pine and spruce, followed by oak, poplar, larch, ash, Douglas fir and wild cherry. Altogether 25 tree species are included into breeding activities. Seed orchard establishment ranges before testing of stands and clonal propagation. Medium intensity tree breeding is prevailing and only in three countries aggressive tree breeding is done. There is a higher concern about forest tree breeding among foresters than in the public. Since only 40 % of the tree breeding programs are on a secure financial base, this must have implications on funding.

Natural regeneration plays a very different role in the different countries, ranging from zero to 85 %. Afforestation of marginal farmlands plays an important role in most of the European countries with a total annual surface of slightly above 200.000 hectares. There exists a trend to favour close to nature forest management. in competition situations protection of nature is mostly favoured in funding as compared to tree breeding. in spite of this the climate towards forest tree breeding is neutral or supportive more than hostile. The last situation occurs only in three countries.

in the majority of the countries tree breeding is handling the conservation of forest genetic resources as well. Therefore tree breeding programs take into consideration the conservation as an integral part of the programs.

A majority of the colleges (16 out of 25) think that a self - imposed ethical code how to use improved material would be useful or necessary. This is especially true for the use of genetically modified organisms.

In a second part the rationale basis for the field of tree improvement in Europe is outlined. Lines of compromise to solve the conflicting situation between future need for wood as a raw material and protection of biodiversity are discussed, e.g. how far a certain area of intensive plantations with genetically improved material could help to conserve natural forests.

Situation and results of breeding and plantation forestry in the American Southeast

Bailian Li
North Carolina State University, Tree Improvement Program, Department of Forestry, 27695-8002 Raleigh, USA
Email: Bailian_Li@NCSU.edu

Forest genetics and tree breeding have made significant contributions to forest productivity and plantation programs over the last 50 years in the southern U.S., where forests comprise more than 50% of the land cover and supply 53% of the timber harvested in the U.S. The southern pines are the most commonly planted species, with about 11 million hectares in plantations. The South plants approximately 1.2 billion seedlings annually, 80% of which are loblolly pine (*Pinus taeda L.*) seedlings and 20% are slash pine (*Pinus elliotti var elliottii Engelm.*) seedlings, and virtually all planting stocks are genetically improved seedlings from seed orchards. Productivity improvement from forest genetics has helped to provide a reliable, ecologically sustainable, and economically affordable supply of wood. The N.C. State University-Industry Cooperative Tree Improvement Program has completed 44 years of genetic improvement for loblolly pine in the southern U.S. The impact of the tree improvement on forest productivity has been substantial through the two cycles of breeding, testing and selection. Trees grown from seeds of first-generation seed orchards have produced 7-12% more volume per acre at harvest than trees grown from wild seed. Genetic gains from second-generation seed orchards over the first-generation are estimated 14-23% additional for rogued seed orchards. Genetically improved stock has also lower infection from fusiform rust, typically 20%-25% below the unimproved seedlots. With additional improvements in quality traits (stem straightness and wood quality), the realized genetic gains in value should be much greater.

Plantation forestry is generally acceptable by public in the southern U.S. because tree planting has been a common practice since 1930 in the region. Forest planting, harvest, and manufacture of forest products provided greater economic returns to the land and more employment opportunities in the region. About 90% of forest land are owned by private land owners and forest industries, and only 10% are in public ownership. Furthermore, short rotation of pine plantations, good management practices for environmentally sensitive areas, limitation on harvesting area, and other self-imposed regulations have all contributed to the public acceptance of plantation forestry. Research demonstration and public education are also important for people to understand that intensively managed plantations are the most effective strategies to meet future demands of wood products without increasing pressures on old-growth and ecologically sensitive forests. Improved wood production on limited commercial lands will reduce the logging pressures on natural forests. By increasing wood production per hectare in plantations, rather than by managing more hectares of forest, genetics, in combination with intensive silviculture, can and will provide better opportunities for the use of natural forests and forest lands for conservation and recreational purposes. Results from two-cycles of loblolly pine breeding strongly suggest that high-yield plantations by genetic improvement can contribute significantly to the conservation and recreational purposes. Results from two-cycles of loblolly pine breeding strongly suggest that high-yield plantations by genetic improvement can contribute significantly to the conservation and sustained use of forest resources.

Introduction and Conclusions of the Beijing consultation 1998

Csaba Matyas
West Hungarian University, Institute of Environmental Sciences, PO Box 132, 9401 Sopron, Hungary
Tel: +36 99 518 395, FAX: +36 99 329 840, Email: cm@efe.hu

The future contribution of forest genetics to sustained management of global forest resources was the subject of a Division 2 consultation held in Beijing, China, 22-29 August 1998. The objective was to reach a consensus on directions and priorities for research in forest genetics and tree improvement at a time when critical financial support for long-term tree improvement research has declined while worldwide demand for wood and fiber production is continuously increasing. in setting priorities, it was recognized that a balance will be needed between long-term genetic improvement research and short-term research focused on the new technologies.

A major research focus will be the genetic background of the adaptive potential of forest trees. This will require the testing of phenotypic variability and plasticity in trees over time in diverse and changing environments, using suitable process-related markers. Research on genetic diversity should be integrated with research on forest ecosystems and conservation of genetic resources, particularly in relation to expected global environmental change. More information will be needed on the genetic consequences of mode of reproduction, breeding and gene flow mechanisms and population structure and size.

There is evidence that properly managed breeding can maintain or even increase genetic variation relative to natural populations and at the same time maximize wood production and reduce the logging pressure on natural forests. in breeding and gene conservation research, the order of priority should be (1) species of current high socioeconomic value; (2) species with clear potential or future value and (3) species of currently unknown value. Gene conservation must be part of silviculture in managed natural forests. New information will be needed of the effects of different forest interventions on adaptive genetic variability in forest ecosystems varying from mature natural stands to fiber farms.

In view of future demand for forest products, tree improvement will continue to be a key factor in sustainable forest development. However, it will be necessary to demonstrate to the forest constituency and the general public that wise management of forest resources with a strong focus on genetic improvement is fully compatible with genetic conservation, and that it is an integral part of the overall maintenance and enhancement of biological diversity. Tree improvement research deserves long term commitment by the public sector in cooperation with private agencies, supported in developing countries by international and non-governmental agencies.

Global Situation of Forest Tree Breeding: An Overview

Eric Teissier du Cros
Institut National de la Recherche Agronomique - INRA,
Unit, de Recherches Forestieres Mediterranenne

Tel: +33 4 90 13 59 11, FAX: +33 4 90 13 59 59, Email: teissier@avignon.inra.fr

The first known document on tree breeding is dated 1749 by the Marine command concerning choice of seed source for *Quercus robur* (pedunculate oak) grown for ship construction. Since then many steps have been made in the management of forest gene resources.

Forest genetics include two major and complementary topics: forest tree improvement/breeding which aims at providing forest reproductive material (provenances, seed orchards, clones) to users, and forest genetics which refers to the science bringing basic information for breeding and gene conservation. Tree breeding is based on two fundamental prerequisites: variability and heritability.

Variability studies among and within species started 150 years ago and have reached full expansion during the second half of the 20th Century. For certain species and in several parts of the world this basic effort still needs to be done with a very simple idea in mind: choosing the right provenance reduces loss due to abiotic and biotic factors, and may provide as much as 30% gain in volume production. Advanced breeding based on detailed knowledge on trait heritability and other genetic parameters may double or triple this figure. Selection and improvement traits are usually classified in 4 groups: adaptation to abiotic factors, resistance to biotic factors, growth and yield, and quality. According to species use and growing conditions in each region, the right strategy and the right traits have to be chosen.

The opposition to exotics and genetic improvement in parts of the " western " world should not be generalised. Forest tree improvement has a long way to go. However the decreasing public financial effort devoted to classical breeding should be channelled and gradually replaced by private recurrent funding or long term contracting with national agencies. Regional networking is suggested whenever common efforts are possible.

Classical breeding should not be opposed to biotechnologies. Both are needed and are interactive, particularly on advanced breeding schemes.

2.02.00 / 2.08.00 Genetic variation

Diallel Crossing in *Pinus cembra*: II Analysis of Genetic Variation at the Nursery Stage

Ioan Blada
Forest Research Institute, Sos. Stefanesti, 128, 11 Bucharest, Romania
FAX: 40.1.240 68 45, Email: icas@com.pcnet.ro

A 10 x 10 full diallel was made in a native population of stone pine (*Pinus cembra L.*) from high elevation, to provide information on the genetic variation and inheritance of important breeding traits. in October 1991, seeds were sown in individual polyethylene pots, in spruce humus. The families, including self-pollinated parents and a mixed open-pollinated control, were arranged in a randomized complet block design with four replications and 12 seedlings per plot. Fifteen traits were measured during nursery testing. in addition, weight of 100 seeds and the cotyledon number were assessed prior and after sowing, respectively. Computer analysis of a balanced modified full diallel using the SAS program produced the results presented below. The most important result was that significant ($p<0.05$) and highly significant ($p<0.01$; $p<0.001$) differences occurred in all 17 traits for general and specific combining ability as well for reciprocal effects. Maternal effects were significant in 13 traits, including diameter and total height. This suggests that the traits are controlled by nuclear (additive and non-additive) and extranuclear genes, and by nuclear x extranuclear gene interactions. Additive and non-additive genetic variances accounted for 25% and 27% for total height at age six and 14% and 22% for root collar diameter at the same age. These figures indicate that both variances were important for growth traits within the tested population. Parents were found with significant general combining effects for growth and other traits. Narrow-sense heritability estimates at family level varied between 0.150 to 0.675 for cotyledon number and lamma shoots, respectively with 0.453 for total height at age six (H.6). By selecting the best 10 to 40 families, a genetic gain in H.6 of 10.6% to 5.5% could be achieved. An extra genetic gain could be also made by individual within family selection. The improvement of growth by using both additive and non-additive gene effects should be possible.

Gene Flow within and among Populations: A Review of Methods and Results from Temperate and Tropical Forest Trees

Reiner Finkeldey
Swiss Federal Institute for Forest, Snow and Landscape Research, Zürcherstrasse 111, CH-8903 Birmensdorf, Switzerland
FAX: +41 - 1 - 739 22 15, Email: reiner.finkeldey@wsl.ch

Gene flow is a key determinant for the distribution of genetic variation within and among populations and thus of outstanding interest both for population geneticists and managers of forest (genetic) resources. Gene flow of plants is mainly mediated by the transport of pollen and seeds. Forest trees species use a great variety of vectors for the transport of their genes and consequently differ widely with regard to their systems of gene flow. Experimental efforts to study gene flow in forest trees have concentrated on the distribution of genes through pollen; much less is known about gene flow mediated by seeds.

Gene markers are the main tools to directly study gene flow and its effect on the genetic structures of populations. Most marker-based studies simultaneously investigate aspects of gene flow via pollen and the mating system of tree populations since both elements of the genetic system of a species are closely interrelated. Uniparentally inherited markers are powerful tools to study gene flow on a large geographic scale. Biparentally inherited markers are mainly suitable to study gene flow within populations but are also widely applied to estimate gene flow parameters such as the number of migrants among populations (Nm). Moderately variable, biparentally inherited gene markers like isoenzymes can be used in order to estimate and compare frequency distributions of marker alleles in the pollen clouds of single seed trees. Major shortcomings of frequently used methods to study gene flow and mating system parameters are a limited variability of marker loci and the violation of model assumptions made in order to estimate crucial parameters.

Most studies on gene flow have been conducted on temperate, wind-pollinated tree species. Results from experiments in closed forests dominated by a single conifer species indicate that pollen of single trees is mainly effective within a distance of less than 100 meters. However, this still implies that hundreds of trees may contribute to the genetic effective pollen cloud of single seed trees as suggested by the homogeneity of pollen allele frequencies in plantations of Norway spruce (*Picea abies*). The importance of long-distance pollen transport over many kilometres has been demonstrated for spatially isolated clonal seed orchards mainly in Scandinavia.

Most tree species are zoogamous and occur in low density in tropical forests. Much less is known about their systems of gene flow, although experimental research on these species has intensified during the past decade. Results from high-density populations of teak (*Tectona grandis*) indicate that pollen movement is mainly confined to near neighbours for this insect-pollinated species in northern Thailand. *Pterocarpus indicus* occurs in medium to low density in tropical forests of Southeast-Asia. An investigation of a population on Luzon revealed considerable amounts of effective pollen movement over distances of several hundred meters. Comparable results were also reported for several trees species of the new world tropics. Pollination by animals turns out to be a very efficient mechanism to ensure efficient gene flow and outcrossing even for species typically occurring in low density.

Efficient gene flow promotes genetic variation within the offspring generation but results in decreased genetic differentiation among subpopulations. Thus, gene flow enhances the evolutionary adaptive potential of populations but tends to decrease the opportunities for the maintenance of local adaptations. It is suggested that future research interprets gene flow as a crucial aspect of the adaptive system of forest tree species, concentrates on endangered, mainly tropical species and takes into consideration the importance of gene flow through seeds.

Using Shoot Growth Patterns to Select Desired Genotypes and understanding adaptation of *Pinus brutia*

Fikret Isik, Kani Isik, Tolga Yildirim and Bailian Li
Southwest Anatolia Forest Research Institute, Post Box # 264, Antalya, Turkey
FAX: +90-242-345 0442, Email: fikret-isik@rocketmail.com

Shoot elongation patterns of *Pinus brutia* have been studied, with the objectives of (i) further understanding the adaptation mechanisms of species, (ii) to aid better selection of desired genotypes and (iii) accelerating the breeding programs. Six natural populations each of ten open-pollinated families were sampled. Data were collected from a provenance-progeny trial destructively. Annual height increment was partitioned to fixed growth (spring shoot) and free growth (summer shoots) and contribution of each one to the annual height increment was measured. Shoot traits of six (ages 7 to 12) consecutive ages were regressed on growth traits at ages 13 and 17 at the same site and at age 18 at another site.

Populations and families did not differ in fixed growth, but they varied in their free growth and in number of flushes except age 10 (significance level ranged from 0.042 to 0.001). Middle elevation populations of the species range had greater annual height increment and free growth cycles than the populations from distal part of range. Second and later free growth cycles were the major cause of the annual height growth differences among and within populations. This was also supported by significant correlations between free growth observed at early ages and height growth at age 17. The coefficients ranged from 0.32 to 0.45.

Linear regression models using the free growth as explanatory variables at ages 7 and 12 and fixed growth at age 12 explained 84% of the variation in height growth at age 13. Whereas number of flushes observed at ages 7 to 12 at one site explained 26% of the height growth at age 18 at another site.

Populations and families from the low and high elevation range had more conservative growth strategy, which is characterized by less free growth and less flushing, but mainly depending on the fixed growth. Favorable environment in the middle elevation range of the species may have favored genotypes with opportunistic growth strategy, making more free growth. Free growth cycles can be used to screen fast growing genotypes as they have an opportunistic growth strategy. in contrast, genotypes showing more conservative shoot growth pattern may be favored for poor and extreme sites, as they have evolved to avoid frost in higher elevations and drought in coastal regions. The differences in shoot growth pattern of the species reflect its adaptation to a wide range of environments, suggesting that shoot growth patterns should be considered when gene conservation strategies are developed.

Inbreeding owing to isolation restricts regeneration in a vulnerable species growing on isolated small islands in Japan

Kiyoshi Nakashima, Ayako Kanazashi
Forestry and Forest Products Research Institute, PB # 16, Norin Kenkyu Danchi-naiTsukuba, 305 Ibaraki, Japan
Tel: +81-298-73-3211, FAX: +81-298-73-1541, Email: kiyoshi@ffpri.affrc.go.jp

The effects of inbreeding, owing to isolation and small population size, on regeneration of a vulnerable tree species *Pinus armandii* Fr. var *amamiana* (Koidz.) Hatusima in Japan were studied in relation to gene conservation. Wind-pollinated cones were collected from 11 trees growing on two isolated islands, Tanegashima and Yakushima, and mature seeds and undeveloped ovules were extracted from each cone. The average number of seeds and ovules per cone was 20.4 and 64.0, respectively. The content of seeds were investigated by using soft X-ray photography and were classified into sound seeds with normal embryo, unsound seeds with abnormal embryo or endosperm, and empty seeds with no embryo. The percentages of unsound and empty seeds were 1.7% and 83.8% respectively, but that of sound seeds was only 14.5%.

The seeds were sown in a growth chamber under controlled condition and the number of normal seedlings and mutant seedlings as well as survival rates were investigated. Germination rate was only 3.9% for all mature seeds and 0.2% for sound seeds with embryo on the average. Abnormal seedlings with yellow or white needles and morphological mutants appeared frequently, but some of them disappeared within a few weeks after germination. These results indicate that small populations and isolation of individuals reduce the chance of outbreeding and increase the frequency of inbreeding. Controlled pollination was applied to restore seed quality and to confirm the effects of inbreeding and outbreeding on regeneration. Eight trees were selected and four of them were used as female trees and the others as male trees. Cross-pollination was carried out between islands, between isolated trees growing on the same island and between trees growing within a small area. Self-pollination was also carried out on trees with a lot of male and female strobiles. Mature cones cross-, self- and wind-pollinated were collected from those trees. Many sound seeds were obtained from cross-pollinated cones; 10.1 times as many as that from wind-pollinated ones. However, no distinct difference was found between self- and wind-pollinated cones in the average number of sound seeds per cone. in cross-pollination, the number of sound seeds per cone was not different among four trees used as a male. This indicates that coefficient of relationship among individuals is not so high that it affects seed quality.

As many trees of this species have already disappeared by felling or insect damage and most of them are isolated in this island, it is hard for female strobiles to get enough pollen from others naturally. From results obtained in our experiments, it is necessary to improve seed quality by controlled pollination and to grow seedlings from those seeds to assist the conservation of this vulnerable species.

Factorial crossing design in *Picea abies L.*: genetic variation in dry matter distribution between components in full-sib families

Gheorghe Parnuta
Forest Research Institute, Sos. Stefanesti 128, Ro-72904 Bucharest, Romania
FAX: +401 240 68 45; + 401 240 60 95, Email: icas@com.pcnet.ro

Keywords: *Picea abies*, narrow and normal crown, hybrid, heterosis, combining ability, dry matter.

Four selected parents of each of two narrow and normal - crowned *Picea abies L.* were used in two separate factorial mating designs. The research was performed to asses the genetic variation within an between the two groups of hybrids. Nine traits were measured at age 4, as follows: total length of stem (TLS), total number of branches (TNB), length of leader root (LLR), total number of roots (TNR), total dry matter: of stem (TDMS), of branches (TDMB), of needles (TDMN), of roots (TDMR), and dry matter of total seedling (DMTS).

Factorial analysis produced the results presented below: ANOVA indicated highly significant ($p<0.01$; $p<0.001$) differences among female effects for TDMS, TDMB, TDMN, TDMR and DMTS for narrow x normal crowned hybrid and no significant for any trait in normal x narrow crowned hybrid. Differences among male effect were significant ($p<0.05$) for DMTS and highly significant ($p< 0.01$) for TDMB and TDMN in narrow x normal crowned hybrid and significant ($p<0.05$) for TDMS and TDMN in reciprocal hybrid. Male x female interaction effects were significant ($p< 0.05$) only for TDMB in narrow x normal crowned hybrid. Positive significant ($p<0.05$; $p<0.01$; $p<0.001$) g c a effects were founded in the female parents for all traits in narrow x normal crowned hybrid and no significant in normal x narrow crown hybrid. No significant s c a genetic effects were found in both types of hybrid families.

Both high - and mid - parent heterosis were negative for all traits in narrow x normal crowned hybrid but positive for all but one traits (TNR) in normal x narrow crowned hybrid. Highly significant phenotipical correlation were found between TDMS on one hand, and TDMB, TDMN, TDMR and DMTS on the other hand in narrow x normal crowned hybrid but in reciprocal hybrid the TDMS was significantly correlated with TDMN only. Also highly significant correlation were found between TDMN and TDMR and between TDMR and DMTS in narrow x normal crowned hybrid and insignificant correlation in reciprocal hybrid. The dry matter of all seedling components was greater in normal x narrow crowned hybrid than in reciprocal one.

Optimum Breeding Generation Interval Considering Build-up of Relatedness

Wei Run-Peng, Dag Lindgren
University of Alberta, Department of Renewable Resources, Edmonton, Alberta, Canada
Email: Run-Peng.Wei@gov.ab.ca

A key problem in forest tree breeding is at what age selections should be made to maximize genetic progress. Conventional treatment of optimizing generation interval may take *e.g.* age-age genetic correlation, breeding time lag, cost and investment interest rate into account.

One among the most important disadvantages with short generation interval is the build-up of relatedness at each generation turn-over. in the present study this is taken into account. The genetic progress is formulated as group merit, which is a weighted average of gene diversity (group coancestry is average coancestry and also loss in gene diversity) and breeding value. Group merit progress per year can be compared over a range of selection ages, and optimum selection age can thus be identified. Hypothetical and real materials were used to demonstrate the effects of relatedness as well as its interaction with other factors on generation interval. Relatedness and breeding time lag increased optimum selection age while strong age-age genetic correlation and large breeding population size favored early selection. Optimal selection age increased as the weight for relatedness increased (equivalently gene diversity become more important). Consideration of relatedness may increase the optimum selection age compared to many suggestions in literature. in order to reduce risks of inefficient early selection, a reasonable high genetic juvenile-mature correlation and sufficiently large breeding population size are required.

2.02.00 / 2.08.00 Genetic improvement

Hybridization dynamics between two southern beeches (*Nothofagus spp.*).

L. Gallo, P. Marchelli and P. Crego
INTA, Forest Genetics Unit, E.E.A. Bariloche, C.C. 277, 8400 Bariloche, Argentina
FAX: +54 (2944) 424 991, Email: lgallo@bariloche.inta.gov.ar

The occurrence of natural hybridisation between forest tree species increases the genetic variation of the ecosystem and therefore must be taken into account in the management and use of its genetic resources. Hybridisation dynamic constitutes an evolutive process from which less has been experimentally proved because of the difficulty for the unequivocal determination of species specific gene markers. The fulfilment of the prerequisites for the origin of inter-specific hybrids (*e.g.* contact of the species involved, overlapping of flowering dates and cross-compatibility) takes place between two southern beeches (*Nothofagus nervosa* and *N. obliqua*) in the template Subantarctic forest of southern South America. Morphological (leaves margin and vein pilosity), phenological and growth traits and allozymic heterocigosity showed the first significant evidences of hybridisation in two years old seedlings of free pollinated families of *N. nervosa*. Hybridisation rates varied between 0 and 80 % among families and differ also among years. Most of the juvenile (up to three years old) hybrid individuals showed also a significantly higher growth rate than that of the "pure" half-sibs. Through the utilisation of three allozymic gene markers a mainly unidirectional hybridisation (*N. nervosa x N. obliqua*) was found. The autofecundation rate was estimated in about 6 %. in the first analysis of the families two gene loci (Adh and Pgi) appeared to have species specific alleles with fixation in monocigous state for each species. An additional analysis of adult trees was done in different populations of the natural forest in order to confirm the allele specificity found in the seedlings. Hundred trees of each species were analysed in pure isolated populations where the gene flow from the other species could be considered as less unlikely. The specificity and fixation of the marker alleles was confirmed. in the sympatric zone around 180 individuals, 100 from each species were also analysed. The genetic inventory confirmed the heterocigous pattern of the hybrids which appeared in about 7 % of the cases.. More than 95 % of the hybrids were masked in *N. obliqua* phenotypes from which only one third were previously suspected to be hybrids based on their bark morphology. The proportion of hybrids in the analysed open pollinated families was bigger than that found in the adult trees of the natural forest suggesting the occurrence of natural selection against them. The speciation process between these two southern beeches is likely to be taking place in the last phases of pre- and post-cigotic incompatibilities.

Norway spruce breeding for growth and adaptedness

Mats Hannerz
The Forestry Research Institute of Sweden (SkogForsk), S-751 83 Uppsala, Sweden
Tel: +46-18-188554, FAX: +46-18-188600, Email: mats.hannerz@skogforsk.se

Sustainable forest tree breeding requires that improvement in one aspect does not lead to deteriorated performance in other aspects. in a long-term perspective, it is crucial that the breeding considers adaptive traits along with other economic traits such as growth or timber quality. Previous experiments in Sweden with one-year-old Norway spruce (*Picea abies* (L.) Karst.) seedlings indicate that progenies from improved seed orchards are more prone to early-autumn frost damage than progenies from unselected natural populations of the same geographic origin. The purpose of this study was to investigate if improved and unselected material differs in level of climate-related damage also after several years in the field, and how this difference is related to the differences in growth.

We compared growth and adaptive traits in progenies from phenotypically selected plustrees, allocated as grafts in seed orchards, and from natural populations of Norway spruce. The study comprised six field trials located in central Sweden. Subsets of up to 114 open-pollinated families from plustrees, originating from central Sweden, were compared with 18 natural populations from Sweden, the Baltic states and Belorussia. The trees were 9-14 years old when measured. Plustree progenies were 11 to 28% taller when compared with unimproved populations from the same geographic area. The plustree progenies had lower frequencies of climate-related damage such as ramicorns, doublestems and frost damage in all of the field trials. Family-mean correlations were negative between damage frequency and height, i.e. tall families were more free from damage. Transfer of populations from south to north resulted in increased growth compared to that of local populations. The best populations, from Belorussia, were almost as high as the plustree progenies. Belorussian populations had, on average, lower frequencies of frost damage and ramicorns than the other populations and the plustree progenies. Spruces from Belorussian populations are characterised by late budburst, thus they are more resistant to early summer frosts. However, they are likely to set bud and harden later in the summer than spruces of central Swedish origin. At one particular occasion with an early autumn frost, Belorussian spruces were more damaged than any other test sort. Plustree progenies were least damaged also at this occasion.

The lower autumn-frost hardiness in seed-orchard material previously observed in one-year-old seedlings is not reflected in overall damage level for the field-grown trees. The explanation might either be that one-year-old seed-orchard seedlings show temporary effects of *e.g.* improved seed physiology, or that autumn-frost hardiness is not relevant for climate-induced damage in the field in southern and central Sweden. The observation from the single occasion with an early-autumn frost argues for that the effects are temporary. Thus, the results indicate that both growth and overall adaptedness to climate are improved in the selected families.

The Slovenian Forest Gene Bank

Hojka Kraigher, Gregor Bozic, Saso Zitnik
Slovenian Forestry Institute, Slovenia
FAX: +386 61 273 589, Email: hojka.kraigher@gozdis.si

Forests cover 53% of Slovenia with the total growing stock of 208.5 million (106) m^3. Sustainable management of forests on the basis of their multiple functions and co-natural orientation of forest management have long tradition, due to the large Karst area, in which already 400 years ago no clearcutting could be allowed as it would have resulted in degradation and erosion of deforested land. The regulatory framework for the protection and management of forests in Slovenia is based on the Forest Act from 1993. It determines the protection, silviculture, exploitation and use of forests as renewable natural resources with the aim of ensuring their co-natural and multi-purpose management in accordance with the principles of protection of the environment and natural values, long term and optimal functioning of forest ecosystems, enabling all their functions. The basis for forest management are programmes of development of the Slovenian forests, forest management plans and detailed silvicultural plans. According to the Slovenian Forest Act from 1993 all forests are managed in a co-natural way, which can be classified as Category VI of the IUCN management categories: 'protected area managed mainly for the sustainable use of natural ecosystems'. From these special protection is given to the Forest Reserves (10% of all forest areas in Slovenia, IUCN category I). Most forest stands are regenerated naturally, only 1/10 th are regenerated by nursery seedling material, while seeds are mostly collected from yearly re-acknowledged seed stands. Therefore no special attention is given to ex situ conservation of forest genetic resources in Slovenia. A limited number of seed orchards have been established in Slovenia about 15 to 30 years ago. These seed orchards are not used for seed production and their future is questionable. International provenance tests have been established for silver fir on 4 research plots, for Douglas fir, for Austrian pine (9+8 provenances) and for beech (31 provenances). Tests of offsprings were established for Norway spruce with 10 provenances. S small living archive of Slovenian clones of poplars exists at the Institute's grounds. The forest seed bank comprises predominantly Norway spruce seed accessions. The main part of the Slovenian Forest Gene Bank is represented by the seed stands. The register includes 409 active seed stands, covering 2313 ha. of these 271 (1821.8 ha) are conifers, 138 (491.1 ha) are broadleaf seed stands. Yearly control of the seed stands, where seed collection is supposed to take place is the main task by staff from the Slovenian Forestry Institute, while revisions are made every ten years. The main concerns in the last few years are linked to preparation of new legislation (according to EU directives & OECD scheme), preparation of the Central Information Data-Bank on the Slovenian Forest Gene Bank, which will be available through the INTERNET and linked to the geographical maps, and to revisions of the regions of provenances in comparison to seed units (based on phytocenological associations, altitude and ground rock types) and with respect to the newly established tests of offsprings.

Incorporating Wood Density in Breeding Programs for Softwoods in Europe

Philippe Rozenberg, Alain Franc, Christine Cahalan
INRA, Station d'Amelioration, Genetique et Physiologie Forestieres, 45166 Olivet Cedex, BP 20619 Ardon, France
Tel: +33 (0)2 38 41 78 73, FAX: +33 (0)2 38 41 78 79, Email: rozenberg@orleans.inra.fr

In European forests rotations are getting shorter, the proportion of juvenile wood in the stem of harvested trees is increasing, and the quality of European softwood is decreasing. One way to compensate for this is to genetically improve wood properties, especially those of the juvenile core.

In many European countries, wood collected from a given stand and even a given tree may be used for a variety of end products. The wood properties which affect end product quality vary from one product to another, and relationships between wood properties and adaptation, growth and form traits are variable. Tree breeding takes many years, while industrial processes change rapidly. It is therefore difficult to define selection objectives for wood properties that are general and constant over time. in this context, the main reason for incorporating wood traits in tree breeding programs should be to avoid unfavourable correlated responses in wood properties when selecting for improved adaptation, growth and form. Computing genetic gains for wood properties is not a priority. Instead, estimates should be made of the co-variation of wood properties with the adaptation, growth and form traits that are the main concern in breeding programs. Wood density is widely regarded as a key trait in determining wood quality, and when measured on a fine scale it is strongly correlated with the properties of many end products. Wood density is generally more highly heritable than growth traits, but the genetic variation of wood density is low and it is sometimes unfavourably correlated with growth and adaptation traits. The most comprehensive data on wood density are computed from microdensity profiles. Progress in computer science has made possible the utilisation of statistical and modelling tools for more efficient use of these data. in this context, we propose original methods, in order to: 1) study the volume growth - wood density relationship, 2) increase description efficiency of within-ring density models, and 3) measure within-tree density heterogeneity from density profiles. Results show that there is a significant clonal effect on the ring density and ring width relationship. This clonal effect is very strong for Douglas-fir and much smaller for Norway spruce. This result suggests that there are selection possibilities at the ring level for Douglas-fir for genetic entries (clones) combining quite fast growth and high wood density. But for Norway spruce, there is a need for finer studies at the within-ring level. Such studies raise the question of the cambium reaction to within-growing-season climatic events: is there genetic variation for the tree reaction to, for example, climatic stresses? What is the consequence of such a genetic variation on basic wood properties? It is possible to simply and objectively describe homogeneity of wood density. There is a highly significant clonal variation for most of the homogeneity traits. Furthermore, very high individual and clonal coefficient of variation let expect high genetic gain when selection is conducted on these traits.

The Domestication of *Acacia mangium*

M. N. Salleh
Technology Park, TropBio Research Sdn Bhd, Level 2;
Enterprise 2, 57000 Bukit, Malaysia
FAX: 603-9682888, Email: tropbio@tropbio.po.my

Acacia mangium has in the past 20 years become the most widely planted timber species in South East Asia. in 1997, a Malaysian company decided to invest in a project to produce improved genotypes for commercial planting, within a time frame of 3 years. This paper presents the case history of the project from the perspective of the scientists involved in this program of accelerated domestication. The program involved the selection and assessment of candidate plus trees, propagation of candidate plus trees, development of pollination and hybridization techniques, testing of hybrids, analysis of growth and form, genetic diversity analysis and the start of a genetic map.

Genetic resources and breeding of *Pinus caribaea* in China

Yongqi Zheng, Huoran Wang
Chinese Academy of Forestry, Institute of Forestry,
100091 Beijing, China
Tel: (86) 10 6288 9645, FAX: (00) 86 10 62872015,
Email: zhengyq@rif.forestry.ac.cn

Pinus caribaea (*Pc*), the most important commercial softwood tree crop in the tropics of China, will become an increasingly important source for softwood fiber for pulp and timber. Plantation area of the species is currently over 50 thousands ha and expected to reach 100-150 thousands ha by the year 2010. The history of introduction and domestication of Pc can be divided into three stages chronologically: species (variety) trials in the early 60s (Cuban variety) and the early 70s [varieties *hondurensis (Pch)* and *bahamensis (Pcb)*], variety/provenance trials in the early 80s and range-wide provenance/progeny trials in the early 90s. Two provenance/progeny trials were established in China using 121 open-pollinated families (14 provenances) of *Pcb* and 217 open-pollinated families (16 provenances) of *Pcc*, respectively through international collaborations. All these experimental populations constitute the base populations of the two varieties.

Significant genetic variation was found in growth traits and pest resistance among the three varieties and among provenances within each variety except Pcc. There was also large family variation within provenances of Pcb. Superior varieties/provenances were identified for different site conditions, Pcc is suitable for the lowland tropics and southern tropics and Pch suitable for inland mountain areas with better provenance from Poptun. However, in Leizou Peninsula, where the tip moth is severe, Pcb (better provenances from Abaco and New Providence) and Pcc are better than Pch.

An extensive population genetic study on natural and exotic populations of Pcc and Pcb, employing isozyme markers, was conducted in order to detect and quantify the patterns and extents of genetic changes in the genetic structure and mating systems of populations that have gone through different domestication schemes. There was significant genetic difference between the two varieties and population differentiation was much larger in Pcb than in Pcc, attributable to the fragmented distribution of Pcb. For Pcc, both single and multi locus estimates of outcrossing rate were significantly less than 1.0 in the island population (Isles of Pine) but in the mainland population (Cuba Island) and the seed orchard, indicating that stronger inbreeding exists in the island population. The small differences between single and multi locus estimates suggest that inbreeding detected be caused by true selfing rather than consanguineous mating. The Chinese material, used as Pcc, differed substantially from the natural populations of both Pcb and Pcc as revealed by either isozyme or cpDNA markers, proving that it is a distinct taxa or hybrids or mixture of seeds. This striking result suggests that breeding program of Pcc in China should be replaced with newly introduced genetic materials.

During the mid 70s, 12 grafted seed orchards or seed stands of Pcc were established in Guangdong and Guangxi provinces using materials selected from the first introduction. Seed production of these was very low, ranging from 8 to 50 kg/ha on year to year basis. Seed production of early-introduced trees peaked in the early 80s, facilitating large-scale plantings of Pcc. Hybrid breeding of Caribbean pines started from the early 80s, mainly by crossing between Pcc and P. *elliottii*. Hybrid of P. *elliottii x* Pch introduced from Australia showed excellent growth performance. Potential of other hybrid combinations among the varieties and *P. elliottii* needs to be further studied in future. The need for continued efforts on genetic improvement on the Pcc and Pcb and their hybrids to adequately conserve and wisely use the genetic resources was recognized.

2.02.00 / 2.08.00 Future of breeding and plantations in a sustainability-oriented world 2

Virgin Forests and Industrial Tree Plantations

I. V. Shutov
Saint-Petersburg Forestry Research Institute, Institutsky pr., 21, 194021 Saint-Petersburg, Russia
FAX: (812) 552-80-42, Email: spb330@spb.sitek.net

Virgin forests can be regarded as a unique depositary of genetic resources and perfect regulator of environmental conditions. The idea of a particular role and significance of virgin forests and the necessity of their conservation as a property of the Earth biota, has become common in social consciousness. in high latitudes of northern hemisphere virgin forests are mostly preserved in Russia and Canada. These forests are underproductive(low-yield), usually timed to permafrost soils and are quite vulnerable as ecological systems. The researches carried out in different countries(including Russia) and wide practical experience show that timber cutting in virgin and natural forests can be replaced by timber production at special industrial tree plantations. This can offer great advantages, especially from the point of view of ecology, ethics and economics. The report will be based on the results of large-scale experiments in planting and growing of spruce(*Picea abies* L.) and pine(*Pinus silvestris* L.) industrial tree plantations in the north-west of Russia. These experiments have been carried out during a period of 25(twenty five)years. During this research the following data was obtained: expedient localization of these plantations depending on climatic and soil conditions, the problems of territory arrangement, optimized according to the wood growing conditions methods of soil cultivation, scientifically grounded rate(regime) of forest stands density in their age dynamics, activities for taking care of the plantations, possible timber increase (6-8 m^3 per hectare a year), turnover of cutting(50-60years), the power of additional carbon flow obtained from the atmosphere(2-2,5 tons per hectare a year), etc. It has also been shown that millions of hectares of land can be used for growing industrial tree plantations in Russia.

On the basis of the data published in different countries it is considered advisable on the behalf of IUFRO to send the following suggestions to UNO:

a) to organize ecological reserves of global significance on the territories where virgin("ancient") forests are still preserved;

b) to attract authority and material(financial) resources of the world community to the matter of organization of the above mentioned reserves and to the necessity of transferring timber production to the industrial tree plantation areas before the end of the forthcoming century.

These suggestions have to be put forward on the agreement with the governments of the corresponding countries.

2.04.01 Conservation and management of forest gene resources

Investigations of an oak of unknown origin

Helmut Guttenberger, H. Pfeifhofer, M. Müller, E. Stabentheiner, Z. Borzan
University of Graz, Institute of plant physiology, Schubertstrasse 51, A-8010 Graz, Austria
Tel: 43-316-380-5633, FAX: 43-316-380-9880, Email: helmut.guttenberger@kfu*nigra*z.ac.at

An unusual oak of unknown origin growing near Zadar, Croatia is called the "Green oak". This tree produces hermaphroditic flowers and flowering is not synchronized with other oaks in the vicinity. The tree has been classified as a putative a hybrid between *Quercus cerris L.* and *Q. ilex L.*, *Quercus viridis* Trinajsti‘. However, this classification is probably not accurate, as a hybrid between a species where acorns mature in the second year (*Q.cerris*) and a species where acorns mature in the first year (*Q. ilex*) has never be verified. To investigate the origin and taxonomic position of this tree, we conducted comparative investigations in wood and leaf anatomy and morphology of flowers and pollen among the "Green oak" and specimens of *Q. cerris*, and *Q. ilex* using a light microscope combined with digital image analysis and a scanning electron microscopy. The hairs of all three oak species were examined using several histochemical reactions and scanning electron microscopy, and the DNA content of nuclei was measured. Volatile compounds of the leaves were determined using gas chromatography. The results of these investigations, and the origin of the "Green Oak"are discussed.

Keywords: *Quercus*, hermaphroditic flowers, hybrid, wood anatomy, leaf anatomy

Data Base on Genetic Resources of Woody Species in the South Forest-Steppe of Russia

V. A. Kostrikin, S.G. Kobzeva
Research Institute of Forest Genetics and Breeding (NIILGIS), Lomonosov str. 105, 394043 Voronezh, Russia
FAX: +7 (0732) 539436, Email: ilgis@lesgen.vrn.Ru

Genetic resource data for numerous woody plants species of the south forest-steppe of Russia (united into the Central Chernozem Region (CChR) and includes Belgorod, Voronezh, Kursk, Lipetsk, Orel and Tambov oblasts) were collected in the database (Pas-op) that was formated by FoxPro 2.6 for Windows. The data base represents an area consisting of the Central Chernozem Region (CChR), which includes Belgorod, Voronezh, Kursk, Lipetsk, Orel and Tambov oblasts. The data base consists of 14 files interconnected as a single informational space.

Presently, the database contains s 2521 records concerning conservation resources of the CChR gene pool. Represented in the data bases are: 23 genetic reserves, 18 clone archives, 7 provenance trials, 1935 plus trees, 6 plus stands, and information about other genetic resources. There are 18 object names in conjunction with the conservation of the gene pool of CChR forest species.

Data base information can provide different characteristics about the primary forest species in the CChR. Characteristics on individual species, the areas of the objects location, and genotype of individual trees are examples of the information within the data base. The data can now used by various statistical packages, electronic tables and text editors. This possibility enabling the use of the information materials in different combinations.

Establishment of Genetic Resource Data Bases for Forest Flora

V. A. Kostrikin
Research Institute of Forest Genetics and Breeding (NIILGIS), Lomonosov str. 105, 394043 Voronezh, Russia
FAX: +7 (0732) 539436, Email: ilgis@lesgen.vrn.Ru

The ubiquity of personal computers and efficient software has become the basis for wide use of data bases in different fields of knowledge. The information is searchable and quickly processed. There is also an opportunity for active exchange of data among specialists. The utilization of such information is increasing with expansion of the Internet.

Data bases of forest genetic resources undoubtably will have a significant role in forestry. The term "genetic resources" is defined here as biological material with useful or potentially useful genetic information of available. Very often genetic resources are forest plots or individual trees, isolated for the conservation of the gene pool. in Russian forestry, genetic resourse data bases can include: gene reserves, plus trees, stands, forest seed orchards, clonal archives, and progeny tests.

A list of indices, defining an object of a genetic resource is more often determined by proper methodic design That`s why compiling of the index list does not arouse any difficulties for a programmer. However, with a great number of different objects, the necessity for creation of a system for database control appears.

Uniformity in species names and corresponding codes are critical for successful widespread use of a genetic resources data base. For information exchange with other resarchers it is important to come an agreement with scientists about coding of table fields. The following principles are suggested for coding species names: 1) the International Code of Botanical Nomenclature should be accepted as a methodological basis of taxon division., 2) scientific names of taxonomic groups should be in Latin, and 3) a common international coding of species names should bea common international coding of species names should be established.

Files were developed to contain taxon of any class of a species up to division. For the formation of databases, correlation tables connecting coinciding fields are used. Hierarchy of the files was provided by indicating of the taxon in one of the code fields. Another database program was written to keep different indices, describing genetic resources, in one unified file. All the files were interconnected as a common information space and represented thousands of infomration bits about the gene pools of forest species.

Pollen Cryopreservation Studies on some Tree Species in the Indian Forest Ecosystem

S. Shashi Kumar, D. H. Tejavathi, and S. Ganeshan
Bangalore University, Plant Tissue Culture Laboratory, Dept. of Botany, 560 056 Bangalore, India
Tel: 910803417492, Email: shashissk@hotmail.com

Forest genetic resources are described as a heritable material contained in tree species ,which may have economic, scientific and social value for the local inhabitants. Pollen has been identified as a source of diversity that can be used in conservation strategies of forest tree germplasm. For precise monitoring of gene flow through pollen procedures need to be developed for long term storage through cryopreservation. *Emblica officinalis* Gaertn., *Cassia fistula* L., *Cassia marginata* Roxb., *Millingtonia hortensis L.*, *Elaeis guineensis* Jacq. and *Pandanus fascicularis* Lamk. were chosen for study. Four species have medicinal value and two species are commercially important. *Emblica officinalis, C. fistula* and *C. marginata* are widely distributed in dry deciduous forest of southern and northern India, while *M. hortensis* and *E. guineensis* were introduced to India from Burma and W. Africa, respectively. *Pandanus fascicularis* is a profusely branched small tree distributed in India, commonly found in the western plains. Protocols for collection, cryopreservation and cataloguing pollen of these species were developed in this study. Pollen collection and extraction procedures were optimized, based on type of inflorescence, pollen production patterns, and physiological characteristics of study species. Viability was assessed by pollen germination using the hanging drop technique for all species except E. guineensis, where a modified cellophane technique yielded superior germination frequencies. Optimum pollen germination was obtained in modified Brewbaker and Kwack's medium, consisting of different concentrations of sucrose, supplemented with inorganic salts. Feasibility of pollen for cryogenic preservation was tested by immersing pollen samples sealed in laminated aluminum pouches in liquid nitrogen (-196°C) for about one hour. pollen was then germinated in vitro, and found to have comparable germination rates to fresh pollen samples. As a result, experiments on long term storage of pollen were initiated and are presently in progress. The results indicate that cryopreservation of pollen could provide the basis for the establishment of a conservation repository of nuclear genetic diversity.

2.04.02 Genetics and traits

The physiological genetics foundation of *Liriodendron* heterosis

Ye Jinshan
Paulownia Research and Development Center of State Forestry Administration, No.3, Weiwu Road, 450003 Zhengzhou, Henan, China
FAX: 0371-5953628, Email: Hou yu-shun [prdcc@caf.forestry.ac.cn]

Heterosis in *Liriodendren* interspecific hybrids, and fixation and utilization of the hetorosis, were studied in this doctoral dissertation using principles and methods of genetics, breeding, physiology, biochemistry, anatomy and biostatistics. The main results are as follows:

1. One-year-old hybrid seedlings of plus-crossing, minus-crossing, backcross and F1-crossing showed universally notable positive growth heterosis. Growth characters of seedlings had extremely significant difference among families and expressed great variation among individuals of family. Growth condition of backcross families was particularly excellent. Thus, family selection, individual selection and utilization of backcross and F2 hybrids have tremendous potential.

2. Having many advantages in photosynthetic area, photosynthetic time, leaf blade structure and resistance of water stress, reciprocal hybrids possessed photosynthetic capacity superiority over parents.

3. The decrease in rate of relative water content, chlorophyll content as well as protein content and increase rate of RNase activity in leaf blades under water stress were *L. chinense (*Hemsl.*) Sarg.* > *L. tulipifera Linn.* > *Plus crossing F1* > *minus crossing F1. L. chinense (*Hemsl.*) Sarg.* was severely damaged by short water stress. Reciprocal hybrids displayed super-parent heterosis of resistance to water stress. Direct evidence from 3H-Gly labeling under water stress proved both that RNase genes of parents and hybrids were expressed in translation level as well as RNase were synthesized de novo and that intensity of RNase gene expression was *L. chinense (*Hemsl.*) Sarg.* > *L. tulipifera Linn.* > *Plus crossing F1*> *minus crossing F1*. Indirect evidences from protein synthetic inhibitor under water stress indicated that RNase activity increase of parents might be involved in cytoplasmic mRNA translation and RNase release, activation and/or synthesis of chloroplast and/or mitochondria, but RNase activity increase of hybrids might originate mainly from cytoplasmic mRNA translation, not from chloroplast and/or mitochondria.

4. Reciprocal hybrids had higher stomatal apparatus density; larger stomatal apparatus opening and more developed vascular system contrasting sharply with parents.

5. The hybrid clones presented great variation of cutting root forming ability among adult and young hybrids. The variation range of cutting root forming ability of young hybrids was much larger than that of adult ones. The root forming ability of basal stem sprouts of adult hybrids was powerful.

Fertility variation and its effect on genetic diversity over generations in finite populations

Kyu-Suk Kang, Dag Lindgren & Adolfo D. Bila
Swedish University of Agricultural Sciences, Department of Forest Genetics and Plant Physiology, SE-901 83 Umea, Sweden
Email: kyu-suk.kang@genfys.slu.se

Keywords: fertility variation, status number, group coancestry, inbreeding, gene diversity, reference population

Gene diversity and inbreeding over five generations are simulated considering fertility variations and population sizes in finite populations. Gene diversity of seeds is influenced by differences in fertility among parents and their relatedness. The overall relatedness can be described as group coancestry. The fertility is expressed as a standardised measure of fertility differences among individuals. Fertility variation causes faster accumulation of relatedness and reduces the effective number (status number) of the seed crop.

Status number (Ns) is defined as half the inverse of group coancestry. Group coancestry is the probability that two genes in a gene pool are identical by descent, and it can also be interpreted as an average of relatedness or as a lost of gene diversity. Group coancestry of the present generation is the expected inbreeding (F) of the following if individuals mate at random and if they are equally fertile. Inbreeding, group coancestry, status number and gene diversity are all relative to a conceptional reference population with an infinite number of unrelated and non-inbred individuals. A small status number means a reduced gene diversity of seeds, because Ns expresses the accumulated genetic drift from the same reference population to which the concepts inbreeding and coancestry refer. The build-up of coancestry and inbreeding during successive generations is potentially a major problem when dealing with small populations (such the breeding populations). The consequences can be predicted, evaluated and monitored in this study.

For the idealised random mating population, relative status numbers (Nr = Ns / N) decline to 0.50, 0.33, 0.25, 0.20 and 0.17 for five consecutive generations, respectively. Also, the variance effective population sizes (Ne(v)) were estimated as infinity over generations when all genotypes had equal fertility. All calculations were made for the constant population sizes over generations where the populations were derived randomly from the zygotes of the seed crop. The importance and magnitude of fertility variation and population size on this decline has been studied. Gene diversity decreased faster as the fertility variation increased. But the effect of fertility variation on gene diversity was not linear.

Predictions over five generations shown that group coancestry and inbreeding accumulated fast, and the status number and variance effective population size decreased remarkably in the first generation shifts. The accumulation of inbreeding and group coancestry was faster and higher when the fertility variation was larger. The loss of gene diversity was proportional to the fertility variation and to the size of the population. The gene diversity was maintained high when provided the breeding population size was reasonable. Long term breeding programs that use small population sizes and low status effective numbers may lead to a loss of gene diversity and do not provide a sustainable long-term breeding strategy. This study helps us to understand how large numbers are required to maintain reasonable gene diversity.

Networking in phenological monitoring for commercial timber species in Peninsular Malaysia

Thai See Kiam, Shashiah Abdul Karim and Abdul Rahman Abdul Jalil

Forestry Department Peninsular Malaysia, Jalan Sultan Salahuddin, 50660 Kuala Lumpur, Malaysia
Tel: +603-298-8244, FAX: +603-292-5657, Email: skthai@forestry.gov.my

Keywords: Networking, phenological, seed, planting materials and procurement.

Many of the commercial timber species in Peninsular Malaysia particularly the indigenous tree species are irregular and unpredictable fruit bearers. Cyclic mass fruiting which usually occurs once in six to seven years, often resulted in sudden availability of huge quantities of seeds over a short period. This situation, coupled with the short storage life of the seeds, requires close monitoring and phenological observations, to avoid loss of potentially good seeds.

A phenological monitoring and reporting system via network of district forest offices is being developed to serve as a tool to enable timely collections of seeds. Phenological plots have been established and phenological monitoring teams formed in each state of the Peninsula to undertake regular observations and monthly reporting to the Forestry Department Peninsular Malaysia Headquarters. The monthly summarised reports will provide a good overview of flowering intensity and amount of fruit crop available throughout the Peninsula. These will be made available to State Forestry Departments for more effective planning of post-collection activities such as transportation, processing, storage, sowing and distribution.

A Forest Genetic Resource Information System (FORGRIS) was developed under the Malaysian-German Forestry Planting material Procurement Programme to centralise phenological information. It is a computerised management tool for the storage and retrieval of a broad range of information on forest genetic resources. This includes an up to date information on resource types; selected plus trees; monthly phenological monitoring as well as seed collection, handling and storage; nursery practices and distribution. FORGRIS comprised six main components from which information can be retrieved namely: Resource Register, Tree Register, Phenological Monitoring Register, Seed Register, Nursery Register and Distribution Register.

At the same time, efforts towards development of infrastructure and manpower are continually being upgraded. Skills of officers in the fields of tree climbing; seed collection technique and handling; storage and phenological observation are further improved through training. A prototype vehicle known as Mobile Seed/Seedling Chamber was developed to assist in the collection and long distance transportation of planting materials. The Existing forest nursery in Lentang, Pahang is being upgraded to become a Forest Planting Material Procurement Centre. in addition to the development of storage facilities for recalcitrant seeds, the Centre will plan and co-ordinate activities related to procurement of planting materials in Peninsular Malaysia. The Centre will also conduct training and research on large scale handling of planting materials, seed testing and documentations.

- Resource Register stores data on the different resource types, genetic information of the population and description of the site.
- Tree Register stores information on selected trees including botanical and common name, phenotypic description, location and site.
- Phenological Monitoring Register contains information on phenological observation of flowering and fruiting of every selected mother trees, as well as general observation within the phenological plot.
- Seed Register contains information on collecting, processing, testing and storage of seed.
- Nursery Register contains information on the production of all nursery-grown planting stock. This includes pre-treatment, sowing, germination and potting of plants.
- Distribution register holds information on distribution of planting materials and keeps the different identification of resource, seed and nursery. It links the information of the origin and handling of the planting materials with the planting site.

Characteristics and inheritance of male sterility of *C. japonica*

Hideaki Taira
Niigata University Graduate School of Science and Technology, 950-2102 Niigata, Japan
Email: taira@gs.niigata-u.ac.jp

Genetic male sterility is a useful trait in plant breeding, especially in angiosperm crops such as corn, onion and carrot. We found a male sterility *Cryptomeria japonica* trees in Japan. Pollen of *C. japonica* is one of the major causes of pollinosis in Japan. We carried out this research in an attempt to male clear the characteristic and inheritance of this male sterility. Microsporogenesis of the male sterile tree proceeded meiosis, however, the microspores collapsed under they were separated from pollen tetrads in locals, resulting in complete male sterility. Most likely, ethylene was responsible for male sterility expression. Mating of male-sterile *C. japonica* and elite *C. japonica*, as well as backcross seedlings of male-sterile trees, were carried out. The seeds from male-sterile *C. japonica* were germinated in an incubator, and grown in a greenhouse. The seedlings were treated with 100 ppm gibberellin in early July 1995, to promote the formation of male flowers. in January 1997, all of the seedlings of elite *C. japonica* produced pollen in its male flowers; however, pollen had not developed in 55 out of 120 backcrossed seedlings. This evidence indicates that the heredity model of male sterility in *C. japonica*, is nuclear genetic male sterility controlled by a pair of recessive genes.

Use of halogens in controlling deterioration of some tropical tree seeds

Alka Bhargava, Amit Sahai, A.S.Bhandari and Vishakha Kumbhare
Tropical Forest Research Institute, Post Box #RFRC, Mandla Road, 482 021 Jabalpur, India
Tel: 91-761-847320, FAX: 91-761-321759, Email: alkamit@hotmail.com

Keywords: *Acacia* catechu, *Pongamia pinnata*, *Shorea robusta*, storability, germination, ageing, vigour.

Halogen treatment of seeds is a powerful tool for controlling seed deterioration in field crops. An attempt was made to use this simple technique during storage of seeds of forest tree species. The most significant results were obtained with sal (*Shorea robusta*), khair (*Acacia* catechu) and karanj (*Pongamia pinnata*). in all cases, halogen treatments extended seed storability, with high germination and vigour in laboratory and field tests.

Sal is one of the most important timber species of the tropical regions and the seeds are an important source of edible oil and butter. The rapid deterioration of these recalcitrant seeds creates several disadvantages for raising planting material as well as for butter extraction. Khair is the chief source of katha and cutch, is a useful timber and fodder species and produces good quality charcoal. Other parts of the tree have a number of medicinal uses. Khair produces good crops of seeds almost every year, but the seeds are very delicate and damaged even by a slight fire. They are also subject to insect attack, and do not store well for more than 6 months, far shorter than other leguminous seeds. Karanj is another multipurpose tree species, the wood being used for making agricultural implements and as a source of pulp. The seeds are valued for their non-edible oil, but they store poorly.

In this study, khair and karanj seeds were collected from the TFRI campus and used immediately. Sal seeds were collected from a natural forest and transported to the laboratory the same day. All seeds were exposed to chlorine and iodine vapours for durations ranging from 4 to 65 hours. Khair and karanj seeds were subjected to accelerated ageing at 100% RH at 420C for 8 days to simulate storage effects. Germination tests were carried out on top of germination paper at 300C in a BOD incubator. Following laboratory testing, selected treatments were field tested. Simultaneously, membrane permeability was studied by measuring the electrical conductivity, dehydrogenase activity and total sugar content of the seed leachate. Treated sal seeds were stored at room temperature, 150C and 80C for 15 days, then sown in the nursery.

Sal seeds treated with chlorine vapour had enhanced storability and tolerance to lower storage temperature. Exposure for 65 hours gave 30% germination in the nursery, even after 15 days storage, while untreated seeds did not germinate. Chlorinated seeds also exhibited increased vigour and faster completion of germination. Iodination had no promotory effect. For khair seeds, the maximal beneficial effect in the laboratory was observed by chlorination for 24h, which also improved the germinability before ageing. Other durations of chlorination and iodination did not have a promotory effect on non-aged seeds. The effect of 48h exposure to chlorine was especially evident by increased germinability of aged seeds. Greater membrane integrity of 24h and 48h chlorinated seeds was demonstrated by lower electrical conductance of seed leachate and reduced leakage of sugars. Therefore, these seeds were subjected to field trials. Following chlorination for 24h, germination in unaged seeds increased to 36.52% compared to 23.75% for the control, and 7.5% for the 48h treatment. Also after 24h treatment, total biomass was 4.37g compared to 3.94g and 3.33g for the control and 48h treatment, respectively. Promotory effect of the halogen treatments was more evident in the aged seeds. Germination percentage, root and shoot lengths of seedlings, total biomass, collar diameter and nodulation were highest in the 24h treated seeds. Even though the germination of the aged seeds decreased as compared to the non-aged, there was an increase in the total biomass of the seedlings, thus demonstrating the beneficial effects of this methodology. Karanj seeds showed a positive correlation between the conductivity of leachate, leakage of sugar, dehydrogenase activity and germination of aged seeds after 24 and 48 hours of chlorination and iodination respectively.

Thus, halogenation has the potential for utilisation as a low cost, simple technique for enhancing tree seed storability even under ambient field conditions.

Introduction of Genetic Resources and Improved Forestry Seed Production in Madagascar

Gilles Chaix, Razafimaharo Vololoniriana, Razafimahatratra Appolinaire, Phillippe Vigneron
Cirad-Forêt Programme Arbres et Plantations, Programme Arbres et Plantations, B.P. 745, Antananarivo 101, Madagascar
Tel: 261-30 23 842 29, FAX: 261-20 22 209 99, Email: chaixg@dts.mgr

Keywords: *Eucalyptus*, genetic improvement, seed orchard, smallholder plantation

Forest products supply more than 86% of the Malagasy domestic energy consumption. Production in the natural forest has decreased and no longer satisfies the local demand of fuel-wood and timber for the ever-growing population. of the 750 exotic species already introduced in arboreta, *Eucalypts* and pines originating from summer rainfall areas have been the most productive. The introduction of *Eucalyptus robusta* and *E. camaldulensis* early in the 20th. Century was particularly successful. These two species now produce more than 1 million tonnes for the yearly fuel-wood supply of Antananarivo. But successive crosses within narrow genetic base populations have resulted in local land races with severe inbreeding depression. Local seed sources cannot match plantation requirements that need 250 kg of eucalypt seeds every year.

For the past 20 years, FOFIFA with Cirad-Forêt has conducted a hardwood genetic improvement programme (funded by the European Union between 1993-97). The main objective is to supply smallholders with locally-improved varieties for a range of wood products. The first step was to introduce new genetic resources for several species to build both the base and breeding populations. Because of the huge ecoclimatic diversity and the range of desired wood products, numerous improved varieties had to be developed simultaneously. Thus, a multiple-population breeding scheme was implemented for several species. Within each population, the improvement strategy was as follows: i) progeny-provenance trials for genetic diversity assessment (base population), ii) selective thinning retaining the best trees within the best provenances or progenies (generation 1, Seedling Seed Orchard 1), iii) harvesting of the open-pollinated seeds for the second generation seed-orchard (SSO 2) and to implement the second cycle of recurrent selection. The seeds produced in the SSO are used for breeding as well as the deployment of varieties. The broad genetic base of the seeds produced by the SSO matches the required plasticity for smallholder plantations with poor silvicultural practices.

Forest plantations are currently established in several ecoclimatic conditions, from the dry South (450 mm of annual rainfall) to the wet East coast (2500 mm), from coastal savannahs to 1600 meters above sea level. Nine contrasting sites were chosen for SSO establishment. To match the actual demand as well as promote poorly-known species, 9 *Eucalypts*, 7 acacias and 8 miscellaneous species were included. The most important ones were: *Eucalyptus camaldulensis*, *E. citriodora, E. cloeziana, E. grandis, E. maculata, E. microcorys, E. resinifera, E. robusta, Acacia auriculiformis, A. crassicarpa, A. mangium, Casuarina equisetifolia, Grevillea robusta* and *Prosopis juliflora*. 5 000 open-pollinated progenies belonging to 400 provenances and 25 species were introduced between 1988 and 1998. Most were collected from their respective natural areas. Seed lots were tested in a complete randomised-block design encompassing several provenances of the same species with 16 tree plots. The high planting density, i.e. 2500 trees per hectare, allowed the combination of provenance testing (at least for initial growth) and orchard objectives. Four to five successive selective thinnings resulted in a final stocking of 80 to 150 trees per hectare at six to seven years old. Thinnings are implemented on the basis of individual tree value, but aim to preserve a broad genetic diversity. Trial replications across several sites permitted a combination of provenance-progeny and genetic-environment interaction assessments, as well as the production of locally well-adapted improved seeds. Last but not least, the 50 SSO already established (70 ha) are used as demonstration plots to promote the use of poorly-known species and improved varieties. Since 1997, new planting programmes have been partially supplied with seeds produced in SSO. Besides the traditional *E. robusta* and *E. camaldulensis*, new species such as *A. mangium* and *E. maculata* (for poles and sawn wood) are now sought after by smallholders.

Forest Tree Seeds at the End of the 20th Century: Major Accomplishments and Needs

David George W Edwards
FTB Forest Tree Beginnings, 4018 Cavallin Court, V8N 5P9 Victoria, BC, Canada
Tel: 250-477 4757, FAX: 250-477 4671, Email: gedwards@coastnet.com

Keywords: seed production, storage, desiccation, longevity, dormancy, testing

Based on the State of Knowledge Report for Research Group 2.09.00 (Seed Physiology and Technology) this paper reviews developments and accomplishments, indicates what remains unknown, and suggests directions for research during the early years of the new millennium. The main focus is on tree seed production, storage and longevity, and seed quality testing and nursery performance. It is pointed out that although conservation efforts are underway, a 1998 estimate declared 10% of the world's tree species as threatened with extinction.

Seed orchards and other tree seed production areas have been developed for numerous economically-important forest species, but the bulk of tree seed crops continue to be derived from wild plants in natural stands. Forest tree seed biology remains poorly researched for many species, but advance-forecasting of good crops is possible in some. However, erratic crop production, uncontrolled insects and diseases, and the need to make collections at the right time to ensure maximum germination and vigour, plus correct post-harvest handling, remain priorities for most species. in general, seed processing methodologies can now eliminate all (or almost all) unfilled seeds, but only one method (a Swedish development) applied to some conifers separates live-filled seeds from filled-dead ones. Despite these difficulties, large increases in tree seed production, particularly in species and provenances selected for desirable attributes, are going to be needed to meet the challenge of successful forest regeneration worldwide. Collaborative efforts to determine more-appropriate species, and to improve production of genetically- and physiologically-improved seeds, are underway in some regions, but these probably need to be broadened. Seed storage, to combat sporadic crops and stabilize supplies to nurseries, remains a major research issue. Three broad classes of seeds, based principally on their desiccation tolerance and sensitivity to low temperature, are now recognized. So-called "orthodox" and "recalcitrant" seeds are opposite extremes of a continuum between which lies a broad spectrum of seeds with "intermediate" storage-behaviour characteristics. The report outlines a number of major findings concerning the causes and reasons for desiccation tolerance. A complex suite of mechanisms is involved, and further research is required to resolve all the components into an integrated system. One notable factor is that, unlike orthodox seeds, cell organelles in recalcitrant seeds remain differentiated and actively metabolic, and vulnerable to any amount of dehydration. Seed dormancy, common in orthodox seeds and some temperate non-orthodox seeds, but rare in tropical species, increases the complexity. Predictions of tree seed longevity are still largely empirical, but data is slowly accumulating. For operational forestry and germplasm conservation, especially for hard-to-store materials, major research efforts continue to be needed.

Even the better moist-chilling treatments to overcome seed dormancy require weeks or months to apply, often only work on some seedlots, or some seeds within a lot. Seed moisture control during chilling produces more rapid, synchronous germination, permits seeds to be cold-stored in a non-dormant state for 1 to several years, is used operationally for several conifers and, when combined with growth regulators, for some broadleaves also. Yet faster, more versatile dormancy-breaking treatments are needed for nursery production and laboratory testing. Difficult-to-standardize subjective tests (such as tetrazolium staining) are still used for tree seeds, but they often underestimate/overestimate seed quality. Laboratory tests that correlate with nursery production on a local level have been developed, but more work is needed to make these applicable regionally. Vigour testing, adapted from agriculture/horticulture, is not widely successful in tree seeds mainly because of the inherent heterogeneity in crops from natural stands, and even those from seed orchards Some indicators, such as respiratory activity of embryonic axes in beech, or of entire subalpine fir seeds, as well as protein levels in fir, have been suggested as possible vigour indices, but much more work is required. A brief review of the organization of the Research Group is appended, and several suggestions for the future are made. Contributors to the SKR are acknowledged.

Planting Dipterocarp Species For Forest Plantations: Is It Viable?

M. Marzalina, Krishnapillay B, Nashatul Z.N.A., Ang K.C., Siti Hasanah M.S., Zaiton S., Fadzlinah Z. and Hamsinah H.
Forest Research Institute Malaysia (FRIM), Seed Technology Section, Forest Plantation Division, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +6-03-6302121, FAX: 603-6367753, Email: mzalina@frim.gov.my

Keywords: seed collection, storage, forest plantation, phenology, recalcitrant

The Dipterocarpaceae has long been accepted as the main family producing valuable timber of medium to hard density. Such timbers were once considered to be Malaysia's main export. However, the current concern for sustainability in wood production and genetic conservation has increased the need to protect more of the natural forest, and to harvest only on a sustainable basis from the productive forest. The timber supply deficits thus created will have to be supplemented through plantation forests.

Because of poor seed availability caused by the gregarious mass fruiting habit that produce crops only once every 3-7 years, dipterocarp species tend to be of low priority for selection for forestry plantation programs. Adding to these difficulties, most species produce seeds that are recalcitrant, and which suffer desiccation damage if dried below a relatively high moisture content. Such seeds cannot be stored for long periods, therefore.

This paper highlights the results of monthly phenological observations in selected forest areas, as well as dipterocarp seed storage studies, conducted over the last 10 years by the Seed Technology Section at FRIM. To maintain a continuous seed supply, collection efforts should be concentrated in seed production areas during mass fruiting years, but should occur also in all phenological observation areas during the off season periods when some trees tend to flower and fruit sporadically. Current research advances in prolonging seed viability after collection, and during transportation, will be discussed.

Wide differences between species in levels of critical moisture content at which viability is lost, were observed. This could be due to the stage of maturity, seed size and structure. Most seeds could be stored for less than two weeks. Several methods for obtaining continuous supplies of planting material are discussed.

Tetrazolium Test: A Tool for Predicting the Viability of Some Tropical Tree Seeds

Mamta Purohit, Alka Bhargava
Tropical Forest Research Institute, Post Box # RFRC, Mandla Road, 482021 Jabalpur, India
Tel: 91-761-847320, FAX: 91-761-321759, Email: alkamit@hotmail.com

Keywords: TTZ, root mean squares, *Acacia nilotica*, *Albizia procera*, *DendroCalamus strictus*, *Sesbania sesban*

The tetrazolium (TTZ) test has been an important and useful tool for determining the viability of a range of seeds since its introduction by Lakon in 1942. The method gained popularity for its simplicity, ease and rapidity of application, and because it can evaluate viability whether or not the seeds are dormant. This study highlights the standardization of evaluation criteria for using the test on seeds of four important tropical tree species. *Acacia nilotica* seeds require a long time to germinate because of their hard seedcoats. Apparently-sound and healthy *Albizzia procera* seeds often harbour insects (as shown by x-ray radiography) and are incapable of germination. Low viablity of Dendro*Calamus* strictus, seeds compounded by gregarious flowering, makes testing the seed lot before sowing imperative. Germination in Sesbania sesban varies because of seed coat and seed size differences.

Seeds were collected from four to nine Indian provenances. Four working samples were drawn for each lot, then subdivided into two subsamples, one for TTZ staining and one for germination testing. Fresh solutions of 2,3,5-tetrazolium chloride dissolved in double-distilled water of neutral pH were prepared. A fragment of the testa of the seeds of *A. nilotica* and *A. procera* was filed off to facilitate imbibition; all seeds were soaked in distilled water for 24h (10h for *S. sesban*) then cut with a sharp blade, or decoated. Seeds were placed in 1% TTZ solution (0.5% for *D. strictus* and *S. sesban*) and incubated in darkness at 30-10C for 24 h. Staining patterns for individual seeds were documented in 6 categories for *A. nilotica*, and 7 categories for the other species, as follows: 1-embryo and cotyledons fully stained. 2-embryo fully stained with less than 3/4 of the cotyledons unstained. 3-embryo fully stained and more than « of the cotyledons unstained. 4-embryo partially stained and very small unstained patches on cotyledons. 5-only embryo stained. 6-embryo unstained and cotyledons stained in patches. 7-unstained seeds.

Division 2

Germination tests were conducted on top of paper (BP for *A. nilotica*) at 30+/-10C for 28 days. Root mean squares were calculated to determine significant differences between staining categories and the appropriate germination test. Staining categories 1 and 7 were recognized as viable and non viable seeds, respectively. The remaining categories each had two possibilities and yielded a different number of combinations of evaluation criteria. Categories, or combinations of categories, giving the least RMS were interpreted as "best", i.e. as viable seeds.

Thus, for *A. nilotica*, combined categories 1, 2 and 3 were best (category 5 was absent); for *A. procera*, combined categories 1 and 2 were best; for *D. strictus*, combined categories 1, 2 and 4 were best; and for *S. sesban* combined categories 1, 2, 3 and 4 were best. Whenever any other category was included in the above combinations, RMS values increased. Staining patterns were documented as line diagrams.

3.02.00 Effects of nursery and silvicultural operations on the environment and society

Effects of Different Mediums on the Growth of Oriental Spruce (*Picea orientalis* (L.) Link.) Seedlings Produced in Enso-Pot Tubes

Sezgin Ayan
Eastern Black Sea Forestry Research Institute, Dogu Karadeniz Ormancilik Arastirma Müdürlügü, 61 040 Trabzon, Turkey
Email: dkoa@escortnet.com

Keywords: Growing medium; Oriental spruce; Seedling product; Enso-pot

Oriental spruce (*Picea orientalis* (L.) Link.) is the main species in the Eastern Black Sea Region of Turkey. Using high quality, container-grown seedlings in the plantation areas is very important, to mitigate against very dense green-cover in the region. The Turkish-Finnish Forestry Project was established in 1992, for producing economical container-grown seedlings in the of Forest Nursery. in this project, production techniques for growing Oriental spruce seedlings under the regional conditions were investigated. Thus, common growing media in the region, sowing times and growing periods in the greenhouse had to be investigated. in this research, forty growing media, two sowing times and two growing periods in greenhouse were studied. Commonly-used local Barma peat was the main component of the media. Thirty-nine growing media were prepared with various supplemental materials (river sand, perlite, composted tea remnant, composted barnyard manure, wood shavings and bran) mixed at different ratios by volume to the Barma peat. Vapo peat (Finnish) was used as a control. For all treatments, height growth, root collar diameter, survival percentage, dry weights and stem weight / root weight ratios of the 2+0 seedlings were measured. The results were:

1. The best height growth under the of Forest Nursery conditions were in the following media respectively:

60% Barma peat + 20% comp. Tea remnant + 20% river sand; 50% Barma peat + 20% comp. Tea remnant + 30% river sand; 50% Barma peat + 20% comp. Tea remnant + 30% perlite; 60% Barma peat + 20% comp. Tea remnant + 20% perlite; 60% Barma peat + 20% comp. barnyard manure + 20% perlite

2. Traditionally, 2+3, 3+2, 4+0 and 5+0 Oriental spruce seedlings have been planted in this region. This study showed that 2+0 seedlings were large enough for planting with the growing media mentioned above, using the Enso-Pot tube system.

Effect of Selection of Soil Type on the Establishment of Ectomycorrhizas and Growth of *Pinus patula* Seedlings in the Nursery

Varadharaja Mohan, K. Nataranjan
Institute of Forest Genetics and Tree Breeding, Division of Forest Protection, 641 002 Coimbatore, India
FAX: 0422-430549, Email: ifgtb@satyam.net.in

Keywords: Ectomycorrhizas; *Pinus patula*; "shola" soil; *Thelephora terrestris; Laccaria laccata; Rhizopogon luteolus*

A *mycorrhizal* association is essential for forest trees. Ectomycorrhizas are found mostly in conifers. in the present investigation, an experiment was conducted to study the effect of soil type on the establishment of ectomycorrhizas and growth of *Pinus patula* seedlings in the nursery. Three different soil types, viz., "shola" soil (forest soil), grassland soil and riverbed sand were used. Initially, both surface-sterilised and non-surface-sterilised *Pinus patula* seeds were sown in "shola" and grassland soils and later, after 3 months, the seedlings were transplanted again to "shola" soil, grassland soil or riverbed sand. The results showed that the local "shola" soil was the best soil type, based on the different growth parameters such as root and shoot lengths root collar diameter, shoot and root dry weight, number of *mycorrhizal* tips and establishment of different *mycorrhizal* types. The *ectomycorrhizal* types found in seedlings grown in the three different soils differed. The *mycorrhizal* types formed *by Thelephora terrestris*, *Laccaria laccata* and *Rhizopogon luteolus* were found only in the seedlings grown in the "shola" soil, whereas the *mycorrhizal* types formed by fungi-like species of Hebeloma and Inocybe were found only in the seedlings grown in the grassland soil. Another *mycorrhizal* type, Cenococcum graniforme was found only in the roots of the seedlings grown in riverbed sand. The significance of the findings is discussed.

Nursery and Plantation Activities for Revival of Tribal Habitat and Lifestyle - A Case Study from Kerala, Southern India

R. C. Pandalai
Kerala Forest Research Institute, Peechi, 680 653
Thrissur, Kerala, India
FAX: 0487-782249, Email: libkfri@md2.vsnl.net.in

Keywords: Rehabilitation; India; Nursery; Afforestation

The outcome of attempts on rehabilitation of two highly degraded tribal settlements in different regions of Kerala State, southern India, are discussed in this paper.

A Participatory Rural Appraisal (PRA) exercise was undertaken to acquire information on the views and expectations of the local population and also to create an awareness about the potential benefits on the quality of life by restoration of their habitat with scientific inputs. A programme was subsequently implemented which was centered mainly around nurseries, planting activities and field training. Species selection, nursery management, silvicultural techniques for plantation establishment in degraded zones and soil/water conservation measures adopted in the study are discussed. The importance of effective human resource development and proper species selection was revealed in the first three years of the project. The paper also discusses the potential for increasing employment opportunities through the afforestation activities and development of self-reliance amongst the local tribal population.

Comparative Studies On Survival and Growth of Seedlings and in *Vitro* Raised Plants of Teak

Shyamal K. Roy, M. Zakir Hossain
Jahangirnagar University, Department of Botany, Savar, Dhaka, Bangladesh
FAX: 880-2-833054, Email: shkroy@juniv.edu

Keywords: Teak; Propagation; Seedling; in vitro culture

Teak (*Tectona grandis*) is one of the important timber trees in South and Southeast Asia. The plant is generally propagated by seeds but the fruit and seed set is very low in this plant. A protocol has been developed for propagation of teak through in vitro culture of shoot tips and nodal explants of seedling plants. Explants were washed thoroughly under running tap water. Surface sterilization was done with 0.2% $HgCl_2$ for 5 minutes followed by washing with sterile distilled water giving 3-5 changes. Explants were cultured in 0.7% agar-gelled Murashige & Skoog's (MS) medium with 3% sucrose and different concentrations and combinations of auxins and cytokinins were used for shoot proliferation. For rooting the regenerated shoots were excised and subcultured on half strength MS medium with a range of concentrations and combinations of auxins. Though rooting was achieved in 90% regenerated shoots, their survival rate in the open field was only 45-50%.

Germination of seeds collected from mature trees was 50-55% but the survival rate of seedlings was 75%. Growth parameters of surviving plantlets were measured at six-month intervals up to 24 months. At the 6th month, the height and base diameter of seedlings were 25 cm and 0.5 cm respectively. in in vitro raised plantlets the height and base diameter values were 20 cm and 0.35 cm respectively. At the 24th month the height, base diameter and diameter at breast height of seedlings raised plants were 198 cm, 3.9 cm and 1.4 cm, respectively. in in vitro raised plants these values were 216 cm, 4.1 cm and 1.5 cm, respectively. Potential growth performance of the two categories of plants is discussed.

Private Individual Tree Nursery Management and their Role on Environmental and Community Forestry in Tanzania: an Overview

I. M Shehaghilo
Usambara Environmental Conservation Organisation,
Post Box # 199, Lushoto, Tanzania

Keywords: Tree nursery, Management, Environmental, Economic, Quality stock

Before 1990, community and individual forestry programmes for environmental and economic purposes in Tanzania depended mainly on the nursery plants raised and managed by trained government nursery managers. The ecological and economic reasons for afforestation have increased significantly in recent times. Because of a general policy of reducing public expenditure by Government, the Forest Department has reduced its production of nursery plants for use by the community and individuals. A few government nursery centres still raise and sell seedlings to individuals, but the costs are generally high. More externally- and internally-financed NGOs are now engaged in planting trees than ever before. They all need tree seedlings, which must be raised and managed in nurseries for about a year before they are ready for outplanting.

To meet this increased demand for nursery stock, many people have organised themselves as individuals or groups to raise tree seedlings and sel1 them at lower prices than those from government or some Non-Governmental Organisation (NGO) nurseries. This has attracted many tree practitioners to buy seedlings from such centres, and hence the number of such centres has increased, as shown by a recent survey in some parts of the country. Such centres have increased much-needed self-employment. Therefore, they have a big role to play in this country. However, some scientific questions arise as to the quality of the nursery stock and the resultant quality of the established trees.

This paper reviews the nursery management practices of private individual small nurseries as compared to the more-organised government nurseries, including seed collection, sowing, nursery cultural operations and management. The effects of plant quality, which may not be noticed until after early field establishment, are discussed.

General Views on Silviculture of Protection Forestry and the Agroforestry Potential in Egypt

Abdelwahab B. El-Sayed
Alexandria University, Forest tree Dept., Aflaton St., El-Shatby, Alexandria, Egypt
Tel: 203-5971960, FAX: 203-5972780, Email:

Keywords: Silviculture; Egypt; Agroforestry; Arid land

This paper briefly describes the silviculture of forest trees on the arid lands of Egypt, the roles they can play and the products they provide. The management of protection plantations (sand-dune fixation, windbreaks, shelterbelts, etc) with particular reference to sand-dune fixation is described. The main objective of management is sustainable protection. Production or other roles should be considered as by-products of sustainable protection, but the income they give should contribute to maintenance. The second part of the paper deals with the agroforestry potential in the arid region of Egypt and begins with a definition of agroforestry. The benefits obtained from agroforestry in arid lands are discussed and a review of the different traditional agroforestry systems is made. Finally, the paper discusses what should be done to improve and to extend agroforestry in Egypt.

3.04.00 Operational planning and control; work study

Investigations on using of geographical information systems on the forest road networks in Turkey

Halis Hulusi Acar, Selçuk Gümüs
Blacksea Technical University, Faculty of Forestry, Department of Forest Engineering, 61080 Trabzon, Turkey
Tel: +90-462-325-3223, FAX: 00 90 462 3257499, Email: hlsacar@risc01.ktu.edu.tr

Because of the deep interference all over the world the forest regions are drawing back to mountainous regions day by day. Forest road network supply easy transportation to forest areas to maintain the usage and protection of forest resources and improvement substructure establishments for forest works.

In forming the forest road networks these are planning-projecting, building and maintenance expenses and such problems, that are hard to solve or expensive. Also cause ecological damages hard to improve and cause loss of forests. in this study we discuss the utilization of geographical information system technique in stages of planning forest road network and the point that we have arrived about this topic in our country.

The planning studies of forest roads in our country with using geographical information system has still at the academic level. We exposed the results of usage geographical information system technique about determination of terrain evaluation for forest road routes, determination of forest road routes, determination of forest roads loads and forest road buildings in studies of planning forest roads, that we have done in last three years.

General Directoried of Forestry started the studies of systematic forest road network planning in 1964 and completed them in 1974. in this studies, only the productive forest area took into account and total road length planned as 144425 km. in recenst years, the improvement of forestry techniques, the wants of rational forestry and the results guided after the application of the plans. According to the new plans total road length is planned as 201810 km. At the end of the year 1998 the 65.75 % of this, 132693 km is constructed.

Research area is between the boundaries of Trabzon Regional Forestry Headquarters, Macka Forest Enterprise. The research area; Ormanüstü planning unit is Education, Research and Application forest of Karadeniz Technical University, Forestry Faculty.

The stand type symbols are appointed to polygons for building database on the stand type digital map. The layer that involves stand typesi combines with the layers involve compartment boundaries and rivers so that the digital stand map is formed for Ormanüstü planning unit. in studies for preparing the forest road network plan first evaluating of terrain were done for forest road routes. For this, the terrain data were collected from different layers of geographical information system database and suitable and non-suitable areas were determined by spatial queries. After this, forest road networks plan alternatives were formed. in these plans, the road loads and requirements of water constructions were determined. As a result, the optimal road network plan is formed according to the evaluation that is made between two alternative.

The built two forest road network plan is evaluated by using Geographical Information System database and analysis, this was impossible by the other classic methods. This showed advantages of using system in alternative forest road network planing operations.

A study on the productivity and work loads of natural forest harvesting in Central Kalimantan

Seca Gandaseca, Tetsuhiko Yoshimura
Bogor Agricultural University, Faculty of Forestry, PO Box 168, 16001 Bogor, Indonesia
Tel: +62-251-628145, FAX: +62-251-621256, Email: seca@indo.net.id

Keywords: Harvesting; Productivity; Work loads; WBGT; Indonesia

It is necessary that productive, ergonomically sound and environmentally friendly harvesting systems should be introduced to Indonesian forestry. The objective of this research is to study and improve the productivity, work loads, noise and vibration in natural forest harvesting for the sake of forestry workers and company profit. in addition, environmental aspects of natural forest harvesting were also investigated, as few natural forests are left in Indonesia nowadays and such forests are regarded as important for the ecosystem and global environment. For these purposes, we conducted the following research in Central Kalimantan in August 1998.

We measured the productivity, work loads and work conditions during felling and cutting trees in the natural forest on the first day. We also measured the same during natural forest harvesting on the next day. This work was done by two workers, such as a skidder operator and his assistant. First, the operator drove the skidder and it moved from the landing to the harvesting site.

The skidder operator assistant was also on it. The skidder sometimes moved constructing skidding roads. At the harvesting site, the assistant pulled out a winch rope and attached it to a log, while the operator was driving the winch drum. Then, the skidder operator pulled in the winch rope and the log was carried to the skidder while the assistant was walking or running to the skidder. After that, the skidder moved to the landing carrying the log. When it reached the landing, the assistant got off the skidder and removed the log form the winch rope. Then, the same cycle was repeated again for another log. To investigate work loads, we used watch-type heart rate memories which measured heart rates of workers at five-second intervals. Furthermore, WBGT, an index of thermal conditions of the work environment, was measured to clarify work conditions.

On the first day, 17 trees, whose total volume is 165.1 m^3, were felled and cut by two workers, such as the chainsaw operator and his assistant. Total time to fell and cut these trees was 5:48:55 excluding lunch time and the productivity was found to be 28.4 m^3/hour. On the next day, 13 logs, whose total volume was 86.0 m^3, were harvested from the natural forest. Total time to harvest these logs was 6:19:35 excluding lunch time and the productivity was found to be 13.6 m^3/hour. The work loads of the chainsaw operator and his assistant were found very high. On the other hand, the work loads of the skidder operator were lower than those of the other workers. The observed WBGT was very high on the forest road while it was moderate in the forest. Noise caused by the chainsaw and skidder was very hard for the operator. Therefore, operators should use ear muffs to avoid damage to his ears although most of operators are not accustomed to using them. Vibration of the chainsaw and skidder was also very hard for the operator. We suggest that chainsaw and skidder operators should not be exposed to vibration continuously for long time and that they should wear gloves of good quality.

Finally, we would like to suggest some points to reduce environmental impacts caused by logging in natural forests. Main roads should be narrower and landings should be smaller. Trees far from main roads or other trees harvested should not be cut and should remain, which would reduce skidding roads and even harvesting costs. Log length should be adjusted or should be shorter in order to reduce environmental impacts caused by logging and to enhance productivity. Winch systems should be improved so that logs can be collected from longer distance, which could reduce skidding roads and even environmental impacts. More buffer zones should be necessary along riparian and protection areas, as such areas are known as environmentally sensitive.

Allocation of Equipment of Forest Extraction by Use of the Geographical System of Information (GIS)

Eduardo da Silva Lopes, Flávio Lopes Rodrigues, Carlos Cardoso Machado, Amaury Paulo de Souza
Forest Science of the UFV - Vicosa, 36571-000 Vicosa, Minais Gerais, Brazil
Email: machadoc@mail.ufv.br

The objectives of that work went use the Geographical System of Information (GIS) as tool in the aid to the location of the productive units of a structure approximately regulated and the allocation of the "Forwarder" and "Guincho Arrastador" in the operation of forest extraction. The work was accomplished using a map in the scale of 1:10.000 of a project of reforestation of *Eucalyptus* of a forest company of Brazil. The project with total area of 441,81 it is characterized by wavy medium relief, presenting polygons of different sizes and ages. Using the program IDRISI (EASTMAN, 1997), version 2.0 for Windows, the entrance of the data was proceeded by means of a rasterization using a mesh of cells of 3 mm x 3 mm, in way to produce digital maps of use of the soil, streams, roads and level curves. Soon after the control method was used by area for definition of the compartments of annual harvest. It was established the slope limit of up to 15§ for the allocation of the "Forwarder" and above 15§ for the "Guincho arrastador". Initially a map of interpolated relief was produced, calculated its slope and reclassification in two slope class as described previously. The map of use of the soil went reclass to obtaining of the *Eucalyptus* areas that will be harvest annually, and soon after, it was made the overlap of these maps with the maps of the areas adapted for each equipment, in way to obtain a general map with all the areas adapted for the allocate of the equipments in the polygons that will be harvest annually and of the areas of forest reservation and of permanent preservation. As a result of this work, it was obtained a digital map of the project contends the delimit of all the areas of forest preservation, permanent preservation, streams, roads and *Eucalyptus* polygons. It was obtained the annual area and the wood volume to be annually extracted for the equipments. However, it was verified that the "Forwarder" will be used in 65.6% of the harvest areas, extracting a total volume of 51498 m^3 of wood for five years, while the "guincho arrastador", in the same period, will be used in 34.4% of the areas, extracting 25730 m^3 of wood. Therefore, the obtaining of those information together the information of revenue of the equipments propitiate to the planner to determine with larger precision the need of equipments for harvest areas, seeking a better alocation of the resources.

Design of an Integrated Forest Management System for Madhya Pradesh: Towards Sustainable Forestry

Ted E.W. Robak, Ragnar Oborn
University of New Brunswick, Faculty of Forestry and Environmental Management,
Post Box # 44555, E3B 6C2 Fredericton, New Brunswick, Canada
Tel: 506 453-4932, FAX: 506 453-3538, Email: robak@unb.ca

The Madhya Pradesh Forest Department (MPFD) is responsible for the management of the forest resources of the State of Madhya Pradesh, a serious obligation given the extent of these forests and their importance to all the people of the State. Besides providing revenues to state coffers, these forests are essential to the welfare of millions of rural and tribal communities and the integrity of natural ecosystems. Responsible, sustainable forest management is the goal of MPFD. Forest sustainability involves the maintenance or improvement of environmental, economic and social values. It is recognized that these forest values have not been adequately maintained in Madhya Pradesh. Some of the major factors that have contributed the deteriorating situation include:

- a rapidly increasing population growth and resulting biotic pressures;
- an over-emphasis on timber production in the management goals;
- inadequate knowledge of forest processes and their valued outputs;
- a lack of strategic, tactical and operational management tools that are needed to plan, implement, monitor and control forestry activities in a complex decision-making environment.

The objectives of forest management in the State have evolved to reflect a more holistic understanding of the value of forests to society. The challenge for MPFD is to translate broad objectives into strategies, tactics and practices that can be implemented and controlled in the context of the resources and time available. This can only be accomplished through a process involving effective planning, organization, monitoring and evaluation of all of the important activities of the Department. The MP Forest Department has initiated a project aimed at producing the information required for such a management process.

The Forest Management Information System (FMIS) initiative involves the design and development of information and decision support systems to support the management functions of all Wings and levels of the Department. This paper, however, focuses on technology that will be used to enhance the sustainable forest management capabilities of the organization: an integrated forest management system (IFMS).

An IFMS is a suite of models and information systems designed to support the major long, medium and short-term decision-making needs of forest managers. IFMSs are intended to ensure that short-term (operational), medium-term (tactical) and long-term (strategic) decision processes are linked in such a way that there is continuity of management decisions across all forest units and over all time horizons. These linkages are accomplished by means of the integrated design and development of databases, models, information and decision support systems and related technologies such as geographic information systems (GIS).

Analyses of the management decision-making needs at MPFD have been undertaken by consultants from India and Canada. A design is presented that is based upon these analyses and experience from previous IFMS research and implementation projects. Although based upon existing IFMS and GIS technologies, the actual system for MPFD will incorporate improved features and capabilities, including closer integration between the IFMS and GIS and linkages to other sub-systems of the FMIS.

The implementation of integrated systems to optimize the use of machinery in forest operations

C. Vila, Marcos Martin, F .
Spain

During the past ten years forest managers and forest organizations worldwide have been looking at sustainable forest management as a concept to introduce in their forestry practices and principles. Sustainability refers to not only forest structure itself but also resources, people and other type of land that closely stand by the forest habitat. These other components of the forestry management environment have to be considered while planning forest management. in fact, scientific/technical forest management should be undertaken for a better reporting on sustainable concepts, which means that forest information, forest planning projection and forest operation budgeting should be supported by concrete reports.

An appropriate management plan in advanced must be a fact for the global addressing of all the activities to be carried out within a forest scenario. This management plan will ensure that all the activities considered in it will be environmentally appropriate, socially beneficial and economically viable. As well, it will consider the long, medium and short-term status for the managers to plan in advance and coordinate these planning phases.

This paper deals with the development of an integrated system for the decision-making support in the use of machinery in forest operations that are included within a management plan. Specially it deals with how the GIS used (CARIS¸ of Universal Systems, Ltd) helps in the evaluation of management unit features and characteristics related to machinery selection information. The parameters defined were: slope, ground strength, ground roughness, forest road density and machinery available on the market. After the GIS has analyzed the management unit parameter, a connection with an integrated forestry management system (IFMS¸ of FORCE/Robak Associates Ltd) is necessary to obtain a unique interface that specifies the spatial data onto a mapping basis.

3.05.00 Forest operations in the tropics

Long-Term Effects of Logging in Wet and Dry Forests in Ghana

Viktor Agyeman, Hawthorne, W. and Abu-Juam M.
Forestry Research Institute of Ghana, University Box 63, Kumasi, Ghana
FAX: 233-51-60121, Email: forig@africaonline.com.gh

Exploitation of timber resources in Ghana is based on the removal of single trees of economic species scattered over a given area of the forest. Felling operations results in the removal of up to 3 trees ha^{-1} in wet and dry forests which affects up to 13% of the total area. Assessment of the impact of logging have in the past focussed on only the short-term effects. The long-term impacts of logging, especially on the regeneration of economic tree species, are unknown. Such data is neccessary to formulate appropriate harvesting control measures. Data on long term ecological impacts of logging was collected using permanent sample plots (PSPs). A total of 12 one ha. PSPs in wet and dry forests were selected on the basis of availability of adequate records of past logging history. PSPs were also selected such that their last year of logging falls into one of three ranges namely: short term (5-10 years old); medium term (15-20 years old); and long term (greater than 20 years old). The results indicate that whereas logging disturbance and tree damage levels are acceptable in the short term, regeneration of economic tree species is low in the long-term. The composition of the regeneration after logging, even in the long-term, does not necessarily mirror the current composition of the mature trees. This drift in forest composition may not be a problem if efforts are successful in generating a market for a wider range of timber species, including lesser used species. The highly variable and patchy nature of species regeneration even in the long term draws attention to the importance of seed trees and timing of logging in relation to seed fall. It is suggested that more attention to the forest cycle is needed to enhance regeneration of desirable species. The paper concludes with recommendations on fine tuning the felling cycle, yield allocation procedures and harvesting controls in Ghana.

Growth, yield and mortality after improved Selective Logging in Tropical Rain Forest of Sabah, Malaysia.

Jan Falck, Trevor S. Udarbe
Swedish University of Agriculture Sciences, S-90187 Umea, Sweden
Tel: +46-90-7865884, FAX: +46-90-7867669, Email: Jan.Falck@ssko.slu.se

In all commercial usage of the Tropical Rain Forests, the harvesting intensity and the technical quality of the harvesting procedure are crucial for sustainable timber production. This study focuses on the response of the residual stand to operational planning and pre-logging treatments. The field study is a comparative experiment using a complete randomised block design where the long term effects of four modes of selective harvesting are evaluated;
unsupervised logging
unsupervised logging with pre-felling climber-cutting
pre-marked skid trails and directional felling
pre-marked skid trails, directional felling and pre-felling climber-cutting
and no logging, i.e. virgin forest as control.

There are four replicates of each treatment which result in a total of 20 permanent plots. Each gross plot is 5.8 ha, with a net plot of one ha in the central part, climber cutting, where allotted, was carried out one year ahead of logging, and the net plots were enumerated before logging. Logging has been done at full intensity. The entire commercial and accessible volume was logged i.e. all trees of commercial tree species with a diameter above 60 cm were harvested, according to the forest law of Sabah. The experiment was established 1992. The plots were logged and enumerated for a second time in 1993, and since then they have been enumerated every second year. For trees above 10 cm dbh enumeration is done on the total area of the net plot. For saplings, seedlings and germlings, the area invented is reduced. Some preliminary results will be available for presentation at the IUFRO-world congress 2000.

The feasibility of directional felling and pre-felling climber cutting was investigated in a preparatory field study. Professional fellers and local fellers were compared. Impact on accuracy in felling, no. of damaged trees in residual stand and gap size was investigated.

Reduced Impact Logging Using Long Haulage Cable Systems in Hill Production Forest in Peninsular Malaysia

Shamsudin Ibrahim, Ismail Harun, Chong Phang Fee & S. Appanah
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Email: sham@frim.gov.my

Currently logging activities in Peninsular Malaysia are confined to hilly areas characterized by difficult terrain and sensitive environments. Poor logging practices, e. g., using heavy machinery (crawler-tractor methods), are very damaging to the forest and often lead to massive environmental damage such as soil erosion and high sedimentation in river systems that reduce water quality. Additionally, the residual crop gets heavily damaged and the overall biodiversity is reduced. Therefore, the current logging practices in Peninsular Malaysia need to be modified to comply to ITTO's Criteria and Indicators for sustainable forest management before the year 2000. in achieving this objective, attempts have been made to review ground skidding techniques currently employed in logging operations in hill forests. A pilot study has been undertaken by FRIM to test an alternative logging method suitable for hilly areas. The new method proved to be cheaper and less damaging to the forest and environment, with only a few modifications to the existing machinery used. The report highlights the methodology of the new logging method and the reduction in damage to the soil and residual stand.

An Assessment of Hollow Logs and Other Logging Residues from Deramakot Forest Reserve, Sabah, Malaysia

James Josue, Zamrie Imiyabir & Michael Trockenbrodt
Forest Research Centre, Dept. Forestry, Post Box # 1407, 90712 Sandakan, Sabah, Malaysia
Tel: 60-89-531522, FAX: 60-89-531068, Email: frc@tm.net.my

Sabah is in the process of implementing sustainable forest management practices in all its natural forest reserves. The management system model was developed by the Malaysian-German Sustainable Forest Management Project at the Forestry Department and tested in the Deramakot Forest Reserve. During logging operations it was observed that the number of hollow logs was very high.

Although marked for harvesting, these hollow logs are usually not felled. The fellers test the trees by pushing the blade of the chain saw vertically into the stem. in some cases, a hollow stem is assumed, if a crown shows large defects like broken branches and a highly reduced number of leaves. The fellers and sawyers at the log landing cut off large parts of the top and lower portions of hollow logs. According to forest management plan for Deramakot, the annual allowable cut (AAC) is 20,000 m^3. After a compartment is harvested, the compartment is closed for many years. If the amount of timber extracted from one compartment decreases considerably due to a high number of hollow trees, other compartment have to be opened earlier than planned.

Thus, if a forest is to be managed sustainably, we must optimize the use of available resources and reduce the logging waste. A study on the utilization of hollow logs and other logging residues was initiated. First, it was evaluated how much timber can be extracted from trees regarded as hollow by the fellers. Secondly, the amount of timber which is considered as timber of low quality (hollow stem parts, upper stem parts, top portions, big branches) was determined. At the same time it was tested whether the methods used for the detection of hollow stems are reliable.

Some results of the study are:
- A high percentage of logs presently considered as hollow and left in the forest still contains large amounts of usable timber.
- The methods for determination of hollow logs or the extent of the hollow are not reliable and have to be improved.
- in view of the improved processing techniques (*e.g.* finger jointing) the quality standards for logs suitable for log sales have to be changed.
- The concept of logging residue utilisation has to be promoted. Education of forestry workers, field staff of the Forestry Department and of the license holders has to be started in order to change their attitude with regard to log quality. A different salary system for tree fellers has to be developed and implemented. They should be encouraged to extract as much timber as possible within the cutting limits and not discouraged as it is currently the case.
- Recovery studies should be started to determine the amount of sawn timber produced from hollow log parts unsuitable for log sale and from other logging residues.
- Feasibility studies (technical, economic), which cover the same area, should be started.

Harvesting Impacts of Tractor and Cable logging Systems in Dipterocarp Forests, Peninsular Malaysia

S. Sasaki, Yamada T., Oikawa R., Ahmad S., Adnan A.
Japan International Research Center for Agricultural Sciences, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +60-3-637-2136, FAX: +60-3-637-2136, Email: shozos@jircas.affrc.go.jp

With the objective of attaining the sustainable forest management for tropical natural forests, it is imperative to reduce the impacts of harvesting on the forest environment. in the selective cutting operation, the residual trees and forest floor are easily damaged by felling and hauling operations. This is especially so in conventional crawler-tractor logging, where the hauling damage can be prominent, while using cable systems can reduce disturbance. We compared conventional crawler tractor logging to cable logging for harvesting impacts. The observations showed more than 50 percent of the conventional harvested area was disturbed by logging operations. Soil disturbances were characterized as "mineral soil exposed with heavy compaction", "mineral soil exposed with light compaction", "mineral soil partially exposed", or "mineral soil not exposed". According to the study, the areas classified as "mineral soil exposed with heavy compaction", and "mineral soil exposed with light compaction" when associated with steep gradient, were likely to remain uncovered with vegetation for an extended time. The components that contribute to such disturbances were construction of landings, steep gradient roads, or heavy traffic on skid trails. Using a cable logging system can contribute to reducing the area of disturbance. Cable logging differs from conventional logging in that it doesn't use tractors which need constructed skid trails We have established a 30 ha research plot for a cable logging using a mobile system in Compartment 51, Jengai Forest Reserve, Terengganu, Malaysia. Tail spar trees are chosen to avoid having machines work on steep slopes, and to minimize road construction. The results obtained from the investigation of the cable logging system will be discussed in this paper.

Forest Operation and Forest-road Networks Design in Multi-Storied Forest Management in Peninsular Malaysia

Isao Sawaguchi
Iwate University, Faculty of Agriculture, 020-8550 Morioka, Iwate, Japan
Tel: +81-1966216233, FAX: +81-1966216234, Email: sawai@iwate-u.ac.jp

"The Multi-storied Forest Management Project" is practiced in Perak State, Peninsula Malaysia, as a part of the Japan International Cooperation Association project. The purpose of this study was to promote the development of the multi-storied forests by establishing techniques for felling and hauling the upper-story tree, *Acacia mangium*. Seventy months have passed since the planting of *A. mangium* upper-story trees, which have grown 233 m^3/ha in volume. *S. leprosula* thirty-five months after planting lower-story trees have reached 5.54 m in height. However, as the ratio of height to basal diameter exceeds 100: 1, trees are strongly tapered. To reduce damage to lower-story trees, a backhoe and an agricultural tractor were added to the logging system.

From the results of logging, the damage ratio estimation of the lower-story trees was simulated by using the Monte Carlo method. The damage ratio differed considerably, depending on planting patterns, height of upper-story trees and felling skills. The results of this survey proved that the felling and hauling of upper-story trees would be technically feasible in the future, except when one row upper-story trees and one row lower-story trees method were employed. The labor productivity was 2.36 m^3/person-day in multi-storied plot, 2.85 m^3/person-day in a four-row plot, and 3.86 m^3/person-day in an eight-row plot. The decrease in labor productivity for multi-storied forest management was caused by the difference in cutting row number. The presence of the lower-story tree did not affect productivity much. Felling, delimbing and bucking costs were estimated at 12 US\$/m^3, skidding costs at 7 US\$/m^3 and transportation costs at 28 US\$/m^3 on a whole. The results of the trial upper-story tree felling and hauling in the survey clearly proved that logging of the upper-story tree would be technically possible. The optimum forest road density in the multi-story forest area was estimated at 26.5 m/ha. This density is likely to change considerably depending on estimated maintenance and administrative costs. Therefore, costs in the tropical area is a critical factor which will determine the level of any permanent forest road networks for sustainable forest management.

Roaded Stream Crossings Decrease Productivity in Forest Transport

Oscar Bustos, Marcelo Hernandez
University of Talca, Forest Engineering Department, Casilla 747, Talca, Chile
Tel: (56) 71-200380, FAX: (56) 71-200455, Email: obustos@pehuenche.utalca.cl

The transport of forest products can be delayed when trucks must travel over difficult terrain. Many forest roads are intersected by permanent streams, where the water usually is diverted through pipes, but sometimes also across the roads. in many cases, culverts may fail because maintenance is lacking. This situation produces a severe loss of soil from the road and further downstream, and the accumulation of excess moisture may also decrease the support capacity of these roads.

Our goal was to quantify the effects that roaded stream crossings have on soil loss and, subsequently, on transport productivity. The study area was located in a forested zone called "Vista Hermosa", which belongs to Forest Licancel Industry S.A. The site included 1187 ha of 24-year-old *Pinus radiata* D. Don, with an average stand volume of 350 m^3 per ha, and a road density of 18 m/ha.
Four road situations were considered: 1) Stream that is crossed by a road with truck traffic; 2) Control: a road with traffic but which is not crossed by any stream; 3) Stream crossed by a road, but which has no truck traffic; and 4) Control: a road which is not crossed by a stream and which also has no truck traffic. Each situation was replicated five times. Data from each situation were collected in sample plots located around cut-and-fill areas and road embankments. in addition, we estimated the loss in transport productivity, based on average truck speed and the amount of time that different truck types would be detained in each of these situations. The situation of a stream crossed by truck traffic produced the largest amount of soil loss (55.66 m^3 per plot).

The least amount of soil was lost from the control (no stream, but with traffic; 14 m^3 per plot). We attribute these results to the effect of water coursing over the road. Transport productivity was 5 to 6% less in the stream-with-traffic situation. When these values are applied to a fleet of 10 single trucks and 10 trucks with trailers, the average number of lost turns per month could be 33.6 and 28.8, respectively, which is equivalent to 1140 m^3 of wood. Our study demonstrates that it is possible to estimate the real effect that water on the road can have on truck speed, and on productivity.

Keywords: environmental factors; forest road; soil loss; truck transport.

Quantitative Analysis of Fragmented Forest Landscape Patterns Resulting from Timber Harvesting Practices: Identifying Key Processes of Harvesting Alternatives for Maintaining Landscape Stability

Masami Shiba
Kyoto University, Graduate School of Agriculture, Kitashirakawa, Oiwake-cyo, Sakyo-ku, 606-8502 Kyoto, Japan
Tel: +81-75-753-6441, FAX: +81-75-753-6451, Email: mshiba@kais.kyoto-u.ac.jp

Most forest landscapes have been influenced by land-management activities. The outcome is a mosaic of natural and managed forest patches that vary in size, shape, and arrangement. Landscape fragmentation is the process of creating an increasingly complex mosaic of patches that result from disturbances such as human activity. Scientists have studied the effects of fragmented forest landscapes on wildlife and other terrestrial and/or aquatic ecosystem characteristics, and have suggested alternative management approaches. However, these management alternatives have not been quantitatively evaluated because of the inherent difficulties in conducting landscape-level experiments. This is because landscapes are spatially heterogeneous, and their structure, function and changes are scale-dependent. While fragmentation will continue in most forest landscapes (as the result of timber-harvesting practices), its effects must be alleviated through new insights into management strategies, as well as by modifying management alternatives based on landscape perspectives.

This article reviews the use of spatial statistics to quantify forest-landscape fragmentation caused by timber harvesting practices over 60 years (1921-1981) in the Kyoto University Forests. The objectives of the research were:

- to identify significant relationships between pattern and process of heterogeneous mosaics in forest patches over time;
- to develop indices of spatial pattern derived from information theory, fractal geometry, and GIS techniques for measuring fragmentation; and
- to describe aspects of forest fragmentation that result from timber harvesting and subsequent coniferous plantation practices.

A 22-year (1974-1996) trend analysis of forest patterns was made by using orthophotography to transfer forest cover types, interpreted from aerial photographs, into image positions, and also for creating a digital elevation model (DEM). Using a Geographic Information System (GIS), we digitized the base maps and prepared separate transparent overlays for the two photo sets. Each patch was then classified according to cover during each period. The location, size, and shape of each patch were further recorded as polygons for subsequent spatial analysis with the GIS.

We used four groups of statistics to quantify landscape heterogeneity and pattern of the patches as they appeared in 1974 and in 1996. These groups were: 1) size, 2) abundance, 3) shape, and 4) spacing. Patch size was expressed in terms of the average patch area and perimeter. Shape was measured in three ways: 1) edge density, 2) fractal dimension, and 3) diversity index. Edge density was simply the ratio of patch perimeter to patch area. The fractal dimension was estimated by regressing the logarithm of patch area on its corresponding log-transformed perimeter. The diversity index was also calculated by using a perimeter-area relationship. Patch abundance included a measure of density and the percent of land in patches. Patch spacing was characterized by measures of the mean nearest-neighbor distance and a measure of dispersion.

Patch abundance and spacing measures provided considerable information on major patterns of forest landscape dynamics over time. Size and shape indices contributed information on specific characteristics of the individual patches. These parameters may be useful for applications designed to study specific interior and edge habitats, or in determining prescriptions for forest cutting patterns and/or cutting-unit size.

Keywords: forest patch; GIS; landscape fragmentation; spatial pattern; timber harvesting.

An Overview of Logging Safety Programs in the USA

Cornelius de Hoop
Louisiana State University Agricultural Center, Louisiana Forest Products Laboratory
School of Forestry, Wildlife & Fisheries, LA 70803-6202 Baton Rouge, USA
Tel: 225-388-4242, FAX: 225-388-4251, Email: cdehoop@lsu.edu

A strong interest has developed throughout the USA to reduce logging accidents and assist loggers with safety programs. Driven by accident costs, liability issues, a desire to improve public image and the threat of additional environmental regulations, the forest products industry has developed a pro-active role in assisting loggers with the education they need to reduce accidents while improving the quality of their work. While the goals of logging safety are the same throughout the country, the methodology to achieve those goals varies. Attitudes vary from voluntary programs sponsored entirely by industry to stricter regulation by government.

Most of the states with a significant amount of forest industry have some sort of logging safety program. Many states (particularly in the southeast) have programs operated by non-profit organizations to educate loggers. Some states make greater use of government regulation and government agencies to do the job, an idea that is generally untenable in the minds of loggers and many other people, especially in rural areas. Although there is a lack of uniformity in the methodology for tackling the logger safety issues, this is generally seen as good. The situation and social culture in each state is a little different, so each state has seized the opportunity to solve the problem in their own way. Loggers and related forestry associations in all of the states are hoping that their initiatives will be recognized by lawmakers and prevent unnecessary new laws and regulations.

In this paper, some typical logging safety programs are described.

An Analysis of the Aerobic Capacity and Physical Working Load in Chain Saw Operators at a Brazilian Forest Company

Amaury Paulo de Souza, Luciano José Minetti
Universidade Federal de Vicosa, Departamento de Engenharia Florestal, 36571-000 Vicosa-MG., Brazil
Tel: +055 31 899 2478, Email: apsouza@mail.ufv.br

This study was based on data from a paper and cellulose company in the State of Sao Paulo, Brazil. Its main objective was to evaluate the operator's physical capacity as well as his working load. The universe of this research consisted of chain saw operators in forest cutting who were developing the following activities: felling, delimbing, logging, stack and stump lowering. in general 85 chain saw operators were randomly sampled, and 51 from those attaining 60% of the total to compose the study on aerobic capacity. According to the obtained results it was concluded that: the highest average aerobic capacity in the population of chain saw operators was equal to 2.93 1 O_2/min, or or 43.59 ml O_2/kg.min or or 14.80 kcal/min. The maximum working load for chain saw operators was equal to 14.80 kcal/min while the useful aerobic capacity was 4.90 kcal/min. Stacking was that activity performed by the chain saw operator showing the highest average energy consumption (8.58 kcal/min) and it was classified as an excessively hard work. Felling, delimbing and logging with an average consumption of 6.58; 7.30 and 7.02 kcal/min respectively were classified as a heavy work. The study indicated that along the working time the operator can perform a highest working load of 4.90 kcal/min (2,352.0 kcal/day) without physical overloading.

The Human Factor in Forest Operations Research

John J. Garland
Oregon State University, OR 97331 Corvallis, USA
Tel: +1 541 737 3128, FAX: +1 541 737 4316, Email: John.Garland@orst.edu

Keywords: ergonomics; human subjects; variation; research; forest operations

Describes the sources and magnitude of variability attributed to human subjects in forest operations research. The research environment of forest operations is characterized as different from other scientific study fields. Reviews human differences contributing to variability in research studies, e.g., sex, anthropometric differences, age, etc. Task differences are noted and the need for a task analysis emphasized. Attitudes, behaviors, and cultural

differences are discussed. Special emphasis is given to research involving learning effects, learning curves, and experimental trials. Some experimental designs are critiqued and the sample sizes for hypothesis testing are examined. Concludes with some practical considerations, improvements from ergonomic research and suggestions for better research for scientists.

Until robots are commonly used for forest operations, humans performing important tasks present substantial challenges to researchers studying these operations. Not all researchers appreciate these difficulties and frequently make conclusions unwarranted by the limitations of the research. Without large scale research efforts involving substantial numbers of operators (perhaps in excess of 35-40 for a study), most reports of findings involving humans would need to be considered case studies, limited to the operating conditions of study area, operations and specific operators.

Sources of variation come from the research environment for forest operations, from the machine-human interface, from the tasks themselves, from the learning effects or experience of workers, from attitudes and motivation resulting in behaviors, from the culture, and what can be collectively described as human differences. Examples of these human differences include:
Gender/sex
Race
Population/anthropometric differences
Intelligence/education
Literacy
Age
Cardiovascular fitness
Other sources of variation can be identified as well.

The magnitude of variation for human performance is shown in sports competition and selected studies to be on the order of 6-300%. A Task Analysis is seen as helpful in making research comparable. Five strategies are discussed to aid researchers with this issue of human variation.
Control the variation
Measure the variation
Use randomization strategies
Explain the sources of variation
Ignore the variation

There is a tendency to continue with the status quo in all forms of human activities. Little pressure actually exists not to simply ignore sources of human variation in forest operations research. However, researchers do so in peril because wrong scientific conclusions are the basis for important decisions: environmental, economic, safety, health, and personal decisions. As a small community of forest operations researchers, the belief in the need to improve is only likely to be supported by internal and peer commitment. Researchers cannot ignore the variation due to humans in forest operations research.

New Ergonomic Principles when Assessing Forest Machines

Sten Gellerstedt
Faculty of Forestry, Swedish University of Agricultural Sciences, Department of Forest Management and Products, Box 7060, SE 750 07 Uppsala, Sweden
Tel: 46 18 673818, FAX: 46 18 673800, Email: Sten.Gellerstedt@sh.slu.se

A new ergonomic guideline handbook to the design and assessment of forest machines has been completed in the Nordic countries. Its purpose is to assist manufacturers when developing new equipment and help improve the machine operators' awareness of good design. The guidelines are mostly functional regarding the operator workplace, controlling the machine and its tools, and maintenance work. The guide's striven is to improve the earning capacity of mechanised forestry operations by meeting the demands of the operators on health, safety and well-being. About 100 organisations in the Nordic countries were involved in the developing of the guidelines. As a foundation, a comprehensive scientific review was done regarding work in heavy-duty terrain vehicles. The new classification system is based on the work task and the conditions in which the machinery is to be used. The principle is that work in a forest machine should give about the same impact on the operator's health and well-being, regardless how the machine is rated. This requires the machine to be used according it's designed purpose, and that consideration is taken to work rate, time worked and the difficulty of the work. If e.g. a machine is uneasy to use, the operator's time at the controls should be reduced.

Keywords: Good design, manufacturing, purchasing aid, health and safety.

A research into the changes of ergonomic characteristics of some chain saws during their usually expected service life

D. Vlado Goglia, Marjan Lipoglavsek, Stjepan Puljak
The University of Zagreb, Faculty of Forestry,
Svetosimunska 25, 10 000 Zagreb, Croatia
FAX: +385 - 1 - 230 22 88, Email:
goglia@hrast.sumfak.hr

The paper presents results of the research carried out into the operating time influence on noise and vibration levels of motor chain saws.. The research was carried out on the sample of 32 (16 Stihl 038 and 16 Husqvarna 266SG) chain saws in order to find out the possible changes that may occur during the four years operation period of the saws. For that reason the tested sample included chain saws that had been in normal operation for one, two, three and four years. All tested saws were used in the same operating conditions during which they had been maintained in the same way. Measurements were carried out on normal production saws randomly chosen. Previous to testing all saws were examined and adjusted in accordance with the producer's recommendations.

The vibrations transmitted to the hands of the chain saw operator were measured in accordance with ISO 7505 measuring procedures. Prior to measurements, the saws have been run and warmed. in accordance with the experiment plan the vibration measurements on front and rear handle were carried out. All three axes were measured simultaneously. During measurement unweighted accelerometer signals from each of the three orthogonal directions were recorded on the tape recorder. The analysis of the recorded signals was made in laboratory conditions using a computer aided frequency analyzer. Vibrations at the front and rear handle were measured at the following working conditions:

a) idling rotational frequency

b) at full load - at the speed at maximum power

c) at racing - at an engine speed which is 133 % of the speed at maximum engine power

For each handle and for each rotational frequency five independent measurement values were taken. After the 1/3 octave band frequency analysis the weighted accelerations as well as the WAS values for each rotational frequency were calculated. The measurements results are presented in tables and diagrams.

The noise level emitted by the chain saws at the same working conditions was measured too. The measurement procedure was in accordance with the ISO 7182. As at vibrations measurement, for each rotational frequency five independent measurement values were taken. Again, the measurement results are presented in tables and diagrams.

The research has shown that there are almost no indications of significant changes of the investigated ergonomic chain saws characteristics during the four-year normal operating period. This conclusion suggests the necessity of monitoring the main ergonomic characteristics of the motor chain saws during operation.

Partially Autonomous Groups in Forest Work in Germany - A Challenge to Meet New Demands for Work Organisation in Forestry

Edgar Kastenholz, Ewa Lidén, Siegfried Lewark
Büro für Arbeitsschutz und Arbeitsgestaltung,
Leimbachweg 10a, 79283 Bollschweil, Germany
Email: kastenho@ruf.uni-freiburg.de

Significant changes are taking place in German forestry. These changes have considerable impact on the organisation of forest work.

- Forest companies and state forest services are reorganising their structure, forest districts and management areas are getting larger.

- The number of forest workers employed by forest owners - the traditional model in German forestry - is constantly being reduced. in some forest districts there are no employed forest workers left at all.

- Contract labour becomes more and more important in Germany. Information on the implications of outsourcing, migrant labour and precarious working conditions is scarce.

Most of the German forest workers are well trained. They are predominantly professional forest workers, having passed a three-year-apprenticeship. It can be assumed that their skills and knowledge in many cases are far beyond the requirements of their recent tasks.

A diminishing workforce and rising professional demands, particularly resulting from changes in the objectives of silvicultural concepts, might lead to conflicts and problems, which may possibly not be solved by conventional changes in work organisation strategies, such as outsourcing and mechanisation.

One way to counteract is to develop groups of forest workers into partially autonomous teams. It can be anticipated, that the implementation of teamwork in partially autonomous groups will lead to job enrichment and an increase of competence. Another

expected result of partially autonomous groups is that the employees develop a closer identification with the enterprise. This usually results in higher job satisfaction, which in turn promotes the achievement of the enterpriseïs objectives. Furthermore, a contribution to the improvement of the working conditions is to be expected.
Pilot projects have been initiated in order to implement partially autonomous groups in German forestry in a standardised way with external moderation, following a concept developed in Swedish forestry. Progress and outcome of these projects are subjects of an extensive research program. A group with five machine operators and supervising foresters has been evaluated. Their task is to perform mechanized harvesting with one harvester and one forwarder.

In this case it could be observed that the group members have experienced both job enlargement and job rotation. The supervisors suggest that yet further tasks could be delegated to the team, *e.g.* work place inspection and handing over the harvested timber to customers. By that, the supervisors can make better use of their own working capacity for planning and controlling. The group members have become fully aware of their big influence on and responsibility for their own working conditions. Among others this has increased the job satisfaction.

Exhaust gases in the forest are going to be a problem in technological transition

Marjan Lipoglavsek
University Ljubljana, Biotechnical Faculty, Departement for Forestry and Renewable Forest Resources, Vecna pot 83, SLO 1111 Ljubljana, Slovenia
Tel: +386-61-123-1161, FAX: +386 61 27 11 69, Email: lipo.marjan@uni-lj.si

Keywords: exhaust gas, CO measurement, chain saw, Slovenia, technological transition

In the past, no attention was dedicated to exhaust gases as a damaging health factor at forest work. Measurements of air concentration of toxic matters gave values under MAC (maximal allowed concentration). Nowadays the CO (carbon monoxide) measurements in the short time intervals prove that the concentrations in some conditions are above MAC during a large part of working time. Too high air concentrations of CO are present at tree felling, at delimbing conifers with large branches and at cutting in dense young forests.

In this paper some results of CO measurement at chain saw cutting on 11 working places in Slovenia are given. 8778 measured data or 24,3 hours were analysed. The widely used types of chain saws of the middle power class (mostly Husqvarna 254 and Jonsered 670) were investigated. The fuel mix of normal benzine and conventional (4-5%) or special (2%) two-cycle motor oil was used. Working operations: felling, limbing, crosscutting simultaneously with measuring lengths were made by chain saw.

The CO concentration near respiratory tract of forest worker with chain saw lies most of the time during chain saw operations under MAC of 30 ppm (0 - 15 ppm). But in short time intervals it can reach the peaks (10 second means) over 250 ppm. This occurs mostly during felling, when the workers posture is bend and his nose is near the chain saw. The duration of these peaks is short, the largest peak over 30 ppm lasted 6 minutes and 40 seconds. CO concentration lies over the MAC values up to 10 % of investigated time. It occurs more often in mature forest at big trees, where felling cut lasts longer. The calculated arithmetical means over the duration of the whole working operation with chain saw were between 5 and 53 ppm. in the whole working time on all working places the mean load was below 30 ppm, because the time share of chain saw operations was always relatively small (52 %). The measured time intervals above 30 ppm of CO occur at limbing (up to 90 ppm) and felling (over 120 ppm) only. Worker's daily CO loads (4 - 26 ppm) are lower than in other similar studies (Stampfer et a. 1997). They were at the vast majority of working places above 7,3 ppm (1/4 of MAC), and therefore measures must be taken to reduce it Investigations of other authors in Western Europe found similar results on peaks and working operations, but their peaks occurred more often, lasted in some cases over 50 % of working time and the calculated working time means were under 30 ppm MAC value too, but higher than in Slovenia. in the same time the measurements of CO blood satiation in Germany gave too high values.

The new studies found that HC (hydrocarbons: benzol, benzopyren et c.) cause different health damages, cancer included. This means that the old MAC for HC are not suitable anymore. The health damages from exhaust gases are important, where the chain saw is primarily used at cutting work. The forestry, the forest employers and above all the forest employees in the countries in transition are not yet ready to pay improvements that producers of chain saws and fuels can make to reduce exhaust gases health damage. Therefore, this is not a technical problem, but rather an economical one.

Comparison of vibrations transmitted to the operator by a saddle type suspension seat and an original seat in a forwarder

Dianne Staal Wästerlund, Tomas Nordfjell
Swedish University of Agricultural Sciences, Division of Forest Technology, Dept. of Silviculture, S - 901 83 Umea, Sweden
Tel: +46 - 90 786 58 00, FAX: +46 - 90 786 62 78, Email: Dianne.Wasterlund@ssko.slu.se

Ergonomically it is more desirable to drive a vehicle off-road in a standing position. Prolonged sitting leads to disruptions in the blood supply causing mineral losses in the bone tissue of the spine, disturbance in the nutrition supply to the intervertebral discs as well as muscle fatigue in the back. Besides a better blood flow, also the load on the discs is 20-40% lower in a standing position than in a sitting. An elevated seat is however required to relieve the strain on the legs. Exposure to whole body vibration may accelerate degeneration of discs and increase the risk for herniated discs. Situated on a normal seat, a machine operator has no choice but to absorb the vibrations transmitted by the seat. Situated on an elevated seat formed like a saddle the machine operator would have the opportunity to rise up while keeping balance with the legs and in such a way avoid exposure to the vibrations transmitted by the seat.

A comparative study was done between a prototype saddle seat and a traditional seat, each mounted on a identical suspension unit and with identical suspension settings. The seats were mounted on a VIMEK 606D forwarder which was driven by two test persons on a test track comprising of a series of even size concrete blocks placed at intervals of 0.8 m for the left wheels and 1.2 m for the right wheels. The forwarder was driven along the track with a speed of 0.35 m/s and 0.51 m/s.

Also the forwarder was driven off the end of a ramp which was 0.3 m high and 3.4 m long at a speed of 0.51 m/s. Acceleration at the floor and seat was measured according to ISO standard 2631. To determine absorbed energy, force and acceleration at the seat as well as beneath the feet were measured with a force plate, build by the department of technical hygiene, national institute of working life, Sweden.

The results of the driving tests along the test track showed that according to ISO 2631 health and comfort evaluation the saddle seat showed significant lower root mean square acceleration levels while the vibration dose values showed no difference. Also a non-significant reduction of absorbed energy was found with the saddle seat. When the forwarder was driven off the ramp both test persons experienced end-stop impacts in all three trials with the traditional seat. With the saddle seat only one end-stop impact occurred for one test subject. End-stop impact occurs when the suspension system of the seat reaches it's maximal comprised level which exposes the driver to very high acceleration levels and is therefore accepted as a health risk.

3.08.00 Small-scale forestry

Twenty years of experience with a cost accountancy network in Farm Forest Enterprises in Baden-Württemberg

Helmut Brandl
Forstliche Versuchsanstalt, Abteilung Betriebswirtschaft, Wonnhalde 4, 79100 Freiburg, Germany
Tel: 0761-4018 262, FAX: +49 761 4018 333, Email: brandl@fva.bwl.de

The paper contents two main parts. in the first part a comparison is made between the requirements for establishing and running a cost accountancy network according to the "Guidelines for establishing farm forestry accountancy networks" (draft, European Forest Institute, 2000) and the facts which happen when establishing and running such a network in the practice. The necessities for a correct and scientific appropriate outline of a network are confronted with the constraints and difficulties when going on work with the forest owners.

In the second part the main results of a 20 year running economic survey with an accountancy network in Baden-Württemberg with more than 170 participants are presented. This overview will show the key figures about profitability, costs, expenditures and revenues in graphs and tables for the years 1979-1998. This case study shows the advantages of long-term data for analysing the socio-economic situation of farm forests. Also the possibilities for differentiation by regions and size-classes are mentioned. Some comparisons with economic results in other types of ownership's complete this part.

Advantages by integrating small-scale forestry and local wood manufacturing

Lennart Eriksson, Ager, B
Swedish University of Agricultural Sciences, Department of Forest Management and Products, Sweden
FAX: 4618673522, Email: lennart.eriksson@sims.slu.se

It is found that small-scale forestry has remarkable advantages compared with large-scale company forestry when a large share of the total revenue is produced as timber of high value. Low indirect costs of equipment used by self-active forest owners give the opportunity to perform thinning operations repeatedly in the same stand. The consequence is that the trees may be cut when they have reached an economically matured status, in other words when the wood characteristics of the trees to be cut will give the best profit in monetary terms.

New studies show that also stands under establishment can be treated to produce timber of high value more efficiently by means of equipment and methods used in the small-scale forestry. Dense stands, naturally regenerated and completed by plantation if necessary, should be kept dense up to a height of 6 to 8 metres. After that, the number of stems should be reduced markedly by means of one or more pre-commercial thinnings. The stand will then deliver timber of high value in a number of thinning cuts "from above". Stands planted in relatively dense spaces (1.5 - 2.5 m) without remarkably high numbers of natural regenerated plants can with advantage be pruned followed by a cut programme similar to that of the naturally regenerated and pre-commercially thinned stand above. Stands with larger spacing (>2.5m) are, owing to a high pruning cost per tree and a long period of healing over, not suitable for production of wood of high value. The most efficient cut programme consists in this case of one or two thinnings from above and an early final cut.

The treatment programmes mentioned require a planning system that discovers the opportunities to use the efficient production alternatives. Since the forest status varies frequently, even within the traditional compartments (treatment units) of a forest estate, the possibility of the technical logging system to vary the treatment gives remarkable increase of the profit in terms of capital value of the forest. Many opportunities to cut trees in thinning give possibilities to perform the treatment programmes, which most efficiently harvest the given trees in different stands at an economically matured status.

The capability of small-scale forestry to deliver selected high value timber in a long and short time perspective can be used advantageously by local wood manufacturing industry. The technical development of equipment to saw, dry, plane, finger join and glue wood has given possibilities to produce advanced forest products efficiently in small-scale wood manufacturing. Advanced vertical integration of the production chain from the forest to the customer, including efficient logistics, is a promising way to increase the competitive strength of the small enterprises. Networks of horizontally integrated wood manufacturing industries is another way to increase competitiveness of local forest based industry, increasingly applied in Sweden today.

Summary of Small-Scale Enterprises in the Forestry Sector in Finland

Pertti Harstela, Katja Turunen, K. Kärhä
University of Joensuu, Faculty of Forestry, Post Box # 111, FIN-80101 Joensuu, Finland
Tel: +358-13-2513625, FAX: +358-13-2513590, Email: pertti.harstela@joensuu.fi

Keywords: Small-scale enterprise, forestry, strategy of enterprise, competitiveness, innovation.

Small enterprises may have an important role in supporting local development in rural areas and also in improving employment. A literature analysis and some questionnaire studies were made in order to find out the prerequisites for small enterprises to compete in the forestry sector as well as to find means to promote the establishment of new enterprises.

The main strategic groups of small enterprises appear to be:
(1) Entrepreneurs in operations which big forest companies desire to direct to smaller contractors.
(2) Enterprises in areas which big companies want to externalise.
(3) Enterprises providing products or services to limited local markets.
(4) Enterprises working with special products, customer-oriented activities or flexible way of production.
(5) Enterprises opening services outside the traditional forestry, *e.g.* nature tourism and memorable experience production.
(6) Enterprises having products with special quality or narrow special knowledge.
(7) Enterprises established to utilise a new innovation. These are, such as, small forest machine or tool manufacturers, measurement equipment manufacturers and computerised system designers.

The first two categories are a necessity for big companies and these enterprises are established without any external support. For developing countries the fifth category may be very interest, whereas the last one is perhaps the most interesting for post industrialised countries. "Innovation is often a new enterprise." thus, real innovations are important, however, innovative working methods also seem be important means in competing in all the above-mentioned groups.

Our theoretical conclusions were that all eight factors (focusing, differentiation, custom-orientation, quality, knowledge, innovative acting, cost-effectiveness and enterprise networks) are highly important in competition. When small tree nurseries and enterprises of graduated foresters were studied, it was found that innovative working methods were in the highest category in all highly profitable enterprises. Some of these working methods are connected to external relations of an enterprise (networks, patents or invincible expertise), while other are internal (innovative acting, cost-effectiveness, high quality and customer-orientation) and some strategic. The best enterprises are good in all these internal dimensions working innovatively. We also designed a theory on how special knowledge gained from a good experience or a high level education may lead to an innovation, and how applying the innovation in production process can lead to a new level of knowledge within the industrial sector in question.

Enhancing the economic decision-making of non-industrial forest (NIPF) owners

Markku Penttinen, Anssi Niskanen, Esa Uotila, Sami Veijalainen, Jukka Aarnio and Jussi Leppänen
Finnish Forest Research Institute, Helsinki Research Centre, Unioninkatu 40 A, FIN-00170 Helsinki, Finland

Keywords: forest management planning, management accounting, ratio analysis, cost accounting, non-industrial private forestry

This paper considers the Finnish experiences in developing special accounting measures for monitoring the socio-economic performance of the non-industrial private forests (NIPFs). These measures improve and combine management accounting and forest management practices based on the relevant forest inventory and book-keeping data, enabling NIPF owners to cope with the economic challenges posed by their holdings. Management accounting, ratio analysis and cost accounting in particular, is utilised in developing and extending accounting practices to cover non-accounting items such as growing stock. The result can also be seen as an improvement and extension of forest management planning.

The theoretical background of several research projects has been synthesised and tailored to yield management accounting systems for non-industrial private (NIP) forestry. Empirical evidence has been widely and systematically employed in developing the management methodology for forestry and in applying statistical methods to testing hypotheses and constructing invariances. The data employed include:

(i) Aggregate regional data: The Finnish Forest Research Institute (FFRI) and the Forestry Development Centre Tapio have collected regional income and cost information on NIP forestry for 30 years.

(ii) The agricultural enterprise and income statistics (AEIS): The agricultural enterprise and income statistics (AEIS) of Statistics Finland is based on enterprise-level forest tax revenue information. The most interesting part of the AIES includes farms which have chosen the new forest taxation based on sales profit in the tax reform of 1.1.1993. The data analysed by the FFRI contains about 5000 observations.

(iii) Farm Accountancy Data Network (FADN): The book-keeping data on nearly 1000 farms from 1976 has been collected in the supervision of the Agricultural Economic Research Institute (MTTL). in addition to agricultural information, this data includes cash-based forestry accounting, which has been improved in accuracy in recent years as a result of scientific cooperation between agricultural and forestry researchers.

(iv) Jointly owned forests (JOFs). The book-keeping, income statements and balance sheets, and forest management plans of 139 JOFs have been analysed as a sample of forestry bookkeeping carried out according to the accounting law. Most of the JOF areas are located in the northern parts of Finland. The profitability of JOFs has already been studied at the FFRI for 10 years.

(v) Case data: "The profitability of NIP forestry" -project collected very detailed test book-keeping data of some 70 woodlots, suited to developing and testing methods of NIPF book-keeping and cost accounting.

(vi) Long term book-keeping woodlots: The FFRI has collected long term NIPF book-keeping records, voluntarily and independently by forest owners, for testing profitability and ratio analysis. At the moment there are records of about 20 case woodlots for periods of minimum 15 and even 45 years records. The data also embraced information concerning the forest management plans and standing timber.

Help for Forest Management Planning: Presentation of a Computerized Model for Private Forest Owners

Olivier Picard
IDF Toulouse, Maison de la Forêt, 7 Chemin de la Lacade, F-31320 Auzeville, France
FAX: 0033 5 61 75 45 09, Email: olivier.picard@wanadoo.fr

This survey is aimed at contributing to thoughts at aiding forest owners to make a decision. It was a matter of specifying which kinds of tools it would be useful to set up to help forest management. The survey covered the strategic aspects of decision that forest owners find themselves faced with. It appears that "classical" economic calculations such as the Current Net Value and the Internal Rate of Profitability, are seldom used to help make an investment decision. Is this because the updating calculations over a period of 30 to 40 years are "not relevant", or does it come from the comparison between different investments ranging further than a generation or, the lack of tools adapted to owner's needs ? The method adopted was to, firstly, define the representative framework of management practices. This was carried out by individual interviews and the main conclusions were shared alternately. Through this survey, management schemes, thoughts about strategic /risk relationships and expectations about decision aid tools have been defined.

The analysis is built around three levels of decisions:

- the strategic level of going from the initial state to the final state in the long term (10 to 30 years).

- the tactical level of being in charge of the management over 3 to 5 years (adapting to changes, markets, new constraints or opportunities)

- annual management follow-up.

Forestry management oscillates between financial and proprietary logic. From self-financing and annual revenue and expenditure balances, the permanent assessment of the stock value and proprietary value, up to a naturalistic logic combined with the search for a revenue/expenditure balance.

Criteria retained in the decision aid tool are quantified and qualified and easily used by forest owners. We have therefore retained three criteria, i.e. money, wood and working time. The indicator retained for each is the flow created.

What is this tool for?

Forecast revenue research, human resource planning, memorising work with a view to succession, justifying the administrator's choices.

Computing, and particularly a data base structure is the solution to process the large amount of data and to structure it according to management targets (regular income, forest value, forest transmission, optimal development of the biological potential), and combined with a cartographic base, the organization of work on the property can be displayed.

Possible outputs can be data files used by forestry co-operatives to programme their wood supplies efficiently. This level optimizes forestry management and wood production by putting them in contact.

3.09.00 Economics and harvesting of thinning

Transition of the residual stand damage after a line thinning operation

Masahiro Iwaoka, Kazuhiro Aruga, Hiroshi Kobayashi, and Siaw Onwona-Agyeman
Tokyo University of Agriculture and Technology, Faculty of Agriculture,
3-5-8 Saiwai-cho, Fuchu-shi, 183-8509 Tokyo, Japan
Tel: +81-42-367-5880, FAX: +81-42-364-7812, Email: iwaoka@cc.tuat.ac.jp

In recent years, the use of large-scale forest machines such as harvesters and forwarders are gradually gaining popularity in Japan. However, most of the plantations were established at a time where the use of such machines was not originally thought of. The introduction of large-scale machines is therefore likely to increase damage to residual stand. in this paper, a report on the transition of the residual stand damage caused by a line thinning operation with a tracked excavator based harvester and a rubber tracked forwarder after five years is presented. The observations revealed that injuries, which were not so severe, did not impair the growth of the trees but light injuries such as those inflicted on outer or inner bark, became more severe like a sapwood injuries. These results showed that injured trees are likely to become weaker to the extent that the injuries could easily become severe even if they are originally very light. The importance of carefully carrying out thinning operations so as to minimize the damage to residual trees were confirmed by this research.

Keywords: Transition, residual stand, damage, tracked harvester, rubber tracked forwarder.

Productivity and costs of group work for harvesting mountainous broadleaf thinning stands

Ante P. B. Krpan, Zeljko Zecic, Marijan Susnjar
Faculty of Forestry Zagreb, Department of Forest Harvesting, Svetosimunska 25, 10 000 Zagreb, Croatia
Email: ante.krpan@zg.tel.hr

Group work was researched for felling, processing, skidding and quality inspection activities in mountainous broadleaf thinning stands with approximately the same terrain and stand conditions. The stands were 55 and 70 years old. in the forest communities of the mountainous beech forest with dead nettle (*Lamio orvale - Fagetum sylvaticae*/Ht. 1938) and the forests of the sessile oak and horn beam with beech (*Epimedio* - Car*Pinetum betuli* var. *Fagus sylvatica*/Ht. 1938/Borth.1963) the main tree species are beech and sessile oak with the addition of other broadleaf species.

Productivity was examined on two groups. The first comprised of five workers (A) and the second of four workers (B). The first group was equipped with two tractors and three chain saws while the second used two tractors and two chain saws as well as other necessary equipment. The effective time for the cutters in felling ranged from 36 to 42.9%, in finishing and measurement 21%, while the effective time for the tractors ranged from 42.4 to 59%. The effective time per tree ranged from 3.62 to 3.77 minutes, i.e. per unit it ranged from 8.46 min/m^3 to 12.91 min/m^3. The daily output achieved by the Ecotrac and Torpedo tractors at a distance of 300 meters was for group A 20.77 m^3/day while the optimised output was 67.02 m^3/day. The output achieved by both tractors in group B was 17.25 m^3/day while the optimised was 30.72 m^3/day. The average performance per worker in group A was 4.15. m^3/day while the optimised was 8.38 m^3/day. For group B the average performance per worker was 4.31. m^3/day and the optimised was 7.68 m^3/day. The optimisation of the groups lowered the unit cost of production (300 m distance) for group A from 39.63 DM/m^3 to 17.49 DM/m^3 and for group B from 40.38 DM/m^3 to 22.73.DM/m^3.

Keywords: group work, thinings, time study, productivity, costs

Environmental Damage Control by Information System for Harvesting Vehicles

Toshio Nitami
University Forest in Chichibu, University of Tokyo, Hinoda 1-1-49, 368-0034 Chichibu, Saitama, Japan
FAX: +81-494-22-0272, Email: nitami@uf.a.u-tokyo.ac.jp

Forest stands are easily hurt and disturbed by vehicles through timber harvesting operations in the natural forest management system. Many standing trees are scratched and hit which leads to degrade storage quality and succeeding small trees are lost which leads to make severe to reforestation. Smart control for harvesting vehicles shorten the skidding paths length between landing sites and timber choking points by suppressing branching out of skidding paths. Number of damaged standing trees and the percentage of diminished succeeding small trees are mainly affected by run-about of skidding vehicles. On the gentle slope and steep terrain, many succeeding trees disappeared. The clear deference was found on the diminished percentage of number of small trees less than 6 cm in DBH. Easy to run-about for the skidder would be the reason for the former and easy to slip downward on terrain slope for timber being skidded would be the reason for the latter. An information system to show the skidder operator favorable paths from a landing to loading points was discussed to reduce excessive run-about of vehicle in the stand.

Field trial for the discussion has been conducting for about forty years in university forest in Hokkaido, University of Tokyo, through its stand based natural forest management experiment. A feller-buncher or a felling staff with GPS device collects GIS datum and they are compiled immediately into a database on a PC in the field or on a PC connected by network. Manual data collection simultaneous for the felling, would be useful even if machine operation is not introduced into the process. This real time GIS system informs the skidder on the location and advancing direction. The information would be transmitted to the skidders through field LAN with radio communication.

The site disturbance would be reduced through shortening total length of skidding paths to the half when branching ratio of skidding paths decreased from 3.5, which was on the field operation trial, to 3.0. The branching ratio was based on the stream system ordering by assuming skidding paths from choking points to landings to the ground water stream system from the source to the mouse.

The path length would especially expected to be short at the gentle slope sites through decreasing dozing frequency for rebunching timber in order to set timbers easy for choking.

The operational damages through the information utilizing system, Real Time GIS, would be at least the half of that of the conventional operation system. The importance and need for control of vehicles operating in the forest stands could be confirmed. Validity of the information system was confirmed on the forest harvesting operation for conservation of forest environment. The information system for this operation control also enables timber assortment design at landings, and affords design for natural forest management with higher accuracy accompanied with stand geographical information.

Damage to Residual Stands from Thinning with Short-span Tower Yarders: Re-examination of Wounds after Five Years

Yasushi Suzuki
Kochi University, Faculty of Agriculture, 200 Monobe-otsu, Nankoku-shi, 783-8502 Kochi, Japan
Tel: +81-88-864-5137, FAX: +81 888 64 5200, Email: suzuki@fs.kochi-u.ac.jp

Keywords: Logging, Residual stand damage, Thinning, Transition of wounds, Wounded wood section.

Residual stand damage from thinning is one of the most important problems in the current Japanese forestry. The reason can be explained as the following three points. (1) Thinning rather than clear-cut is preferable cutting method from both environmental concern and forest management. (2) Mechanized thinning, which has been used in the present decade, often causes damage to residual stands of dense man-made forest managed under traditional procedures of Japanese forestry. (3) Japanese timber market requires higher quality for domestic logs in contrast to imported logs.

There are three main subjects on residual stand damage. The first subject is on logging technique by which the residual trees are damaged. The second and the third are on growth and quality of residual trees, respectively. Wounds on damaged trees may reduce their expected growth after the thinning. Wounded sections of damaged trees may develop stain or decay in the wood section and degrade their market value as saw timber. The present study focuses on the last point: transition of wounded sections of damaged trees.

The author investigated wounds of residual trees and compared their current status with the status of five years ago when the stands were thinned. Five plots were established in a typical man-made forest of Japanese cedar (*Sugi*; *Cryptomeria japonica*). A short-span tower yarder logged the plots in 1994 through 1996. This report describes the result of the year 1999 investigation on two of the five plots that were thinned in 1994. The other three plots will be investigated in 2000 and 2001.

The investigated two plots are 0.3 ha in area and had 85 damaged trees. On the damaged trees there were 225 wounds in total. Status of the wounds was defined as four levels of severity that are defined from their appearance. Dimensions and severity levels of the wounds at the time of 1999 were examined and compared with those of 1994. Ten damaged trees were selected for inspection of wounded wood section. The selection was made concerning the distribution of severity levels as well as management plan of the forest. Wounded sections of the sample trees were cut and corresponding disks were obtained for detailed inspection of wound area.

Most of the wounds with lighter severity level have already healed by occlusion or disappeared. Heavily damaged but now healed wounds are smaller in horizontal dimension. Lightly damaged but now badly developed wounds are smaller in vertical dimension. Inspection of wound sections revealed that most wounds developed discolored area in the wood. Only the lighter wounds that had healed earlier have no or smaller discolored areas. Discolored areas of the wounds with still exposed cambium have larger widths than the original wound widths. As a conclusion, horizontal dimension or width, rather than vertical dimension or length, of wounded area significantly affects healing or occlusion of wounds.

3.10.00 Harvesting, wood delivery and utilisation 1+2

Cut-To-Length Logging Systems of Tomorrow

Sten Gellerstedt
Faculty of Forestry, Swedish University of Agricultural Sciences, Department of Forest Management and Products, Box 7060, SE 750 07 Uppsala, Sweden
Tel: 46 18 673818, FAX: 46 18 673800, Email: Sten.Gellerstedt@sh.slu.se

This article discusses the potential development of a logging system in which logs are made at the stump from a harvester, and carried to the landing by a forwarder. The focus is on Sweden, but the proposal has international out-looks. Trends in logging over the past decade are described, and used to envision the next decade. in the analysis, I consider wood markets, the call for sustainable forest management, safety and health, system produc-tivity and utilization, as well as operational organization, operator education, and technical development. Three mechanized logging methods are compared, as well as three different forest-worker education systems. Possibilities exist for using advanced electrohydraulics, and GPS/GIS. I also include a discussion about the trend toward purpose-built harvesters.

The use of cut-to-length logging will in-crease worldwide, especially in central Europe. Hindrances that are found when introducing cut-to-length systems include operator education, work crew organization, supply of maintenance service, and capital that is bound in other logging systems. Future cost reductions can probably be achieved through more-precisely planned and completed logging operations. This will require motivation by the work force. A crucial element will be to invest in building mutual trust between all parties concerned.

Keywords: ergonomics; forest machine; future; logging method; maintenance; operator education.

A state-of-knowledge report on harvesting, tree processing, and product quality

Daniel Guimier, Loren Kellogg
Forest Engineering Research Institute of Canada, 580 Boul. St. Jean, H9R 3J9 Pointe Claire, Qc, Canada
Tel: 514-694-1140, FAX: 514-694-4351, Email: daniel-g@mtl.feric.ca

This paper identifies key scientific, technical, and social issues relevant to harvesting, tree processing, and product quality. Here, we portray the present state of knowledge relative to each of these issues. Based on a survey of world experts on the various topics, and on the authors' own experiences, the paper highlights what we currently know and what issues are not fully understood from the point of view of scientific research. in some cases, technical solutions may not exist and, therefore, will warrant additional research or development.

The scope of this paper is narrowly defined to address issues that are directly part of the Research Group 3.10.00 mandate. Specifically, we cover technical and operational aspects related to the harvesting and processing of trees, primarily in non-mountainous terrain. Our discussion deals with operational considerations, environmental issues, productivity and cost, machine design, and wood product quality.

Within the above-defined scope, the report sets out to answer the following questions:

- What are the key scientific and technical issues?

- What do we know and what warrants additional research?

On the issue of equipment productivity and the cost of operations, we identified gaps in the modeling of equipment operating under a wide variety of conditions, and in the understanding of the operator's impact on productivity. Our review also uncovered a number of gaps in the technology used in existing equipment; technologies such as traction systems, controls, hydraulics, and vision

require refinement or adaptation to become more useful for the forestry machines of tomorrow. Wood product quality must also be optimized; understanding the interrelationship between wood cost and wood value is a research area that receives and warrants significant attention. 'Social issues in forestry' is another area identified as critical and in need of additional attention.

This broad review of the state of knowledge relating to harvesting, tree processing, and product quality has uncovered a large number of areas that require more science, more technology, and, therefore, more R&D. in general, we conclude that, whereas the basic functions are generally understood, the main gaps usually lie in understanding how one function affects other functions and the overall system. Many research groups now strive toward modeling whole systems and obtaining a clear vision of the overall picture.

Use of Information Technology (IT) to Improve Wood-supply Chains in German Forest and Wood industries

Markus Hecker
University of Freiburg, Forest Products Laboratory, Werderring 6, D - 79085 Freiburg, Germany
Tel: +49-761-203-3764, FAX: +49-761-203-3763, Email: fobawi@ruf.uni-freiburg.de

Forest industries in Central Europe and, especially, in Germany are now at a disadvantage on the international timber market. Very traditional customs and structures, such as motor-manual harvesting systems and tree-length logging, are still most common, but the random-length logs they produce cannot be used without further manipulation. Although the point of sale between forestry and woodworking industries is at the roadside, customer demands necessitate the implementation of a complete wood-supply chain.

In contrast to practices in Sweden and Finland, modern logistic concepts and harvesting technologies currently are not applied here. Mechanized harvesting systems, however, are now used more frequently, particularly to reduce the harvesting costs incurred by early thinnings in younger stands. Because technology recently has been further developed, harvesters can also operate in older stands and on steep terrain. Improvements in production and marketing systems are necessary to capitalize on the benefits gained with this newly-mechanized harvesting.

The main part of this paper is a comprehensive presentation of the necessary improvements being made within the wood-supply chain, as it is conducted under German conditions. Objectives of this on-going investigation are to develop routines for expediting the flow of materials, to apply new techniques for simplifying and reducing transportation, and to improve communication among market partners by providing modern IT tools. A review of the potential for further rationalization of harvesting operations also is provided.

Field trials and studies of raw-material flow in sawmills showed that using the bucking-to-order or bucking-to-value algorithms available from the onboard computers in harvesters provided significant economic benefits. Similar calculations were also made for added values along the wood-supply chain, as derived from the application of newly developed transportation systems. A new communication network has been organized to improve information exchange between market partners; its structure and advantages are discussed here. Applications are envisioned for using Internet websites for marketing purposes.

Study results also are discussed. in addition to drawing some final conclusions, the importance of appropriate education programs is deduced from the personal challenge of modern IT applications.

Keywords: added values; information technology; mechanized harvesting; transportation; wood-supply chain.

Harvesting and the Economics of Thinning: A State-of-Knowledge Report

Pieter D. Kofman
Danish Forest and Landscape Research Institute, Kvak Moellevej 31, DK 7100 Vejle, Denmark
Tel: +45 75 88 22 11, FAX: +45 75 88 20 85, Email: PDK@FSL.DK

The practice of thinning is necessary for timber stand improvements such as concentrating the annual growth increment in fewer trees but of better quality. in addition, thinning may help prevent wind throw, forest fires, insect damage, etc. However, thinning is increasingly difficult to carry out because of high labor costs and the low prices received for small assortments. Large fluctuations in assortment price nearly prohibit long-term planning.

New technologies, e.g., multiple tree handling, computers, and central tire inflation, may possibly reduce the costs of thinning. Even more important than during ordinary harvesting are the links in the forestry wood chain, which operate together to improve quality and reduce costs. These can be accomplished by improving the logistics of all the related operations.

Although research is still focused on finding more rational ways to harvest and transport wood, attention should be increased on combining silvicultural and operational research to make stands more easily harvested. Many of these issues will be addressed at the next meeting of 3.09.00, to be held in Canada in September 2001.

Keywords: forest wood chain; mechanization; motor-manual operation; new-product development; thinning costs

Future Scenarios for Wood Procurement

Timo Antero Leinonen
Mikkeli polytechnic, School of Forestry, Metsäopistontie 100, FIN-76100 Pieksämäki, Finland
Tel: + 358 40 5266834, FAX: +358 15 7861450, Email: timo.leinonen@nikkarila.pieksamaki.fi

Forestry work has changed rapidly during the last decades. Some problems have also arisen; for example, loggers have become unemployed while, at the same time, there has been a lack of professional harvester operators. Whenever a long-term investment is made - whether in industrial plant, machinery, or education - reliable knowledge about the future is always valuable. A decision made today has later consequences. Forecasting over a limited time period is specific to each branch of human activity, and can vary from days to decades. The period used for future studies is

considerably longer than that for conventional forecasting.

The aim of this study was to analyse the changes in wood procurement until 2030, using future-study methods. The scope of the study was forest industry, wood-based energy production, exports and imports of round wood, and international investments. Scenario methods were applied here. These methods were based on the presumption that no single predictable future existed, but a number of futures were possible. Decisions made today impact the future. The objective was to collect, analyse, and present, in written form, the knowledge of experts in forest technology. The results did not conflict with the principles of forest-related scenarios created by other scientists. Such factors as globalization, energy production, nature conservation, and employment will affect forestry and wood procurement in the future.

Delphi is a commonly used method for future studies. The base material for Delphi was collected in a seminar and through thematic interviews. Answers in this study were completely anonymous. People involved in the study were not able to associate an answer with any particular person. The five scenarios were described in written form, and the collected data enabled many more scenarios to be devised. This method traditionally begins with three to six scenarios, which are supposed to cover the possible futures from negative to positive. The five final scenarios used here were 1) Junkyard, 2) Low price, 3) Single-grip harvester and forwarder, 4) Terminals, and 5) Advanced Cut-To-Length.

The most important resource is not a natural resource like forests, but a human resource such as knowledge. Natural resources, e.g., the amount of area covered by forest, are restricted by physical factors. The degree of utilization and the value of products may be increased by using human resources. This improves employment rates and standards of living. in Finland, knowledge is vital concerning forests, forestry practices, and wood procurement and processing. The deepest possible crisis results when forest-related knowledge vanishes.

Keywords: future studies, scenarios, wood procurement.

The Implementation of Bucking-to-Order Harvesting Systems in Germany - Risks and Limits of Advanced Harvesting Techniques

Johannes Ressmann
University Freiburg, Forest Products Laboratory, Werderring 6, D - 79085 Freiburg, Germany
Tel: +49761 2039242, FAX: +761 2033763, Email: fobawi@ruf.uni-freiburg.de

Because of relatively high timber prices, the German forestry industry has not been forced to rationalize logging operations as much as was necessary in Scandinavia. Motor-manual harvesting systems and the production of tree-length roundwood were and are still most common. Harvester technology was established in Germany following heavy storms in 1990 that blew down entire forests.

However, these harvesters cut only two or three different lengths of sawlogs and a pulpwood assortment, on a schematic basis. Except for a minimum specified diameter, crosscutting is done independent of any particular top diameter. This production of roundwood does not fit the demands of specialized sawmills for well-defined ratios of log length and top diameter.

The onboard computers of modern harvesters can optimize the bucking of stems to achieve maximum value or fulfill a sawmillïs demand list. With support from the State Forest Service, harvesting contractors, and some sawmills, the Institute of Forest Utilisation and Work Science has conducted a two-year investigation of when and how a bucking-to-order harvesting system could be applied under German forestry conditions. During this time, order lists for typical sawmills have been created. in several field trials, we compared the accuracy of measurements by harvesters as well as the success in distributing logs (characterized by their length and top diameter) to fulfill the sawmillïs demand list. We used simulation routines to analyze the monetary benefit of this new system versus that associated with standard bucking.

In most cases, our accuracy of measurement was high under test conditions. However, general guidelines for calibration are necessary at the national level. Mill requirements for raw material can be formulated in price and demand lists. Following these lists in typical stands can change the total volume and revenue that can be realized. Total revenue can vary by about 10% when different bucking instructions are used, which can significantly affect the financial results of forest enterprises. Therefore, the use of simulation tools will become more important in pre-harvest planning.

Although the concept of virtual organization and operation is still far into the future, forest enterprises and the sawing industry can profit from the advanced cut-to-length systems already in place. Improving the general harvesting and processing conditions will be necessary to permit practical implementation of this technique. Maintaining a permanent supply of raw material to the sawmill could cause further problems. To totally optimize this complex system, an on-line data link between the harvesters would be helpful. An integrated optimization program could constantly control the processing status and adjust the entire chain of production. International competition for timber markets also will force the German forest industry to rationalize the wood-supply chain. Our proposed advances in the shortwood system could be one part of the possible solution.

U. S. Forest Engineering and Operations Research and Education in the Future

Bryce J. Stokes, Joseph McNeel and Richard Brinker

Tel: +1-202-205-1147, FAX: +1-202-205-2497, Email: bstokes@fs.fed.us

Forest engineering and forest operations have provided the ways and means of utilizing a great natural resource for the control and benefit of mankind. The discipline has been critical to the development of our resources, and will continue to play an important, if not pivotal, role in both the consumption and conservation of our forests. Research and education in this discipline provide scientifically-based methods for managing our forest resources wisely and effectively. Trained professionals apply science and new technologies in a changing world to ensure sustainability. This requires that innovative techniques and advance technologies be discovered and applied in road building, operations planning, road-layout design, harvesting, and regeneration. More will be demanded from the forest operations researcher, educator, specialist, and practitioner in forest resource management during the 21st century.

This paper provides a brief history of forest engineering and operations, and describes how this discipline and profession continue to meet challenges in timber production, conservation, and social forestry. We also explore programs for education and application of forest-engineering principles. Funding sources and specific research goals have changed as personnel prepare for the future. The profession of forest engineering and operations will market what it does best, while integrating with other professions to resolve critical challenges, and providing the leadership necessary for sustainable forest management in the 21st century.

The Dynamic Analysis of Soil Deformation Caused by a Semi-legged Vehicle

Kazuhiro Aruga, Masahiro Iwaoka, Hideo Sakai and Hiroshi Kobayashi
University of Tokyo, Graduate School of Agricultural and Life Sciences
1-1-1 Yayoi Bunkyo-ku, 113-8657 Tokyo, Japan
FAX: +81-3-5800-6994, Email: aruga@fr.a.u-toyo.ac.jp

Keywords: extended distinct element method; soil deformation; reaction force of soil; pantographic leg; semi-legged vehicle

A semi-legged vehicle that has two front stabilizer legs with pads, two rear legs with wheels and a hydraulic boom for working implements and for moving the machine, has been studied for use in forest operations on steep and difficult sites. The hydraulic boom is lowered to the ground and the stabilizers are raised so that the machine rests on only the boom and the rear wheels and moves by applying hydraulic power to the boom. If these wheels are free-rolling and receive no driving power, great forces act on the boom. The machine sometimes has difficulty in moving on soft soils because the boom sinks into the ground. The machine needs to be improved to reduce the holes dug by the boom. Soil deformation caused by the machine was analyzed by EDEM (Extended Distinct Element Method).

FEM (Finite Element Method) has been applied to analyze soil stress and strain. Soil deformation caused by the machine can not be analyzed by FEM because of the shear band and high degree of material movement. in this study, EDEM was introduced. EDEM can analyze uncontinuous materials as it represents soil as independent particles. EDEM can also analyze continuous materials by introducing pore-springs to represent surrounding fill materials. Based on Newton's law, independent equations of motion for each element are established. A Voigt-type dynamic model of the contact point is created and is composed of an

elastic spring and a dashpot. By solving all equations of motion progressively, the motion of elements in the time domain can be followed.

In this method, soil strength was mainly decided by the spring constants and the coefficient of rolling friction. The spring constants were decided by simple shear tests or triaxial compression tests. The coefficients of rolling friction were decided by experiments with soils and a pantographic leg. The forces reacting on the leg were measured while the leg was moved in soils. in this simulation, the coefficient of rolling friction was determined by trial and error. As for the effect of compaction in soft and hard soil, the difference in reaction forces could be expressed. Phenomena such as soil particles not falling into the holes dug by the leg could also be expressed, when the proper criteria were set up in the simulations.

External forces acting on the machine were gravity and the forces reacting on wheels and the boom. in this study, only the forces reacting on the boom were calculated by EDEM. Motion such as lowering the boom to the ground, raising the stabilizers, advancing the machine and soil deformation could be expressed. The effect of the area of the foot was simulated. When the machine with a larger foot area moved on soft soil, the step became longer and energy efficiency became higher. On the other hand, the step scarcely increased and energy efficiency became lower on hard soil because the reaction forces of soil increased.

Mitigating Forest Site Impacts -Role of Woody Biomass and Root Mass Decomposition

Marilyn A. Buford, Bryce J. Stokes
USDA Forest Service, Vegetation Management and Protection Research
Post Box # 96090, DC 20090-6090 Washington, USA
Tel: +1-202-205-1561, FAX: +1-202-205-2497, Email: mbuford@fs.fed.us

Keywords: site restoration; impact mitigation; carbon sequestration; mulching; soil carbon

Many forest sites are depleted and have limited amounts of soil organic matter, nutrient pools, and carbon capacity. Over many rotations, forest operations contribute to soil impacts by changing soil structure and removing above- and below-ground woody biomass. Limited research has been conducted on understanding the role of biomass in below-ground processes, especially decomposition rates for buried/incorporated woody biomass and root masses. Little is understood about the effects of incorporating carbon on soil carbon availability, carbon retention, and ultimately, nutrient cycles as a way to mitigate forest soil impacts. Little, if any, work has been completed on understanding and optimizing woody biomass form and composition to lengthen carbon sequestration periods, increase soil organic matter, and/or restore and improve site quality.

A potentially effective means of increasing and stabilizing carbon in forest soils is through incorporation of biomass as a forest operational treatment. Mulching and rotor-tilling are methods that have been evaluated for incorporating logging slash and residual vegetation into the soil -- practices with potential for site conversion, fuel load reduction, restoring degraded soils, and enhancing productivity. Direct burial of biomass may offer carbon sequestration potential and long-term site quality enhancement. A synthesis of information on operational aspects of below-ground incorporation of buried/incorporated woody biomass is presented as are research needs pertinent to understanding and managing the potential for woody biomass incorporation to mitigate forest soil impacts.

Tree root development in compacted soils due to logging operations

Robert Robek, Hojka Kraigher, Bostjan Kosir
Slovenian forestry institute, Vecna pot 2, 1000 Ljubljana, Slovenia
FAX: 386 61 273589, Email: robert.robek@gozdis.si

Introduction

In the investigations of the environmental stress caused by logging operations we often lack the parameters for alteration detection and judgements. in study the authors have analysed the tree root length structure and small root biomass structure as indicators for stress situations caused by soil compaction.

Material and methods:

Two studies were conducted: pot experiment in nursery and skidder compaction field trial. in pot experiment the four year spruce (*Picea abies* (L.) Karst.) seedlings from nursery were assigned to one of the following treatments: field control, pot control and compacted pot. Roots were washed free of media, scanned and replanted. Field control samples were planted back into the field in nursery. Pot control samples were planted into the homogenised soil from nursery in tin pots and grown in controlled conditions. Compacted pot samples were planted into tin pots like control samples but the soil surface was compacted with 100 kPa and later on treated like pot control samples. After one year the samples were dug out again and the root systems were analysed using manual and computer assisted procedures.

In the second study the unloaded hydrostatic driven skidder Woody 110 (Perkins engine 76.5 kW, mass 5.5 t; 5.3 m x 2.1 m with 500 mm standard tyres) performed 10 passes on the undisturbed brown forest soils at the soil moisture near field capacity. Before and after traffic the cylinder cores at 10 cm depth were taken and soil dynamic deforming module and terrain profile was measured on 6 profiles. Six months after the trial roots in the wheel rut were analysed using the computer assisted root morphology and the root biomass structure analysis.

Results

One year of growth of seedlings in pots resulted in over six fold increase of the total root length in control pots and compacted pots compared to the field control seedlings using computer assisted root morphology measurements. The errors of the computer assisted root length measurements were compensated using T/L ratio (number of tips per meter of total root length). When applied TL ratio statistically significant difference between the control pots compared to the compacted pots was obtained.

The alterations of the soil physical properties in field compaction trial was confirmed with bulk density, percentage of coarse pores and soil dynamic deforming module. Applied traffic caused significant alterations in average values of the total root biomass on both analysed depths as well as alive root biomass and live/dead ratio on the upper 10 cm. We found less alive fine and small

root biomass in the compacted soils. Computer assisted analysis of the fine and small root morphology confirmed the observations during processing of the volumetric samples. The average TL ratio between the compacted and control roots form the 10-20 cm depth significantly differ. The difference in fine root structure goes on the account of the short root decline and the relative increase of the dead thicker small roots.

Discussion

In artificial and natural conditions the significant alterations regarding root morphology were observed. Root morphology of alive fine roots in disturbed mineral soils has showed decrease in the amount of nutrient-uptake-active short roots. Fine and small roots have shown high sensitivity for harvesting impacts but existing measurement methods are too laborious for practical indicator. Further investigations must involve root vitality determination instead of alive/dead classification based on visual criteria. The correlations between root morphology and visual disturbances are needed. Regarding plant rooting the area of direct vehicle-ground contact can be considered as a long-term reversible handicapped area. in sustainable forestry temporary ground corridors have to be evaluated and managed as a distinct disturbance category.

Biodegradable oils in the operation of forest machines

Alois Skoupy
Mendel University of Agriculture and Forestry, Dept. Forestry and Forest Products Technology
Zemedelska 3, CZ-613 00 Brno, Czech Republic
Tel: 420-5-45134103, FAX: 420-5-45211422, Email: skoupy@mendelu.cz

Forest machines need for their operation relatively considerable amounts of oils both for oil fillings and dissipative lubrication of cutting elements of logging machines. Losses of these oils in the natural environment appear to be the cause of soil and water pollution. A number of countries, particularly European ones, tries to prevent the pollution using laws on the obligatory use of biodegradable oils.

The paper presented deals with selected aspects of these measures:

- Measuring the dispersion of oils and its possible concentration on the soil surface. To evaluate oil dispersion a radio-indicator method has been developed making possible to quantify oil dispersion immediately after cutting.

- Evaluation of the usability of oils at low temperatures. A new method has been developed making possible to evaluate pumping ability of oils and to determine the minimum temperature of usability with the accuracy of 1°C.

- Evaluation of the temperature-oxidation stability - oil polymerization, which can be the reason of the increased failure rate of some operational parts of forest machines.

- Diagnostic signals for determination of the service life of fillings for hydraulic mechanisms and gear boxes. It is possible to say that oil should be replaced at that time when peroxide number reaches its maximum value and its decrease begins.

As for the evaluation of oil usability under low temperatures and their temperature-oxidation resistance it is possible to say that procedures contained in the International Standard Organisation (ISO) Standard proposals do not provide utilisable results.

The aim of the paper is to contribute to achieving the state when ecologically more suitable oils characterized at the same time by excellent technical parameters will be used. Thus, one of the most important negative effects of forest machines on the natural environment would be minimized.

Keywords: forest technology; forest machines; biodegradable oils; oil dispersion; oil evaluation

Harvesting impacts and long-term site productivity: the South African experience

Colin Smith
Institute for Commercial Forestry Research, Post Box # 10028, 3209, Scottsville, South Africa
Tel: +331 62314 FAX:, FAX: +331 68905, Email: colin@icfr.unp.ac.za

The widespread use of mechanical harvesting machinery during clear-felling operations in South African forest plantations has led to concern about potential effects on long-term site productivity. This paper describes the results from a series of long-term field trials, carried out by the Institute for Commercial Forestry Research (ICFR) during the last decade, addressing the effects of soil compaction and disturbance on soil physical properties and tree growth.

A wide range of harvesting operations were tested on a number of sites throughout South Africa which were planted to species of *Eucalyptus* spp. (mainly E. *grandis*) and *Pinus* spp. in general, soil compaction/disturbance has resulted in a range of growth responses from a 6% increase to an 21% decrease in growth for *Eucalyptus* spp. and a 47% decrease for *Pinus* spp. depending on site characteristics and age of trees. The effect of soil compaction on tree growth depended on soil texture and depth. The greatest negative effect on tree growth occurred on silt loam soils and a slightly positive effect on very sandy soils. Measurements taken across the trial sites indicated that the effect of soil compaction on available water capacity (AWC) was complex and soil texture dependent. On the older trials, soil compaction levels, as measured by penetrometer soil strength, were still very high 5 and 7 years after the harvesting treatments. Changes in soil physical properties following the impacts helped explain growth differences but it is likely that nutritional effects were also playing an important role.

The lack of major growth decreases of *Eucalyptus* spp. following substantial compaction and disturbance in some cases can be attributed to a number of factors. in most growing regions South African forestry soils have inherently low bulk densities due to high topsoil organic carbon contents. On such soils low to moderate soil compaction may improve water holding capacity of the soils following compaction in generally water-limiting environments. It is likely that the negative effects of compaction on root development may be offset by perforation of compacted soils by root channels from previous rotations and by root systems gradually overcoming compacted zones. The effects of soil disturbance, *e.g.* rutting, loosening and compaction in close proximity caused by logger operations, have had a greater affect on growth than operations causing deep compaction. This suggests that key growth processes, such as fine root development and nutrient cycling in the topsoil, have been affected. Cumulative effects of site damage are unknown and will be difficult to detect without multi-rotational trials being established.

4.01.04 Using models for forest growth and stand dynamics to evaluate sustainability

The characterisation and incorporation of spatial stochasticity in individual tree growth models

Julian Christian Fox
The University of Melbourne, Institute of Land and Food Resources
School of Forestry, Victoria 3052 Parkville, Australia

This paper will outline a methodology for the characterisation and incorporation of spatial stochasticity in individual tree growth models. The methodology was developed in response to a growing realisation that the individual trees of forests are not spatially independent. The spatial processes of competition and environmental heterogeneity operating among individual trees in proximity create an observed spatial dependence in individual tree attributes (Matern 1960). Competition for limited resources creates a negative dependence of a tree's size and growth on that of its neighbours, while environmental heterogeneity creates a positive dependence as neighbours are subject to similar local environmental conditions. Spatial dependence has been observed in tree diameters or basal areas (Reed and Burkhart 1985), tree diameter increments (Biondi et al. 1994), tree heights (Samra et al. 1989), tree height increments (Samra et al. 1989) and the residuals of individual tree growth models (Lui and Burkhart 1994b). The presence of spatial dependence in individual tree attributes invalidates many of the classical statistical procedures (Matern 1994). Thus the only valid statistical interpretation of spatially distributed individual tree attributes is as a field of dependent random variates from an unknown stochastic process (Tomppo 1986). It is the central aim of this research to identify this unknown stochastic process. Further, the spatial stochastic component of individual tree models is rarely studied (Dennis et al. 1985) but is universally prevalent in applications of individual tree models (Burkhart and Gregoire 1994). A methodology for characterising and incorporating spatial stochasticity in individual tree models will be described. Important stages in this methodology include.

- Identifying an optimal individual tree growth model for a particular forest setting.
- Identifying an optimal spatial stochastic structure.
- Interpretation of spatial stochasticity in terms of the causal biological
processes of competition and environmental heterogeneity. Resolving the spatial stochastic component attributable to each biological process.
- Modelling spatial stochasticity through stand development.
- Incorporating spatial stochasticity in individual tree growth projections using stochastic prediction frameworks.

The central objective of this paper will be to determine if the characterisation and incorporation of spatial stochasticity improves the accuracy and precision of individual tree growth models for long and short term projections of forest growth. Independent validation datasets will be used to assess the performance of models whose spatial stochasticity is characterised and incorporated against the purely deterministic alternative. Sensitivity analysis will be used to illustrate the sensitivity of model accuracy and precision to differing magnitudes of spatial stochasticity. This research will determine if the characterisation and incorporation of spatial stochasticity is worthwhile in terms of improved model performance. Spatially explicit individual tree data from both the native and plantation estates of New South Wales, Australia, will be used for developing the methodology as well as for validation.

The ratio of live crown length to sapwood area as a measure of crown sparseness: relation to relative social position, foliage loss, and growth potential

Douglas A. Maguire
Oregon State University, Department of Forest Resources, 209 Peavy Hall, OR 97331 Corvallis, USA
Tel: 541-737-4215, FAX: 541-737-3049, Email: maguired@ccmail.orst.edu

In many temperate forest species, sapwood cross-sectional area at some height on the stem serves as a very effective surrogate for tree leaf area due to the physiological balance between the conductive capacity of sapwood and the transpirational surface area of foliage. Live crown length also functions as a powerful predictor of tree growth and vigor due to its correlation with the total photosynthetic capacity of the tree. However one possible pitfall of live crown length is variation in leaf area density allowing total leaf area to vary for a given crown length. For example varying defoliation by insects or premature needle loss from fungal diseases may not change the live crown length, but would result in a significantly sparser crown with lower total leaf area. in absence of significant pest problems, similar variation in crown density can be observed across a range in site quality for many conifer species in western North America. Assuming a close dynamic equilibrium between foliage amount and sapwood area, the latter measure may be more reliable under such pest conditions or site variability. Application of sapwood area to indicate total foliage area, however, provides no evidence of biologically significant differences in leaf area density. in this regard, an index that combines both live crown length and sapwood area adds considerable predictive power to either dimension alone. Specifically, the ratio of live crown length to sapwood area can be interpreted as an index of crown sparseness: the greater the length of live crown needed to accumulate a given amount of leaf area (as represented in sapwood area), the sparser the crown must be. To assess its potential performance, CL:SA was computed for Douglas-fir trees over a range in size, stand density, site quality, and condition. This index ranged from 2 to 100 when expressed as cm:m^2 with a mean value of approximately 12. in general, individual trees with a high CL:SA have a lower relative height within the stand; however, even after correcting for stand density and the relative size of a tree within the stand, individual tree basal area growth increases significantly with decreasing CL:SA. Similarly, this index increases with increasing severity of needle loss on sites where Swiss needle cast is causing premature loss of foliage in western North America. Patterns in the variation of CL:SA within a tree, among trees within a stand, and among stands across western Oregon lend some insight into the complexity of this variable, as well as its potential diagnostic power.

Allocation of Leaf Area to Integrate Stand Structural Features into Forest Management Decisions

Kevin L. O'Hara
University of California, Division of Forest Science, 145 Mulford Hall #3113, CA 94720-3114 Berkeley, USA
Tel: 510 642-2127, FAX: 510 642-6632, Email: ohara@nature.berkeley.edu

Integration of stand structure features into management objectives is a frequent requirement of evolving forest management strategies. These strategies attempt to accommodate multiple resource objectives through design and maintenance of certain types of stand structures. Generally, these objectives are met by stand-level treatments which create stands with a variety of tree ages, species, and canopy strata. A method of integration of structural features through distribution of leaf area has been developed to design structures for management of multiaged stands. Stands are designed by allocating leaf area to stand components such as stand age classes, species, or crown class groups. Increment of stand components can be predicted from component leaf area. Stand volume increment is obtained by summing the predicted increment of individual stand components. Measures of tree vigor, other stocking parameters, and structural development can also be projected over time. The result is a flexible system for designing stand structures using variables that are important to assessing ecosystem function and productivity. This system is appropriate for stands with two or more age classes, or stands typically described as uneven-aged. Applications from several stand types including *Pinus ponderosa*, *Pinus contorta*, and mixed *Picea abies/Pinus sylvestris* are presented.

Accounting for interactions in hypothesis testing of simulated scenarios with a forest growth process model

Pablo Parysow
Arizona University, School of Forestry, PO Box 15018, AZ 86011-5018 Flagstaff, USA

Comparison of scenarios through process models is an important aspect in ecological simulation. However, uncertainty (estimation error) is usually not accounted for in simulation studies that compare scenarios. in this work we propose and approach for hypothesis testing through process models accounting for uncertainty in treatment entities (model factors that represent the scenarios or treatments) and external entities (remaining model factors) that interact with treatment entities. External entities may be thought of as a representation of the environment where the simulation experiment is conducted. The method presented here generalizes previous work which assumed no interaction between external and treatment entities. The proposed approach analyzes differences between predictions produced by the treatments, rather than absolute values of predictions from each treatment. Low-order orthogonal polynomials are fitted to identify entity interactions in the process model. The example analyzed to illustrate this method is based on indirectly testing the effect of tree spacing on the growth of a forest stand of a tree species for which spacing is inversely related to wood density. Specifically, we applied a forest growth process model to test the effect of different wood densities (resulting from two initial spacings: 3 and 6 meters) on the growth of basal area in a stand of red pine (*Pinus resinosa* Ait.) from ages 36 to 60 years in the Great Lakes region of North America. in turn, we used results from a field study to characterize the effect of spacing on wood density. Accounting for uncertainty in interacting external entities produced a variance of the mean difference between predicted treatment means that was six times larger than the variance obtained when that source of uncertainty was not accounted for. Basal area resulting from the wider spacing was significantly greater regardless of whether uncertainty in interacting external entities was accounted for. However, the power of the test was considerably affected by the type of uncertainty accounted for.

Individual-based modelling of tropical forest growth and yield: structure and calibration of the SYMFOR 2000 modelling framework

Paul Phillips, P.R. van Gardingen, G.J. Lawson, A.D. Friend, D.C. Mobbs
The University of Edinburgh, Institute of Ecology and Resource Management

FAX: +44 131 667 2601, Email: Paul.Phillips@ed.ac.uk

For several years there has been an identified need for predicting the effects of silvicultural intervention on future forest growth and yield. Forest concession companies in Indonesia collect data from permanent sample plots (PSPs), but these data are not, in general, analysed. Scientific researchers, forest managers, policy makers and certification bodies are all interested in using PSP data to predict forest growth and yield. SYMFOR 2000 is the latest version of SYMFOR (Sustainable Yield Modelling for tropical Forestry), which is designed to meet these needs for such users.

SYMFOR is a computer simulation program using PSP data in a framework designed to house individual-based forest growth and yield models. It makes predictions about the future growth and yield of tropical forests following silvicultural interventions. The individual-based nature of the framework allows an explicit and unique treatment of the processes of damage and silvicultural techniques, such as the creation of logging skidtrails, damage due to felling and enrichment planting, and allows alternative methods to be tested on simulated forest. A combination of deterministic calculations and Monte Carlo representations of real stochastic processes lead to a realistic representation of growth and other forest processes in most areas of lowland dipterocarp forest in Southeast Asia.

The framework currently contains a process-based tree growth sub-model and empirical sub-models of tree growth, natural mortality, ingrowth and damage, as well as several silvicultural management option routines. The process-based tree-growth model incorporates the effects of competition for light, water and nutrients to predict individual tree growth after each model time-step derived from the "Hybrid v3.0 model"(Friend et al. 1997. SYMFOR gives a representation of the environment in which each tree grows, from which the response and interactions of individule tree sub-models can be calculated. Other sub-models necessary for simulating the state of the forest are empirical, having been devised and calibrated directly from real data.

The paper describes the framework, the models within it, the calibration process and the uncertainty of results arising from the models. Comparisons are made between the empirical and process-based tree-growth models, and also between individual-based models and other model types more traditionally used for tropical forestry. The paper concludes that whilst different model types may be appropriate for different applications, the influence of specific silvicultural interventions may best be predicted using individual-based models, and that these have an important role to play in future sustainable forestry management practice.

Modeling effects of metabolism and 3D crown structure on tree growth

Risto Sievänen, Eero Nikinmaa, Christian Messier and Jari Perttunen
The Finnish Forest Research Institute, Vantaa Research Centre, Post Box # 18, FIN-01301 Vantaa, Finland
Tel: +358-9-85705373, FAX: +358-9-85705361, Email: risto.sievanen@metla.fi

We give an overview on the functional-structural tree models (FMSs) that are outgrowth of developments in process-based models (PBMs) on one hand and morphological tree models on the other. We analyze what kind of phenomena can be best studied using FSMs and outline briefly the structure of FSMs. We identify the distribution of metabolites and growth as one of the main focal points to be investigated in conjunction with FSMs. We discuss different approaches that can be applied in construction of the model component for distribution of growth. We present allometric relationships, the pipe model theory, and more complicated methods that are based on considering the translocation of metabolic products.

Then we present a FSM Lignum that treats a tree as a collection of a large number of simple units that correspond to the organs of the tree. The model describes the three-dimensional structure of the tree crown and derives growth in terms of the metabolism taking place in these units. The time step is one year. The structural units are tree segments, branching points and buds. A branching point separates each pair of tree segments. The buds produce new tree segments, branching points and buds. The tree segments contain wood, bark and foliage. A model tree consisting of simple elements translates conveniently to a list structure: the computer program implementing Lignum treats the tree as a collection of lists.

We have adjusted Lignum to a number of tree species, *e.g.* Scots pine (*Pinus sylvestris* L.) and sugar maple (*Acer saccharum*). The structural units of Lignum have been modified for each modeled tree species. We discuss what kind of modifications different tree species (broadleaf versus conifer) require. We present simulations that depict how the physiological traits and branching patterns affect tree growth in different light climates corresponding to different stand structures. Finally, in the light of the simulations, we discuss the utility of FSMs as a component of stand level growth models.

Uneven-aged forest management, does it combine sustainability and productivity?

Hubert Sterba
University of Agricultural Sciences in Vienna, Institute of Forest Growth and Yield, Peter Jordanstrasse 82, A-1190 Vienna, Austria
Tel: +43-1-47654/4201, Email: sterba@edv1.boku.ac.at

Uneven-aged Forest Management (Plenterwald, Dauerwald) is frequently assumed to better meet the requirements of sustainability than even-aged forest management with clearcuts, and at the same time allow high revenues, thus being most productive in terms of economic values too. The objective of this presentation is to compare productivity in terms of growth and yield and in terms of monetary value using a combination of growth series methodology and an individual tree growth modelling approach.

By definition, in uneven-aged management sustainability of wood production is given on the stand level and not only on the level of the management district. Thus, to compare the two systems, clear cut and uneven-aged management, the unit to be compared with the steady state uneven aged stand must be a series of even-aged stands, their ages ranging from 0 (clear cut) until rotation age (Hundeshagen's "Normalwald") on the same site. This can be achieved by (i) searching for such stands, assessing their increment and estimating the volume removed by thinning, or (ii) using an individual tree growth modelling approach, thus simulating thinning an even-aged stand in a way that results in an uneven-aged structure similar to that of the steady state uneven-aged stand. in a combination of both approaches first two growth series were built by selecting stands representing the following stand development stages in two different regions, thus resulting in a total of 16 plots:

Clear cut system: (1) Clear cut, (2) Pole stage stand, (3) Near mature stand, (4) Mature stand.

Transition system: (1) Mature stand with regeneration < 1.3 m, (2) Mature stand with regeneration > 1.3 m, (3) Two storey stand, (4) Steady state uneven-aged stand

In order to not confuse species mixture effect with that of uneven-aged management, only pure Norway spruce stands were selected, allowing only for less than 10% basal are of other tree species. The individual tree growth models MOSES and PROGNAUS were used to simulate the transition from one stage to the next. By trial and error the type of thinning and individual tree harvesting was searched for, which best produced the structure of the following development stage, measured in terms of volume per hectare, tree number and dbh-distribution. Finally the harvesting in the steady-state uneven-aged stand was simulated for forty years in a way that its dbh-distribution stayed unchanged.

Using assortment tables and models to estimate harvesting and hauling costs allowed to convert productivity in terms of wood into monetary values. in this way three management systems could be compared: 1st the clear cut system with a 125 year rotation, 2nd the "natural regeneration system" where the old stand is removed as soon as regeneration is established, and 3rd the steady state uneven-aged management system. These comparisons were based on the following assumptions: (1) The felling and harvesting system is the same in all three management systems, namely tree felling by chain saw and hauling by assortments. in this harvesting and hauling system the costs per m^3 depend on tree size, branchiness of the trees and other technical parameters; (2) There is always sufficient natural regeneration, not hampered by anything except by competition; (3) There are no differences in wood quality produced in all three management systems, except those resulting from tree diameter and height.

The main results are: (1) The mean annual increment (m.a.i.) in the clear cut system is lowest; (2) Mean diameter of the harvested volume increases distinctly from the clear cut systems to the steady state uneven-aged management system, and thus revenues per year and hectare increase in the same direction.

Dynamics of height differentiation in single tree growth models for young Norway spruce plantations

Sauli Valkonen
Finnish Forest Research Institute, Post Box # 18, FIN-01301 Vantaa, Finland
Tel: +358 9 857 051, FAX: +358 9 857 05 361, Email: sauli.valkonen@metla.fi

Keywords: modeling, simulation, stand dynamics, stand structure, growth, *Picea abies*.

A tree level growth and yield model set has been constructed for simulating the development of young Norway spruce (*Picea abies* (L.) Karst.) plantations under alternative treatment regimes in Finland. A major part of the model set consists of height distribution and individual tree height growth models for spruce and two admixture species.

The height growth model has two components: A potential growth (dominant height) model, and a multiplier model that accounts for the variation between trees within a stand. The chosen model structure is intended to produce an exact match between stand level dominant height development and the average height increment of each dominant tree, and to describe the height differentiation within stands that results from growth variations between individuals.

Surprisingly wide height distributions were observed in the data from 36 even-aged young stands. Most of the height differences had resulted from growth differences during the earliest years, when the variation in microsite properties, weed competition, and biotic and abiotic damages tends to be largest. Having overcome the conditions that induced a slow start, most (but not all) small trees increased their height growth. Competition between trees was not intensive enough yet to control their height growth. Additionally, individual trees showed large growth variations between successive periods. A substantial proportion of the spruces had emerged from natural regeneration, adding younger individuals to the smaller end of the height distribution. All these components resulted in a lively random type exchange in tree social positions that decreased in frequency and amplitude with increasing stand height.

The single tree height growth multiplier model was designed to account for all these elements except for the random growth variations. The use of random parameters in nonlinear models might offer a way to solving the problem. The single tree model is intended for use in concert with the dominant height growth model, expressing the general relationship between height and height growth in the population. The model set results in constant height positions, slightly increasing absolute height differences and decreasing height ratio differences between trees except for the extreme smallest trees that retain their low social positions.

4.01.08 Effects of environmental changes on forest growth

Recent changes in climatic conditions and their potential role in accelerated tree growth on sites in Central Europe

Hans-Peter Kahle
University Freiburg, Institute for Forest Growth, Bertoldstrasse 17, D-79085 Freiburg, Germany
Tel: +49 761 203 3739, FAX: +49 761 203 3740, Email: kahle@uni-freiburg.de

Keywords: Forest growth; forest site productivity; climate change; time series modeling; geostatistical modeling

On many sites in Europe forest productivity has increased considerably during recent decades. Accelerated tree growth is especially pronounced on sites in Central Europe. Some exceptions seem to lie on the periphery of Europe where the signal is less strong. in a current multidisciplinary pan-European study hypothesized important causes of the observed tree growth acceleration are investigated: (1) changes in physical climatic conditions (2) increased atmospheric deposition (esp. nitrogen) (3) increased carbon dioxide fertilization, and (4) changes in land use.

In this report the potential role of recent changes in climatic conditions (primarily air temperature and precipitation) in accelerated tree growth is addressed. The retrospective growth data used in this study originate from several case studies as well as from forest inventories. Time series of meteorological parameters have been obtained from meteorologic monitoring networks. Both data sets are analyzed in the temporal and spatial domain using uni- as well as multivariate statistical methods. Trend-analysis methods are used in order to detect systematic changes in the behavior of the time series, whereas changes in the realized spatial patterns of the variables of interest are identified and described using geostatistical methods.

Climatic conditions have considerably changed during recent decades. The changes in Central Europe are characterized by a strong seasonal component: winter months have become significantly warmer and wetter, whereas during the summer months the probability of moisture shortage resulting in drought stress for forest trees has increased.

Empirical models describing the relationships between variations in weather and tree radial growth are retrospectively parameterized on a subset of the data. These models demonstrate that moisture availability is control-ling tree growth on many sites in Central Europe. Based on time varying coefficient models it is shown, that trees have responded increasingly sensitive to variations in moisture availability during recent decades. However, these findings are curious, because at the same time growth accelerated. Results of the multivariate statistical analysis indicate that beside meteorological parameters additional factors have to be taken into account in order to describe the observed growth changes. A detailed outlook on how these complex interactions will be approached in the ongoing research project is given.

The likely effects of increasing CO_2 and temperature on forest growth in different regions of the world

Miko U.F. Kirschbaum
CSIRO, Forestry and Forest Products, PO Box E4008, ACT 2604 Kingston, Australia
Tel: +61-2-6281 8252, FAX: +61-2-6281 8312, Email: Miko.Kirschbaum@ffp.csiro.au

Climate change can affect forest growth through many processes, and the ultimate response in different systems may be affected by the response of any one of those processes, or through their interactions. The work presented here concentrates on two aspects of climate change, increasing CO_2 concentration and temperature.

Increasing CO_2 concentration directly affects photosynthesis and stomatal conductance, and increasing temperature affects photosynthesis, organic matter decomposition rates and vapour pressure deficit of the air and thereby the water loss from tree canopies. Increasing temperature can also reduce frost damage in cold regions, but increase heat damage in regions that are already hot.

In addition to these direct effects, there are many indirect effects. For example, the sensitivity of photosynthesis to CO_2 concentration increases with increasing temperature, and the optimum temperature for photosynthesis increases with increasing CO_2 concentration. There are further feed-back effects between carbon gain, water economy and nutrient availability.

Because of these interacting factors, the response of forest growth to CO_2 concentration and temperature can be different for regions currently experiencing different temperatures, and it can shift with changes in the degree of water and nutrient limitation in different systems.

Some of these differences between regions are fairly obvious: growth in boreal systems is more likely to benefit from increasing temperature than growth in systems already experiencing super-optimal temperatures where further increases in tmpeature are more likely to have negative effects. Similarly, it is now fairly well established that the response of systems to increasing CO_2 concentration is more pronounced under warmer, and under water-limited, conditions than under colder conditions or conditions with adequate water supply. Other interactions are less obvious: how would growth under water-limited conditions in cool conditions respond to increasing temperature relative to the growth response of similarly water-limited forests already growing under warmer conditions?

The effect of these direct and indirect effects and their interactions following climate change are reviewed. A range of responses are investigated in detail with the forest-growth model CenW. It simulates the response of forest growth and the storage of soil organic matter with climatic changes. The interactions between these various factors on ultimate forest growth are described for forests in different regions of the world.

Recent changes in atmospheric deposition, soil chemistry, and stand nutrition as possible causes for an increased forest growth in Europe

Joerg Prietzel
Munich University of Technology, Chair of Soil Science, Am Hochanger 13, D-85354 Freising, Germany
Tel: +49 8161 71 4734, FAX: +49 8161 71 4738, Email: prietzel@boku.forst.uni-muenchen.de

Keywords: Forest growth; Europe; recent changes; stand nutrition; soil chemistry; atmospheric deposition

For many intensively-studied forest stands in Europe, a significant positive shift in growth has occurred during the last 50 years. The systematic growth increases were particularly pronounced in Central Europe and southern Scandinavia. The respective area has been also subject to changes in forest utilization practices and climate conditions, as well as to increased atmospheric deposition of nitrogen and soil-acidifying agents. Atmospheric N and acid inputs often exceeded ecosystem demand and acid consumption by weathering processes, respectively.

Consequently, a significant N soil acidification and eutrophication, which often by far exceeded natural rates, was noticed for many European soils. Soil acidification becomes become evident by a considerable decrease of the soil pH and a distinct depletion of base cation pools in the rooted topsoil within a few decades. N eutrophication of forest soils becomes evident by either a decreased forest floor C/N ratio, or by an increased pool of humus in the humic topsoil, with its C/N ratio remaining unchanged.

Long-term (20 to 40 yr) temporal courses of stand nutrition in Central European forest ecosystems, which often had been depleted seriously in N, P, and base cations by intensive, non-sustainable forest utilization for centuries, indicate a recent recovery of the nutrition status of many European forests. This recovery is particularly distinct for N, which is probably due to high atmospheric N deposition. Besides other factors, this improvement in N nutrition is suggested to be a key factor for the increased growth that has been reported recently for many European forests. However, there is also evidence for a tendency towards imbalanced nutrition on N-eutrophicated, acidified sites. For these sites, in the long run increasing nutrient imbalances may jeopardize forest growth and ecosystem stability.

At present, information about the intensity of the mentioned changes in soil chemistry and stand nutrition as well as of recent growth increases in European forests, and the relationship between these factors is hardly available on a spatial scale, but only for selected study sites.

This contribution summarizes the currently available information regarding the relationships between changes of the growth and the nutritional status of European forests. It links the observed relationships to atmospheric deposition and soil chemistry, and tries to draw some preliminary conclusions concerning the potential causes for the recent growth increases that have been observed for many European forests. Additionally, a comprehensive research approach to obtain more detailed information regarding the spatial pattern of changes in the growth of European forests and the dependence of these changes on changes of important growth factors, is presented. This research approach is currently being realized within the EU-funded research project REGOGNITION, where Relationships Between Recent Changes of Growth and Nutrition of Norway Spruce, Scots Pine and European Beech Forests in Europe are investigated by intensive collaboration of 25 research groups in 14 European countries.

Accelerating forest growth in Europe

Heinrich Spiecker
University Freiburg, Institute for Forest Growth, Bertoldstrasse 17, D-79085 Freiburg, Germany
Tel: +49 761 203 3739, FAX: +49 761 203 3740, Email: instww@uni-freiburg.de

Keywords: Forest growth; forest site productivity; European forests Growth of European forests has changed considerably in recent decades. Forest growth has increased on many sites. The observed changes may have been caused partly by inconsistencies in inventory methods, by changes in forest area, by changes in species as well as in age composition. Excluding these factors various studies showed that site productivity has increased on many forest sites.

An increasing growth trend has been observed in the southern regions of Northern Europe, in most regions of Central Europe and in some parts of Southern Europe. Only in exceptional cases site productivity has decreased. Possible causes for the changes in site productivity are changes in land use, in forest management, in natural disturbances and in climate such as CO_2 increase and nitrogen deposition. The changes in site productivity may have been caused by one factor, a factor combination or by regionally changing factors which finally had similar effects on growth. The significance of each factor possibly varies in space and time. Growth responses to the influencing factors are modified by site and stand conditions. The observed results led to intensive public discussions, because they were connected with forest decline, an emotional topic, especially for the German public.

The long-term increase of growth clearly indicates changes of site conditions. Consumers of wood may appreciate the increased wood resources. Increased carbon storage potential may be an other effect of faster forest growth. However, these changes may also be associated with ecological and economic risks. Increased growth affects nutrient cycling. Changes in nutrient and water supply may also affect species composition and tree health. The density of forests is rising, if removals do not increase at the same time. Dense forests offer less space for light demanding tree species and ground vegetation to live and therefore may affect biodiversity. Higher trees and a high standing volume may increase the risk for water stress and storm damage. Wood quality may be altered as well. Changes in site productivity have an impact on forest management, for example on species selection, amelioration, regeneration techniques, weed control, tending, pruning and cutting strategies (incl. allowable cut). Past growth observations may not reflect actual growth adequately. Therefore, improved anal-ysis and prediction tools are needed to ensure continuous sustainable management.

As long as neither the causes of the observed growth changes are fully understood nor future development of the causing agents can be predicted the risks involved in these changes cannot be assessed in a reliable way. The amount and complexity of the scientific problems evolving from the observed forest growth trends show that solutions can only be developed by the cooperation of scientists covering various disciplines on a European or world wide level. One approach to get a better understanding of the possible causes is the RECOGNITION research project which is coordinated by the European Forest Institute and funded by the European Union. in this project 25 partners work together.

4.01.00 / 4.02.00 / 1.07.00 Using growth models for better forest management in the tropics

A system for yield regulation in natural tropical forests

Denis Alder, Howard L. Wright
Consultant in Forest Biometrics, 9 Stansfield Close, Headington, OX3 8TH Oxford, United Kingdom
Email: d-alder@eurobell.co.uk

Conventionally, yield regulation in natural forests uses either aggregated stand tables and simple assumptions of growth and mortality rates which treat the forest as spatially, floristically and structurally homogeneous, or complex dynamic models that require extensive permanent sample plot information. This paper presents a method of yield regulation based on equal volume coupes that can be derived from static inventory information alone. The method allows for spatial variation in stand structure and composition. Growth parameters for species are estimated from tables of pan-tropical growth rates allied to information on typical size, wood density, and ecological guild. Logging damage and stand density effects on growth are also allowed for based on pan-tropical studies. The method seeks to provide sustained volume production over time from the whole managed area. Constraints can be imposed at the species level reflecting statutory, environmental, or commercial limitations. The system is packaged as a Windows-based computer program. It is designed to be practical for both small-scale management typical for community and for larger industrial-scale logging, and is especially intended for situations where local permanents sample plot data is limited or absent.

Natural forest productivity in several Venezuelan life zones and possibilities of their ecological sustainable management

N. de Bello, Torres-Lezama, A. and Ramirez-Angulo, H.
Universidad de Los andes, Grupo de Investigación BIODESUS. INDEFOR Facultad de Ciencias Forestales y Ambientales, Vía Los Chorros de Milla, Marida, Venezuela
FAX: 58 74 714643, Email: [rhirma@ing.ula.ve] torres@ing.ula.ve

The understanding of changes in the productivity of natural forests helps to adopt valid options for forest management planning and the development of systems that assure forest sustainability. in this paper we study interannual variation of tropical forest biomass productivity in several life zones (sensu Holdridge) of Venezuela. This is possible because this country has a network of growth permanent plots that has been measured with a near annual frequency for over 30 years; an exceptional case in the tropics. Twenty four 0.25 ha (50 x 50 m) plots, located in six life zones, were chosen: tropical thorn woodland (T-tw), tropical very dry forest (T-vdf), tropical moist transition dry forest (T-m/df), tropical moist forest (T-mf), tropical lower montane moist forest (T-M-wf) and tropical montane wet forest (T-M-wf). Forest productivity is estimated based on successive measurements, from the time of plot establishment, of tree girth at breast height, subsequently converted to diameter (d). Aerial biomass is calculated with individuals of d 10 cm by life zone and for the total period through regression equations developed for tropical forests. The T-mf (km92) presented the highest mean productivity with 3,83 Mg ha^{-1} yr^{-1}, following in descendent order the T-m/df (2,86), T-mf of Rio Grande (2,64), T-vdf (2,33), T-M-wf (2,09), T-tw (-0,01) and the T-M-wf) (-0,43). These results are interpreted with regard to climatic characteristics, soil texture, carbon and nitrogen soil content, and forest dynamics.

Growth Performance and Yield Potential of *Populus Deltoides* Bartr. in Agroforestry Plantations in Punjab, India

R. S. Dhanda, I.B. Kaur
Punjab Agricultural University, Department of Forestry & Natural Resources, College of Agriculture, Ludhiana, 141004 Punlab, India
FAX: 91-161-400946

The economy of the Punjab State, situated in the north-western part of India, is mainly agrarian 83-84% of its total geographical area under cultivation. The recorded forest area in the state is just 5.6% of which only 2.7% has a crown density of 40% and more and are distributed largely in the form of strip plantations along the roads, rainway lines and canals. The rest are just of protective nature in the submontane Shivalik out crops, with no dense forest worth the name. The agriculture in the state is highly capital-intensive and over-exhaustive on water and soil resources. Such a land use scenario transformed the state into a wood-deficit state, where 95-98% of its industrial and construction timber requirements are met with imports from other states. The adoption of *Eucalyptus tereticornis* plantations in agri silnvicultural system by the farmers in early eighties turned the state surplus in eucalypti timber (dhanda, 1989). The farmers had to resort to distress sale of farm grown timber. Now the farmers in the central part of the state are planting populas deltoides in agroforestry and are having sugarcane, wheat, oats, winter fodder potato and turmeric crops along with poplar tree crop. The growth of Poplars in agri-silvicultural system is quit encouraging and farmers are harvesting poplar trees at a short rotation of 6 to 7 years when they attain 90cm GBH or more.

The present study was undertaken to assess the growth performance and productivity of poplars in agroforestry both in riverine belts and tablelands under different cultural and management conditions. Four plantations of each age from one-to-four year were selected in both locations and tree parameters like DBH, total tree height, clear bole, utilisable bole height, basal area, and crown spread of poplars were recorded. The mean DBH in riverbed plantations ranged from 6.8cm (1-yr) to 19.4 (4-yr), while it was from 5.1cm to 17.72cm, respectively in tableland plantations. Generally the DBH for river - bed plantations was more than that table land plantations. Similarly, in observations for total tree height, utilisable timber bole height, clear bole and basal area were recorded and compared. This will be dealt in detail in full-length paper. The timber volume production in riverbed plantations ranged from 9.08 mü/ha (1-yr), to 113.87mü/ha (4-yr) while it was 5.95 mü/ha (1-yr) to 79.90 mü/ha (4-yr) in case of tableland plantations. The timber weight production ranged from 5,21m tonnes/ha (1-yr) to 92.9 m tonnes/ha (4-yr) in riverbed plantations, while it was 2.35 m tonnes /ha (1-yr) to 64.85 m tonnes (4-yr). The production was generally more (42.5-43.3%) in riverbed plantations producing an MAI of 28.48mü/ha/annum at four years age.

The similar aged plantations in these two situations were compared on the basis of silvicultural treatments and soil characteristics. The overall performance of riverbed plantations was better than tableland plantation, verified through students' t-test. The riverbed plantations performed better as this weregiven proper cultural treatments viz., soil working, irrigation and fertiliser application and fare care operations by resident farmers. Also the water table was higher in reverie belt which definnitely contributed towards better growth of poplar during summer. It is, thus, clear that poplar plantations in agroforestry system require proper care and silvicultural treatments while the neglected plantations suffer and not put up sufficient growth.

The second cut for hill dipterocarp forests: What growth and yield models indicate?

Ismail Harun, S. Appanah
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6342633, FAX: 603-6302321, Email: ismail@frim.gov.my

Growth and Yield models are explored for data from logged over Dipterocarp forests data at two scales: predicting the diameter growth, percentage mortality and number of recruits for individual trees per hectare per year and predicting the growth, mortality and recruitment in terms of basal area per hectare. The data for model fitting consists of all trees 10 cm DBH and above in 18-1 hectare growth and yield plots established after logging. Growth and Yield models (individual tree and plot scale) are developed for a permanent sample plot data set established and re-measured over a 15 year period. The models predict that the next harvest will consist primarily of non-Dipterocarp species, due to high mortality of residual *Dipterocarps* and low recruitment. A sensitivity analysis indicates that the mortality rate has the biggest influence on the forecasts, and obtaining more precise estimates of mortality is needed. Because the mortality for *Dipterocarps* was still high (3-4%) up to 10 years after logging, mortality models fitted using these data may be overestimating future mortality, as there is evidence that the mortality drops to 1 or 2 percent by the 15th year. Nevertheless, the observed high levels of mortality during years 1 to 10 are real and result in considerable reduction in the stocking of *Dipterocarps* in the stand. This indicates that the effects of harvesting may last over longer time periods than previously thought and several modifications and refinements are needed in order to improve existing harvesting and management system of Dipterocarp forest in Peninsular Malaysia.

A new approach for AAC calculation in tropical moist forest - An example from Sabah / Malaysia

Jochen Heuveldop, Thomas Ditzer, Achim Droste, Reinhold Glauner
Institute for World Forestry, Federal Research Centre for Forestry and Forest Products, Leuschnerstr. 91, D-21031 Hamburg, Germany
Tel: +49-40-739 62 100, FAX: +49-40-739 62 480,
Email: heuveldop@aixh0001.holz.uni-hamburg.de

Keywords: growth & yield; tropical rainforest; annual allowable cut; management planning

The annual allowable cut (AAC) for a forest management unit in Sabah, Malaysia, is derived by a recently developed method which links a process oriented growth model with a Geographic Information System. The investigations, where the area- and volume-control systems are combined, have been carried out in the 55,000 hectares Deramakot Forest Reserve, consisting of heavily logged over and partly degraded lowland dipterocarp forest.

Underlying principle for this approach of calculating the AAC is to rehabilitate the forest conditions by increasing the present growing stock to its optimum, where maximum increment of commercial species can be obtained. The management concept comprises a modest, gradually increasing timber harvest under strict control of harvesting techniques, natural regeneration, and silvicultural measures.

The commonly applied estimations of annual growth are based on small scale sample plots representing minor portions of today's degraded stand types. Data obtained by such empirical method in selectively logged stands cannot be extrapolated to the wide range of devastated forest structures with the required precision. Instead, this would lead to a bias in the prediction of the potential growth and thus to a non representative calculation of harvestable volumes and regeneration time.

For the here presented growth / increment estimations the process-oriented model FORMIX was applied to determine stand development in five species groups on three site qualities in four stand structure types. The model satisfactorily represents forest dynamics and timber increment in degraded and heavily logged forest stands.

Species grouping is based on light response classes and supported by photosynthesis measurements; site quality assessment uses plant-available water and exchangeable nutrients in soils up to 50 cm depth. Stand structure types are derived from 1:25,000 aerial photos using crown parameters for identification.

The model simulates forest development with and without timber harvesting. Silvicultural standards are considered by defining a cutting diameter threshold, by limiting the number of trees to be harvested per unit area, and by prescribing a minimum number of seed trees to be retained after harvesting (i.e. volume control). The GIS environment enables the connection of the aforementioned stand and site classifications to a spatial database. The thus produced site-specific-stand-type map (SSST) includes three crucial forestry planning parameters: increment, harvested volume, and area.

By selecting areas to be harvested in 10 years intervals (i.e. area control) and defining a preliminary working cycle of 40 years, this approach leads iteratively to a realistic, site-and-stand-specific and area-related calculation of stand improving sustainable harvesting-levels.

The calculations reveal that timber harvesting is presently possible. However, harvesting levels range from 200 m^3 to 10,000 m^3 per year for the next 60 years depending on the silvicultural standards applied. Thereafter an increase to 80,000 m^3 would be possible if harvesting damages are kept at 20%, at least three mother trees per hectare are retained, and the threshold for the minimum number of trees to be harvested per unit area is neglected.

Patterns of vegetation recovery on the 1922 and 1959 lava flows on Mount Cameroon

Nouhou Ndam
LIMBE Botanic Garden, Mount Cameroon Project, P.O.Box 437, Limbe, Cameroon
Tel: 237 43 18 85 extension 381, FAX: 237 43 18 83 381,
Email: mcplbg@iccnet.com

To assess the role of volcanic eruptions in the maintenance of species richness on Mount Cameroon, the resulting course of primary succession and the mechanisms controlling this were investigated. in 1995, a census was carried out of the vegetation on the 1922 and 1959 lava flows; the results were compared with those of surveys carried out in 1936/37 and 1951. Numbers of plants and species were significantly different between the two lava flows (P = 0.001), but not between the edges and centre of each flow. The primary succession process was complex with a high turnover of species, a larger number appearing and disappearing from the lava flows between 1936 and 1995 than numbers persisting throughout. The results are compatible with a relay floristics model of succession. However, given the slow rate of vegetation development of the sites it is questionable whether the high rate of species turnover reflects mechanisms of facilitation and then competitive exclusion. It may be more of a reflection of stochastic processes in the populations of the species. Trees > 1 cm DBH tend to colonise from the edges of the flow towards the centre whereas the distribution of seedlings and herbaceous plants seems to reflect a more stochastic colonisation process. It will take 300 to 600 years for the initial forest to be reconstituted on those lava flows as estimated from current trend of species composition, basal area and density. About 8% to 18% of species colonising the lava flows are unique to this type of environment, therefore contributing constantly to the richness of the biodiversity on Mount Cameroon.

Simulation models as a tool for sustainable forest management in Venezuela

Hirma Ramirez-Angulo, Torres-Lezama, A. and M. Acevedo
Universidad de Los andes, Grupo de Investigación BIODESUS. INDEFOR. Facultad de Ciencias Forestales y Ambientales, Vía Marida, Los Chorros de Milla, Venezuela
FAX: 58 74 714643, Email: rhirma@ing.ula.ve

Use of simulation models have become wide spread as a tool for natural resource study and management. Particularly, simulation models are a valuable tool in predicting the responses of forest ecosystems to natural and anthropogenic disturbances, given the complexity and longevity of such systems. Consequently, since the seventies a considerable number of simulation models have been developed with that purpose, mainly for temperate forests. in the tropics, however, these models have been scarcely applied, despite the fact that forest management is the subject of strong criticism. Venezuela is one of the few countries where this approach is developing; since 1993 we have worked steadily on this line of research line, which is specially oriented towards the study of forest dynamics in order to analyze and predict the effect of several management strategies. This has been possible in great extension due to a network of permanent plots established in the sixties. in this paper we present a particular case study of the application of an individual-based model (ZELIG) to a Venezuelan western plain forest, classified as tropical dry transition to humid, after Holdridge. We used a data set with over 35 years of measurement from the University Forest "El Caimital" to parameterize the model. Due to the large number of tree species (64), and the difficulty to run the model for such a number, we selected the top 14 species based on a Value Index (VI = 75%). This index is calculated dividing relative basimetric area by relative stand density. The remaining species were classified in six ecological groups, according to their light requirements and maximum tree height. The values of the parameters to run the model were obtained, and a good adjustment was reached after contrasting the model results with the field data. Based on this parameterization the model was applied to predict selective logging effects on forest dynamics. Four selective logging options were simulated with regard to the minimum felling diameter legally established for Venezuela. in the first option, we harvested the total merchantable stand and considered vegetation damage caused by current logging methods; in the second, the damage was estimated for a planned logging; in the third option we only harvested approximately 50% of the total merchantable stand under the current logging method; and, finally, in the fourth option we cut the same proportion as in the third but vegetation damage was estimated for a planned logging method. For each logging option the following parameters were evaluated: mean stand density, mean basimetric area and total timber biomass. Furthermore, we determined the degree of ecological sustainability depending on the level of remaining forest recovery with respect to the initial values of the non logged forest. We also calculated the benefit/cost relationship. in conclusion, the last option assured a faster forest recovery, but from an economic point of view the first option resulted more profitable in a short term. These results show the necessity of reconciling ecological and economic interests in order to pursue sustainable development. The social aspect should be incorporated as well.

Optimising planting density of banana to improve resource use efficiency and productivity of smallholder rubber lands in Sri Lanka.

V. H. L. Rodrigo, C.M. Stirling
Rubber Research Institute of Sri Lanka, Department of Plant Sciences, Agalawatta, Dartonfield, Sri Lanka
FAX: +94 34 47427, Email: dir rri@edb.tradenetsl.lk.

Perennial tree crops, such as rubber, play an important role in income generation for smallholder farmers in the humid and sub-humid tropics. Because rubber provides no income during the early years of establishment, farmers are advised to utilise the wide spaces between immature trees to grow shorter duration crops. The versatility of banana, being both a food and cash crop makes it an important component of these intercrop systems. The Rubber Research Institute of Sri Lanka (RISL) currently recommends a planting density of one row of banana between each row of rubber; this is based largely on the performance of banana when grown as a monoculture and is designed to impose minimum risks of latex yield losses through competitive effects on rubber. Prior to this study, there had been no systematic evaluation of the effects of planting density on productivity of component crops and so it was not clear whether the present recommendations represented an optimal use of land during the unproductive phase of rubber. The overall aim of this study was to determine the extent to which planting density of banana could be manipulated to improve resource use and productivity of immature rubber lands.

A large-scale experiment was established on 5 ha. Treatments comprised, sole crop rubber (R), sole crop banana (B) and three intercropping treatments consisting of an additive series of one (BR), two (BBR) and three (BBBR) rows of banana to one row of rubber. Biomass productivity increased in direct proportion to planting density in the rubber/banana intercrop. Despite an increase in leaf area index and shading with planting density, there was no evidence that growth was limited by light. Instead, growth of both rubber and banana benefited from mutual shading in the high density BBBR crop with a 20 and 41 % increase in biomass per plant of rubber and banana, respectively relative to the single row BR intercrop. As a result, the Land Equivalent Ratio (LER) for biomass increased 76% from the BR to BBBR intercrop. Treatments had little affect on bunch yield per banana plant or harvested percentage, with mean values of 6.2kg and 65% respectively. As yield per plant was similar across treatments, yield per hectare increased three-fold from the current recommended BR to BBBR intercrop resulting in an estimated 350% increase in profits from the banana crop during the establishment phase.

Increased productivity in the high density intercrop was driven by an increase in resource capture per unit land area and on average, radiation and water use in the BBBR intercrop increased by 73% and 140%, respectively, over the currently recommended BR intercrop. Increased shading in the BBR and BBBR intercrops had no major impact on photosynthesis and respiration per unit leaf area.

Consequently, the increase in light-use efficiency and whole plant photosynthesis (due to the larger canopy under shade) were identified as major factors responsible for the improved biomass productivity per plant in the high density intercrops. Intercropping also had beneficial effects on growth of rubber, resulting in an increase in both girth and plant height. The increase in of intercropped rubber has been sustained through to the sixth year of growth with the result that tapping will start earlier in the intercrop than in the sole crop rubber. We conclude that amongst intercrops, the highest density BBBR treatment always performed best in terms of both stand parameters and performance of individual component crops. The implication of these findings for improved income generation on smallholder rubber lands is discussed.

4.02.01 Forestry products collection and sustainable forest management

Urban Tree Database Information System (Infoplant): Dissemination of Research Findings

Mohammad Adnan, Ahmad Azaruddin Mohd. Noor, Azali Adnan
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6342633, FAX: 603-6302105, Email: adnan@frim.gov.my

Urban forestry and tree planting activities are now receiving due recognition. to make Malaysia a "Garden. To this effect, dissemination of urban tree information is very crucial and would give a great impact to the landscaping activities. Realising this, and towards making Forest Research Institute Malaysia (FRIM) a center for the Malaysian Urban Forestry research, FRIM is making the first move to bring the wealth of information on urban trees into superhighway by developing a web base computer application known as Plant Information System - INFOPLANT. It is a dynamic database system containing useful information on trees for urban landscape purposes. The system will serve as an effective tool for the dissemination of information on urban trees to the public. As it contain up-dated information gathered from experts. The InfoPlant will intensify and facilitate research work in the related fields.

Infoplant was initiated and created based on systems that were already established in other country like in the USA. Infoplant, the first of its kind in Malaysia is an interactive and dynamic program. It was designed to match specific tree species to particular uses and sites based on compatibility characteristics. The database system includes descriptions and pictorial information of tree species. It provides ready information for fast and effectual retrieval. At present there are informations for 164 urban tree species with 32 parameters/criteria and a total of 365 pictures. This number will increase so as to achieve a target to cover all trees that grow in urban areas and that are proven suitable for urban landscaping. Major advantages of the system includes on-line access via internet, easy-to-work and user friendly, practical and time saving. The development of the database system was divided into two stages. in the first stage, existing records and data in dbase file were converted into Microsoft Access file. A search request was then developed based on the existing and additional parameters or field using Visual Basic Application Software that resulted in the stand-alone version of Infoplant. Stage two concentrated on further enhancement and improvisation of Infoplant Database System into the Internet version using Internet Database Converter. To subsequently strengthen and support the system, apart from accessing Infoplant Database for plant search, users may also access other additional and related information pages which are created and displayed in this web site. This includes plant check list, plant price guidelines, nursery information and pictorial guidelines to tree planting. The release of Infoplant is definitely in line with government's aspiration towards both the greening program and IT development. It aims to provide an interesting platform for FRIM in packaging, disseminating and commercialising information on urban trees and landscaping as well as to enable the general public to retrieve it comfortably. As a technological solution for information dissemination, Infoplant will ultimately evolve to integrate the latest supporting technology available.

Role of Local People in Sustainable Management and Conservation of Bamboo and Rattan Diversities in Bangladesh

Ratan Lal Banik
Bangladesh Forest Research Institute, P. O. Box 273, 4000 Chittagong, Bangladesh
FAX: 880-31-681584, 681566, Email: bfri@spnetctg.com

Bangladesh is basically a plain land country lies in the north-eastern part of the South Asian sub-continent. The state owned forest occupies about 14% land of the country which is mostly located in the hills and coastal areas. The country enjoys a tropical monsoon climate. The population of Bangladesh is about 13 million, of which 0.13 million is tribal people. So the 98.7 per cent are plain land people (Bangalees). There are 14 identifiable tribes mainly residing in the hills. Both bamboo and rattan are most priority plants of the country. The natural bamboo and rattan forests are located in the hills while people of vast plain land have been cultivating them in rural areas. Bamboos are being used as a main construction material for about 90% of the rural housing. The economy of the country mostly depends on agriculture. Almost all the agricultural implements are made of bamboo. The use of bamboo as a raw material for the pulp and rayon mills has added its importance to the national economy. Both bamboo and rattan are important raw materials for cottage industries and generate employment for the rural poor. Presently there is a shortfall of bamboo resource by 82 million culms. The increased productivity through sustainable management by application of indigenous and modern knowledge can fill the gaps. There are about seven species of bamboo occurring naturally in the hills. Among them M. baccifera is most common and constitute 80-90 per cent of the total bamboo vegetation. Besides these about 30 species of bamboo have been cultivated in the plains of Bangladesh. Among them *Bambusa balcooa* Roxb. and *B. vulgaris* Schrad. are most common. Rattan being a climbing palm grows naturally in the high forests. Only two genera of rattans *Calamus* and *Daemonorops* occur in the country. *Daemonorops* is represented by a single species *D. jenkinsiana* (Griff.) Mart. and *Calamus* is reported to be represented by 9 species. Among them *C. guruba* and *D. jenkinsiana* are commonly used by the local people for weaving and binding purposes. Due to clear felling forestry operations rattans are disappearing in an alarming rate. The hill tribes usually lead nomadic lives. However, in some settled areas of the forest people have been cultivating some bamboo and rattan species in their homesteads and farm land from generations for day to day uses. Agroforestry practice, and shifting cultivation (Jhumming) are traditional systems for sustainable management and conservation of bamboo resource. During jhumming for up-land rice cultivation, the tree seedlings are also planted. Occasionally rattan seedlings and bamboo propagules are planted as inter crops. Jhumias (shifting cultivators) maintain genetic diversity by borrowing or exchanging propagules. Harvesting of rattan cane starts from 7 or 8 years after planting, when the stem become mature and reaches 6-7m in length. Out of 10 rattan species only *Calamus tenuis* is widely cultivated in the plain land homesteads, specially in marshy low lying areas. Both in hill forests and plain land rural areas local people are managing and conserving diversities of bamboo and rattan resources in sustainable way mainly on three principles-utilisation, cultural value and ritual belief, and environmental stability. An endeavour has been made in this paper to discuss these principle in details.

Recherches sylvo-pastorales prioritaires en Afrique de l'Ouest

Ronald Bellefontaine, AndreD., Cesar J., Dia A., Maiga A., Mbaye M., Ickowicz A., Petit S., Toutain B., Zoumana C.
CIRAD-Forêt, BP 5035, 34 032 Montpellier, France
FAX: (33) 4 67 59 37 33, Email: ronald.bellefontaine@cirad.fr

La gestion durable des formations ligneuses sèches d’Afrique de l’Ouest est à un tournant de son histoire. Les changements quantitatifs et qualitatifs déterminants, qui ont marqué au cours des vingt-cinq dernières années ces formations ligneuses fragiles, mettent en évidence les faibles possibilités de reconstitution et posent la question des seuils critiques à ne pas dépasser si l’on vise la pérennisation de ces écosystèmes. Les réflexions menées par ce groupe de chercheurs sur divers terrains portent principalement sur deux zones écoclimatiques, celles correspondant aux climats désertiques et sub-désertiques (dénommée ici zone saharo-sahélienne), et aux climats tropicaux secs et sub-humides (dénommée zone soudanienne au sens large).

L’impact du pastoralisme sur les formations ligneuses, associé ou non à celui des feux de brousse (accidentels ou provoqués), ainsi qu’à celui des autres activités humaines, comme la cueillette et l’exploitation forestière, a fait l’objet de nombreuses études sectorielles, dont on tire déjà d’importants enseignements. Malgré cet apport, divers thèmes d’actualité mériteraient encore un éclairage particulier. Il s’agit par exemple de suivre la baisse de fertilité des sols de ces formations boisées, de la poursuite d’études de régénération de la végétation ligneuse (notamment la multiplication végétative naturelle), du fonctionnement hydrique de certains écosystèmes, des conséquences de l’émondage répété sur la vitalité des arbres fourragers, de la concurrence et / ou de la complémentarité de l’exploitation des productions forestières et pastorales, etc. Au niveau culturel et socio-économique, les processus de prise de décision des pasteurs, leurs choix stratégiques et les pratiques d’exploitation des ressources face à la concurrence exercée par les agro-pasteurs, le savoir faire traditionnel, l’importance des revenus tirés de l’exploitation de produits ligneux et pastoraux sur l’économie des foyers, etc... sont encore insuffisamment connus. Mais, face à la nécessité de développer des actions d’aménagmen» à une échelle plus large que la station, les principales lacunes à combler se situent au niveau des multiples interactions, telles que « arbres-ruminants », « strate-herbacée-strate ligneuse », « pratiques pastorales-gestion des arbres », « couverture végétale-feu-sol », etc.

La production durable et simultanée de bois-énergie, de produits forestiers non ligneux et de produits animaux, nécessite une nouvelle approche, globale et non sectorielle. De plus, celle-ci est à situer dans un contexte de décentralisation et de co-gestion contractuelle des ressources naturelles par les populations. De nouveaux modes d?exploitation des ligneux apparaissent, induits par la croissance de la démographie et par la mise en valeur de terres marginales.

Une recherche-action, basée sur de nouveaux outils, est proposée ici afin d’améliorer les modalités d’exploitation des ressources sylvo-pastorales et de pouvoir proposer rapidement des solutions à la demande des habitants de ces deux régions. Parmi ces outils, l’appui de la modélisation de processus biologiques ou de prélèvement, ou l’analyse sur des représentations spatialisées, trouvent naturellement leur place. Pour évaluer l’impact des nouvelles règles nées de la cohabitation avec des agro-pasteurs sur les pâturages herbacés et ligneux, les systèmes multi-agents devraient être plus fréquemment utilisés afin de modéliser à la fois les pratiques coutumières, le fonctionnement de l’écosystème et la dynamique sociale.

Après une esquisse synthétique des principaux acquis des dernières recherches, les auteurs présentent un choix de thèmes prioritaires de recherche en sylvo-pastoralisme adaptées à des deux régions.

Rural communities as a corner stone of sustainable forest management

Mohammed Ellatifi
Forest Service, PO Box #20100, Casablanca, Morocco
FAX: +212-2-98 24 28, Email: m.ellatifi@ellatifi.8m.com

Forest ownership is very variable throughout the world; the percentage of state-owned forests goes from near 100% to less than 50%. But whatever is this percentage, the populations living in the forest neighborhood play a key role in its preservation and its development if people are are intensely and continuousely involved in its management. On the opposite -and this is particularly true in rural areas of developing countries-if the grassroots communities are ignored and not fully involved in what scientists are planning and doing alone in the forest, the population could become the major source of prioblems for the forest, putting in jeopardy its preservation and causing in some areas its degradation and even itsdisappearence. This paper analyses the situation in developing countries, and put emphasis on the necessity to consider people as part and parcel of the forest environment. Their hope, their vision and their basic needs should carefully examined, with them, and included in abnu sound sustainable forest management. Examples of successful, as well examples of failibng forest managements are given and analysed in some countries. Lessons are brought up from these cases, and field-tested recommendations are given for the general preservation and development of our forest environment.

Data collection for sustainable forest development

Ravindra B. Lal, Lokho Puni & Charru
Government of Manipur, Special Secretary (Forests & Environment), Imphal, India

Sustainable development of a country particularly in tropics will greatly depend on scientific management of its natural resources. in India, forest is considered an important natural resource. The resource management planning requires availability of adequateand authentic data. The main agencies, that are involved in forestry data collection in India are Forest Survey of India(FSI) and State Forest Departments (SFD). The Indian Council of Forestry Research and Education (ICFRE) also undertake Collection and compilation of forestry data through various State Forest Departments. However, the forestry data collection in India is still inadequate and at times not upto data to facilitate resource management planning. No organised market structure for forest produces particularly for non-timber - Forest - Produces (NTFP) can be developed without reliable data. This has a direct bearing on the economy of tribals and rural poors who greatly depend on forests for their sustainance. Similarly, for large scale afforestation planning, it is not enough just to have basic forestry data but also we must have information on meterological data, soil types, genetic variability, availability of seeds of various species etc. The present paper focuses on the need for authetic data/collection kinds of data required problems associated with data collection and possible improvements in existing system of data collection using latest trends in Information Technology.

Keywords:- Resource, data, forestry, Planning, sustainable development

The characteristics of forest ecosystems with its sustainable utilization around Yalu Tsangpu Grand Canyon of Tibet

Bosheng Li
Institute of Botany, The Chinese Academy of Science, 20# Nanxincun, Xiang San, Haidian District, 100093 Beijing, China
Email: zhchen@caf.forestry .ac.cn

There are three kinds of characteristic with forest ecosystem obviously have been summarized via the six times of the field investigation around Yalu Tsangpu Grand Canyon region over past ten year .

1. Abundance of forest ecosysterm biodiversity reach a peak value on the zone of identical latitude throughout the world. As a result of the strong influence on it's warm ~ humidity current with moisture passage come from Indian ocean through Yalu Tsangpu Grand Canyon, therefore the distribution of tropical monsoon rain forest ecosystem up to 290 30'north latitude. Around Yalu Tsangpu Great Canyon region, the low mountain ever green and semi-ever green monsoon rain forest; the montane everygreen and semi-everygreen broad leaf as well as the subalpine taiga niddle leaf forest have been composed of a richest mountain forest ecosystem in order of vertical zones. Within this region, Only 2,200 square meter is less than1.8% of Tibet total area .So far we know, there are:

3768 species of vascular plants, accounting for 65% of the total species found in Tibet .

512 species of mosses amounting 65% of the total species found in Tibet .

686 species of fungi taking 78% of the total species found in Tibet .

206species of rust amounting 77% of the total species found in Tibet .

63 species of of mammals, taking 50% of the total species found in Tibet. 232 species of birds ,amounting 49% of the total species found in Tibet. 25 species of reptile taking 43% of the total species found in Tibet. 19 species of amphibious animal amounting 47% of the total species found in Tibet.

1500 species of insect ,taking 60% of the total species found in Tibet.

2. The Yalu Tsangpu Grand Canyon with it's length, depth, and water flow hit an all ~ around world supreme. The biological species on richest and original forest on densest, covering in high snow mountain and deep valley, composed of a most magnificent landscape in the world.. There is a most attractive canyon nature reserve for ecotourism as well.

3. Owing to advantageous water heat regimes, the biomass and growth rate of Taiga needle leaf forest around this region meet top level in the world .

According to the characteristic has been described above, the masterplan on forest ecosysterm protection with its sustainable utilization should be carried out in scientific way as following:

- in the southern the part of Yalu Tsangpu Grand Canyon reign is the area of the biodiversity on richest will be built a protected area at national level as a gene bank of mountain bio-resource for biodiversity conservation and sustainable utilization.
- in the northern part of Yalu Tsangpu Great Canyon reign, the national forest Park will be established. Via the ecotourism as an appropriate means of helping to achieve poverty alleviation. and change the traditional practices, such as timber extraction and slash-and-burn cultivation.
- On the periphery of Yalu Tsangpu Great Canyon reign, the sustainable forestry base under scientific management will be built up for the economic timber supply.

Development of Fuel Wood in Chinese Rural Area

Huiqing Li
Chinese academy of forestry, Research institute of forestry, 100091, China
Tel: 0086-10-62889669, FAX: 0086-10-62872015,
Email: lihuiqin@rif.forestry.ac.cn

The potential amount of fuel wood in 17 provinces of China can't meet the need. About thirty percents of forest consumed every year is for fuel, so the study on development of fuel wood in Chinese rural area is very significance. The dissertation includes four parts. The first part reviews the present situation about fuel wood consuming in Chinese rural area. The requirement and provident of fuel food in Chinese rural area is compared, and how much of forest consumed as fuel wood every year is analyzed. From these materials and analysis, we can get the idea, The rural community is poorer, and their connection with fuel wood is more closely. Being short of fuel wood has lead much more forest cut down for fire that is one important factor effecting climate changing all over the world. So that developing fuel wood is urgent. The second part forecasts the role of developing fuel wood in Chinese rural area. Firstly it can resolve the most important problem for community in aural area where fuel wood is the main energy resource. Secondly it would prevent a mount of forest being destroyed that is helpful for improving on environment quality, so it can reduce the loss bring about by natural disaster. Thirdly it would bring direct income for those poor community, for example, Providing for forage, fruit, and etc. and if fuel wood can be planted in a large area, it can be made used for papermaking and other industries. From the forecast, we can see that once fuel wood is planted in large area, it would benefit the aural people in many perspectives. The third part looks into the elements that have prevented fuel wood developing in rural area. Poverty is the most important element. One hand the rural communities are wishing to get fuel wood, on the other hand they are eager to get direct economy reciprocation and have no much more interests in planting fuel wood. Then having no ownership of fuel wood they planted is another main element that caused fuel wood be destroyed seriously. Other elements are also analyzed. These elements are obstructive to fuel developing. The fourth part looks for ways that lead fuel wood to sustainable management. The first step is the ownership exchanging. For example, the ownership of fuel wood should belong to the local people and not to state. Then management technology should be improved on. For example, the administrating system should accept the free market rule that is who gets benefits should response for. Let people, who need fuel wood mostly, take part in making decision, and the main thing state should do is to stimulate and encourage the local people on policy. Then long-term task, invest and others are also be plunged into for fuel wood sustainable management.

Participative Strategic Planning for Sustainable Community Forestry in Chihuahua, Mexico

Concepción Lujan Alvarez, Joel A. Diemer, Lois Stanford
Universidad Autonoma de Chihuahua, Privada de Avenida Quinta Sur No. 1102, C.P. 33000 Ciudad Delicias, Chihuahua, Mexico
Tel: Office(14) 72 19 67, Email: clujan@smart.net.mx

Chihuahua, Mexico has 5.1 million hectares of forested area that occupies 27% of the states total area. During historical development, Chihuahuas forests typically were harvested by private enterprises and, rarely, by ejidos and communities. Folllowing the Mexican Revolution, the government instigated agrarian reform programs, establishing the ejido as a land grant to peasants.

Peasants or ejidatarios have use rights over the land and harvest the ejidos forest resource communally. Over time, ejido communities often included both ejidatarios, with land use rights, and avecindados, those who live in the community but do not exercise land rights and cannot participate in harvesting forest resources as owners but they can just participate as workers. Thus neither ejidos nor their communities have obtained the major benefits from forest resources. However, they now demand to participate actively in the productive process to obtain more benefits. New forestry strategies propose to integrate social and economic development with environmental protection, and to expand participation of different sectors.

This research study focused on strategic planning for sustainable community forestry in Chihuahua, Mexico. The research focused on two forest ejidos in the Sierra Tarahumara: Basihuare and Cusarare. We hypothesized that Basihuare (the intervention community) would have more positive and statistically significant changes in attitudes toward community development than Cusarare (the control community). Our objectives were: 1) assess the current forest resource management in both communities, 2) conduct participative strategic planning methodology (Search Conference) for forest-based community development to achieve a greater awareness of development needs, positive attitude change and to design a strategic action plan for a future community, and 3) assess the attitudinal and perceptual impact of the strategic planning intervention (SPI) of local people toward community development.

A static group comparison was conducted in this study. The study consisted of applying a pre-test (attitude questionnaire) in both communities. The questionnaire consisted of 20 statements, including questions about local peoples participation and the design of strategic action plans for community development, among others. After that, a SPI was conducted in Basihuare. Later, a post-test (same as the pre-test) was applied in both communities.

In addition, qualitative research including ethnographic interviews, participant observation, direct observation, and follow-up encounter provided further insights into evaluating the forest resource management, and the impact of the intervention. Comparisons were carried out between two ejidos before and after conducting the SPI to measure the changes in attitudes The results showed that: 1) ethnographic interviews were a valuable complement to and cross-check on the participatory approaches to obtaining views from the community members about their community forest resource management, and 2) the SPI achieved a greater awareness of development needs and created more positive attitudes and perceptions about community development (Basihuare). As a result, it is possible to note that SPI significant changed the respondents attitudes and perceptions in intervention community. Statistically, there were significant differences in attitude changes in people that participated in the SPI (Basihuare) compared to people who did not (Cusarare). Additionally, the planning conference helped the Basihuare community to design its own strategic action plan for future development. The community not only developed its own strategic action plan, but also, because of the participative and democratic process they used, they developed community plans. in the research, even though, Basihuare lacked financial resources for investment, profits from its sawmill, and resource planning, local people did not display negative attitudes toward for community development in the future. If resources are available, they are motivated and interested in implementing the action plans for their community. The results confirm the initial hypothesis and suggest that the study can serve as a model for the application of the Open Systems approach to the development of sustainable community forestry for the Sierra Tarahumara and elsewhere.

Forest Research and Sustainable Forest Management in Estonia

Yuri Martin, Rein Ratas
Toompuiestee 24, 15172 Tallinn, Estonia
FAX: 372 62 62 801, Email: Dr. Mohammed ELLATIFI [m.ellatifi@mailcity.com]

Forests (2.01 million hectars) cover about 48% of the territory of Estonia. Since 1940, forest area has increased by 1.07 million hectars. The gross annual increment is 9.5 million cubic metres. Timber and timber products account for up to 18% of Estonian export. Forest and timber related production forms 1/3 of the GDP.

The objective of forest related research is to provide scientific background information in support of practical decision-making in forest management, conservation and multiple use of forests.

To complement investigations on forest ecology, increased emphasis will be laid on analysing the entire chain of forest-based production. Other priority areas of research include the development of environmental monitoring systems, research on biodiversity management and environmentally friendly forest management. Forest research will also support the formulation and evaluation of forest related policies by conducting scientific analyses on key issues.

Basic research is integrated with teaching activities in the Faculty of Forestry of Tartu Agricultural University. Institutional environment will be developed in view to enable research and development activities to be carried out in collaboration with forest enterprises.

To rationalize resource utilization, full benefit will be taken of the research carried out within the international research community. Long-term empirical research programmes will be concentrated in areas where the peculiarity of Estonian conditions warrants the effort. in order to ensure balanced development of forest research and efficient use of resources, the identification and implementation of research programmes will be carried out in coordination with other forest related research institutions.

Today, Estonian science of forestry receives only 2% of the finances allocated to the scientific research sector from the national budget.

In 1998, the total volume of cuts was 6 million cubic metres. The total annual maximum volume of wood harvesting in all Estonian forests not exceeding the sustainable level, is 7.8 million cubic metres. Forest, as a renewable resource, should be used within the limits of its regeneration. in our forests we have stopped excessive felling already in 1961. The area of protected and protective forests will be maintained at the current level (15% of the total forest area). The leading role in environmental and forest policy and legislation belongs to the National Forestry Board (NFB) which operates within the administrative area of the Ministry of the Environment. The NFB is responsible for the implementation of forest policy, monitoring of forest resources taking into consideration the environmental, social and economic factors, biodiversity both on the stand and landscape level.

Sustainable forest management in Estonia is based on:
- scientific research;
- Act on Sustainable Development (1995);
- Forest Act (1993, 1998);
- Law on Protected Areas (1994);
- National Environmental Strategy (1997);
- National Forest Policy (1997);
- Development Plan for the Estonian Forest Sector (1997);
- European Union Habitats Directive, including NATURA 2000.

The Challenge of Meeting Domestic Energy Demand in Sub- Saharan African countries

K. S. Nketiah
Forestry Research Institute of Ghana, University PB 63, Kumasi, Ghana
FAX: 233-51-60121, Email: forig@africaonline.com.gh

Most Sub-Saharan African Countries depend heavily on wood for their domestic fuel. Even though the countries are rich in vegetation, there are localised wood deficits. Moreover, wood resources are often far removed from areas of population concentration. Populations are growing at very high rates, and with that, increasing demand for wood for fuel.

These countries are characterised by strong traditions and cultures, some of which are inconsistent with modern day scientific thinking.

People still cling to traditions and customs some of which are inimical to sustainable forest management and hence sustainable supply of fuel wood. Even though the use of wood for fuel has been a century old practice, woodfuel is not given the requisite attention in national energy balances; forest policies also do not give due prominence to woodfuels.

Attempts at meeting future demand (for woodfuels) have been rather haphazard and unsustained or isolated. Instead of planning to increase the supply base, countries have resorted more to control measures most of which have been difficult to enforce or police. Such measures have included bans, fines and legislation. Some countries have also tried to promote substitutes for woodfuel. Others have tried to introduce fuel-efficient production- and conversion technologies and devices. Due to the generally weak economies of these countries, the interventions have invariably had a donor-assisted component.

This paper looks at efforts made by different countries to meet demand for wood fuel for domestic use. Various supply scenarios are evaluated and realistic proposals made for meeting domestic fuel demand in this sub-region on sustainable basis.

Gestion de la Biodiversité: Relations aux plantes et dynamiques Vegetales chez les Dani de la Vallée de la Baliem en Irian Jaya, Indonesie

Yohanes Purwanto
Indonesian Institute of Sciences (LIPI), Laboratory of Ethnobotany, Research and Development Center for Biology, Jl.Ir. H. Juanda 22, 16122 Bogor, Indonesia
Tel: 62 (251) 322035, FAX: 62 (251) 325854, Email: herbogor@indo.net.id

This study was conducted in order to have a better understanding in the interrelationship between the Dani-Baliem and their environment as well as the evolution of their traditional activities in its ecosystem. The consequences of their activities in the evolution of environment are shown by different methods that they modify, utilise, manage its environment and its vegetation diversities.

This research consists: analyses the knowledge and utilization of vegetation and its environment. We also describe the field organization and the local knowledge of botany. We treats the agriculture activities of the Dani-Baliem. The other, this research also analyse the floristic diversity in different environment existence in the Baliem valley. This part consists of analyse floristic of the primary forest of different altitude, secondary forest (fallow system of different ages), transition zone (zone ecotone), home garden, villages and sacred sites. and than, we discuss the relationship between the Dani-Baliem and their environment based on their knowledge of plants, its utilization, its dynamic vegetation and its floristic diversity. Here we discuss environment by confronting the point of view of Dani-Baliem and the ecology, in the way how they exploite them. in conclusion we emphasized how the Dani-Baliem influence the evolution of their environment and the floristic diversity.

Estudio florístico de diversidad de especies en bosques de premontana en la Cordillera de Guaniguanico

Yudel Garcia Quintana, Yarelys Garcia Garcia
Universidad de Pinar del Rio, Marti final # 270, CP 20100 Pinar del Rio, Cuba
Email: dptopfor@netupr.upr.edu.cu

A lo largo de los últimos diez años la conservación de los bosques se ha convertido en un tema de gran prioridad, tanto para los que formulan políticas como para el público en general en todas partes del mundo. En 1992, los bosques templados y tropicales tuvieron un lugar prominente en la agenda de la Cumbre de las Naciones Unidas sobre Medio Ambiente y Desarrollo (CNUMAD), Río de Janeiro. A pesar de estos esfuerzos, la destrucción y deterioro de los bosques ha ido en aumento; provocando serios daños sociales, ecológicos y económico e incluyen pérdidas de biodiversidad y tierras natales para los habitantes de los bosques. Actualmente en Cuba los territorios con vegetación natural son escasos y se encuentran en áreas montañosas, cársicos, pantanosos, serpentiníticos y otros que poseen suelos de escaso valor agrícola. En cambio se caracterizan por un elevado endemismo en ocasiones a nivel local.

Nuestros bosques presentan un elevado grado de alteración y destrucción, sin contar las áreas que han desaparecido completamente producto de la acción antrópica. Es por ello que los estudios de diversidad en zonas montañosas adquieren gran importancia y sirven de base para la protección y conservación de la flora. Los bosques de premontaña contiguos a los mogotes cársicos de la Cordillera de Guaniguanico, al norte de la Provincia de Pinar del Río son de gran riqueza biológica. El estudio de la diversidad florística de un área de 5018 m^2, se realizó a través de la metodología de Brawn Banquet, basados en índices matemáticos, a partir de seis muestras donde se contó el número de individuos y se calculó en cada muestra; evaluándose la biodiversidad de especies bajo diferentes condiciones ecológicas, además del estudio edafológico y climático, determinando a través de la ecuación universal una pérdida de suelo de 90 toneladas por hectáreas y un clima típico de la región insular.

Los resultados florísticos condujeron a calificar la zona como bosque degradado, cuantificándose una inmensa pérdida de recursos madereros, fundamentalmente de Cedrela odorata, madera preciosa de alta demanda en el mercado, lo cual representa el no aprovechamiento de este recurso en la construcción de inmuebles, conociendo que con ese volumen (24.92 m^3 por hectárea) se pueden fabricar 24 juegos de livin y 104 sillones, equivalentes a una pérdida en ingresos de 199200 pesos para esa porción de la Cordillera. Esta investigación realizada en un lote forestal del municipio La Palma perteneciente a la Sierra del Rosario, Cordillera de Guaniguanico permitió recomendar especies para otros sitios degradados específicamente en zonas montañosas; además de recuperar una zona de este tipo desvastada por el hombre y los resultados fueron excelentes. El objetivo del trabajo es proponer un proyecto, incluyendo métodos silvícolas con vistas a recuperar, rescatar y conservar esta formación boscosa compuesta por un gran número de especies autoctónas.

Problematique de l'amenagement des Forêts Naturelles des Zones Tropicales Seches

Bassirou Sougoufara, Souleymane Gueye
DEFCCS, BP. 1831, Dakar, Senegal
Email: Dr. Mohammed Ellatifi [m.ellatifi@mailcity.com]

Le présent mémoire souligne d'abord la complexité de la tâche de l'aménagiste de forêts naturelles tropicales par rapport à celle des zones tempérées. Ensuite il passe en revue les principales contraintes que peut rencontrer cet aménagiste dans sa mission, contraintes générées par les divers facteurs d'évolution d'ordre physique, humain ou technique. Partant de la necessité de l'adoption d'une approche terroir dans l'aménagement de forêts naturelles (AFN) en zones tropicales sèches (ZTS), impliquant d'une part, une responsabilisation et une participation effective des populations rurales locales dans la conception, la mise en oeuvre et le suivi de l'aménagement préconisé, et d'autre part, une intégration des divers systèmes de production existant (Agriculture-Elevage-Forêt) il analyse les interfaces entre ces derniers et propose le développement des interelations positives et des actions à mener pour réduire voire lever celles négatives.

Mots-clés: Facteurs d'évolution, Approche Terroir, interelations entre systèmes de production.

Population dynamics of tropical trees in the Western Ghats of Tamil Nadu, South India

S. M. Sundarapandian, P.S. Swamy
Madurai Kamaraj University, School of Biological Sciences
Department of Plant Sciences, 625021 Madurai, India
Tel: 91 452 858928, FAX: 91 452 859139, Email: E-mail: smspandian@hotmail.com

The tropical forests at Veerapuli and Kalamalai forest reserve, falling within the Agastyamalai hill range (a proposed Biosphere Reserve), is considered one of the 18 hot spots of biodiversity in the Indian sub-continent. During the past few decades these forests were subjected to unscientific exploitation particularly for agriculture, construction of hydroelectric project raising monoculture plantations and other developmental activities. in addition to that the deciduous forests in these regions also affected by annual fires during summer. Such anthropogenic perturbations have often resulted in gradual fragmentation of these forests and such fragmentations inturn has lead to loss of biodiversity. Successful conservation of theses forests will ultimately depend upon the clear understanding of the forest ecosystem dynamics. Therefore, the present study was undertaken (1993-1996) to evaluate short-term population dynamics of trees in both tropical deciduous and evergreen forests in Veerapuli and Kalamalai Reserve Forest in the Western Ghats of Tamilnadu, South India by permanent plot method i.e. thirty randomly located 10 x 10 m^2 permanent quadrats in each study site; 10 in each sub-site.

Mortality of trees (> 10 cm Girth at breast height - GBH) was lower in both the forests compared to recruitment. As a result, there was net gain in population density of trees. Similarly an increase in basal area per hectare was also recorded. The increase in population density and basal area of tree species could be because of their entry into adult stage from the already existing sapling and seedling bank. Both mortality and recruitment of trees were greater in the evergreen forests when compared to that of deciduous forests. Comparatively low recruitment of trees in deciduous forests could be attributed to annual wild fires caused by human interference. in the deciduous forests no adult trees of *Dalbergia latifolia* were found, but the young ones (seedlings) were appeared during the rainy season. This could be ascribed to persistent soil seed bank or immigration of seeds from the neighboring area and also may possibly through vegetative reproduction. However, the survivorship of these

seedlings were very poor and which could be due to wild annual fire caused by anthropogenic perturbations. Greater recruitment of trees to compensate mortality has resulted in a net gain of population in evergreen forests. This net gain of population may be attributed to favourable microclimatic conditions for better growth and survival of seedlings. Greater mortality of juveniles compared to that of adults occurred during the study period. This could be due to intense competition for limited available resources at the juvenile stage. However, population dynamics of trees at species level varied considerably. The present study suggests that the forest ecosystems here are at building phase and needs long-term demographic studies to understand the regeneration niche.

Indigenous Forest Management System (IFMS) and Forest Products Commercialization: The Upland People's Strategy on Forest Conservation in the Cordillera Region, Philippines

Fatima T. Tangan
Ecosystems Research and Development Service,
Department of Environment and Natural Resources,
Loakan Road, 2600 Baguio City, Philippines
FAX: 0063-442-4531, Email: erds-car@mozcom. Com

The Cordillera Region is rich with endemic and exotic species whether shrubs, trees or vines. From generation to generation various tribes in the region have somehow practiced their indigenous knowledge in the management of the forest. Thus, different terms were created by the natives to describe their different forest conservation measures. For instance, saguday is describe as a former portion of the communal domain originally awarded to an individual family devoted to pine plantation, and of which continue to be corporately owned by the second generation of heirs. Other forms of forest management includes Komonal, Tayan and others depending upon the forest type and tribe who practices the system.

A case-study on the commercialization of forest products (wildfood plants, bamboo, rattan, medicinal plants, etc.) had been carried out as a part of larger project which was conducted in some communities of the Cordillera Region. The topic to be presented covers specifically how the natives protect and manage their ancestral land domain claims at the Mt. Pulag National Park while wildfood and medicinal plants and other products are extracted for their domestic and economic needs.

Other features of the study are the advantages and disadvantages of the proclamation of Presidential Decree 75 in 1987 and Republic Act 7586. The problems on land tenure as affected by conflicting Presidential Decrees, Migration of other tribes within the region and dependency of the people in the forest will be presented. The contribution of the local people in educating the tourist as a livelihood option and the role of the research service of the Phil. Government during the experimentation stage will be discussed.

The various forest products whether raw or processed which has played integral part on the daily life of the people and its implication to the conservation and management of the forest were documented. Likewise, data on the role of women and men in these indigenous forest management system (IFMS) whether in the protection and utilization were gathered and analyzed.

The objectives of the study are (1) to document the different indigenous forest management practices in the Cordillera Region, (2) to assess the bio-physical component of the Mt. Pulag National Park, (3) to determine the attitudes and perceptions of the indigenous peoples regarding Presidential Proclamation, (4) to determine the role of men and women in the establishment, preservation management and utilization of the various indigenous forests.

4.02.03 / 4.02.06 Update calibration and enhancement of forest inventories through the inclusion of remotely sensed data

Vertical and horizontal integrated inventory of forest resources

Alparslan Akca
Institut fuer Forsteinrichtung und Ertragskunde,
Buesgenweg 5, 37077 Goettingen, Germany
Tel: 49-(0)551-393473/72, FAX: 49-(0)551-399787,
Email: aakca@gwdg.de

With the ever increasing use of the forest for purposes other than wood production, such as recreation, watershed management, wildlife refuges, protection of nature, etc., the scope of forest inventories has been expanded.

A complete forest inventory for timber evaluation should also provide so-called non-timber information on:
* Recreational, touristic interest
* Soil and land use capabilities
* Watershed values
- Biodiversity
* Protection of nature, impact of deforestation

It is not sensible, nor even possible, to compile all forest-related or relevant information into one forest inventory. On the other hand, an inventory corrected with this in mind, is not only cost-effective and time-saving, but also provides the opportunity of documenting environmentally-relevant information, which can be analyzed in view of ecological landscape management.

In order to make sound political, administrative and management decisions at the different levels, it is necessary to have reliable and current data relevant to forest resources and the changes therein. Forest inventories can usually be categorized into four levels, according to the scale or size of the inventory area studied and their significance and relation to economical and ecological forest management policy, regional planning, planning at the forest enterprise and stand level.
* National (or international forest inventories)
* Regional forest inventories
* Forest enterprise inventories
* Forest stand inventories

In most cases, and in the majority of countries, the inventories are carried out independently at the different levels so that an information flow between the varying levels is not possible. in the age or time of informatics, a "vertical" integration would be very valuable for decision making at all levels. An effective forest inventory concept should integrate the information flow of all four levels, as described above, taking the necessity of the information required at the varying levels into account. This means that the national, regional, enterprise and stand level inventories must originate from a joint inventory concept, filtering down from the top level, i.e., from a national inventory down to a stand inventory and/or from the bottom to the top level.

The efficiency of forest inventories can be increased by employing remote sensing methods using aerial photographs, air-borne scanner and satellite images. in the last years, remote sensing methods have undergone a very rapid development because new, high-resolution sensors and perfect data processing methods are being developed, which allow economical digitized data recordings on a large scale. Traditional aerial photographs are still being employed as valuable supplementary inventory aids, especially at the enterprise and stand levels. However, aerial photographic methods can only be effectively applied in combination with terrestrial recordings and mathematical-statistical methods. Taking this into consideration, aerial photographic methods can applied at varying levels of intensity, from the most simple to the most complex analytical evaluation, depending on the subject of interest.

Complementary methods to assess forest landscape structure: Shannon's entropy and fractal dimension of remotely sensed imagery

Piermaria Corona, Marco Marchetti, Carlo Ricotta, Roberto Scotti
Universiti degli Studi di Firenze, Istituto di Assestamento e Tecnologia Forestale (forest management institute), Via S. Bonaventura, 13, 50145 Firenze, Italy
FAX: +39055319179, Email: corona@cesit1.unifi.it

Landscape structure, interpreted as indicator of functional processes, has become a main attribute of multiresource forest inventories, enhancing its value with respect to society needs. This approach implies effective use of earth observation techniques and geographic information systems, enabling a global view of the inventoried landscape mosaics. The objective of this paper is to discuss two complementarily targeted approaches to assess forest landscape structure and complexity: a method based on information theory as introduced by Shannon, and one based on the estimation of local fractal dimension. Both methods together provide an objective assessment of landscape structure at the given resolution.

Estimating the Density of Rare Tree Species - A case Study from Ethiopia

Alfred de Gier, G. Dessie
International Institute for Aerospace Survey and Earth Sciences (ITC), Hengelosestraat 99 Post Box # 6, 7500 AA Enschede, Netherlands
Tel: +31 (0)53 4874309, FAX: +31 (0)53 4874399, Email: degier@itc.nl

Rarity is one of the problems in biodiversity assessment, because estimates of the density of these species are often imprecise. It is therefore necessary to identify sampling designs, which can yield precise estimates. in this research a relatively new method called adaptive cluster sampling was applied to a forest area in Ethiopia, and compared with simple random sampling. The comparison of adaptive cluster sampling and simple random sampling was based on the relative efficiency of their variances. The results reveal that under certain conditions, adaptive cluster sampling of rare species is more efficient than simple random sampling. The degree of efficiency of this sampling design was found to be influenced by the level of rarity, and the size of the rare species groups.

Automatic estimation of volume factors in real stands by digital image processing

Kim Dralle
The National Forest and Nature Agency, Haraldsgade 53, DK-2100 Copenhagen, Denmark
Tel: +45 39 47 25 16, FAX: +45 39 47 98 99, Email: kdr@sns.dk

A practical application of automatic stem number estimation by kernel smoothing on digital aerial photos is presented. This application improves forest inventory results compared to results obtained by established methods, for *e.g.* Norway spruce (*Picea abies* [L.] Karst.), through improved stand level stem number estimates. Rough estimates of tree characteristics such as height and diameter of the mean tree corresponding to basal area retrieved for example by ocular assessment can, in a roundabout way, be used to assess other volume factors. However, the first step to improve stand level volume factor estimates is to obtain sufficiently accurate estimates of stem number. Kernel smoothing of digital aerial photos is demonstrated to yield this stem number estimate in real stands. Further, it is demonstrated how the method in a second run will provide individual tree characteristics such as position in a global co-ordinate system, heights and diameters. A comparison to other "similar methods" as for example ray tracing will be presented.

Climatic Regions Classification of Taiwan

Fong Long Feng, Jian-Tai Kao
National Chung Hsing University, Dept. Forestry, Taichung, China-Taipeh
Tel: 886-4-2854060, FAX: 886-4-2873628, Email: flfeng@nchu.edu.tw

The ecosystem should be based on multiple factors. Ecosystems are defined by multiple factors. As Sokal (1974) pointed out, "Classifications based on many properties will be general: they are unlikely to be optimal for any single purpose, but might be useful for a great variety of purposes." This is termed a "natural classification". and some scientists use land-use, landscape vegetation pattern, ... et al. But most scientists use the criteria of climatic characteristics, because climate is the limit factor of biology distribution. There are three methods: regionalization, map-overlay, and multivariate clustering method introduced to reclassify the climatic regions in Taiwan. There were 8 climatic regions by regional and Zheng-Xiang Chen (1957) abbreviated regions from 20 climatic sub-regions that used 100 climate stations according to Thornthwaite System. The map-overlay method was used Holdridge life zone classification model to produce 11 climatic regions in Taiwan. There are 948 habitat clusters reclassified into climatic region diagram by average linkage method by multivariate clustering method. These 948 habitat clusters in Taiwan environment factor database were clustered from the 1km*1km grid of Taiwan by 12 habitat factors. The 12 habitat factors include elevation, slope, aspect, mean temperature per year, mean high temperature of July, mean low temperature of January, total precipitation per year, precipitation winter semester, precipitation summer semester, soil class, soil texture, soil effective depth. The relationships among each classification system were discussed in the paper.

The climatic region maps and the intercross tables are showed the relationships among the Chen's climatic regions, Holdridge life zone classification model in Taiwan and climatic cluster regions in different levels. There are 8 Chen's climatic regions in Taiwan, which were (1) North-East (NE), (2) North (N), (3) South-West (SW), (4) South (S), (5) East Coast (E), (6) Central Mountain (CM), (7) West Coast (W), (8) Peng-Hu (PENG), according to factors: (1) monsoon (2) precipitation (3) potential evapotranspiration and moisture balance (4) average annual thermal efficiency. The factors used in Holdridge life zone classification model were (1) mean annual bio-temperature (2) average total annual precipitation (3) potential evapotranspiration ratio to map-overlay. There are 11 life zones developed with Holdridge model. Those zones are (1) sub-alpine rain forest (2) mountain rain forest (3) mountain wet forest (4) lower mountain rain forest (5) lower mountain wet forest (6) lower mountain moist forest (7) subtropical moist forest (8) subtropical dry forest (9) tropical wet forest (10) tropical moist forest (11) tropical dry forest. The climatic regions diagram shows there are stable climatic clusters where Euclidean distance between 0.8 ~ 1.4. There are plain, slope-land, mountain, northeastward wet forest, southwestward wet forest, slope-land where summer monsoon and winter dry, like Tai-Wu, Ma-Jia region, southern wet forest, Da-Wu-Mountane region as stable climatic clusters. The difference among three methods were due to diverse in interest classified factors.

Forest and Woodland Ecosystems in Dinder National Park: A challenge to integrate Conservation

Salwa M. Abdel Hameed, Nadir M Awad, Amna A. Hamid
Wildlife Research Centre, Post Box #16- Elmourada, Omdurman, Sudan
Tel: 313532-314798, FAX: 491(11) 777017-770735, Email: amnahamid@hotmail.com

National Park status is desirable for most conservation areas because this confers greater legal security for the land and usually allows greater power of control and law enforcment. However, with human population increasing rapidly and the short-full in food production increasing annually, many national parks in Africa have become islands of natural resources in good condition surrounded by high human population densities occupying degrading lands. The conservation of the biological diversity they contain affect the livelihoods of the rural populations in the surrounding because of the regulation needed to support conservation. DNP in Sudan is facing the same situation.

Knowledge of the nature and seriousness of any conflict require accurate assessment and true evaluation of the resources available and the needs of the local communities. A vegetation and landscape survey including interpretation of Land Sat MSS images and aerial photographs, was conducted in Dinder National Park, accompanied by social studies via questionnaires and informal interviews during 1996-1999. The landscape ecology vegetation map was produced. Four major landscape units were found:- alluvium, clay plain, depressions, hills and pediments with varied soil types and vegetation subsystems. The distribution of the vegetation in DNP seems to be influenced by several factors; water regime, topography, soil types and human activities in the park. The local communities (Rahad villages and Maggno indigenous population) in their sharp reaction against laws and regulations resort to antagonistic actions, utilizing the resources illegally. They suffered from penalty and under development. Their continuous demand for the resources might lead to severe destruction of the productive ecosystems Riverine forest and Woodland ecosystems have great potentiality of providing wide range of economic, social and environmental benefits. New strategy for management, utilization and conservation should be addressed to suit the new concept of community based integrated resource conservation, in order to safe guard the remaining resources towards sustainable development.

Modeling regeneration establishment for Austrian forests using neural networks

Hubert Hasenauer, Dieter Merkl
University of Agricultural Sciences, Institute of Forest Growth Research, Peter Jordan Strasse 82, A - 1190 Vienna, Austria
Tel: +43 1 47654 4205, FAX: +43 1 47654 4242, Email: hasenau@edv1.boku.ac.at

Artificial neural networks represent a computational methodology widely used to uncover the structure of a large variety of data. in general, one may recommend the application of neural networks in areas characterized by noise, poorly understood intrinsic structure and random impacts. Each of those characteristics is present in predicting regeneration establishment within uneven aged mixed species stands. in this paper we describe the design and estimation procedure to predict regeneration situation in uneven-aged mixed species stands using neural networks. The result of the study is that the number of juvenile trees per unit area and the relative percentage of individuals by tree species can be predicted with neural networks and that the estimation procedure is more accurate versus the conventional statistical approach based on regression analyses.

Keywords: Regeneration, Neural Networks, Uneven-aged mixes stands

Draining and secondary inundation in the Leningrad Region

V. K. Konstantinov, G.B.Velikanov
Saint-Petersburg Research Institute, Institutsky pr., 21, 194021 Saint-Petersburg, Russia
FAX: (812) 552-80-42, Email: spb330@spb.sitek.net

During the last two centuries approximately 750-800 thousand hectares of forest stock in Leningrad region were drained. That is no less than 14% of its area or 55% of the water-logged land. At present the area with still working draining systems is reduced to 480 thousand hectares. Region forests growing on water-logged lands (with peat or without it) are divided into four main groups. The first, the second and the forth groups are represented by pine, spruce, birch and partly by other broad-leaved forests, which refer to swampy-grassy soil on the eutrophic peat, grassy-bog mossy(grassy-sphagnous) on the mesotrophic peat and long mossy-blueberry on the peaty(less than 0,2-0,3 m of peat) and mineral gleysol soils, respectively. The third group(named "bog-mossy") is characterized by pine forests on the oligotrophic and oligotrophic-mesotrophic peat.

Draining of the first and the second forest groups produces the greatest forestry effect. The quality of locality increases from IV-V to II-I, and the annual mean increment of timber is 2-5 m^3 per hectare. in the third and the forth groups the annual mean increment doesn't exceed 0,5-3 m^3 per hectare.

Secondary bogging of drained lands happens because the work of draining channels deteriorated due to the lack of care and inadequate extent of draining(density and depth of channels), established in the projects. Losses of annual increment of timber due to the bad condition of channels reach about 30-60%. More than that, up to 50-60% of drained and adjacent to them earlier drained lands are flooded because of beavers' dams, built on the channels.

Up to 200-300 hectares are flooded by roads; approximately the same territory is flooded by reservoirs. Nowadays, among the factors determining bogging dynamics the leading one comparable to the natural process of bogs-growing is a technogenic factor; that is construction of roads, dams, oil and gas pipe-lines.

Forecast of the balance between over-drained and drained lands for the next twenty years indicates reduction of the area with provided draining norm on 112 thousand hectares; 70 thousand hectares will be transferred into the category of secondary bogging. It is necessary to take prompt measures to carry out repair works in the draining systems.

Technological Inventory for Norway Spruce in Italy

M. Negri, C. Pollini
Wood Technology Institute, National Research Council,
Via Biasi 75, I - 38010 S- Michele a/A, Italy
FAX: +39.0461.650045; Email: negri@itl.tn.cnr.it

Knowledge of the quality of timber produced in natural forests allows for rational management. Although in forests growing in the Alpine chain the productive function plays a complementary role, the revenue from timber sales covers the cost of cultural and thinning operations. Since the quality of the timber is strictly related to the quality of standing trees, a large study to relate the properties of trees to the properties of sawn timber was carried out.

A thematic map on wood quality is therefore an important element towards better planning and management of forest assets and of mountain areas in general.

The main objective of the research is to identify significant correlations between the morphological parameters of standing trees and the quality and quantity characteristics of the products obtained from primary processing, such as defining wood quality on a geographic scale and thus creating a specific thematic map.

The research was conducted in the forests in the province of Trento (Italy). The prevailing species in this Alpine area, and also the most interesting from a commercial standpoint, is Norway spruce (60%). Consequently, this species was chosen as the subject of this study.

The study can be divided into three distinct phases.

The first phase foresees:

- the preparation of a set of operating tools (methods, protocols, instrumentation, classifications, etc.) suitable for identifying the main parameters that will be considered for the study on correlations between standing trees and timber characteristics;

- the writing up of a visual classification of standing trees, with allocation of each single plant to quality classes;

- the calculation of the sawn yields according to round wood quality and determination of the Quality Index (QI) of the visual classes adopted (QI indicates the value of the unit volume of round wood expressed as the value of the final boards).

The second phase consists of extensively applying the protocols and methods perfected in the first phase. A map of a small pilot area is prepared, on which wood quality is indicated both in terms of the "intrinsic quality" of the raw material and in terms of the value of the final assortments obtained. Mapping is performed on the basis of a very high number of sampling areas concentrated in a restricted area so as to obtain a dense sampling lattice. The pilot area is selected so as to contain areas with various exposures and gradients and to cover a wide altimetric range. The identification of the laws of distribution of the variability of the parameters researched allows us to modulate the mesh of the sampling lattice necessary for the third phase.

Preparation of the standard map constitutes the third phase of the study. The model obtained can then be applied progressively to the forest areas with production functions in the provincial area.

Monitoring Forest Cover Changes in Malaysia Using Remote Sensing Technique

Aswati Surep
Forest Research Institute Malaysia (FRIM), Regional Centre for Forest Management, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6377633, FAX: 603-6377233, Email: aswati@psph.frim.gov.my

Forests are a renewable resource that play a vital role in the development of the national economy. Malaysia is endowed with extensive tropical forest resources. It was reported in 1992 that about 19.06 million ha or 57.9% of total land area is covered by forests. Remote sensing is acknowledged as the most powerful tool to monitor detect any changes of a forested area. This paper reviews the potential of using remote sensing technique in detecting land use and land cover changes in Malaysia. Studies in Sabah (197601983), Rawang (1988-1995), Sungai Buloh Forest Reserve (1988-1995) indicated that that were significant forest cover changes occurring in the study sites. Causes and rate of forest cover change were quantified and discussed. The usefulness of remote sensing technique in detecting forest change in Malaysia has been explored significantly. Although much of the efforts are still at the infant stage, the potential use of the technique at the operational level is very promising.

Monitoring for Survival Rates of Young Plantation Trees in Japanese Mountainous Region Using Landsat TM data

Yukio Teraoka, Akihisa Hirata, Shigeru Iida, Nobuya Mizoue, Shigejiro Yoshida, Morio Imada and Susumu Inoue
Kagoshima University, Dept. Environmental Science and Technology, 1-21-24 Koorimoto, 890-0065 Kagoshima, Japan
Tel: +81-99-285-8574, FAX: +81-99-285-8575, Email: teraoka@env.agri.kagoshima-u.ac.jp

According to the increase of plantation area, the afforestation has progressed to inaccessible mountainous regions located at high altitude and in cool temperate conditions. The plantations in inaccessible mountainous regions were liable to be under severe conditions because of Kyushu Deer (*Cervus nippon*) grazing impacts freezing and drought damages. Therefore, unsuccessful plantations have been increasing with planted trees' disappearance and competition with naturally invaded broad-leaf trees. It was hard to monitor the state of every plantation by field observations because of lack of time, efforts and costs. Then, the effective method has been needed for monitoring the state of unsuccessful young plantations in inaccessible mountainous regions. The objective of this study was to develop the method to estimate the survival rates of planted trees in young Sugi (*Cryptomeria japonica*) and Hinoki (*Chamaecyparis obtusa*) plantation sub-compartments by analyzing the Landsat TM data. The study sites were young plantations in Kyushu University Forests in Miyazaki that were located in southern Kyushu, Japan and within the cool-temperate deciduous zone. The series of plantation has been developed since 1978 under the clearcutting system in blocks surrounded by shelterbelts. Each cutting block was divided into slope units by slope azimuth because the survival rates have varied with azimuth. The method of this study was composed of three principle parts. 1) Interpreting survival rate of planted trees on a pair of aerial photograph. 2) Field measurements of spectral reflectance on both planted trees and grass to examine the difference in spectral reflectance characters of two vegetation types. 3) The analysis between the TM data and the survival rates of trees under two MODELs. MODEL I using NDVI and MODEL II using the TM band 3 digital number (DN) for detecting the difference in spectral reflectance between planted trees and grass. As the results, 1) there were wide differences in the survival rates among slope units and also among cutting blocks, and a northern exposure slope had a relatively high survival rate comparing to a southern exposure slope. 2) It was difficult to estimate the survival rates of planted trees by NDVI. 3) DNs in the TM band 3 were preferable to estimate the survival rates of planted trees. The relationship between survival rates and average DNs for northern and southern exposure slope groups showed strong negative correlations with the coefficient of determination 0.98 and 0.62. in addition, two correlation lines had the same regression coefficient from the result of 5 % significant level test. From this the difference in intercepts of both lines might indicate the reflectance characteristics of two slope azimuths. This study would supply the effective monitoring method for unsuccessful plantations in inaccessible mountainous regions.

Inventory of Remote Sensing Applications in Forestry: State of the Art

Yousif Ali Hussin, Witske Bijker
The International Institute for Aerospace Survey and Earth Science (ITC), 7500 AA Enschede, Netherlands
FAX: (31) 53-4874-399, Email: hussin@itc.nl

To consistently and repeatedly monitor forests over large areas, it is desirable to use remote sensing data

and automated image analysis techniques. Several types of remote sensing data, including Aerial photography, Optical Multispectral Scanner, Radar, Lidar (Laser) and Videographic data have been used by forest research and operational agencies to detect, identify, classify, evaluate and measure various forest cover types and their changes. Over the past decades tremendous progress has been made in demonstrating the potentials and limitations of the applications of remote sensing in forestry.

For several types of applications of remote sensing in forestry in specific regions of the world such as tropical areas, users of forest information are demanding new establishment of sensors and platforms. in order to see what kind of information we can extract from the current remote sensing sensors and platforms, an inventory of all remote sensing applications in forestry is needed.
This paper presents a literature review of the use of remote sensing for measuring, estimating or describing forest characteristics and mapping forest cover types. It deals with all forest types around the world, on all latitudes and climates, natural as well as man-made, but not with other land cover types. The paper starts with an introduction to remote sensing, followed by definitions of forest types and characteristics, as will be used in the remainder of the paper. Then an overview of the applications for forestry per type of sensor "type" which defined by the portion of the electromagnetic spectrum that is used and the way of recording (digital or analogue), not by the platform. The paper will then discuss the applications of the sensors in forestry. A section on synergy, where applications using a combination of different sensors are reviewed. The publication ends with conclusions and an outlook.

Remote sensing can detect, identify, classify, evaluate and measure various forest characteristics in two ways: qualitatively and quantitatively. in a qualitative way remote sensing can classify forest cover types to: coniferous and deciduous forest, mangrove forest, swamp forest, forest plantations, etc. While the quantitative analysis can measure or estimate forest parameters (*e.g.* dbh, height, basal area, number of trees per unite area, timber volume and woody biomass), floristic composition, life forms, and structure.

4.02.05 Remote sensing and forest monitoring

Global Observation of Forest Cover: How IUFRO can help achieve an elusive goal

Frank Ahern, Jacques Trencia, Tim Perrott, Carolyn Goodfellow
Canada Centre for Remote Sensing, GOFC Project Office, 588 Booth Street, K1A 0Y7 Ottawa, Ontario, Canada
Tel: (613) 947-1295, FAX: 1-613-947-1385, Email: Frank.Ahern@ccrs.nrcan.gc.ca

Keywords: remote sensing; monitoring; global forests; forest cover; forest changes; climate change; biodiversity

Since the launch of Landsat-1 in 1972, earth observation satellites have been promoted as a means of obtaining information about forests and other natural resources on a global scale. Many organizations, including international agencies, the global change research community, and non-governmental organizations have had a long-standing interest in such information. National forest ministries are also interested in the "big picture", and are often willing to participate in efforts to assemble regional and global information. More recently, additional impetus has come from several international conventions. All of these groups have recognized the impossibility of assembling a reliable, global picture of forest conditions (especially forest changes) from the diverse and inconsistent data obtained by hundreds of different agencies using different methods for different purposes. Although satellite data cannot provide all of the information required (e.g., stand age), they are the only source available for objective, timely and consistent worldwide forest observations. The IUFRO working group on Remote Sensing and World Forest Monitoring has completed a landmark document which provides guidelines for combining plot measurements with remote sensing observations to produce a consistent global picture.

However, the potential of satellite observations to monitor forests on a global scale has not yet been realized. Recognizing this, the Committee on Earth Observation Satellites selected Global Observation of Forest Cover (GOFC) as one of six pilot projects which form the core of its Integrated Global Observing Strategy.

The GOFC strategic design calls for implementation of three major components: forest fire monitoring and mapping, forest cover characteristics and

changes, and forest biophysical processes. Forest cover characteristics and changes is the most difficult component to implement, but is also the component of greatest interest to a wide variety of potential users. During GOFC's design phase and early implementation, institutional and technical challenges have been identified which must be addressed before this component can be realized.
Institutional action is needed to:
- develop mechanisms which make information more accessible and easy to use;
- foster a policy environment that promotes the broadest sharing of remote sensing information on forests;
- overcome shortages of technical skills in remote sensing and GIS which exist in many organizations.
Technical challenges include:
- acquiring and processing fine resolution (~25 m) data for a large fraction of the world's total forest area;
- merging data from multiple satellites in an optimum fashion;
- developing appropriate information products which can be produced in a highly automated manner (to minimize costs);
- detecting and quantifying changes which result from partial removal of trees;
- collecting and analyzing substantial amounts of in-situ and airborne data for calibration and validation;
- ensuring the continuity of fine resolution data with global coverage;
- making information available in a rapid, simple, and meaningful way to all interested parties.

GOFC is intended to address global information requirements related to international policy, particularly with respect to the sustainability of forest resources, climate change and biodiversity. There is a crucial need to demonstrate and evaluate products which can provide such policy-critical information, and to develop the infrastructure needed for data and information sharing.

Direct research priorities include developing, testing, and automating the extraction of information from large regional and global data sets, combining satellite, aircraft, and ground observations. It is hoped that these research efforts will spur international capacity building, particularly in developing countries, and lead to increased use and sharing of earth observation data and derived information products.

Forest Information from Remote sensing - Biomass and Wood Volume assessment and mapping

P. Kennedy, S. Folving, C. Estreguil, M. Rosengren, E. Tomppo, J. M. Pereira, M. Nilsson
Space Applications Institute, Joint Research Centre of the European Commission, Sector for Forest and Catchment Studies, Environment and Geo-Information (EGEO) Unit, 21020 ISPRA (VA), Italy
Tel: +39 0332 785009, FAX: +39 0332, Email: sten.folving@jrc.it

Keywords: Remote sensing, bio-mass, volume.

In 1997 the CEO (Center for Earth Observation) Project launched two application projects in support to the FIRS (Forest Information from Remote Sensing) Project. One of these projects, the FMERS-II project, was a research and development study to investigate if existing remote sensing data could be used for inferring two of forestry's important variables, namely above ground woody biomass and volume of forest and other wooded land. The study investigated three different spatial resolutions of RS data, namely, medium resolution (100-300m from the IRS-WiFS), high resolution (less than 100m, from Landsat-TM), and very high resolution (less than 10m obtained from aerial photos). Two different approaches were tested. The application of K-nearest neighbour classification and estimation method (kNN), and regression models.

Two test sites were used for the study. One in the Atlantic-Mediterranean region of central Portugal, and one in the Boreal zone in northern Sweden. The latter was extended to western Finland to evaluate the performance of the models when extrapolating them to areas outside the calibration site. A comparative analysis between TM-derived estimates in the Finnish NFI and the WiFS-derived estimates gave results of mean biomass of 59.5 tonnes/ha and 58.3 tonnes/ha respectively.

Whereas the results from the Boreal site were convincingly good, those for the Portuguese site were rather poor. The reason for the poor results from the Atlantic-Mediterranean test site is not completely clear. Possible explanations include the heterogeneity of the stands, the presence of an established understorey (which influences the spectral signal) and the inadequacy of the available ground data for correlative and calibration analyses. More research clearly has to be carried out in order to reach a better understanding of the potential of using RS data for estimating biomass of the complex and heterogeneous forests and shrublands of the Mediterranean.

Following the results from FMERS-II, the monitoring of biomass and volume in the boreal forests could be carried out on an operational basis using remotely sensed data. The medium resolution WiFS data render the possibility to cover Europe (in approximately 40 scenes) with an appropriate temporal frequency and at a relatively low cost. The derived information could be foreseen to support the EU's external commitments, such as the Kyoto Protocol and serve as input to internal policies of the Union, such as the European Forest Strategy.

The role of scale in monitoring tropical forest from space

Vladimir Kremsa
Research Center for Applied Science and Advanced Technology, Legaria 694, Col. Irrigacion, 11500 Mexico City, Mexico
Email: Vkremsa@vmredipn.ipn.mx

Keywords: remote sensing, cartography, forest monitoring

The effects of spatial and temporal scales must be considered in both theoretical and applied forested landscape ecology.The structure, function and changes of forested landscapes ate scale dependent, because of their spatial heterogeneity. Recent theoretical developments in landscape ecology have emphasized the relationship between pattern and process and the effect that changes in spatial scale have on our ability to extrapolate information across spatiotemporal scales. The landscapes have critical thresholds at which ecological processes will show dramatic qualitative changes. Different landscape indices may reflect process operating at different scales. Quantitative methods linking spatial patterns and landscape-ecological processes at broad spatial and temporal scales are needed. One of the methods that can be applied to forested landscape data collection, processing and interpretation at multiple spatiotemporal scales is remote sensing. The article describes the theoretical principles of space, time and scale concepts (effects of scale changes, impact of scale on analysis) in landscape ecological monitoring and analysis of forested landscapes in the tropics, as well as operational spatiotemporal scales for forested landscape analysis with the examples (deforestation, patch dynamics, ecotones, etc.). Hierarchical organization of landscapes (with examples and corresponding soil, vegetation and land units according to the classification of selected authors), recommended mapping scale and remote sensing platforms are given.

Classification of the native vegetation of the Conguillio's National Park in the andes Mountain in Central Chile through Landsat-TM images and Geographical Information Systems

Nelson Herno Ojeda Ojeda, Miguel Angel Herrera Machuca
Universidad de Cordoba, Avenida Men,ndez Pidal s/n, Aptdo. de Correos 3048. 14080, 14080 Cordoba, Espana
Tel::++34 957 218657, FAX: +34 957 21 8563, Email: am2ojojn@.uco.es

Keywords: National Park, Forest Ecosystem, Remote sensing

Natural forest ecosystems belonging to Mediterranean-Temperate climate in Central-Southern Chile have been deeply harvested. However some relicts are remained in andes Mountain. A good sample of that is placed in the National Park Conguillio. in this National Park there are several species of great scientific importance such as the millenarian conifer *Araucaria araucana* in cohabitation with some hardwoods belonging to *NothoFagus* genus.

This study has a main purpose to classify the Park cover in different category of ecological importance in a volcano environmental. The above is reached through the visual and spectral analysis of Landsat TM "Volc n Llaima. The false color image TM3,4 and 5 allowed the analysis of landslide in forest areas. From the NDVI 29645,8 ha of vigorous vegetation was detected. At the same time 3157 ha in critical conditions were observed. The same Index registered a positive value (0,13) in beds of basaltic lava colonized by liqueur. Furthermore the band 1,2,3 have allowed the detection of 33 categories recognizing forest, grasslands, beds of lava, shadows, water, soil and snow. The k obtained in this study was of 68%, in the case of the forest cover the reliability was of 77% as an average.

Monitoring of protection forests in Alpine region

Mathias Schardt, Klaus Granica, Ursula Schmitt & Heinz Gallaun
Joanneum Research, Wastiangasse 6, A-8010 Graz
Fax-Nr.: 0043-316-876-1720
Email: mathias.schardt@joanneum.ac.at

Alpine forests are exposed to immediate and considerable environmental threat. This is due to an aggressive development drive in the past, huge numbers of tourists as well as environmental damage. Particularly protection forests have recently been subjected to particularly damaging natural as well as anthropogenic influences. The catastrophic storms of 1990 and 2000, the resultant, and lasting problem of the bark beetle, and global climatic changes have weakened the resilience of alpine forests. The culminative effect of all these factors often proves disastrous, resulting in irreversible changes in the composition and distribution of alpine forest cover. Far-sighted national and cross-border planning is necessary to ensure that preventive measures can be implemented by Forest Authorities and Nature Conservation. The success of such measures crucially depends on the availability of information about the distribution and condition alpine protection forests and their development dynamics. The Forestry Services in Austria are responsible for these measures. For long term planning most of them have installed a Geographical Information System (GIS) using different raster and vector based data, but they do not have enough data to cover the entire region of interest.

Behind this background a pilot project concerning the assessment and monitoring of forest parameters in alpine regions by means of satellite remote sensing for its use in protection forest planning and control was carried out. The results of this project will be introduced in this paper. Quantitative parameters, such as species composition, natural age and crown coverage, have been assessed using SPOT4 satellite data. It can be stated that with the new mid-infrared band of SPOT4 the main tree species spruce, larch and broadleaf could be separated. The results also demonstrate that in comparison to Landsat TM data the SPOT4 data yield significant improvements in terms of species discrimination, crown coverage estimation and age determination. Using these results the planning personnel of a Country's Forestry Service can improve the planning and controlling tasks with region covering data.

Remote sensing as a source of information for nature protection of landscape and National Parks

Emilia Wisniewska
Institute of Geodesy and Cartography, Department of Cartography, Jasna 2/4 St, 00-950 Warsaw, Poland
Tel: (48 22) 827 03 28, FAX: (48 22) 827 03 28, Email: emiwis@igik.edu.pl

Keywords: remote sensing, nature protection.

Changes in the environment have caused the necessity of large-scale monitoring and cartographic presentation of its condition and the changes it is undergoing. The Institute of Geodesy and Cartography conducts work on the use of a remote sensing and geographic information system for forest monitoring. The Kozienice Landscape Park pilot project aims to create an operational geographic information system for forest monitoring, updating and mapping.

The created forest information system gathers information on the environment from many sources in two related databases: spatial and relational. The spatial database contains not only information obtained from satellite images and also digitised data from topographic and thematic maps. The relational database is created from inventory information from forest management and other information on the environment. This is related to spatial information through reference to actual forest stands, compartments and units of forest administration. The use of data gathered in the geographic information system describing the state of forest stands allows for a more detailed classification of satellite images.

The results of the above study have brought to the conclusions about forest monitoring with the use of a remote sensing. They regard the selection of the best satellite images channels and stands parameters which can be differentiated and cartographically presented as separate classes.

The geographic information system serves for spatial analyses and may be used as a tool for the cartographic presentation of gathered data and results of spatial analysis.

The GIS, containing remote sensed data and other information about the forest, can play a large role in nature protection, correct running and management of the forest. The advantage of these systems is the possibility to combine multi-source and multi-type information about the environment, conduct spatial analysis, update databases, and edit maps and reports.

4.02.07 Scenario approaches, models and assumptions behind the forestry analysis used in regional, national and global policy making

Large-Scale Forest Scenario Analysis in the United States: Comparison of Approaches

Ralph J. Alig, Darius M. Adams, Richard Haynes
USDA Forest Science, Pacific North West Research Station, 3200 SW Jefferson Way, OR 97331 Corvallis, USA
FAX: (541) 750-7329, Email: aligr@ccmail.orst.edu

The Timber Assessment Market Model (TAMM) and the Forest and Agriculture Sector Model (FASOM) are examples of two large-scale forestry scenario models that have been employed to analyze the U.S. forest resource situation. The models have been applied to make projections of the U.S. forest sector in regional and national studies, such as the periodic Timber Assessments and Updates by the USDA Forest Service. The purpose of the Timber Assessment is to analyze the timber resource situation over the next 50 years to provide indications of the future cost and availability of timber products in the context of U.S. demands. The analysis also identifies resource situations that may be judged desirable to change and developing opportunities that may stimulate both private and public investments.

The TAMM system has been used for more than 15 years in the quinquennial Timber Assessments and Updates. Using a price-endogenous, spatial equilibrium approach, market solutions are obtained one period at a time using either reactive programming or direct optimization of the nonlinear objective function, depending on the model version. The TAMM system projects prices, consumption and production of softwood and hardwood sawtimber products, and harvest of timber from private lands using an annual time step. Exogenous projections of land allocation are provided by regional area change models, and timber growth and yield projections by the area-based Aggregate TimberLand Analysis System (ATLAS). Exogenous projections of forest management investment are based on single-acre analyses and expert opinion. Projections of fiber products and fuelwood, which were part of the earliest version of TAMM, are now derived from models linked to TAMM through demands for, and prices of, roundwood and residues. On the resource side, the TAMM system uses parameters for most behavioral equations (e.g., private timber harvest) that are estimated from historical data. Private timber supply functions are derived from explicit hypotheses of intertemporal harvest behavior for industrial and nonindustrial owner classes. The relations link harvest to prices, inventory levels, interest rates, and for nonindustrial owners, income from nonforest sources.

The FASOM model is a linked model of the U.S. forest and agriculture sectors developed for use by the U.S. Environmental Protection Agency in studies of global change and energy policy. FASOM is an intertemporal, price endogenous, spatial equilibrium model in which market solutions are obtained each decade in the entire 100-year projection period at one time. Endogenous variables include: (I) land transfers between sectors; (ii) forest management investment activity; (iii) timber harvest and log prices for nine U.S. regions, two species groups, and three classes of products; and (iv) agricultural prices and production in eleven regions for 40 primary and 46 secondary commodities. The FASOM model draws upon demand-side information from the TAMM system, as well as also utilizing ATLAS timber yields.

With respect to analyzing forest scenarios, use of the TAMM and FASOM models can be complementary when analyzing forestry and natural resource policies. For example, the intertemporal optimization framework of FASOM allows ready examination of adjustments or responses to policies that may fall outside the historical range of observations. Examples of large-scale scenarios the models have been employed to examine include: log exports, carbon sequestration through tree planting, reduced public timber harvest, recycling of wastepaper, global climate change, farm programs, production of short-rotation woody crops for pulp fiber, biomass production for energy, agricultural land reallocation programs to promote environmental goals, and sustainability of production in both sectors.

Analysis of Flow-Stock Relationship through Stimualation by Means of a Forest Optimization Model

Ricardo Armando Bratovich, Julio Eduardo Arce, Raúl Marcos Marlats
Universidad Nacional de La Plata, Virrey Cevallos, 646 – 7°"A", 1077 Buenos Aires, Argentina
Tel: +54-11-4381-4149, Email: rbrato@cvtci.com.ar

Simulation is a very powerful tool in the planning of companies and institutions in the field of forestry, since it allows to carry out different sensitivity tests in different scenarios within a field that has two main features. The first one is that, from the relative comparison of the impacts of the main factors affecting wood supply and demand, it can be seen that, in most cases, the demand for primary forest products takes much shorter to change than the supply of those products. The second special feature is that in forestry systems, the production level of a certain period depends on the production level of previous periods, thus giving rise to a particular interaction between long and short term supply and demand: ceteris paribus, the more wood is used up today, the less we will have tomorrow, and surely at a higher price. The planning methodology this paper will use, based on lineal programming, proves to be an extremely useful tool when it comes to understanding some basic forestry relations such as the one between production flow and stock. The model was applied to planted poplar forests belonging to a paper producing company in the province of Buenos Aires, Argentina. This company obtains their raw material mainly from their own forests, and gets the rest from the market.

The flow-stock relationship can be managed so as to reach specific operative and strategic aims of the company. The managing of flow an stock may allow to handle the response capacity of a forest facing changes in the demand, by increasing several times its regular production in a certain period of time so as to supply the factory when there is a shortage in the market. The model can be used as to a simulation tool to show the evolution of stocks with different extraction flows for all planning horizon. This will allow to fix the new extraction flows to be applied to the forest in order to obtain the necessary stock at the right moment. It is shown the way the model carries out the planning, keeping the stock levels at a minimum, which is important if the consequences of the existence of stock on the accounts of the company are born in mind. On the one hand they generate costs - opportunity, insurance and maintenance costs- which have an effect on the results account; on the other they increase the assets. Both consequences reduce the income yield capacity of the company, thus making it necessary to keep stock levels at a minimum, so that they can allow to bring together the process of primary production and the industrial one. Through a better understanding of the basic developed relationships, it is shown the way companies with their own plantations can not only use them to cushion the effects of the market over the short-term supply, but also handle them so as to avoid shortages in the mid and long term.

This helps solve the problem of many forestry system managers who pose the question of how the forest is to be handled so as to satisfy immediate needs, changing at the same time its structure in order to be ready for future circumstances. On the whole, good handling of the flow-stock relation of forestry systems belonging to industries can allow to put into practice an administration policy in order to avoid risks of depriving the factory of supply.

Timber production possibilities of the Norwegian forest area and measures for a sustainable forestry

Hans Fredrik Hoen, Tron Eid & Petter Ökseter
Agricultural University of Norway, Department of Forest Sciences, P.O.Box 5044, Aas, Norway
FAX: +47 6494 8890, Email: hans.hoen@isf.nlf.no

A public discussion on how to bring forest management practices in a more environmentally oriented direction is going on between Norwegian organisations of forest owners, environmentalists, forest industry and governmental offices. Certain requirements or standards as they may be stated in certification documents or as governmental policies are likely to appear in a near future.
In addition to timber the forest is producing a number commodities not traded in any market. If the management of the forest area is designed mainly with respect to timber production, the effects of this management on the provision of the non-market commodities may be negative. On the other hand, an environmentally designed management may reduce timber production. The aim of this paper is to present some long range timber production analyses where the objective has been to map consequences for potential harvest level and net present value, related to varying forest treatments in a environmentally oriented direction as might be defined in the future.

Analyses are done with GAYA-JLP, a model based on simulation of treatment schedules for individual management units and linear programming for solving the management problem at forest level. The analyses cover the productive forest area in Norway. This forest area is divided into 10 regions. Sample plots from the National Forest Inventory are aggregated into 1000 treatment units for each region, i.e. the entire forest area is described by 10000 units. The forest management problems are solved at county level, while the country level results are obtained by summing over the individual regions.

The analyses aim at providing a realistic description of the timber production possibilities of the productive forest area in Norway given consistency in treatments with respect to the real rate of discount. Management strategies with maximization of the net present value (NPV), with and without a non-declining felling path constraint, have been analyzed. The following environmentally oriented

constraints on forest management practices, separately and joint, have been analyzed:
- certain areas of current old growth forest set aside for permanent protection
- minimum target levels for area covered by old growth forest through time
- leaving continuity trees after final felling
- restricted management practices for border zone areas around lakes, rivers, streams, swamps, agricultural land and roads

The results include estimates on possible development for a period of 100 years with respect to potential harvest levels and volume of growing stock. The NPV according to a real rate of discount of 2.5% and with a non-declining felling path constraint, was reduced by 8.7% when 5% of the total area was set aside for protection. The corresponding NPV reductions were 2.4%, 1.0% and 12.7% respectively with a minimum target level of 10% for area covered by old growth forest, by leaving 10 continuity trees ha^{-1} and with restrictions on management practices for a medium border zone width (15 m) around lakes, rivers, streams, swamps, agricultural land and roads.

What will the European forest look like in 2050?

Gert-Jan Nabuurs, Risto Päivinen, Mart-Jan Schelhaas, Ari Pussinen, Eric Verkaik, Alexander Lioubimow, & Frits Mohren
European Forest Institute, Torikatu 34, Fin 80100 Joensuu, Finland
Tel: +31.317.477897, FAX: +31.317.424988, Email: G.J.Nabuurs@ibn.dlo.nl

In Europe, where wood production used to dominate the goals of forest management, nature conservation values are now becoming more important as well. These changes in management may have large implications for the long-term development of the forest. The other potential changes are related to environmental changes, like the climate change.

This article describes an instrument -the European Forest Information SCENario (EFISCEN) model - which provides an insight in the long term implications of these changes. It is a harmonised tool for natural resource analyses of the forests in 30 European countries. A whole new database has been gathered with the help of practically all national forest inventory institutes. EFISCEN uses an area matrix approach to simulate the forest development for a period of 50 to 70 years

Two case studies utilising the model have been described - one in Leningrad region in North-Western Russia, and one comparing the EFISCEN results with national scenarios compiled by UN/ECE-FAO in the European Timber Trend Studies.

Three Approaches for Large Scale Forest Scenario Analysis in Finland

Tuula Nuutinen, Seppo Kellomäki, Gert-Jan Nabuurs
Finnish Forest Research Institute, Joensuu Research Station, Post Box # 68, FIN-80101 Joensuu, Finland
Tel: +358 13 2514043, FAX: +358 13 2514111, Email: tuula.nuutinen@metla.fi

In Finland, three models have been applied for large-scale forest scenario analysis. The oldest, METLA, is a forestry model designed in the 1970s for the regional and national analysis of timber production based on the sample plot and tree data of the Finnish National Forest Inventory (NFI). SIMA is a gap-type ecosystem model utilised in 1990s for regional predictions on how the changing climate may affect the forest growth and timber yield in Finland. The European Forest Information Scenario Model (EFISCEN) is originally a Swedish area matrix model developed in the early 1980s.

In the SIMA model the growth of trees is based on the diameter growth, which is controlled by light conditions, temperature, soil moisture and nitrogen. The same factors control the success of regeneration, which can be based on natural processes or planting. The thinning rules and the length of rotation can vary according to site type, dominant tree species, and location of stand.

The thinning limits are defined according to dominant height and basal area, and the length of rotation by the mean diameter of trees in the stand.

According to the SIMA simulation based on the permanent sample plots of the NFI the stocking on mineral soils (ca. 80 percent of the total stocking) would increase from the current (1990) 1535 mill. m^3 to 1898 mill. m^3 by the year 2050, if standwise silvicultural recommendations were applied. in this scenario fellings on mineral soils would exceed 80 mill. m^3 in the period of 1990-2000 and drop thereafter close to 24 mill. m^3 - rising up to 50 mill. m^3 during the next few decades. Under the gradual elevation of temperature at the rate of 0.04 $^oC\ yr^{-1}$, the stocking stabilised at the level of 2000 mill. m^3 by the year 2040.

The EFISCEN model requires area, volume and increment data per age class by forest types. The user specifies future development of demand at the national level and possible afforestations. Based on growth dynamics, age class distributions, and theoretical management regimes, the model calculates if and where to harvest, and generates projections of growing stock, increment, timber harvest volumes, age class development over time by country, region, and species. According to EFISCEN scenario based on data provided by the Finnish NFI the average annual felling would remain at 55 the level of mill. m^3 until 2040. The corresponding growing stock would exceed 2500 mill. m^3 in 2040.

The METLA model consists of two parts: an automated stand simulator based on individual trees and the optimisation package based on LP. A finite number of sound and acceptable management schedules - differing from each other, for example, by timing of management activities - are simulated for each sample plot. Hundreds of variables describing the management schedules are produced. The variables available in the LP problem and the report writer describe the state and the development of the forests, as well as forest production and its economy over the calculation period. The optimiser selects simultaneously the production program for the whole forestry unit and the corresponding management schedules for sample plots. The management of forests is endogeneous.

Since 1980's three national level analysis with a standard set of three scenarios based on data from NFI have been carried out. The first scenario resembles the EFISCEN scenario and the second SIMA scenario. The third scenario was allowable cut calculated by maximising the net present value of the future revenues subject to non-decreasing flow of timber, saw logs and net income over a 50-year period. The recent estimate of this maximum regionally sustained felling for the period 1996-2006 was 71 mill. m^3 (of which nearly 90 percent on mineral soils) and rising close to 80 mill. m^3 by 2040. The stocking would remain stable.

4.02.00 / 4.11.00 Design of small and large scale multipurpose forest inventories

Extending forest resource assessments to landscape inventories

Peter Brassel
Swiss Federal Institute of Forest, Snow and Landscape Research, Birmensdorf, Switzerland
Email: Brassel@wsl.ch

The first swiss national forest inventory (1983-1985) was planned as a multipurpose and multiresource inventory in forested aereas. in the second NFI (1993-1995) the list of attributes to be assessed was extended in order to obtain information on Non-Wood Goods and Services. Among others new attributes describing forest margins and tree resources outside the forested area were introduced.

In the third NFI the information provided will be extended from forested areas to fallow land and extensively managed areas. in addition to the primary objectives of the forest inventories the structural and biological diversity will be emphasized.

The paper discusses the process of transferring an information needs assessment to the final system of nomenclature and measurement rules of attributes, the evaluation of data sources (terrestrial survey, satellite imagery, digital aerial photography) and the comparability problems with previous inventories.

Temporal and spatial error budgets for woody plant biodiversity

George Gertner, Xiangchi Cao and Guangxing Wang
University of Illinois at Urbana Champaign, Department of Natural Resources and Environmental Sciences, W503 Turner Hall, Illinois 61801 Urbana, USA
Tel: (217) 333-9346, Email: gertner@uiuc.edu

In this paper, a stochastic dynamic monitoring/modeling system for plant and forest biodiversity is presented. The system can project biodiversity both in time and in space. With the system, spatial and temporal error budgets can be generated. The error budgets show the overall uncertainty of regional and localized estimates/predictions of biodiversity. The uncertainty can be partitioned according to different types of error sources within and outside of the system. Some of the errors that are accounted for are sampling errors, measurement errors, mapping errors, calibration errors, prediction errors. The error budget provides a means for the systematic improvement of a system and its inputs. Based on the error budgets, recommendations can be made for reducing the more important sources of controllable errors. Results for one case are presented.

Bayesian synthesis for assessing uncertainty in mechanistic models

Edwin J. Green
Rutgers University, Ecol Evol & Natl Res, 14 College Farm Road, NJ 08901 New Brunswick, USA
Tel: (732) 932-9152, FAX: (732) 932-8746, Email: green@crssa.rutgers.edu

As concerns over global change heighten, some forest modelers have begun to emphasize the use of mechanistic models of forest growth, derived from specific theories regarding tree and/or stand development. Some believe that such models have greater potential predictive accuracy than more traditional empirical models. However, it is often difficult to assess the error associated with predictions from mechanistic models. in this paper I present the Bayesian Synthesis method for constructing posterior distributions of model predictions. I will demonstrate the method with a naive two parameter model, and then present results obtained for PIPESTEM a realistic mechanistic forest growth model.

On bootstraping species diversities indices

Biing T. Guan, Y. M. Perng
National Taiwan University, Department of Forestry and Department of Agronomy, China-Taipeh
Email: btguan@ccms.ntu.edu.tw

Species diversity indices are central to environmental monitoring and management. Under its current paradigm, it is explicitly assumed that changes in species diversity represent changes in the target ecosystem's compositions, abundance or both. Thus, species diversity indices are used as estimators of ecosystem conditions. However, as estimators, statistical properties of species diversity indices are poorly understood, especially how to obtain standard errors for such estimators for constructing confidence intervals and hypotheses tests. in this paper, we will discuss the use of bootstrapping for obtaining standard errors for commonly used species diversity indices. in particular, the setup of resampling schemes will be thoroughly discussed for applications in ecology.

Tree resources outside the forest: how to assess a scattered heterogeneous resource?

Christoph Kleinn, Alfred de Gier
Tropical Agriculture and Higher Education Center (CATIE), Costa Rica
Tel: +506 556 1530, FAX: +506 556 7954, Email: ckleinn@catie.ac.cr

Presence, relevance and functions of tree resources outside the forest (TROF) are highly diverse and locally different. They occur in natural and cultivated landscapes, and serve then a number of ecological (like conservation of biodiversity, erosion control, carbon sequestration), and economic functions (like provision of timber, firewood, fodder, fruits, shadow for cattle).

Being present in various land use classes, this resource does not form a land use class by its own. in many regions, the decreasing forest cover, the increasing forest fragmentation, and the presence of trees in agroforestry systems make its relative importance grow.

However, compared to other natural resources little is known about tree resources outside the forest on a large area basis. Large area assessments are difficult for several reasons: the resource is highly heterogeneous as to floristic composition, spatial arrangement and dimensions, and has a relatively low density. To come to regional estimates, ways have therefore to be found how to efficiently combine different data sources like field measurements, remotely sensed data, and existing statistics.

This paper outlines an EU funded research project, that aims at developing a method of how to a assess tree resources outside the forest (TROF) and integrate them in a geographical information system, and at capacity building in a number of relevant institutions in the region. The study sites of the project are located in Central America. The general relevance of the resource from a Central American point of view is addressed, as is the definitions and classification issue.

Infrared-triggered camera: a tool for measuring the biological diversity

Toru Koizumi, Tsuneaki Yabe, Carlos Eduardo Rittl, Niro Higuchi, Leonid G. Kondrashov
Forestry and Forest Products Research Institute, Kyushu Research Center, Kurokami 4-11-16, Kumamoto, Japan
Tel: +81-96-343-3168, FAX: +81-96-344-5054, Email: tyabe@ffpri-kys.affrc.go.jp

Keywords: biological divesity; mammal; infrared-triggered camera; terra-firme forest; boreal forest

We used an automatic camera for recording mammalian inventory and evaluated its validity in the tropical forest (terra-firme forest) of Brazilian Amazon and the Russian boreal forest. The camera system consists of a passive infrared sensor and a 35-mm fully automatic camera with flash. The sensor has a wedge-shaped or a cone-shaped detection field. It records a warm-blooded animal passing through a detection field because it differentiates between animal heat and background field. However, sensor is triggered when sunlight moves across the sensor window. Therefore the sensor was hung or placed on a pole 1.0-1.3 m above the ground so that the sensor detected vertically to minimize the false triggering. The sensor was shielded in a plastic tube. The camera has an automatic film advance devise and built-in flash. It is modified to be triggered by an electrical signal from the sensor and equipped with data back that allows to record the time and date of exposure on each photograph. Camera was attached to the sensor with a cable so that we could choose the appropriate placement of the camera and the sensor flexibly. The camera and controls of sensor were packed in a plastic box and weatherproofed. Bait was placed in the center of detection field.

In Brazil, we conducted investigation for terrestrial mammals in a terra-firme forest located 60 km north of Manaus. We recorded 24 species and 3 genera based on about 8300 pictures taken between February 1996 and March 1998. Varisized mammals were recorded, ranging from mouse (*Neacomys sp*) to puma (*Puma concolor*). This indicated that vertical detection reduced the size-related (therefore, species-related) bias of the sensor pointed out by Wilson et al. (1996). We identified 63.6% of the midium and large mammals (body weight > 500g) in a list by Voss and Emmons (1996), which was compiled from trappings and direct observations for 5 years. The cameras newly recorded 4 species that Voss and Emmons expected the appearance but could not record actually.

In Russia, 2-week investigation was conducted in September 1999 in the boreal forest located 45 km south of Khabarovsk. We focused on Muridae and Sciuridae, relating to the seed dispersal. 8-10 species were expected to occur in the study area. of these mammals, 6 cameras recorded 3 species and 1 genus, while only two species were captured by 20 live-traps during the same period. This showed that infrared-triggered cameras were effective to record the species composition of the mammalian community within a limited period.

The method we adopted here has some disadvantages. For example, classification of related species belonging to the same genus was difficult even on the clear photograph, especially in a group of Muridae. Information on weight, and reproductive condition cannot be also obtained with cameras. On the other hand, infrared-triggered cameras have several advantages over other methods, such as trappings and direct observations. The animals do not have to be captured. Large areas can be surveyed by only a few people, and investigators do not have to attend constantly. These advantages are effective to record rare and cryptic species. in addition, combination of infrared-triggered camera with trapping and marking will provide valuable data on abundance, movement, and activity of mammals inhabiting in the forested environment.

Efficient Modelling of Stem Curves

Jouko Laasasenaho, Heikki Karttunen and Mark-Leo Waite
University of Helsinki, Department of Forest Resource Management, PL 24 (Unioninkatu 40 B), 00014 Helsingin yliopisto, Finland
Email: Jouko.Laasasenaho@helsinki.fi

The purpose of this research is to investigate the possibility of deriving accurate stem curve models with small numbers of sample trees. The stem curve model investigated is based on relative stem diameters and relative stem heights and can, in principle, be derived by a single sample tree. The main issues investigated are (i) how many sample trees are required in order to achieve a given accuracy and (ii) how should the sample trees best be selected. The accuracy of a given stem curve model is mainly quantified by the accuracy of the predicted total stem volume.

The research material comprises 2326 scots pine (*Pinus silvestris*) sample trees covering the whole of Finland. Each sample tree was measured for diameters at 14 different relative heights. The jack-knife technique is utilized extensively in the analyses which were performed with common spread-sheet software extended by specific stem curve modelling functions. The resulting software can be used for deriving totally new stem curve models. Functionality for utilizing derived stem curve models, for *e.g.* volume calculations, was also included. The investigation showed that since relative tree form is independent of tree size, accurate stem curve models can be derived by as few as five sample trees.

Optimal Forest Inventories based on the anticipated variance

Daniel Mandallaz
ETH Zürich, Zürich, Switzerland
Email: Mandallaz@fowi.ethz.de

This work presents optimal sampling schemes for forest inventory. The sampling procedures are optimal in the sense that they minimize the anticipated variance for given expected costs or conversely, the anticipated variance is the average of the design-based variance under a local Poisson model for the spatial distribution of the trees. Exact and best feasible approximations are given for two-phase two-stage cluster sampling schemes. The resulting optimal inclusions probabilities are a combination of probability proportional to prediction and probability proportional to the expected error. Simulations and practical examples illustrate the theory.

Guided transect sampling in theory and practice

Göran Stahl
Swedish University of Agricultural Sciences, Dept of Forest Resource Management and Geomatics, S 901 83 Umea, Sweden
Email: Goran.Stahl@resgeom.slu.se

Guided transect sampling is an inventory design developed to incorporate high-resolution prior information in the selection of inventory paths within transect based inventories. It consists of two stages. in the first, strips too wide to be entirely sampled are laid out in the area of interest. in the second, prior information - *e.g.* from satellite imagery - is used to decide the exact route of a transect through each first stage strip in a PPS-sampling manner. Primarily, the method is developed to increase the efficiency of transect based methods when sampling sparse populations. in theoretical studies, results have been promising. The relative efficiency of the method, in relation to a "non-guided" alternative, increases the sparser the elements of interest are. in practise, problems of two basic kinds are encountered. Firstly, the method may lead to increased costs due to complicated fieldwork. For example, the method relies on the use of GPS differential in real time. Secondly, it is not possible to follow the exact paths of the predetermined transects in field. Therefor, the precision of estimates will decrease slightly.

4.02.00 / 4.11.00 Forest resources assessment 2000

The Global Forest resources assessment 2000

Robert Davis, Peter Holmgren
FAO, Forest Department, Via delle Terme di Caracalla, I-00100 Roma, Italy
Tel: +39 06 57051, FAX: +39 06 57052151, Email: robert.davis@fao.org

The presentation will reveal the final results of the Global Forest Resources Assessment 2000 (FRA 2000). For each country, available information about extent, composition, protection and utilisation of forests have been compiled and analysed. Special attention has been given to estimate the rate of change of forest resources and to document the underlying factors. This presentation is the first occasion for presenting the global forest change estimates. The FRA 2000 is a transparent process in the sense that all background material and analyses is published. This means that the FRA 2000 constitutes a comprehensive baseline survey of forest resources in all countries.

In addition to the country-by-country survey, the FRA 2000 also includes an objective pan-tropical remote sensing survey of forest cover change; production of global maps of forest cover and ecological zones; and special studies on various aspects of the interaction between people and forests. in total, the results of FRA 2000 will consist of 11 printed volumes, plus a comprehensive presentation on the world wide web.

FRA 2000 is carried out by the Food and Agricultural Organization of the United Nations (FAO) with the assistance of donors, partners and member countries. One important partner is the UN Economic Commission for Europe, that constitutes the focal point for temperate and boreal countries. FAO has been given the mandate to regularly report on the world's forest resources by its member countries, that also take active part in the assessment. It is expected that FRA 2000 will stimulate discussion at all levels, as well as foster decision-making on the management and protection of forests on a global scale.

Accuracy and Reliability of the Temperate and Boreal Forest Resources Assessment (TBFRA) 2000

Michael Köhl and Risto Päivinen
TU Dresden, Forest Biometrics and Computer Sciences, Wilsdruffer Str. 18, D-01737, Tharandt, Germany
Tel: +49-35203-381615, Fax: +49-35203-381628
Email: koehl@forst.tu-dresden.de

Keywords: forest resources assessment, TBFRA, systems of nomenclature, harmonisation, standardisation

Data collection of the TBFRA 2000 is based on a questionnaire approach utilizing forest resources assessments conducted on the national level. Despite the fact that standardized terms and definitions have been formulated for the TBFRA, data submitted are subject to different sources of errors affecting the reliability of the TBFRA results.

In this presentation the reliability and accuracy of the TBFRA 2000 are evaluated in terms of effects of differences in the national and TBFRA systems of nomenclature, non-responses, assessment period and likely ranges of true values.

The UN-ECE/FAO Forest Resource Assessment 2000: an overview

Alexander V. Korotkov
UN Economic Commission for Europe, Geneva, Switzerland
Email: Alexander.Korotkov@unece.org

The UN-ECE/FAO Temperate and Boreal Forest Resources Assessment, as a part of the Global FRA-2000, was launched soon after the high level expert consultation held in Kotka (Finland) in June 1996 had proposed the Global Framework (guidelines, key parameters, terms and definitions) for the Assessment. The main instrument of the data collection for TBFRA-2000 was a detailed enquiry built on the above global platform, and circulated to national correspondents of the 55 temperate and boreal industrialised countries. The majority of countries have satisfactorily replied to the challenging enquiry (25 tables with more then 500 parameters) by August 1998. The range of the information which was received from countries (and analysed) is extremely wide; the quality of country replies was good in general, taking account the complexity of the task of national correspondents to respond to all the questions, and to adjust national data to the TBFRA standards.

Since UNCED (1992) many industrialised countries have reviewed (and revised) their national forest policies, and have prepared strategies on sustainable forest management (SFM). The on-going international forest policy dialogue under the CSD/IPF/IFF umbrella has noted the importance of FRA-2000 process to provide factual, comprehensive and reliable information at the global international level, which would serve the SFM objectives. The results of the assessment are expected to be widely used by researchers in different areas of the forest sector, as well as by many others working closely with forests and forestry (ecologist, environmentalists, forestry specialists, forest engineers and managers, forest products suppliers, wood consumers, forest practitioners, etc).

The interim temperate/boreal FRA-2000 information, covering 36 participating countries, was reported to the pan-European Ministerial Conference on the Protection of Forest in Europe (Lisbon, June 1998). The Main TBFRA-2000 Report on the forest resources presenting more than 2.4 billion hectares of forest and other wooded lands will be published by the Year 2000. The statistical and descriptive country information has been analysed by high level experts in the specific thematic areas. The Assessment will cover the following main issues: Area of Forest and Other Wooded Land (OWL): Situation and Changes, Ownership and Management Status of Forest and OWL, Wood Supply and Carbon Sequestration: Situation and Changes, Biological Diversity and Environmental Protection Forest Condition and Damage to Forest and OWL, Protective and Socio-Economic Functions, etc.

The TBFRA-2000 data set will be the most comprehensive international assessment ever made for the temperate/boreal forests. The information on forest and other wooded land areas, species distribution, naturalness of forests, their availability for wood supply, growing stock, increment, ownership, fellings and removals, biodiversity, non-wood goods and services, forest condition and damages, etc (in digital and textual formats) will be structured into an electronic database and made available on Internet.

4.04.00 Advances in combining productity and sustainability in forest management

A New Planning Approach and Criteria used for Sustainable Forest Management in Turkey

Üal Asan
University of Istanbul, Forest Management Planning Department, Bahçeköy, 80895 Istanbul, Turkey
Tel: 90 212 2261103-272, FAX: 90 212 2261113, Email: uasan@domi.com.tr

A new planning approach titled as Functional Planning (FP), and the criteria which should be used for sustainable management planning in the Turkey's forests are pointed out in this paper. After giving a short knowledge about the forest resources, and forest functions expected from the forests in the country, basic principles of the FP approach which was developed for the forest enterprises managed for timber production as well as the other protective functions of the forests such as erosion control, water yield, visual effect, recreational use and, wildlife habitats and bio-diversity are presented. The concepts of "Continuous Forest " and, "Sustainability" are also elaborated in short in the paper. The planning procedure followed in construction of FFM, and in separation of different working circles, combination of various management objectives are clarified. Advantages of the New system as flexible and capable in order to realise the rational utilisation of the forest resources in the case of multiple use forestry, and its current deficiencies which should be promoted for more effective use are explained in the paper basing on experiences gained in the last ten years.

Keywords: Sustainable Forest Management, Functional Planning, Multiple-Use, Turkey

Sustaining Wildlife Populations in Productively Managed Forests

Michael Bevers, Curtis H. Flather, John Hof, H. Fred Kaiser
USDA Forest Service, Rocky Mountain Research Station, 240 West Prospect Road, Colorado 80526 Fort Collins, Colorado, USA
Tel: (970) 295-5911, FAX: (970) 295-5959, Email: mbevers@fs.fed.us

Keywords: Spatial optimization; Harvest scheduling; Population Persistence; Reaction-diffusion

Wildlife population status is becoming a key consideration in determining whether wood fiber production from managed forests can be sustained. Concerns for wildlife have become a very important part of public land management in many parts of the world, and are being given increased weight on privately owned lands. Jointly maintaining wood fiber production and wildlife populations requires the ability to spatially and temporally design silvicultural activities so as to mitigate negative impacts on wildlife habitat. Consequently, research efforts blending wildlife population persistence with traditional forest management modeling can potentially play a crucial role in maintaining future forest productivity. The purpose of this paper is to synthesize recent and ongoing research combining population reaction-diffusion models with spatial forest management optimization methods for planning the location, timing, and intensity of harvests that will simultaneously sustain wildlife and wood fiber production. Following the introduction, Part I of the paper describes a discrete space and time approach to reaction-diffusion modeling that addresses the effects of various contiguous or fragmented habitat systems on wildlife populations. An ability to model survival of dispersing organisms as a function of the amount of available habitat surrounding breeding sites, with a suitable distance decay, is the primary feature of this method. Part II of the paper discusses stochastic considerations. We explore the differences in results from deterministic versus Monte Carlo simulations of population abundance, distribution, and critical habitat thresholds in discrete reaction-diffusion models. Implications regarding the application of mathematical programming for habitat design are discussed. Although much research on the topic of uncertainty remains to be done, initial indications are that deterministic methods suitable for optimization modeling are reasonably robust with regard to prescribing suitable habitat arrangements. Part III of the paper demonstrates how reaction-diffusion can be combined with other ecological factors that limit populations to form spatial optimization models. These models are suitable for identifying efficient forest management opportunities and for estimating tradeoffs between wood fiber production and wildlife population response. An example combining distinct forage and breeding site requirements with reaction-diffusion processes demonstrates the approach. Possible limitations, alternative approaches, and further research needs are discussed.

Putting Sustainable Forest Management into Practice in Peninsular Malaysia: Minimum Requirements

Christoph Muziol, Gerd Weinland and Rolf Krezdorn
Malaysian-German Sustainable Forest Management and Conservation Project / GTZ, Forestry Department Peninsular, c/o Forestry Department Peninsular, Jalan Sultan Salahuddin, 50660 Kuala Lumpur, Malaysia
Tel: +60-3-294-8859, FAX: +60-3-294-3945, Email: gtz_muz@forestry.gov.my

The goal of Sustainable Forest Management (SFM) is to manage forests as multifunctional resources. This paper describes the strategic approach to SFM recommended for Peninsular Malaysia. It focuses on three minimum elements required for SFM, which are (1) Forest Zonation, (2) growth-based yield regulation, and (3) the mitigation of the environmental impact of forestry operations, especially road construction and harvesting. The implementation of these elements is also indispensable for successful Forest Management Certification.

Forest Zonation is based on Forest Function Mapping. Its objective is to safeguard the various forest functions within each Forest Management Unit. It ensures that the needs of human society are compatible and balanced with the production and buffering capacity of the natural environment, and derives specific functions (e.g. soil conservation) for each forest area. Based on that, the synoptic process of Forest Zonation results in the differentiation of three Forests Zones: "Protection", "Timber Production" and "Restricted Timber Production". The latter two (minus permanent infrastructure areas) constitute the Net Production Area, which is the basis for the calculation of the Annual Allowable Cut (AAC).

The simple area-based yield regulation currently used in Malaysia is appropriate only for uniform virgin forest. The majority of forests, however, are now logged. Having developed differently depending on the harvesting intensity, site conditions and silvicultural treatments, they are much more heterogeneous. Therefore, area control should be replaced by a volume-based yield regulation, which takes into account the present growing stock (provided by a Forest Management Inventory), growth data from representative (i.e. local) permanent sample plots, computer-based growth simulation, and deductions according to the extent of harvesting impacts on the residual stands.

To mitigate the impact of logging on the natural environment (residual trees, soil, water, and habitats) areas assigned for Timber Production must be logged strictly following Reduced Impact Logging standards (i.e. improved tractor skidding). In Restricted Timber Production areas, furthermore, only Low Impact Logging with aerial yarding technology (e.g.cable crane systems) is admissible.

All prescriptions are included in Forest Management Plans, which cover individual Forest Management Units over a planning period of 10 years.

Timber production possibilities of the Norwegian forest area and measures for a sustainable forestry

Tron Eid, Hans Fredrik Hoen & Petter Ökseter
Agricultural University of Norway, Department of Forest Sciences, Post Box # 5044, N -1432 A, Norway
Tel: +47-64948901, FAX: +47-64948890, Email: tron.eid.@isf.nlh.no

A public discussion on how to bring forest management practices in a more environmentally oriented direction is going on between Norwegian organisations of forest owners, environmentalists, forest industry and governmental offices. Certain requirements or standards as they may be stated in certification documents or as governmental policies are likely to appear in a near future.
In addition to timber the forest is producing a number commodities not traded in any market. If the management of the forest area is designed mainly with respect to timber production, the effects of this management on the provision of the non-market commodities may be negative. On the other hand, an environmentally designed management may reduce timber production. The aim of this paper is to present some long range timber production analyses where the objective has been to map consequences for potential harvest level and net present value, related to varying forest treatments in a environmentally oriented direction as might be defined in the future.

Analyses are done with GAYA-JLP, a model based on simulation of treatment schedules for individual management units and linear programming for solving the management problem at forest level. The analyses cover the productive forest area in Norway. This forest area is divided into 10 regions. Sample plots from the National Forest Inventory are aggregated into 1000 treatment units for each region, i.e. the entire forest area is described by 10000 units. The forest management problems are solved at county level, while the country level results are obtained by summing over the individual regions.

The analyses aim at providing a realistic description of the timber production possibilities of the productive forest area in Norway given consistency in treatments with respect to the real rate of discount. Management strategies with maximization of the net present value (NPV), with and without a non-declining felling path constraint, have been analyzed. The following environmentally oriented constraints on forest management practices, separately and joint, have been analyzed:
- certain areas of current old growth forest set aside for permanent protection
- minimum target levels for area covered by old growth forest through time
- leaving continuity trees after final felling
- restricted management practices for border zone areas around lakes, rivers, streams, swamps, agricultural land and roads

The results include estimates on possible development for a period of 100 years with respect to potential harvest levels and volume of growing stock. The NPV according to a real rate of discount of 2.5% and with a non-declining felling path constraint, was reduced by 8.7% when 5% of the total area was set aside for protection. The corresponding NPV reductions were 2.4%, 1.0% and 12.7% respectively with a minimum target level of 10% for area covered by old growth forest, by leaving 10 continuity trees ha^{-1} and with restrictions on management practices for a medium border zone width (15 m) around lakes, rivers, streams, swamps, agricultural land and roads.

Swedish efforts for a sustainable, multi-resource forestry: the role of research in management planning

Ljusk Ola Eriksson, Tomas Lämås, Ola Sallnäs
Swedish University of Agricultural Sciences, Department of Forest Resource Management and Geomatics, SE-901 83 Umea, Sweden
Tel: +46 (0) 90- 786 5840, FAX: +46 (0) 90- 77 81 16, Email: ola.eriksson@resgeom.slu.se

Keywords: Data acquisition; Ecosystem functioning; Spatiality; Planning system

Until the late 80's sustainability to Swedish foresters essentially meant safeguarding the timber production potential of the land base. Today, forest management in Sweden, as in many other places, means the management of multiple resources. These resources include, e.g., biodiversity, recreation, hunting, carbon sequestration and reindeer herding. At the same time, market pressures require that the timber production is made more competitive and environmentally friendly. The increased complexity of forest management has created a surge for improved decision support.

The research community has answered to the demand for improved decision making capability in several different areas. They can be grouped under three headings: general knowledge concerning the forest ecosystem, models for ecosystem functioning including silviculture and the growth process of the trees, and management planning methods.

Much research is directed towards modelling the effects of forest management on ecosystem functioning, such as the consequences of fragmentation on species diversity and acidification of streams and lakes. Active research is also conducted in carbon and nutrient budgeting and estimation of effects of global warming.

Results of research concerning tree growth, silviculture regimes, forest survey methods etc., are contained in computer based systems for forest resource management developed the Faculty of Forestry of SLU. Systems have been developed for forest management planning at a company level and for the analyses of timber yield, growing stock etc., on a regional level. The systems were, however, initially designed in the 70's and almost exclusively directed towards timber management. When the biodiversity issue emerged, methods and instruments to be incorporated in forest management planning were requested. in the beginning of the 90's, case study areas were established by companies and research institutions. A number of conceptual planning models for "ecological landscape planning", such as the ASIO and the Key Habitat – Corridor Model, were elaborated in a more or less formal collaboration between companies and researchers. Typically, however, the latter planning instruments and traditional timber management planning have been used simultaneously but not in an integrated manner.

Another area of research of interest for resource management is improved methods for data acquisition. For example, by combining remote sensing data with ground measurements, estimations of spatial continuous forest parameters can be obtained to describe forest landscapes. That the spatial arrangement can be depicted is essential for the management of many resources. Moreover, methods for gathering data on rare objects also exist, primarily for biodiversity management. Typically, these methods are based on field measurements but methods using the combination of remote sensing and field measurements are under development.

Unless planning for different uses can be made simultaneously, dangers of sub-optimality are obvious. Therefore, research efforts in different areas need to be gathered in a common framework. The Faculty of Forestry has initiated a project for the development of a new system for forest management. It should be designed (i) with a modular structure to allow for the development of different applications, (ii) with the landscape as the basic planning unit, (iii) with the tree as the basic unit of projection of the tree layer, (iv) with models for processes interacting with the management of the tree layer, and (v) with models for risk and uncertainty of data and model projections.

One of many challenges is to be able to give a reasonable description of the landscape, not only in terms of trees but also, for instance, of soil conditions. Another is to try to combine empirical models for tree growth with process models. Although the working name of the project, Heureka, may be associated with a flash of genius, the efforts of coming years will rather be Herculean.

Estimating the thresholds of criteria and indicators in Japan

Takayua Hiroshima
University of Tokyo, Lab Forest Manage, Dept Forest Sci Grad School Agric Life Sci, 1-1-1 Yayoi, Bunkyo-Ku, 113-8657 Tokyo, Japan
FAX: +81-3-5689-7253, Email: hiroshim@fr.a.u-tokyo.ac.jp

Thresholds of criteria and indicators accepted in Montreal Process countries were estimated using a linear programming model. The concept of thresholds contains "feasible region" and "optimum solution", which mean region of indicators satisfying the conditions of sustainable forest management and optimum value of indicators in the feasible region respectively. First, four criteria were selected for the subject of this study, which are

-Biological diversity, -Productive capacity, -Carbon cycles and-Socio-economic benefits, and then tentative indicators, -Area of old growth forest, -Growing stock of commercial forest, -Growing stock of total forest and -Harvesting volume were set for each criteria at the national level.

Next, the thresholds of the indicators were estimated using a linear programming model. The model covers the entire forest in Japan which is divided into four groups, private plantation forest, national plantation forest, private natural forest and national natural forest and has some basic parameters such as planning horizon and number of age class which are set for ten terms (= fifty years) and seventeen classes (= eighty five years). in the model decision variables are cutting area by group, term and age class and objective function is to maximize the total harvesting volume in the planning horizon. Constraints consist of the requirements for sustainable forest management that all of indicators are basically non-decline over planning horizon and some other equations such as cutting regulations, forest transition and so on. The requirements related to sustainable forest management are as follows: 1. Area of old growth forest is non-decline. 2. Normal age class distribution is achieved for ending forest structure. 3. Area of commercial forest is constant. 4. Growing stock of total forest is non-decline. 5. Harvesting volume is non-decline and cannot increase by more than ten percent from the preceding harvest. Last, optimum solution was found and feasible region was sought by a method of parametric linear programming. in the constraints indicators are defined as accounting variables by term, so thresholds have time-series change. To seek the feasible region, the value of optimum solution is given to the indicator by a new equation and the value is changed to find out the region where solution exists. The result was that optimum solution of harvesting volume reflects the trade-off relation toward other three indicators because only harvesting volume corresponds to _gactivity_h and others _gresource_h in the model structure. and each feasible region becomes broader as time passes because the choices of solution become wider in the final stage of planning horizon than the early stage. It was concluded that the concept of threshold is efficient in judging the progress toward sustainable forest management.

A spatial approach to participatory planning in forestry decision-making

Leena Hytonen, Leskinen, P. & Store, R.
Finnish Forest Research Institute, Kannus Research Station, Post Box # 44, FIN-69100 Kannus, Finland
FAX: +358 6 8743 201, Email: leena.hytonen@metla.fi

During the last ten years the concept of the sustainability of the forestry has been extended from economic sustainability to include also ecological and social sustainability. To reach ecological sustainability *e.g.* The Finnish Forest and Park Service applies landscape ecological planning for large (10 000-150 000 ha) forest areas. Participatory planning, is one mean to reach the social sustainability. Important question is the ability to produce planning solutions which are acceptable for the decision-maker and the interests participated.

In participatory forest planning public is allowed to tell their opinions about forests and forest management. Public is those people to whom current decision-making affects. in participatory planning they also have right to expect that their opinions are somehow taken care of. The nature of the information concerning public's values and opinions is that it is context dependent. This means that values and opinions are valid only in certain situation. Situation is part of those peoples lifeworld. When managing qualitative information in decision-making, the context should be involved too.

In this paper/poster, an approach is presented to collect and analyse qualitative and geographic information and to process it to quantitative and spatial format. in this study the qualitative research analysis, numerical preference analysis and spatial analysis are utilised.

For example, the Finnish Forest and Park Service receives a great amount of qualitative information about publics' opinions and values as meeting records, letters, and personal contacts during the participatory planning process. Participants have messages concerning hunting, beautiful landscapes, picking wild berries etc. These messages usually refer to certain location, i.e. include geographic data. in this approach messages are analysed by their contents location and context. Qualitative methods, making typologies searching facts and norms, and discourse analysis are used to understand relevant context and situation. Context determines the classification of the messages by their contents. A database for GIS application is created.

Geographical Information System (GIS) applications offer many tools by which information from different sources can be connected and used in the analysis. Cartographic modelling is an area of application for spatial analysis employing concurrent analyses of many sources of information. Using cartographic modelling and modern decision-analysis methods to combine the data collected in the process of participatory planning enables better understanding and visualisation of the different objectives of people. in spatial analysis, an aggregation method is needed to combine individual preferences. in this task, two different approach are being discussed. in the first approach, each individual evaluates the relative magnitude of his/her proposed areas, and the overall preferences are aggregated over individuals. in the second approach areas are classified and the relative importance of classes are determined with respect to large-scale potentials of the planning area.

The advantage of this approach is the ability to carefully organise qualitative information into quantitative format. The most preferred areas are named and their relative magnitude according to the participants preferences are measured. By integrating qualitative and spatial analysis it is also possible to clearly point how and where the participants' opinions have been taken care of. This could be used as a tool to motivate participants behind the decision.

Incorporating Ecological Information into the Forest Management Planning

Jyrki Kangas, Annika Kangas
Finnish Forest Research Institute, Kannus Research Station, P.O. BOX 44, FIN-69101 Kannus, Finland
FAX: +358-6-8743201, Email: jyrki.kangas@metla.fi

Keywords: Ecological modelling; Expert judgements; Forest planning; Multi-functional forestry; Optimization; Uncertainty

Ecological information about the impacts of forestry on the environment, such as the effects on wildlife populations, and assessments of ecological sustainability have rarely been used in calculations of forest management planning. However, some applications exist where models predicting sizes of wildlife populations, habitat suitability, or biodiversity have been used in optimization calculations. The most important reason for not using ecological information in calculations of forest management planning has been the lack of information that can be used in numerical planning packages. These packages, usually based on mathematical optimization, require the ecological knowledge to be presented in the form of relatively simple models. However, all available information should be utilized in decision making. Ignoring other kinds of ecological knowledge than only numerical models based on empirical research would mean waste of valuable information.

There usually exists much more or less qualitative information of the ecological consequences of alternative treatment schedules and production programmes. One such source of information is the expert knowledge held by ecologists. There exist some applications where expert judgment has been utilized in choosing the best management alternatives, with respect to some ecological concerns.

It is also possible to model these expert opinions to a form of mathematical model, which can then be utilized in optimization calculations. On the other hand, models describing population dynamics, for example, are too complicated to be used in usual planning packages. Thus, the information included in such models needs to be reformulated to a simpler form in order to be applicable.
Often, the uncertainty involved in calculations has not been taken into account in forest management planning. The uncertainties inherent in ecological considerations probably are greater than uncertainties of, for example, growth and yield predictions of the growing stock. Information on the uncertainty involved in the decision support is useful in any natural resource and environmental decision making. For example, when evaluating the ecological sustainability of alternative production programmes for a forest area, it is important to know the risk that the sizes of populations of species of interest would fall below presumably critical limits (if the management alternatives chosen in the programmes would be implemented). This is especially the case with rare species. The uncertainty needs to be taken into account in planning to minimize the risk of the population sizes falling below a given threshold value, or to become extinct, due to forestry actions.

In this presentation, possibilities to use different forms of ecological information in optimization calculations of forest management planning are presented. Also the importance of being aware of the uncertainty involved in ecological assessments applied, as well as the possible consequences of ignoring the uncertainty inherent, are discussed. Examples of utilizing ecological knowledge in forest management planning are given. These include modelling suitability of forest habitats for black grouse (*Tetrao tetrix*, *Lyrurus Tetrix* L.) on the basis of pairwise comparisons data, and using an ecological threshold function as a multiplicative part of a utility model in multi-objective optimization calculations.

Application of Criteria and Indicators for Sustainable Forest Management to GIS-based Multiple Criteria Decision Making Approach for Forest Conservation Planning in Kinabalu Region, Sabah, Malaysia

Mui How M. Phua, Mitsuhiro Minowa
Fac of Agric and Life Sci, Univ Tokyo, Department of Forest Science, Laboratory of Forest Management, Yayoi 1-1-1, Bunkyo-ku, 113-8657 Tokyo, Japan
Tel: +81-3-3812-2111 ext. 5221, FAX: +81-3-5689-7253, Email: phua@fr.a.u-tokyo.ac.jp

In 1994, during the Second Meeting of the Intergovernmental Working Group on Forests, forest was recognized as having cross-sectoral linkages that can be dealt with integrated landuse planning. Recently, the importance of the GIS-based multiple criteria decision making (MCDM) approach in planning has been widely recognized. The MCDM approach implies a process of assigning values to alternatives that are evaluated along multiple criteria. However, there have not been criteria in common for landuse planning involving forested land.

Development of the Criteria and Indicators for Sustainable Forest Management (C&I) was initiated in 1992 by International Tropical Timber Organization (ITTO), followed by other efforts such as Montreal and Helsinki processes. The C&I contain the most important forest functions that provide various benefits to the society. However, the forest functions have not been incorporated into the landuse planning process. The C&I have great potentials not only in dealing with the sustainable forest management but also in landuse planning at regional level as far as forest is concerned. in this study, we propose the application of the C&I to the GIS-based MCDM approach for forest conservation planning in Kinabalu region, Sabah, Malaysia.

The study area is located in western part of Sabah, Malaysia. Urbanization has been spreading out from the state capital, Kota Kinabalu. As a result of timber harvesting and agricultural land conversion, forest has rapidly disappeared in this area. Major conservation effort in this region is represented by the initiation of Kinabalu Park (735 km^2) in 1964. Encroachment occurs in western and northern parts of the park boundary by local farmers. in 1986, illegal logging was spotted in northeast side within the park. This shows the conflicting nature of landuse activities in this area.

The criteria adapted are biodiversity conservation and soil and water conservation. Evaluation of forest conservation priority based on these forest functions would satisfy the maintenance of ecological balance and vitality and safety to human lives. in this study, a criterion representing human impacts on forests is also devised as potential threats to forests. in the ITTO's C&I human impacts on forests are emphasized only within the permanent forest estate.

The indicators, adapted from the C&I or devised, are generated from map sources or derived by using known relationship between a spatial factor and the indicator. Forested areas are prioritized to produce a forest conservation zoning map based on a computed conservation coefficient. The results are compared to existing protected areas. It is conceivable that high conservation priority areas are representations of the important forest functions that maintain the ecological vitality and balance, and to ensure safety of the society. in short, forest conservation planning using GIS-based MCDM approach has gained legitimacy from the application of the C&I. As such, community of forest science profession has contributed toward a better construction of criteria and indicators for landuse planning.

The Analytic Hierarchy Process in Natural Resource and Environmental Decisionmaking

D. Schmoldt, Kangas, J., Mendoza, G., and Pesonen, M.
USDA, Forest Service, Southern Research Station, VA Blacksburg, USA
Email: dlschmol@facstaff.wisc.edu

The analytic hierarchy process (AHP, developed by Thomas Saaty in the 1970's) has been applied to a variety of decision-making problems. For example, it has been used for planning, resource allocation, and priority setting in business, energy, health, marketing, forest management, and transportation. Three important components of the AHP that facilitates the analysis of complex problems are: (1) decomposition of a problem into a hierarchy consisting of a goal and subordinate features of the problem, (2) assignment of a numerical weight to each element in the hierarchy (through pairwise comparisons between elements at each level), and (3) aggregation of those weights into an overall preference score for the alternative decision outcomes.

The AHP is relevant to nearly any natural resource/environmental management application that requires multiple opinions, multiple participants, or a complex, decisionmaking process. Considering the complexity of most management issues and compliance regulations, the AHP can extend to a wide array of managerial and planning tasks. in addition to its breadth of application, the

AHP is relatively easy to apply, to understand, and to interpret.

4.04 Recent advances in forest resource management and economics

Does standard discounting incorrectly show an advantage of leveraging forestry investments with debt?

David Klemperer
Professor of Forest Economics, Department of Forestry
Virginia Polytechnic Institute and State University,
Blacksburg, Virginia 24061, USA

Typically one uses a risk-adjusted discount rate (RADR) larger than the risk-free rate to calculate the net present value of a project with risky cash flows. In those cases, one can show a present value advantage of borrowing funds at a loan interest rate lower than the RADR. This results because, under the above conditions, the negative present value of loan payments will be less than the positive loan value. Using a zero inflation example for simplicity, at a 5% loan interest rate, annual payments on a $100,000, 10 year loan will be $12,950. Incorporating this loan into a discounted cash flow analysis using a 7% real risk-adjusted discount rate, the negative present value of loan payments is $90,955, or $9,045 less than the loan amount, thereby boosting the project's present value. However, the borrower should view loan payments as risk free cash flows based on a legally binding contract, in which case payments should be discounted with a risk-free rate, say 3%, which is lower than the risk-adjusted rate and lower than the loan interest rate. In that case, the negative present value of loan payments will *exceed* the loan value because the loan interest rate will be above the risk-free discount rate. For the above example, the negative present value of loan payments would be $110,466 at 3% interest, which is $10,466 more than the loan amount. Thus, the previously-calculated present value advantage of borrowing is really a disadvantage. Analyses show how results will vary depending on levels of relevant interest rates, inflation, income tax interactions, loan duration, project life, and the degree to which borrowing increases the overall risk of a project. Forest policy implications are that typical discounted cash flow analyses of leveraged forestry investments could make borrowing appear deceptively attractive. The result could be overpayment for leveraged investments in forested properties or forest management. The analysis raises interesting questions about economic efficiency. Do incorrect analyses of leveraged investments cause a sub-optimal distortion toward higher borrowing levels? Could the result be higher-than-optimal levels of leveraged forestry investment, strictly from a financial efficiency viewpoint? Further research is needed to determine the degree to which such inefficiency is manifested in actual practice in forestry and other investment areas.

Forest Ownership as an Inflation Hedge

Antrei Lausti
Helsinki School of Economics and Business Administration, Center for Doctoral Programs,
Runeberginkatu 15 A, 00100 Helsinki, Finland.
Tel: +358943138371, Fax: 358943138305, E-mail: lausti@hkkk.fi

Keywords: forest ownership; private housing; return and risk; inflation; hedging

This paper analyses the extent to which forest ownership, private housing and stocks were a hedge against the expected and unexpected components of inflation in Finland, using the traditional method of dividing inflation into expected and unexpected components. The expected inflation is proxied by the inflation forecasts of the Research Institute of the Finnish Economy (ETLA). Unexpected inflation is the difference between actual inflation and this inflation forecast.

A novel contribution of this study is to construct and use comprehensive, national return series for forest ownership to estimate their relationship to inflation. This estimation of the inflation-hedging characteristics of forest ownership is also the first to use systematically created value-weighted return series that include all economically relevant roundwood assortments. Moreover, this study is the first in Finland to estimate the inflation-hedging of other asset classes than stocks, namely, private housing, in addition to forest ownership.

Results indicate that forest ownership did not provide a hedge against expected inflation over the period 1973-1998 at all, but provided some hedge against expected inflation over the period 1978-1998. One reason for this may be that expected inflation was at very high levels during the 1970s. To summarise, it can be said that the forest ownership has provided a hedge against expected inflation only to some extent and has offered a very effective hedge against unexpected inflation. Forest ownership, or more precisely stumpage prices, have however been a leading indicator of the inflation trend. Private housing provided a hedge against unexpected inflation at a statistically significant level. Forest ownership and housing provided some hedge against expected inflation, but not at a statistically significant level.

Stocks did not provide a hedge against expected inflation at all; in fact, the relation was even negative, but stocks provided some hedge against unexpected inflation, although not at a statistically significant level. It seems that forest ownership and private housing are better assets than stocks for the institutional investor in terms of inflation hedging. Both these asset classes have provided effective hedges against unexpected inflation. It is valuable to have a hedge against unexpected inflation, because an inflation hedge against expected inflation can often be obtained through bond markets.

When the longer five- and ten-year holding periods are considered, the results are almost the same. Forest ownership is a hedge against expected inflation to some extent and a very effective hedge against unexpected inflation. It turned out that the longer the holding period, the more effective a hedge forest ownership has provided against expected inflation as well. These inflation-hedging properties of forests may support regeneration and other investments by forest owners and therewith economically sustainable forestry.

Trees outside forests: why should foresters think about this resource?

Christoph Kleinn
CATIE, Costa Rica

Trees outside the forests are increasingly discussed as an important natural resource. Agroforestry and urban forestry are but two examples of disciplines dedicated to trees outside the forestry context. While the great majority of studies on trees outside forests has a local, small area focus, the present paper attempts to look at it from a large area, landscape perspective, discussing the different functions of trees outside forests. Some preliminary results of studies in Costa Rica are presented that underline the relative relevance of this resource. Comparisons to the forest resource are made, though one should clearly see trees outside forests as a resource on its own, that needs particular attention and a particular management.

4.11.00 / 4.01.03 Planning of long-term observations

Long term observations and research in forestry

Christoph Kleinn
Tropical Agriculture and Higher Education Center (CATIE), Costa Rica
Tel: +506 556 1530, FAX: +506 556 7954, Email: ckleinn@catie.ac.cr

Long term and large area are amongst the principal characteristics of experiments and observations in forest research. When the International Union of Forest Research Organisations (IUFRO) was founded in 1891 one of the most urgent tasks was the exchange of knowledge and experience regarding the planning of long term experiments. While in those days long term experiments were mainly conducted to study timber production, it is nowadays widely accepted that long term experiments are an outstanding tool to describe, quantify and model the effects of changes in environmental conditions.Various aspects are relevant in the context of long term observations: statistical considerations with respect to plot number, plot size, number of replications; aspects of data management; practical aspects of establishing long term experiments.

This paper summarizes an IUFRO 4.11 International Symposium that was held in February 1999 in CATIE, Costa Rica.

Characterization of central tendency and spatial variability of growth and mortality of forests: A comparison of some statistical models

George W. Weaver, Harun, Ismail; Appanah, S.
USDA Forest Service, 3200 Jefferson Way, OR 97331 Corvallis, USA
Tel: 541-758-7779, FAX: 541-758-7760, Email: george.weaver/r6pnw_corvallis@fs.fed.us

Forest growth can be expressed as single tree annual diameter increment or as annual basal area increment for an entire stand. Mortality can be expressed as single tree annual probability of mortality or as annual basal area lost to mortality. These measures exhibit differences in variation over time as well as differences in central tendency, depending upon whether they are expressed at the individual tree or whole stand spatial scale of measure. This talk will contrast/compare several models for characterization of central tendency and variation of these measures of growth and morality: generalized least squares, generalized linear models

(Poisson regression for growth, logistic regression for mortality), and quantile regression. Estimates of central tendency are similar for these models, the biggest differences between the models are in the way that they model the variation of growth and mortality rates over time. Differences between the models indicate the degree to which they partition the variability in growth and mortality as spatial variation or random variation. Differences between the models will be illustrated using a 15 year permanent sample plot data set from a Hill Dipterocarp Forest in Peninsular Malaysia.

Long-term experiments: long-term commitments

Andreas Zingg
WSL, Birmensdorf, Switzerland
Email: Zingg@wsl.ch

Long-term experiments in forestry research lay within a area of conflict: on side research needs good data *e.g.* long data series of optimal quality, on the other side there are costs and long-term commitments which are necessary to get such data. Long-term commitments can be guaranteed best by forest research institutes. But due to shortage of funds these long-term commitments are questioned in such institutes too. Forestry research and research in related fields, *e.g.* in other ecosystem types, is based on long-term experiments because of the relatively slow development in these ecosystems. Therefore changes in such ecosystems can be monitored only using adapted "slow" research methods. Investments, as long as the experiments are not intensive studies usually are overestimated. This can be shown on the basis of long-term recorded time studies. Examples of long-term experiments illustrate the usability of data which exceeds often the questions asked, when the experiments were started.

4.12.00 Integration of GIS and Remote Sensing for Assessment of Forests and Landscapes

Forest Cover Change Assessment at the Pan-Tropical Scale using Earth observation satellite data

Frederic Achard, Hugh Eva, Philippe Mayaux, Tim Richards and Hans-Jürgen Stibig
Joint Research Centre of the European Commission, Space Applications Institute, 21020 Ispra (VA), Italy
FAX: +39-0332-789960, Email: frederic.achard@jrc.it

Of major concern is the issue of forest distribution. Assessing the state and the evolution of tropical forest cover is relevant for studying the impact of human activities on the global environment.

New information technologies make possible the development of more advanced systems of data gathering and analysis which can accurately assess the current status of forest cover.

In the framework of the TREES-II project, techniques for the assessment and monitoring of moist tropical forest cover are developed at the pan tropical level. These techniques make use of an extensive satellite data set analysed in an ad-hoc manner. This paper presents a new approach for the assessment of deforestation rates in the moist tropical regions for the period 1992 to 1997 using Earth observation techniques. The approach is based on intensive sampling with fine spatial resolution satellite image pairs, focusing on the most active deforestation areas.

As a first step the humid tropical forest belt was mapped using coarse spatial resolution imagery (NOAA-AVHRR), with fine spatial resolution satellite data (Landsat-TM) used as a reference data source. The 1.1 km resolution of NOAA AVHRR is well adapted to the geographic scale of the monitoring exercise (pan tropical). However, this spatial resolution leads to a loss of detail that makes it difficult to derive a good proxy variable for the measurement of deforestation rates.

At the global level a sampling scheme for forest change assessment has been defined using sampling units independent of any particular satellite sensor. For this purpose an equal probability sampling frame has been chosen.

In the case of spatially correlated data, such as forest cover change, estimates can be improved by performing a preliminary stratification to reduce the variance of the estimated variable. However, at the pan-tropical scale little reliable spatial information is available to stratify on the basis of deforestation rates. Stratification is performed using percentages of forest area (derived from the 1.1 km resolution maps) and areas of known current or recent deforestation activity (elucidated from expert consultation) estimated for each sampling unit.

Sample site selection is performed by using a sample frame based on a tessellation of hexagons on a sphere. This approach allows for sensor independent sample from which unbiased estimators and error variance may be computed.

This sampling scheme is currently in the implementation phase. The total target sample size has been set up to ninety-five as a feasible target linked to availability of resources. Observation units have been selected and image pairs for the nominal period 1992 to 1997 have been acquired. These image pairs are currently being photo-interpreted on-screen by local experts who have ground knowledge of the forests. Digital copies of the interpretations will be collated and analysed and estimates of deforestation rates over the observation period determined. The latest results of estimation of forest cover change in the humid tropics will be presented during the congress.

Monitoring forest fuel maps for helping control and prevention of forest fires

Carlos Bahamondez, Gerardo Mery
Instituto Forestal de Chile, Huérfanos 554, Santiago, Chile
Email: Carlos.Bahamondez@helsinki.fi

The aim of this study is to provide a direct, rather simple and friendly methodology for monitoring forest fuel maps. The classification of the vegetation cover of Chile in fuel classes according to its inherent flammable characteristics was the procedure utilized for developing the maps. The forest fuel maps were developed in order to provide basic information for applying fire behavior models. The use of these models facilitates forecasting and control of forest fires. Additionally, application of the models allows an optimal resource assignation for forecasting, prevention and extinction of forest fires. Two methods for monitoring fuel maps were compared, namely the principal component method and the images difference method. These methods haven been used in many forestry applications and are well documented. However, their utilization for monitoring of fuel maps seems to be a novelty. For carrying out the comparative study, satellite imagery data, ground field information and forest fuel map classification in a pilot area were utilized. The satellite material consisted of two SPOT scenes of the same area (the pilot area covered approximately 20 000 hectares and it was located in Malleco Province, IX Administrative Region in the central-south part of Chile) acquired in 1991 and 1994. The Chilean Forest Research Institute (INFOR) provided ground field information as well as the fuel map of such an experimental area. The methods were selected considering that they can be applied in a straightforward manner and they do not specially demand sophisticated software. The results pointed out that both methods are not necessarily mutually excluding, but are rather complementary ones. The application of principal component method demonstrated that this approach is particularly sensible to detect small changes of canopies as well as large and destructive ones like clearcuttings or forest fires.

Although images difference seems simple and highly intuitive compared with principal component method, it became time consuming when a large amount of information is processed. Therefore, in the latter case - that is the usual situation that one can expect when monitoring forest fuel maps - principal component demonstrated to be more efficient. Finally, some recommendations are concluded.

User Requirements for remote sensing-based spatial information for the sustainable management of forests

Alfred de Gier, Edouard Westinga, Sjaak Beerens, Patrick van Laake and Herman Savenije
International Institute for Aerospace Survey and Earth Sciences (ITC), Hengelosestraat 99 Post Box # 6, 7500 AA Enschede, Netherlands
Tel: +31 (0)53 4874309, FAX: +31 (0)53 4874399, Email: degier@itc.nl

Sustainable forest management requires proper decision-support systems. The effectiveness of these, however, is jeopardized by problems related to the timely availability of relevant information, as confirmed, e.g., in Agenda 21, the Intergovernmental Panel on Forests and the Intergovernmental Forum on Forests. The FAME (Forest Assessment and Monitoring Environment) concept addresses this problem, by suggesting an end-to-end forest assessment and monitoring system, ranging from data acquisition, up to the delivery of information to the desk of the user.

As a first step, the Dutch government charged a consortium of Dutch organizations and FAO with a User Requirements Study to assess the needs for spatial information on forests from a user perspective. This study included an interactive questionnaire survey among stakeholders/users, detailed studies in four tropical countries, an assessment of capabilities of current and planned remote sensing-based systems, the development of an international user network and an international workshop. The study revealed a substantial and urgent global need for spatial data and information on forests, referring to both "state" and "change" parameters. This was particularly observed at a local and at sub-national levels. These information needs cannot be fully satisfied by current or near-future remote sensing-based systems. On the other hand, there is a considerable under-utilization of existing data sources. Accessibility to and affordability of existing data and information are the major constraints for all users, with distribution being the weakest part of the chain. The concept of an "end-to-end" information system was re-defined, including the required information infrastructure, comprising data capture, data acquisition and distribution, data processing, data integration and capacity building as essential components. An information strategy at national level should support this system. Furthermore, international protocols are needed for the exchange of data. A further validation of the end-to-end concept is needed.

European forest mapping and monitoring within the frame of the FIRS (Forest Monitoring from Remote Sensing) Project - a review on progress and results.

Sten Folving, Pam Kennedy
Joint research Centre of the European Commission, Sector for Forest and Catchment studies, Environment and Geo-Information Unit, 21020 Ispra (VA), Italy
Tel: +39 0332 785009, FAX: +39 0332 789469, Email: Sten.folving@jrc.it

The FIRS (Forest Information from Remote Sensing) Project was launched early 1994 as the main European forest activity of the EU Space Applications Institute under the 4th FrameWork Programme. After a two-year foundation action phase, during which studies on regionalization and stratification of pan-European forest eco-systems and on European forest nomenclature for remote sensing applications were carried out, the project launched several major application studies in collaboration with other services of the European Commission.

The four most important studies concerned: 1) The provision of a 1km forest probability map of the pan-European area based on NOAA-AVHRR data; 2) an evaluation of high resolution satellite data for mapping European forest types and other wooded land --followed by a study on using medium resolution (200m) satellite data for regional mapping of forest and OWL; 3) a study on the assessment of above ground biomass and volume in Mediterranean and Boreal forest types using high resolution imagery; 4) a study on the assessment of changes in forest areas using high resolution satellite data combined with a study on the development of methods for assessing the structural diversity, at a landscape level, of forested areas in various European test sites. All studies have been carried out under external contracts on a competitive basis. They have been supported by in-house and external software development.

Based on the results from the first phase of the FIRS Project new forest mapping and monitoring activities have been defined and launched for the 5th FrameWork Programme. These activities are strongly linked to the support of the development of rural areas, both regarding economic aspects, but also regarding environmental issues. They will, among other things, address the development of operational Criteria and Indicators on sustainable development and bio-diversity, the development of automatic or semi-automatic methods for assessing forest growth conditions and forest health, and, new means for assessing the protective function of forests. Methods for integration of statistics and mapped information from Earth Observation data will be developed in support to the EFICS (European Forest Information and Communication System).

Forest Cover Monitoring and Assessment in South and Southeast Asia

Chandra Prasad Giri, Surendra Shrestha
Asian Institute of Technology, UNEP Environment Assessment Programme for Asia and the Pacific, Post Box # 4, 12120 Klongluang, Pathumthani, Thailand
Tel: (66-2) 524-6236, FAX: (66-2) 516-2125, Email: cpgiri@ait.ac.th

Keywords: Forest Resources, Deforestation, Remote Sensing, GIS

Deforestation is one of the major environmental concerns in South and Southeast Asia. Accurate, timely and accessible information base on the present status of forest resources and their change patterns is lacking in many countries. This is one of the limitations in formulating sound forest resources planning and management strategies at national, regional and global levels. The present study provides a synopsis of forest cover monitoring and assessment project of UNEP Environment Assessment Programme for Asia and the Pacific. Monitoring and assessment was performed using time series coarse spatial resolution satellite data such as NOAA AVHRR. The paper presents the outcome of forest cover change analysis of 12 countries in South and Southeast Asia. Major deforestation fronts (called "hot spots") were identified and investigated in detail using high-resolution satellite data such as SPOT and Landsat supported by field information. GIS and socio-economic databases were prepared and used for further analysis. The major forest cover change patterns and underlying causes of deforestation and forest degradation were underlined. Policy options to arrest the problem of rapid and unprecedented forest cover change were suggested.

Relationship between Forest Parameters (Volume and Basal Area) and Jers-1 Sar Backscatter

Khali Aziz Hamzah
Regional Centre for Forest Management (RCFM), Kepong 52109, Kuala Lumpur, Malaysia
Tel: 603-6377633, FAX: 603-6377233, Email: khali@frim.gov.my

Keywords: JERS-1 SAR, backscatter coefficients, peat swamp forest.

The empirical relationships between Japanese Earth Resources Satellite-1 Synthetic Aperture Radar (JERS-1 SAR) backscatter and two forest parameters (volume and basal area,) are evaluated. These parameters were collected from nine field plots covering a wide range of peat swamp forest classes including Primary, Regenerating and Disturbed forests. The backscatter coefficients were extracted from SAR image acquired in a dry season. A window size of 5x5 pixel was used to suppress the effects of speckle and to correspond to the size of the actual field sample plots. The relationships were evaluated by correlation and linear regression analyses. Results show that basal area and volume (forest parameters that are commonly used in forest inventory) exhibit positive correlations with backscatter coefficients for the dry season SAR image. The highest significant correlation (r= 0.7186) was observed between the dry season JERS-1 SAR backscatter coefficients and forest basal area. This suggest the usefulness of JERS-1 SAR data in determining the density of peat swamp forest stand.

Large Digital Aerial Imagery Mosaics in Land Use and Forestry Planning

Mikael Holm, Janna Puumalainen, Janne Sarkeala, Seppo Väätäinen & Markku Rantasuo
VTT Automation, Measurement Technology, P.O.Box 13002, FIN-02044 VTT Otakaari 7, Finland

The poster presents the latest developments of an airborne digital camera image acquisition and image mosaic creation. The developed methods are reviewed for their potential for land use and forestry planning particularly in regions where the use of traditional optical remote sensing data is difficult, for instance in the tropics.

Airborne digital camera imagery is a convenient tool for gathering rapid and accurate true or false colour data of the environment with an adjustable resolution of 0.4 - 4 m. The image acquisition can be done from below the clouds and the image quality can be assessed immediately. One of the main problems, however, has been that in order to analyse large areas thousands of images are needed, and a single image only covers a small proportion of the area of interest. A related problem is that the images often have large radiometric and geometric differences.

In order to overcome these problems a system has been developed for collecting the data and creating large image mosaics. The airborne part of the system includes digital camera, GPS, navigation and camera control hardware and software. After the flight the mosaics are created semi-automatically on a standard PC. in order to obtain a result of good radiometric and geometric quality a photogrammetric mosaic is made by correcting for aircraft inclination, camera distortion, terrain elevation differences, sun angle differences and local radiometric differences. Digital terrain models can be created internally or entered from external sources to eliminate the prevailing elevation differences, i.e. to produce an orthomosaic.

The system is in operational use and more than one million hectares on four continents have been imaged and processed for forestry mapping, land use planning and monitoring of natural resources. Further developments are on way for digital infra-red imagery, image processing system based on parallel computers and for automatic single tree detection based on pattern recognition.

The system is in operational use and more than one million hectares on four continents have been imaged and processed for forestry mapping, land use planning and monitoring of natural resources. Remote sensing and spatial data for the establishment and visualisation of 3D computer landscape models for impact assessment

Barbara Koch, Harm J. and Reidelstürtz P.
University of Freiburg, Forestry Faculty, Tennenbacherstr. 4, 79085 Freiburg, Germany
Tel: 0049-761-203-3694, FAX: 0049-761-203-3701, Email: ferninfo@ruf.uni-freiburg.de

In many cases there is a need to assess and visualise the landscape in order to evaluate measures, which are suspected to have an impact on the landscape. There are many methods to assess a landscape, according to beauty, individuality, diversity or other parameters to estimate the impact of measures on landscapes. Until now the assessment of the impact on the landscape was in general based on qualitative parameters and 2D data based visualisation like maps and photographs. Nevertheless for the acceptance and realisation of planned measures, the inclusion of quantitative parameters and a 3D data based visualisation seem to be good tools.

A research project at the department of remote sensing and landscape information systems deals with the potential of 3D landscape models for the development of for quantitative impact assessment parameters and visualisation. The models were based on photogrammetric measurements from aerial photographs on one hand and auxiliary spatial data from different data pools on the other hand.

The measurements were taken with an analytical plotter (Zeiss P3) which was connected to a CAD-programme (Bentley MicroStation). The measurements included the land-surface as well as surfaces of different forest stands, roads, individual trees and houses. Objects close to the planned impacts (power-lines) were measured, the other objects were modelled based on auxiliary spatial data.

The planned power-lines were also modelled with MicroStation.

In contrast to photographic layout manipulations, this method is based on 3D data. That allows to visualise the impact on the landscape from each position within the model and to calculate quantitative parameters like sensitivity of the landscape, visibility of the impact, a.s.o. on a solid 3D geometric basis. There were two categories of parameters derived from the model, the first was used to assesses the sensitivity of the landscape to possible impacts. The other category is used to quantify the size of the impact. in addition to the usual planners point of view, in which the landscape is studied from above, the individuals point of view, which studies the landscape from within, was used to calculate the visibility of the impacts. Various images and animations of the landscape models were rendered, to visualise the impact, in addition to the above mentioned parameters. Most visualisation products employed the individuals point of view from within the landscape.

In addition to the assessment of the status quo, different situations could be simulated in the model, including variants or future changes, like the growth of vegetation or seasonal aspects.

Identification of landscape types in Croatia using remote sensing methods and spatial analysis

Vladimir Kusan, Renata Pernar, Oleg Antonic
University of Zagreb, Faculty of forestry, Svetosimunska 25, HR-10000 Zagreb, Croatia
FAX: +385-1-218616, Email: vladimir.kusan@zg.tel.hr

Landscape analysis is the process of describing and interpreting the landscape ecology of an area. Resource patches and a landscape network of connecting corridors are identified, described and classified. Theusual set of data acquired for a landscape analysis includes :topographic maps, forest cover maps, digital elevation models, satellite images and air photos. A geographic information system is very useful inthis process. In the process of landscape analysis combined methods of remote sensing, spatial analysis and terrestrial works should be used to identify and quantify landscape variables and/or spatial, temporal and functional aspects of landscape.

In Croatia there are a variety of different landscapes, from lowlands inthe north, hilly and mountain region in the middle and the coastal areasin the south. Different agricultural use and urban development in such variety influenced very much the forest landscapes. The investigation of relationships between different agricultural, urban and forest types was performed on the set of 15 x 15 kilometres LandsatTM subscenes. The subscenes were chosen around the most important settlements in all regions in Croatia. On each subscene the several classification methods were used to describe land use of each region.The accuracy of each classification was calculated using topographicmaps, fotointerpretation and terrestrial work. The best classification of each subscene was used for landscape analysis. The results show how many different landscapes can be found in Croatia.

Estimation of Land Cover Change in Peruvian Tropical Rainforests using JERS-1 images

David Lopez Cornelio
Shimane University, Faculty of Life and Environmental Science, Office #505, 690 Matsue, Japan
Email: a98950@matsu.shimane-u.ac.jp

In Peru, nearly 1,800 acres of tropical and subtropical forests are cut daily, amounting to 670,000 deforested acres each year; this phenomena eliminates critical habitats for wildlife and plants species (Peru ranks number two in the world in bird diversity, number three in mammal diversity and number five in plant diversity, within it's borders exists 83 of the world's 114 natural community types). An accurate and up to date assessment of forest area and rates of depletion is fundamental to the development of improved national forest management strategies. Satellite observations provide an objective and quantitative approach to the measurement of land-cover change; a research is proposed in order to determine the land use change, the conversion from active agriculture to secondary forest (re growth), infer the patterns of land use by type in the long term considering the past and present trends, and propose an ideal map of sustainable land use according to the ecological and socioeconomic characteristics of the site, in a representative area of Peruvian tropical rainforests (Iquitos region, a 75km x75 km area located in the Amazon watershed at 3*43*46" South Latitude, 73*14*18" West Longitude) using JERS-1 images. The Japanese Earth Resources Satellite - 1 has been continuing to observe and collect data since 1992 with a mission data recorder by the high performance Synthetic Aperture Radar (SAR) and Optical Sensor (OPS); TNT mips will be used in order to process the images, a processing system for geo spatial analysis with fully integrated GIS, CAD, TIN, desktop cartography and geo spatial database management.

A forest inventory and information system for forest operations and planning

David H. McNabb
Forest Resources Alberta Research Council, Bag 4000, Alberta T9C 1T4 Vegreville, Canada
Tel: (780) 632-8264, FAX: (780) 632-8379, Email: dhmcnabb@aec.arc.ab.ca

The measurement, classification, and interpretation of forest resourcesfor a multitude of forest values is constrained by single purpose databases of often poor quality. Contemporary data bases must allow spatial and temporal manipulation to meet the dynamic planning and operational needs of forestry. The Alberta Research Council in partnership with private industry has developed and tested an integrated hardware andsoftware system that automatically links digital image data with elevation that has many uses in forestry. The initial product of this system is the automated production of ortho-rectified images and photo mosaics. Other software has been developed that analyses these primary data to give tree location, crown diameter, height, and species, which are combined to produce forest inventories. New software to automate the mapping of landforms and combining landform and other forest attributes into a system to automatically map soils is also under development. These data are also being used to automate the polygonization of the stand boundaries, soils, and ecosites with expert systems and user defined attributes. The combined applications he combined applications are an integrated inventory and information system that will have multiple values in developing forest management plans and implementing operations.

Multiple Criteria Analysis and Geographic Information Systems for Assessing Criteria and Indicators in Sustainable Forest Management

Guillermo A. Mendoza, Ravi Prabhu
University of Illinois, Department of Natural Resource and Environmental Sciences, Urbana, USA
Tel: (217-333-9347), FAX: (217)-244-3219), Email: gamendoz@uiuc.edu

Keywords: Criteria and indicators, multi-criteria analysis, geographic information systems

This paper describes applications of Multiple Criteria Analysis (MCA) in assessing criteria and indicators (C&I) in evaluating sustainable forest management. The MCA methods include: ranking, rating and pairwise comparisons or Analytic Hierarchy Process. These methods were used in a participatory decision making environment under two evaluation approaches; a top-down approach and a bottom-up approach. The former involves a team of interdisciplinary experts from different disciplines such as social forestry, resource economics, ecology, forest management, silviculture, and forest policy and administration. The latter involves a local team representing various stakeholders, interest groups, and other community people affecting, and affected by, the management of the forest. The top-down approach essentially consists of selecting relevant sets of C&I from a generic set such as those proposed by the Forestry Stewardship Council (FSC) and the Center for International Forestry Research (CIFOR). The bottom-up approach involves both the generation of sets of C&I and their final selection at the field level by local forest communities and other stakeholders. Both approaches are structured and organized in a participatory decision making environment.

In addition to describing the procedural details of the two approaches above, the paper also describes the concepts and the underlying theory behind the MCA methodologies. Computational details and other concepts related to consistency of group decisions, priority rankings, and the estimation of relative weights or degrees of importance of each C&I as estimated by the MCA methods are discussed. The steps involved in the application of the MCA methods in assessing C&I on a Forest

Management Unit (FMU) are also described. The evaluation process detailing how the Teams provide their expert opinions on each C&I along with their judgment on the suitability and applicability of each C&I to a FMU is also described. Ultimately, the estimation of a performance index of the FMU based on the ranked or prioritized list of C&I is also described.

A forest concession located in central Kalimantan, Indonesia is used as the FMU for the case study. Results from the study show that the multicriteria methods are effective tools that can be used as structured decision aids to evaluate, prioritize and select sets of C&I for a FMU. Feedbacks received from the two Teams and other participants indicate that the methods are transparent easy to implement, and provide a convenient environment for participatory planning and decision making especially for a complex problem such as the assessment of sustainable forest management.

Finally, the paper also describes an integrated modeling framework for assessing forest sustainability using the biodiversity conservation criterion. The framework essentially involves two general methodologies -- Geographic Information Systems (GIS), and MCA. in assessing overall sustainability using the biodiversity-based C&I elements, the Analytic Hierarchy Process (AHP) is used to determine the relative importance of each C&I. Besides measuring the relative importance of each C&I, their impacts (i.e., degree of negative and positive impacts) are also calculated using a method based on fuzzy set theory. Ultimately, the integrated MCA and GIS-based model allows the estimation of area-specific sustainability index values. Hence, sustainability can be measured particular tracts of land, which can also be geographically identified on the ground (i.e. site-specific). An illustrative example based on an actual forest in Indonesia is described to demonstrate the applicability of the model.

Mapping of 'Green' Cover in Putrajaya New Township Using Landsat Tm

Aswati Surep
Forest Research Institute Malaysia (FRIM), Regional Centre for Forest Management, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6377633, FAX: 603-6377233, Email: aswati@psph.frim.gov.my

The need to manage the resource in a more sustainable way and the changing demands of society on its forest are confronting the modern forester. Rapid population growth and development activities has caused high growth of urban environmental quality and traffic disturbances. The objective of this study is to assess the usefulness of Landsat TM data in "green" cover mapping of a new township Putrajaya. A Landsat TM image of 126/58 (path/row) in Computer Compatible Tape (CCT) form, taken on June, 1996, with less than 5% cloud, was acquired for image processing and analysis. Results indicated that band of 4-5-3 False Colour Composite (FCC) was the best combination for the purpose of the study since it can clearly differentiate the "green" cover. A supervised classification of the image result in 12 classes of "green" cover categories. A total of four classes were allocated as potential sites for the development of a forest landscape map. The overall accuracy obtained for this study was 70%. Urban forestry landscaping and planning has great potential in Putrajaya because the area is still mostly surrounded by a "green" cover.

4.04.02 /4.13.00 Sustainable forest management under conditions of growing global pressures

Possible unfair competition from international taxation differences: examples from Scandinavian and other selected countries

Finn G. Andersen
Norwegian Agricultural Economics Research Institute, Postboks 8024 DEP, 0030 Oslo, Norway
Tel: + 47-22-36 72 33, FAX: +47-22 36 72 99, Email: finn.andersen@nilf.nlh.no

Keywords: Taxation, Forestry, Scandinavia

This paper will deal with taxation of forestry, both in principle and with description of the actual tax scheme in some selected countries. Forestry taxation is of course part of the general tax regime in each country, but in this paper the emphasis is attached to possible special taxation conditions to forestry.

The main purpose of a national taxation scheme is to confiscate capital from the citizens for public use. in addition to this main purpose, there can be many other purposes the politicians also want to stimulate for instance development of forestry.

In forestry it is most common that income assesses directly to the annual result. Both in Sweden and Norway there are different possibilities to distribute the annual result for a couple of year. The mean reasons to insert these rules is to cut the top of the result in years with special high cutting and with that a high income. Some years ago the marginal tax rates were extreme high in the Scandinavian countries and therefor the permission to distribute the result for several years was of big importance.

To day the marginal tax rates are lower so the distribute rules are of less importance than earlier.

Another way to assess the yield of forest is to use sustainable yield, annual increment or area of productive forestland as base for taxation. The taxable amount is for example total annual increment or total productive forestland multiplies with a standard value. in Norway the annual increment was the base for income taxation till 1954 as the productive forestland was it in Finland down to 1993. Finland has now changed over to assess the annual result but with a voluntary changeover period till year 2006. The tax system Finland now leaves has given tax advantage to active forest owners and tax intensification for more passive owners.

Directly taxation of the annual result stimulates to save capital in standing timber and forest regeneration, and can in this way be an obstacle to increase the cutting volume. The increase of capital in the forest will not be taxable before the timber is sold.

In some countries as United Kingdom and the Netherlands, forest incomes from woodlands are taken completely out of the scope of income tax. This tax exemption applies to sales of both felled and growing timber, but other incomes as shooting rights are taxable. On the other hand there are no deduction for operating expenses etc. The reasons for the income tax exemption are both to get more standing timber and the multifunctional use of land.

In a lot of countries they are in the beginning to try to use subsidies and tax structure to support environmental quality and sustainable economic development in the forestry.

In many countries they use a lower VAT rate than the standard rate for sale of timber and other forest products. Some of the EC countries also made use of a special system with flat rate for farmers. The flat rate scheme should be a neutral system, but as a matter of fact in some countries the system uses to subsidise the farmers.

International Interdependencies of the Forest Accounting System and Their Effects on Business Management

James N Hogg, Hans A Jöbstl
Jaakko Pöyry Consulting (UK) Ltd, Century House, Station Way, SM3 8SW Cheam, Surrey, United Kingdom
Tel: +44 181 770 2144, FAX: +44 181 770 2115, Email: james.hogg@poyry.co.uk

Forest business accounting has long proven its positive contribution to management of forest enterprises. Accounting supports the management in monitoring the success of fulfilling the business strategy be it continuation of the business or shareholder value creation. Due to the high proportion of small-scale holdings only a small part of forest management units utilise accounting to support decision-making and information. The variety of business accounting systems around the world is also reflected in the accounting of forest enterprises. While most rules and regulations of standard business accounting can be applied in forest enterprises, some particularities of forestry have posed problems for both foresters and accountants: The nature of the forest asset as appreciating, self-regenerating asset and the long time horizons involved in forestry can be considered as the two most important specific problems.

The valuation of the forest assets and treatment of growing stock changes through growth, management and removals and the reflection of these values in accounts has not only engaged the minds of leading forest economists since the last century, but is also facing forest enterprises and corporations around the world. While the treatment in internal operating accounts is up to the information requirements of the enterprise and therefore developed individually to the demands of management, the financial reporting legislation determines the reflection of forest assets in external accounts.

Globally a number of methods has been developed to capture forest values and their change in accounting, but a both accurate and feasible method remains elusive.

The different methods contrasted using examples from Europe, North America, Asia and Oceania show the interdependencies of forestry accounting practices with cultural traditions, forestry practices, legislation, economic theory, etc. Differences as paramount as the distinctions between Central European small-scale forestry, Tropical concession forestry or large-scale plantation forestry in Oceania also exist in the different methods of accounting for the growing stock and its changes.

While international accounting harmonisation aims at improved comparability and the emergence of multinational forest industries results in increased attention from the accounting profession, the task of finding more accurate and workable methods will remain a challenge for the next millennium.

The Evolution of Forest Regimes in India and China (A Comparative Analysis)

Shashi Kant
University of Toronto, Faculty of Forestry, Toronto, Canada

Neo-classical framework based on profit maximization leading to a single equilibrium is not sufficient to understand the dynamics of forest regimes. in the world of imperfect markets, transaction costs, and uncertainties, the observable regularities are not a solution to a static problem, but are outcomes that understandable dynamic processes have produced from known and plausibly conditions in the past. These dynamic processes can be understood in the framework of evolutionary economics which has the elements of increasing returns, path dependence, multiple equilibria, institutional hysteresis, and adaptive efficiency. The dynamics of forest regimes in India and China is analyzed in this framework. in India, forest regimes have completed a full cycle from the community regime in the pre-British period through state regimes during the colonial period and the first post-independence phase, and finally back to community-based regimes in the 1990s. in China, forest regimes have also completed a full cycle but starting from private ownership in the hands of landlords and bureaucrats prior to 1950's and reverting back to private regime in the form of household responsibility system in 1980's. in India, during the colonial period, change in forest regimes has been discontinuous but path-dependent in a geographical sense which reflected organizational inertia of colonial structure developed in other countries. in the first phase of post-independence period, many self-reinforcing mechanisms such as increasing returns organizational and institutional inertia, and adaptive expectations contributed to temporal path dependence. in the second phase, forest regimes have moved closer to adaptive efficiency. in China, in late fifties and early sixties, the transition from private regime to commune system was discontinuous, and was a result of organizational energy similar to change in forest regimes in India during colonial period. However, continuation of commune system demonstrated the prevalence of different elements of path dependence.

The latest reforms, in both countries, can be characterized by search for equity-consistent economic efficiency, devolution of the decision making to local communities, and adaptive efficiency. Multiple equilbria are another common feature in both countries. These common elements and their impacts on sustainable forest management elements from two Asian giants with different governance structures can be used for designing forest regimes for sustainable forest management in developing economies.

Operations research, economic planning and decision models: how can international co-operation help administration and decision making in forest enterprises

Jean-Luc Peyron
ENGREF/INRA, 14, rue Girardet, CS 4216, F-54042 Nancy, France
Tel: 00 33 (0)3 83 39 68 31, FAX: 00 33 (0)3 83 32 73 81, Email: peyron@Engref.Fr

As in most of the research fields, international co-operation is essential to improve the grounding in decision making relative to forest enterprises. The general reasons underlying this statement are probably the same in each part of sciences and refer to the similarities between questions raised in different countries, to the complexity of the real world in comparison with available analysis methods and models, to the weakness of means allocated to research beside the hugeness of the task, and to the continuous change of social demand that requires to solve permanently new problems. Obviously, after they are brought back to the administration and management of forest enterprises, these items are worth being commented.

Forest management has been developed at the international level for about three centuries. France, Germany and Austria have played a major role at the beginning. Methods elaborated in these countries have then been exported to the rest of the world where they have been adapted to other situations and supplemented with new tools, exported in their turn and so on. Thus international co-operation is an historical fact. Today, there is still a more favourable context because common international issues have been highlighted, such as habitat conservation programmes, carbon sink issues, criteria and indicators for sustainable forest management, ecocertification and labelling, environmental accounting.

Decision making is a complex subject that uses advanced developments in operations research, economic theory, statistics and even computer science. According to this complexity, any co-operation is essential to progress, not only interdisciplinary one but also international one. This is all the more true that many new methods are nowadays available, that some fundamental economic concepts are not yet quite clear (*e.g.* discount rate value), that risk and uncertainty are involved in the processes under study, that environmental considerations have to be integrated with economic ones, that biological bases become more and more important in economic models.

It must be recognised that ecology, on the one hand, and forest products, on the other hand, concentrate most of attentions on them. Conversely, only a few researchers work on forest economics in each country. in such a context, international co-operation gives the opportunity to gather complementary approaches on the same subject, to create synergies between researchers, to broader the scope under consideration, to generalise existing methods and, in a dynamic perspective, to increase the chance, when a new problem occurs somewhere, to find first features in another country.

Keywords: decision making, quantitative methods, economic planning, international co-operation, forest management.

Sustainable Forest Management Under Conditions of Growing Global Pressure - Challenges for Forest Enterprises from International Agreements to Market Pressures

Roger A. Sedjo
Resources for the Future, 1616 P Street NW, Washington, D.C., USA
Tel: (202) 328 5065, FAX: (202) 939 3460, Email: sedjo@rff.org

This paper briefly describes some of the recent changes designed to promote sustainable forest management globally. These changes can have important implications for the types of products that reach markets, the cost and availability of various wood products and, importantly, on the comparative competitive position of various regions and countries. The discussion examines these implications with particular focus on the comparative advantage and the comparitive position of various countries for forest products trade. The role of forest certification and ecolabeling is also discussed. The paper argues that the regions advantaged and disadvantaged are importantly related to the "rules of the game" as reflected in the various standards applied for sustainability.

Pricing Carbon Retention by means of Reduced Impact Logging: a Case Study from East Malaysia

John Tay, J.R. Healey and Colin Price
School of Agricultural and Forest Sciences, University of Wales, Bangor, Gwynedd LL57 2UW, UK
Tel: +44-1248-382454 / 382281 / 351098, Fax: +44-1248-354997, E-mail: c.price@bangor.ac.uk

Reduced impact logging in tropical countries enhances the local sustainability of forest management. It also significantly reduces the amount of carbon volatilised during and after logging. For this reason, it may attract finance globally as a means of achieving carbon offsets. A model of forest regrowth and of necromass dynamics allows long-term estimation of the impact of different logging systems on both crop regeneration and on carbon fluxes. Overall, reduced impact logging had the expected advantages over conventional logging. However, there were several kinds of additional financial outlays. Moreover, the reduced volume yield from reduced impact logging means that either a large opportunity cost is incurred; or, to achieve a given level of production, a greater area must be exploited. This spillover effect can be incorporated in cost–benefit analyses. These show that, according to the assumptions made about the appropriate level of analysis and the discount rate adopted, the cost of retaining carbon by reduced impact logging may be much greater, or much less than carbon prices which have been derived in other ways.

5.01.00 Wood quality

The control of cambium activity and wood formation in forest trees

Roni Aloni
Tel Aviv University, Department of Plant Sciences, 69978 Tel Aviv, Israel
FAX: 972-3-6409380, Email: alonir@post.tau.ac.il

The problems to be dealt with concern the biological control of wood production in forest trees and solutions for improving wood quality and productivity by hormonal modifications. As the vascular tissues are complex, being comprised of several types of cells, they are induced by a number of developmental signals which flow in the axial and radial directions. The hormonal signals control the type of differentiating cells, their wall structure and chemical composition. Therefore, understanding the nature and biology of the signals is needed for improving tree quality and productivity by genetic modifications. Studies on transgenic plants with altered levels of hormones confirm this general strategy for improving wood production and quality. The major signals that control cambial activity and xylogenesis are the following four hormones: auxin, cytokinin gibberellin and ethylene. (1) Auxin is the primary controlling signal involved in all aspects of vascular differentiation. The continuity of the vascular tissues along the plant axis is a result of the steady polar flow of auxin from leaves to roots. Low level streams of auxin induce phloem in strands and phloem anastomoses between the strands, while higher auxin levels induce xylem. Auxin which moves preferably through the cambium controls together with gibberellin, the activity of the cambium. Auxin also controls the gradual increase in vessel size from leaves to roots. During evolution, increased sensitivity of the cambium to auxin occurred in limiting environments resulting in the development of the specialized ring-porous wood that maximized the efficiency of water conduction. The wide earlywood vessels in ring-porous trees are induced by low-level streams of auxin at early stages of bud development. (2) Cytokinin from the roots increases cambium sensitivity to shoot signals and promotes vascular differentiation along the tree axis. (3) Gibberellin which promotes tracheid elongation, has become during evolution a specific signal for fiber differentiation. From the original mechanism for tracheid differentiation in conifers, a combination of auxin and gibberellin, the signals for each xylem element in angiosperms became specific: auxin by itself induces vessel elements whereas gibberellin, in the presence of auxin, induces fibers. Auxin and gibberellin are the factors that control the structure of lignin in the cell walls. (4) Ethylene produced in the xylem seems to be a major signal in controlling the initiation, size and spacing of rays. Ethylene also reduces vessel width, promotes tracheid differentiation in the radial direction and is involved in reaction wood formation.

Wood Quality Challenges and Prospects for the New Millenium

David J. Cown, Phil Wilcox
New Zealand Forest Research Institute, PO Box 3020, Rotorua, New Zealand
Tel: +64 7347 5525, FAX: +64 7347 507, Email: cownd@fri.cri.nz

As the world's natural forest continue to decrease in area and production, the role of plantations will inevitably become more important. They will serve to increasingly supply the wood products needs of expanding populations and simultaneously reduce the need for the harvest of natural forests. The wood characteristics of plantation-grown material cannot be assumed to be the similar to the same species from natural forests: factors which can strongly influence physical properties and performance include:

The potential for plantation-grown wood to supplant natural forests is great because there are greater options for

- species selection
- site and climate
- silvicultural regime
- genotype selection

A large body of research results already exists comparing the wood properties of plantation and natural forests. in some species (eg pines) which exhibit strong juvenile wood characteristics, it is common to observe a decrease in average quality when expressed in terms of properties such as wood density, fibre length, spiral grain. This is mainly because artificial forests are encouraged to growth rapidly and are harvested at relatively young ages, resulting in a significantly higher proportion of juvenile wood. To counteract these, often negative, effects, silvicultural management enables some operations such initial spacing, thinning and pruning and manipulation of felling age to improve general log quality and uniformity (size, shape, branching).

Characteristically, the effects of features such as hidden internal defects, (decay, compression wood) are less in managed plantations.

In some parts of the world, plantations have become the dominant form of commercial forestry during the past 50 to 100 years, and many lessons have been learned along the way. The importance of matching species (and provenances) to available sites is now accepted. There are many examples of outright failures with species which have specific requirements. A broad trend is apparent:

1. Species trials and selection of "winners"

2. Development of management schedules to maximise growth rates

3. Commencement of tree improvement programs focused on volume production

4. Selection and propagation of genotypes yielding desirable wood characteristics

Wood products manufacturers and end-users are increasingly seeking uniformity in wood properties and predicability in performance attributes. We are about to enter an era in which the power of molecular breeding technology will be challenged to extend both the range and uniformity of available wood properties from plantations. Clonal forestry offers some exciting possibilities.

Mechanical Properties of *Acacia mangium* planted in Sarawak, Malaysia

Alik Duju, Takashi Nakai
TRTTC, Forest Department, Sarawak, Km10 Old Airport Road, 93660 Kuching, Malaysia
Tel: +60-82-612211, FAX: +60-82-612490, Email: nakaisan@ffpri.affrc.go.jp

Ten trees of 13-year old *Acacia mangium* were sampled and fifty-four small clear specimens were tested. The British Standard (BS 373.1957) method on testing small clear specimens of timber was adopted to obtain the strength properties of the species. It was found that the mean values of modulus of rupture, modulus of elasticity and compressive strength tested at green condition were 86.4 MPa, 10.9 GPa and 36.8 MPa respectively. The average moisture content was 114 % and their basic density was 0.51 g/cm^3. Based on their compressive strength, the timber was classified under Strength Group C by Burgess's grouping. It was revealed that the strength properties and basic density were higher at outer portion compared to the inner portion of the wood.

Keywords: *Acacia mangium* small clear specimens, strength properties and basic density

Density and Sapwood Variation of Malaysian-Grown Teak

S. C. Lim
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, FAX: +603-6367753, Email: limsc@frim.gv.my

Five trees each of plantation-grown teak in Malaysia ages 8 and 28 years were studied. Discs of 50mm in thickness were cut at 10%, 30%, 50%, 70% and 90% heights of the clear bole. The sapwood thickness was measured at four different positions of a disc and an average sapwood percentage was calculated. For the density determination, specimens were obtained from the same disc at two radial directions opposite each other with three samples at each radius. The volume of sapwood presence was fond to be quite substantial in both the 8 years and 28 years old teak. The results of the study also indicate that three was a slight decrease in the sapwood percentage with age. On the variation in density, it was found that the Malaysian-grown teak was comparable to teak found elsewhere. Age of the tree has also been found to have a significant effect on the density of the timber.

Physical and Anatomical Features of *Acacia mangium* planted in Sarawak, Malaysia

Andrew Tukau Salang, Tomoyuki Fujii
Timber Research and Technical Training Centre, Km. 10, Old Airport Road, 93660 Kuching, Sarawak, Malaysia
Tel: 082-612211 (O), FAX: 082-612490 (O), Email: trttc@po.jaring.my

The *Acacia mangium* is a major species planted in the reforestation sites throughout the State of Sarawak. To complement reforestation project, the economic utilisation of this species must be found in order to be sustainable. The utilisation potential depends on the properties of the timber. This study investigated and quantified the physical and anatomical features of 13-year old *Acacia mangium* planted in Compartment No. 8401 and 8402 in Sampadi Forest Reserve, Lundu, Kuching, Sarawak. in this study, 12 timber sample discs were collected at DBH and specimens were made from two strips crossing one another through the pith at 90°. The physical features that are important to the utilisation aspect of the timber are the thickness of sapwood, colour and density.

The anatomical features that have the greatest influence on wood properties and secondary processing are the vessels parameters (such as vessel grouping and arrangement, diameter, content,

frequency and vessel element length), and fibre parameters (such as length, diameter and fibre wall thickness).

The average thickness of the sapwood is 11 mm, whitish in colour and the heartwood is slightly pale brownish to purplish brown on prolonged exposure. Average oven-dried density of 469 kg/m^3, substantial variation amongst trees from 419 to 584 kg/m^3, higher variation within a tree of 340 kg/m^3 at the pith and 585 kg/ m^3 at the sapwood, and density increases towards the sapwood. Mostly solitary vessels, multiple vessels common especially multiple of 2; average diameter of 200 µm*, progressively increases towards the sapwood; 4 vessels/mm^2*; evenly distributed. Average vessel element length of 332 µm that also increases towards the sapwood. The average fibre length is 1,073 æm that also increases towards the sapwood. Fibre length variation is higher from the pith up to 80 mm radially and variation decreases to constant length towards the sapwood. Preliminary findings showed that fibre diameter and fibre wall thickness do not showed significant increases from the pith to sapwood. Preliminary results as some measurements and counting are still not completed and this data will be amended in the paper later.

Effect of environmental factors on the fibre properties of Norway spruce (*Picea abies* [L.] Karst.)

Pekka Saranpää, H. Mäkinen
Metla - The Finnish Forest Research Institut, PO Box 18, FIN-01301 VANTAA, Finland
Email: pekka.saranpaa@metla.fi

Wood quality is an important basis for forest industry. While the external features of the trees, *e.g.* branchiness, straightness of the stem, have received attention from tree breeders, the physical and chemical properties of wood have been less studied, except for specific gravity. Until now the pulp and paper industry has examined the physical properties of the fibres and the chemical composition of wood mainly after processing, but the biological aspects related to wood formation have not been studied. However, variation *e.g.* in the fibre length and cell wall thickness, or the chemical composition of the wood have influence both on the quality and quantity of the end products. The variation of fibre properties in pulp could be due partly to the processing methods to methods of forest management, seasonal and environmental factors, and to the genetic characteristics of the trees. The main cause for the variation of fibre properties within-tree is the maturation of the cambium (cyclophysis, topophysis).

We have studied the changes in tracheid length, cell form, lumen diameter and cell wall thickness from the pith to the bark and at various heights in the stems of Norway spruce with image analysis using thin sections cut by a cryo-microtome. A fast and convenient method is described to analyse the dimensions of tracheids from a thin section. The analysis is based on 2-dimensional fast Fourier transformations. Data created by the model will be compared with the original data. Cell wall thickness will be analysed accurately with the method.

The effect of fertilization on wood structure of Norway spruce is also investigated. Trees (34-years-old) have been fertilized and irrigated the last 10 years. The structure of the annual rings is compared with samples from control trees without fertilization. in this way we could study how mature wood structure is affected by increasing diameter and height growth. According to the preliminary data, cell length decreases slightly with increasing diameter growth but tracheid diameter remains unaffected. Tracheid diameter is correlated more strongly with distance from the pith than with ring number from the pith.

Pulping, Bleaching and Papermaking Characteristics of Some Native Sumatran Hardwoods

Yu-Chang Su, I-Chen Wang
Taiwan Forestry Research Institute, China-Taipeh
Email: ycsu@serv.tfri.gov.tw

Thirty-seven native species of Sumatran hardwoods were collected and analyzed for their chemical compositions. Subsquent to kraft pulping, bleaching and handaheet making, their pulping characteristics were elucidated. Lignin content of the woods ranged from 37.6 to 20.2%, averaging 29.6%; holocellulose contents were 76.7 to 55.7%, averaging 68.6%; Alcohol-benzene extractive contents ranged widely, from 1 to 18.1%. Pulp yields ranging from 34.7 to 51.7% of bone-dry wood at an equivalent kappa number of 20. Pulp yields tended to decrease slightly with increasing wood densities. Chemical charges also tended to increase with wood density; but digester efficiency was higher with higher density woods. in terms of pulpability, *Diospyros puntielosa* and *Poyena* sp. were the best, while *Alphonsea javigata* and *Palaquium gutta* were the worst. A standard regime of C-E-D-E-D bleaching sequence could give all the pulps brightness of 80% ISO or better. PC numbers of the bleached pulps were generally acceptable. Average breaking length, tear index, bursting index and compound strength index were 6.94 km, 11.6 mN·m^2 g^{-1}, 4.97 kpa ·m^2 g^{-1}, and 8.83, respepctively. Pulp from Artocarpus eluticus had the best strength index, while

Tetramerista celabra pulp showed the poorest strength index. Bleached pulps showed the same order of strength ranking for these two species.

Impact of precommercial thinning on tree and wood characteristics, Product quality and value in Balsam fir

Shougong Zhang, Y. Corneau, and G. Chauret
Chinese academy of forestry, Forintek Canada Corp, 319 rue Franquet, Sainte-Foy, G1P 4R4 Quebec, Canada
Tel: 86-10-62884229, FAX: (418)-659 2922, Email: tony.zhang@qc.forintek.ca

Based on a 47-year-old precommercial thinning trial, this study examined the response of various tree and wood characteristics, product quality and value in balsam fir to different thinning intensities. in 1995 (35-year after precommercial thinning), 150 merchantable trees were selected to cover all the merchantable diameter classes in the control, moderate and heavy thinning plots. Based on the sample trees, impact of precommercial thinning on a number of parameters was evaluated at the diameter class level. Parameters studied include tree diameter, tree height, tree volume, tree taper, live crown length and width, length of the log without live crown, branch diameter, bark thickness, wood density, heartwood content, moisture content, log volume recovery lumber volume recovery, lumber grade recovery, lumber dimension recovery, lumber value recovery, lumber strength and stiffness, chip volume and value recovery, chip and paper properties, and total value recovery. Furthermore, this study examined the 25- and 35-year response of selected parameters (e.g., basal area, tree diameter, merchantable volume, product value) at the stand level.

Based on the responses, optimal thinning intensities were recommended for specific objectives and for different industries. Other important questions (e.g., when to thin balsam fir stands, which stands should be thinned) were discussed.

Compared to trees of the same diameter class from control plots, the trees from thinned plots are generally characterized by a shorter tree height, a larger tree taper, a larger live crown width and branch diameter, a shorter length of the log without live crown, a lower tree volume and lumber volume recovery, and a lower total product value recovery per tree. Lumber from trees of the same diameter class in heavily thinned plots has a lower recovery for the best grade, and a lower MOE and MOR value, but moderate thinning has a relatively limited effect on lumber strength and stiffness. On the other hand, tree and wood characteristics, product quality and value vary remarkably with tree diameter.

This study shows that a thinning intensity of 3,500 trees/ha or less is required to achieve a significant gain in tree diameter. Furthermore, precommercial thinning of dense balsam fir stands also increases merchantable wood volume and product value at the stand level. Overall, this study suggests that precommercial thinning of very dense young balsam fir stands appears to be an effective and viable silvicultural treatment. It can reduce rotation age by up to 10 years. A reduced rotation age will also reduce the possible occurrence of rot and decay in balsam fir stands. Furthermore, a larger tree diameter in thinned stands will reduce harvesting and manufacturing costs, and produce larger dimension products. Since the difference in stand value between thinning intensities of 1,000 to 3,500 trees/ha is relatively limited, an appropriate thinning intensity to be taken for balsam fir, to a large extent, depends on what the industry really wants to achieve. For the lumber industry, a thinning intensity of 2,500-3,000 trees/ha is required to maximize the stand (product) value and to produce quality products. For lumber producers whose major objectives are to maximize diameter growth and to minimize rotation age, a heavier thinning intensity of 1,000-2,000 trees/ha could be considered, but in this case product quality may decrease significantly. For both pulp/paper industry and panel industry, a thinning intensity of 2,500-3,000 trees/ha appears to be optimal.

Occurrence of Pith Flecks in Tropical Timbers of Malaysia

Ani Sulaiman
FRIM - Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, FAX: +6036367753, Email: anis@frim.gov.my

Pith flecks are abnormal parenchymatous tissues embedded in the wood as irregular strands and on longitudinal surface appearing as a streak. Th affected tissues showed large parenchyma cells with random orientation. Pith flecks were formed as a result of traumatic conditions during tree growth, which injure the cambium locally. Such xylem formation may be caused by many factors such as mechanical wounding, harsh environmental conditions (drought, wind or low temperatures), microbial infections or insect attacks. The abnormal xylem may vary in structure according to the cause and tree species involved. Callus may be formed by the proliferation of parenchyma cells adjacent to the cambial injury and eventually restored the orderly divisions of cambial cells.

Normal cells on all sides enclose the callus or pith flecks. The size of the callus pocket presumably corresponds to the extect of the injury. Malaysian timbers showing the presence of pith flecks are those from the family Aceraceae, Alangiaceae, anacadiaceae, Anonaceae, Apocynaceae, Aquifoliaceae, Bombacaceae, Burseaceae, Combretaceae, Casuarinaceae, Celasstraceae, Polygalaceae, Rosaceae, Sapindaceae, Sapotaceae, Sterculiaceae, Theaceae and Thymetlaceae.

Analysis and classification of acoustic emission waveform

Shih-Hao Lee
Chi-Yi Institue of Technology, The Department of Forest Products Industry, 600 University Road, 600 Chi-Yi, Taiwan, R.O.C.
Tel: 886 5 2717510, FAX: 886 5 2717497, Email: Shlee@rice.cit.edu.tw

Keywords: Fracture; Acoustic emission; Signal processing; Cluster analysis; Classification

Detection of AE (acoustic emission) from failure of wood is becoming more important as wooden frame houses grow rapidly in Taiwan. AE is released energy from micro or macro fracture of material. To classify the relationship between wood fracture and AE, AE signals were recorded during the bending test of red oak and their features of AE were extracted and analyzed. The event rate feature might be excellent indicator of loading phase. Features in time and frequency were selected for classification. Cluster analysis showed that AE signals could be successfully classified. Each class might be associated with individual fracture source from fiber breakage, debundling, debonding and matrix cracking.

Predicting the strength of sawn products based on X-ray scanning of logs

Johan Oja, Stig Grundberg, Anders Grönlund
Lulea University of Technology, Skelleftea Campus, SKERIA 3, S-931 87 Skelleftea, Sweden
Tel: +46 910 585373, FAX: +46 910 585399, Email: Johan.Oja@tt.luth.se

The successful running of a sawmill is dependent on its ability to achieve the highest possible value recovery from the saw logs. Today many sawmills are increasing the amount of customer adapted products. One such trend is that strength graded lumber is becoming more common. When sawing lumber for strength grading in special dimensions it is very important to select the right logs, i.e. the sawmill must be able to predict the strength of the sawn products before the actual sawing operation.

The strength of the sawn products is correlated to density and knottiness. in order to be able to measure internal properties of saw logs an industrial X-ray LogScanner has been developed. Simulations have shown that this scanner can measure variables that would be possible to use for prediction of the strength of the sawn products, *e.g.* knot volume and green density. Hence, the aim of the study was to investigate the possibility of predicting the strength of centerboards from Norway spruce (*Picea abies* (L.) Karst.) saw logs, based on simulated X-ray LogScanner measurements.

The study was based on eight logs. Two fast grown and two slow grown logs from northern Sweden and two fast grown and two slow grown logs from southern Sweden. After CT-scanning, four centerboards were sawn from each log and the modulus of elasticity and the bending strength of the boards were measured. The CT-images were used for simulations of the industrial X-ray LogScanner resulting in simulated measurements of knot volume and the green density of heart and sapwood. Finally multivariate models were calibrated using PLS-regression. These models predict the bending strength and modulus of elasticity based on the variables measured by the X-ray LogScanner. Both bending strength and modulus of elasticity were defined as the mean value of the four boards from each log.

The results were very promising with strong models for prediction of both bending strength (R2=0.73) and modulus of elasticity (R2=0.77). The results also showed that the measured variation of knot volume between different parts of the log explains some of the difference in strength between different centerboards from the same log (R2=0.41).

The study is based on a very small material with a number of special properties. The fact that the logs are of approximately the same dimension and that all logs have relatively large amount of heartwood probably makes the predictions better compared to a larger and less homogenous material On the other hand the large logs have other properties, *e.g.* large pith shakes and four boards from each log, that make it more difficult to predict the strength of the boards.

White Spruce behavior during compression perpendicular to grain

Taghi Tabarsa, Y.H. Chui
University of New Brunswick, Faculty of Forestry & Environmental Management, E3B 6 C2 Fredericton, NB, Canada
Tel: (506) 453 - 4501, FAX: (506) 453 - 3538, Email: y702@unb.ca

The intention of this study was to provide an advanced understanding of wood behaviour during transverse compression at ambient and elevated temperatures. in addition the feasibility of a mechanical based model for predicting wood behaviour in transverse compression based on cell geometry and cell wall properties was examined. A new test procedure and apparatus were developed.

This study was carried in two phases: in phase one, specimens of white spruce were subjected to compression tests under microscope at room temperature at three levels of magnifications (low, medium, and high). Wood behaviour at different levels such as: gross behaviour (specimen possessing several annual rings), one annual ring, early-wood, late-wood, cell wall deformation, and mechanism of failure (collapse) was characterized. in addition load-deformation data was collected during compression tests under microscope at low and medium magnification. Geometry of all cells located in one annual ring subjected to compression test was measured. Cell wall properties (modulus of elasticity and yield point) was determined based on transverse compression test results and average cell geometry of same annual rings. The validity of findings of this study was approved during verification tests. The second phase of this study is in process, during this phase the effect of temperature on cell wall properties will be investigated. The results of this study will provide valuable benefits for modelling applications.

Effect of Open-Shed Environment on the Edgewise Bending Properties of Laminated Veneer Lumber

R. C. Tang, J. H. Pu, J. N. Lee
Auburn University, School of Forestry, USA
FAX: +334-844-4221, Email: tang@forestry.auburn.edu

In recent years, Laminated veneer lumber (LVL) members have been popularly used in the light- and medium-frame of building constructions as headers, joists or flanges in I-beams because of its high strength and uniform stiffness and they can be fabricated in unlimited lengths and/or sizes. At present, most experimental works concerning the structural performance of LVL are conducted under constant relative humidity (RH) and/or temperature. However, LVL is a layered structural wood composite made of veneers which are biological materials and hygrothermal-elastic in nature. Obviously the large fluctuation of RH and temperature in our living environment will have some weakening effect on LVL's structural performance but such information is very limited.

Thus, experiment of long-term exposure of LVL in open-shed environment will provide useful information for wood composite industries to improve LVL's manufacturing design as well as for Timber Engineers to better design structures that are using LVLs as components.

In this study, the effects of open-shed environment on the edgewise bending properties of LVL were investigated. Three types of 13-ply LVL were fabricated with southern pine veneers of B, C, and D grades and liquid phenolic formaldehyde and their layups were: LV L^{-1}: all B grade veneer; LVL-2: two plies of B grade veneer on both faces and all C grade veneer in the core plies; and LVL-3: all D grade veneer. The dimension of specimens was 3.8 cm (thick) x 8.9 cm (deep) x 244 cm (long). Twenty five randomly selected specimens in each LVL type were edgewise bending tested after being exposed under the open-shed environments for one and two years.

Air temperature, as hot as 37.8 C (100 F) and as cold as -9.4 C (15 F), under the open-shed roof was recorded. The highest temperature recorded on the inner surface of open-shed roof was 52.2 C (126 F) while average values of 43.9 C (111 F) and 37.2 C (99 F) were recorded respectively on the top and bottom specimens in the LVL pile when the air temperature was 37.8 C (100 F). During a year, many high RH (90-98%) days were observed while lowest RH recorded was 23%. Testing results from previous studies indicated that structural performance of southern pine LVL was affected by the veneer grade and MOR values: 77.44 MPa, 72.30 MPa and 51.13 MPa and MOEs: 14.64 GPa, 14.25 GPa and 11.56 GPa, for groups of LVL-1, LVL-2 and LVL-3, respectively, evaluated under constant 65% RH and 23.9 (75 F) were used as controls for comparison in this study. After 1-year open-shed exposure, 8.9%, 13.0% and 4.9% reduction in MORs were observed respectively in LVL-1, LVL-2 and LVL-3 and further reductions, 11.4%, 13.7% and 15.3% were recorded in the specimens subjected to 2-year open-shed exposure. The reduction of MOEs for these LVLs after 1-year open-shed exposure was insignificant, and however, 6.6%, 16.8% and 13.1% reductions were observed in the members after subjected to 2-year exposure.

Thus, tests of longer open-shed exposure of LVLs may be needed for the development of models for accurately predicting the degradation rate of MOE and MOR due to the long-term open-shed environmental exposure.

5.03.00 Protection of Wood from decay and fire

The Effect of Borate Preservatives on Preventing Decay of some Wood Species Used in Egypt

Hussein Ibrahim Mahmoud Aly, I.E.A. Kherallah, M. Abou El-Seoud and A.S.O. Mohareb
Alexandria University, Forestry and Wood Technology Dept., Alexandria, Egypt
FAX: 00203-5446914, Email: hussein@safwa.com.eg

This investigation was carried out to study the effect of boric acid and borax against wood decay fungi. It also aimed to study the penetration and retention of borate in selected woods. The fungus species, which showed serious affect on poplar wood, were *Schizophyllum commune* Fr. and *Trichoderma viride* (Fr.) Pers. The EC50 values were varied according to preservatives and fungi types. Wide effect of boron compounds against the two species of fungi was detected.

The results indicated that the ability of boron penetration in selected wood species was significantly increased by increasing the wood moisture content. The mean values of penetration in poplar wood were 5.95 mm and 15.32 mm at 12% and 80% MC, respectively. On the other hand, boron retention in seasoned poplar wood was higher than that of the poplar wood of 80% MC in outer layers.

Also, there were significant differences between the retention of boron in *Casuarina glauca* at 12% and 40% MC. This study is considered the first investigation in the wood preservatives field of imported wood species in Egypt.

Keywords: boric acid, borax, penetration, retention, *Casuarina glauca* .

Leaching Characteristics of Water Borne Preservatives According to Tree Species

Ayben Kilic, Hasan Vurdu, Hikmet Yazici
Zonguldak Karaelmas University, Faculty of Forestry, 74100 Bartin, Turkey
FAX: +90.0378.2277421, Email: Mehmet Sabaz [peyzaj74@turnet.net.tr]

In this study, leaching degrees of four different tree species impregnated with Tanalith C-S a waterborne preservative were determined.

Scotch pine, Fir, Beech and Chestnut were impregnated by 3 % Tanalith C-S. Wood samples were prepared in three different dimensions as 50*x*25*x*15, 30*x*20*x*10 and 10*x*10*x*10 mm. Using thirteen different methods leaching degrees of wood samples were determined.

Results showed that, among four tree species the highest leaching was found in Scotch pine. Leaching was found to decrease in the order of Fir, Chestnut and Beech respectively. When comparing the effect of dimension, it was found that there is a linear relation between leaching and sample dimensions. The eluted preservative increased by the increase of sample dimension. Highest leaching occurred in 50*x*25*x*15 mm.

Application of Electron Microscopy in Wood Protection Research

Adya P. Singh, B.S. Dawson and A.H.H. Wong
New Zealand Forest Research Institute Limited, Private Bag 3020, Rotorua, New Zealand
Tel: +67-7-347-5889, FAX: +64-7-347-9380, Email: singha@fri.cri.nz

Keywords Electron microscopy, Wood biodegradation, Wood protection, Preservative penetration, Coating penetration

For decades electron microscopy has played a crucial role in understanding the process of wood formation and has helped unravel those factors and processes affecting the utilization of wood. A notable example of the extensive application of Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM) in wood processing is in the field of wood protection research, in particular, wood preservation. Extending the service life of wood requires effective protection of wood from the factors which adversely affect its performance. The methods of protection with wood preservatives and other wood protecting chemicals (including coating materials) vary depending upon the environmental conditions to which wood is exposed. Optimization of the performance of these wood protectants depends on detailed knowledge of the mode of interactions between these chemicals, the wood substrate and their target degrading organisms. Such ultrastructural studies have made significant in-roads in understanding the fundamentals of deterioration in a selection of important tropical and temperate wood species by specialized wood-degrading bacteria and fungi. For example such studies have helped confirm the high preservative or wood extractive tolerance of wood-degrading bacteria and specific rot fungi attacking certain preservative treated and naturally durable timbers, respectively. Indeed a thorough understanding of wood degradation factors, assisted in part by advances in EM, has helped advance the field of wood protection research overall. Examples of the use of electron microscopy in the research work related to these areas will be presented, including studies on wood biodegradation and patterns of penetration and distribution of preservatives, protective coatings and other wood protection and property enhancing substances.

Fire Performance of Hardwood Species

Robert H. White
USDA, Forest Products Laboratory, One Gifford Pinchot Dr., WI 53705-2398 Madison, USA
Tel: 1-608-231-9265, FAX: 1-608-231-9508, Email: rwhite/fpl@fs.fed.us

In this era of performance-based building codes, there is an increased need for models and data pertaining to the fire safety of building materials. in addition to data for the prescriptive regulatory fire tests, material property data are needed to optimize the advantages of the performance-based building codes that are being introduced worldwide. in this review of our research on the fire performance characteristics and fire safety engineering of wood products, we will present results on the fire performance of hardwood species. Two broad areas of fire safety engineering of materials are (1) Fire initiation and growth, and (2) Fire containment.

Fire initiation and growth include ignition, the spread of flames, and fire growth to flashover conditions. The introductions of heat release calorimeters in the 1980's reflect the changes from older prescriptive fire tests to tests that produce data suitable for fire safety engineering analysis. With information on ignition characteristics and heat release rates, it is increasingly possible to model the spread of flame over a material and the fire growth in a room. The best known of the heat release calorimeter is the cone calorimeter. The worldwide use of the cone calorimeter has increased the availability of information on ignition, heat release and smoke development of materials. Research in this area includes a study on the fire performance of hardwood plywoods.

Fire containment is mainly the fire resistance or fire endurance of structural members and assemblies to contain a post-flashover fire. Unlike the tests for fire growth, the test for fire resistance of members and assemblies has remained essentially the same throughout the world. The fire endurance of wood members often depends on the charring rate of the wood. The charring rate of wood has been extensively researched. Recently, the charring rates of composite lumber products of both softwood and hardwood species have been investigated.

Like most wood properties, fire performance properties are affected by density, moisture content, and chemical composition. The high densities of many hardwoods contribute to relatively low flame spread indexes and slow charring rates. However, the low lignin content of the hardwood species reduces the residual char content which results in higher flame spread index and faster charring rates. Fire retardant treatments can be used to increase the residual char content. The limited extractive contents of hardwood species contribute to reduced flame spread and heat release.

Wood protection of six U.S. species by NHA: the wood anatomical perspective of fungal decay

Alex C. Wiedenhoeft, Regis B. Miller, Willy Stockman, and Frederick Green III
USDA, Forest Service, Forest Products Laboratory, One Gifford Pinchot Drive, WI 53705-2398 Madison, USA
Tel: 608-231-9200, FAX: 608-231-9592, Email: acwieden@facstaff.wisc.edu

Progress in understanding the mechanisms of wood decay has not resulted in concomitant improvements in protection of wood from decay. Most wood preservatives fail to target decay-specific processes, but rather are broad-spectrum biocides. in part, this failure comes from a lack of understanding of wood itself, how wood preservatives bind to and interact with wood, and the steps fungi must use to colonize wood in order to destroy it.

Sapwood of six U.S. species with different pit types were selected: spruce (*Picea sp.*), red pine (*Pinus resinosa*), western red cedar (*Thuja plicata*), northern white-cedar (*Thuja occidentalis*), yellow birch (*Betula alleghaniensis*), and poplar (*Populus sp.*). Blocks were cut into 19 mm cubes and then were vacuum treated with a 1% aqueous solution of the calcium precipitating agent N-napthaloylhydroxylamine (NHA). Half the treated samples were leached for two weeks in daily changes of distilled water, untreated control blocks were added, and then all blocks were subjected to a modified ASTM D-2017-81 standard soil-bottle test. Three bottles were prepared for each treatment (leached, unleached, and untreated, per fungus, per wood species) with two blocks per bottle. Four fungi were used: the brown-rotters MAD 698 *Postia placenta*, MAD 6137 *Tyromyces palustris*, MAD 617 *Gloeophyllum trabeum*, and the white-rotter MAD 697 *Trametes versicolor*. One block of each treatment was removed at four weeks and another at eight weeks and was sectioned for light microscopic evaluation of colonization progress. At twelve weeks, the remaining four blocks were ovendried and weight losses were calculated.

Anatomical observations were broken into two categories; comparisons among the softwoods and comparisons among the hardwoods. Four softwoods were chosen to represent variations in specific and general features. Spruce and red pine both have axial and radial resin canals and ray tracheids, but red pine has large fenestriform cross-field pits and spruce has small piceoid cross-field pits. Northen white-cedar and western *red cedar* are softwoods that lack resin canals but have taxodioid cross-field pits. These pits are smaller than those of red pine, but larger than those of spruce. Furthermore, northern white-cedar is known to have a differentiated torus in the circular bordered pits, whereas western *red cedar* lacks a well-differentiated torus.

The hardwoods were chosen because they are diffuse-porous woods with similarly sized vessels and little axial parenchyma. Birch has scalariform perforation plates while poplar has simple plates, but the spaces between bars are ample for hyphae to pass through with ease. The major differences between these woods are in the nature of the pitting; birch has minute intervessel and ray-vessel pits whereas poplar has large intervessel pits and large, simple ray-vessel pits.

With the exception of *Tyromyces palustris*, which caused an average of 25% weight loss in both unleached and leached samples, the fungi caused generally less than 10% weight loss in unleached NHA-treated blocks, and roughly 13% weight-loss in leached blocks. The untreated blocks showed an average of more than 45% weight loss. By light microscopy, differences in the degree of colonization and visible damage to the wood between untreated, leached, and unleached blocks were evident at both four weeks and eight weeks.

The anatomical observations indicated that NHA did not prevent colonization of any of the woods studied. Despite this failure to prevent colonization, NHA did decrease the weight loss caused by these decay fungi.

Current experiments examining the potential cytotoxic properties of NHA are incomplete, but suggest that NHA protects wood in part by inhibiting normal cellular processes in basidiomycete fungi, rather than targeting wood decay mechanisms as expected. Localizing the preservative to the pit membranes is nonetheless an elegant delivery system perhaps fungi, which typically seek the pits to pass from cell to cell, encounter locally high concentrations of a toxic substance and are partially thwarted.

Common Problems of Inadequate Treatment of Mixed Species of Peninsular Malaysian Hardwoods with Copper-Chrome-Arsenic Preservatives for Structural Use

A. H. H. Wong, S.C. Lim, K.H. Henriksen, K.T. Choo, S. Salamayh, and J. Mohd. Dahlan
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +60-3-6342633, FAX: +60-3-6367753, Email: Andrew@frim.gov.my

Industrial timber preservation has had a long history of development in Malaysia, virtually from the time when the nation's sawmill industry developed from about the beginning of the twentieth century. Wood preservation research in Malaysia began in 1918 with research activities focusing treatment of Malaysian hardwoods of quality strength and permeability with oily creosote for use as railway-sleepers and in ground-contact. Performance of such wood products was gauged from numerous wood durability field trials conducted by The Forest Research Institute Malaysia (FRIM) particularly through the 1930's and 1950's. From these trials commercial hardwoods of high strength group and permeability with preservatives were identified apart from the durable woods, and many of these woods are members of the Dipterocarp species. >From the 1960's the water-borne Copper-Chrome-Arsenic (CCA) gradually replaced creosote for both economical and environmental reasons, with the introduction of the Bethell process in the country. Through much of the 1980's and 1990's, shortfall in quantities of commercial logs has led to the wider treatment of lesser used species conveniently grouped as the mixed hardwoods with a mixed of dense and light material and preservative permeability. The wider use of competing materials made of concrete and galvanized irons from the late 1980's have replaced treated wood for ground-contact applications. Currently practically all CCA treated hardwoods in Peninsular Malaysia are used in the building industry for roof and ceiling construction (roof rafters, purlins and battens), and essentially for above-ground contact.

Occurrences of inadequate treatment of such wood products with CCA in the building industry are not recent, being a major factor prompting the preference for alternative construction materials for ground-contact use since the 1980's. Due to changing availability of wood resources, an increased utilization of lesser used mixed hardwoods with a dearth of research on their wood properties and inadequate appreciation of correct industrial wood treatment or pre-treatment conditions, are among the common problems in the production of quality CCA treated wood.

Inadequate treatment of hardwoods with CCA is also attributed to the lack of a regulated wood treatment industry, despite the existence of official national standards on wood preservation in Malaysia. Inadequacies of certain specifications of CCA treated wood in these national standards and building by-laws also need to be redressed.. The inevitable abuses of preservative treatment with CCA, in the midst of a price- (versus quality-) competitive domestic market for CCA treated products has prompted action for improvement in wood treatment. This paper highlights the wide range of mixed species Malaysian hardwoods used in the building industry and their relative permeability to CCA preservatives, wood durability or strength groupings, examples of poor pre-treatment timber conditions, adoption of inadequate Bethell process treatment schedules, and examples of inadequate preservative penetration and retention versus that for for well treated mixed hardwoods. A summary outline of a national quality control system for CCA treated Malaysian hardwoods is proposed to overcome production of CCA treated wood which does not meet the required preservative retention for protection against a termite and decay hazard in the country.

5.04.00 Wood processing into the next millenium (I)

Control of quality of sawn wood in the state of Paraná, Brazil

Martha Andreia Brand, Danièlle Previdi Olandoski
Universidade Federal do Paraná - FUPEF - Rua Bom Jesus, 650 - Juvevê - 80.035-010 - Curitiba - PR - Brazil
Tel: (5541) 352.2443, Fax: (5541) 253.2332; E-mail: fupef@floresta.ufpr.br

Palabra clave: Calidad de madera asserada, Paraná, Brasil.

Las ventajes del control de calidad en el sector maderero son obvias, pero en Brasil el es solamente praticado en las maderas aserradas destinadas para exportación. Asi es que se percibe la necesidad de realizar trabajos de investigación con el objetivo del control de calidad en la industria maderera en general, y principalmente en aserraderos, donde el problema es mayor, con un gran desperdicio de matéria prima y generando mayores costos de producción.

El trabajo desarrollado en el Centro de Estaciones Experimentales de Cangüiri, de la Universidad Federal de Paraná, localizadado en la región metropolitana de Curitiba, Paraná, tuvo como objetivo principal la determinación de calidad de la madera aserrada de 60 rollizos de *Pinus spp*, por el método de clasificación por defectos.

Los rollizos fueron clasificadas en 6 clases segun la longitud y la distribuición diamétrica, con 10 rollizos en cada clase. Estos rollizos fuerón aserrados en sierra sinfin ancha para retirar los costaneros, sierra circular para retirar recortes y sierra circular pendular para despuntes. Fue realizada la clasificación visual cualitatiba de las tablas, antes de secar, con base en las normas TB 397, NB 1381, PB 1560, CB 205 e EB 2169, elaboradas por la ABNT (Asociación Brasileña de Normas Técnicas) para clasificación de madera aserrada de coníferas provenientes de rreforestación para uso general, adecuadas por las investigadoras.

La calidad de las tablas fue evaluada segun 4 clases: en la 1ª clase ausencia de bolsas de resina y médula y el número y gravedad de los defectos deberia ser menor en relación a las clases posteriores. En la 2ª clase podria presentar médula en menos de la mitad del espesor y menos de 1/3 de la longitud de la tabla, diferencia entre una extrenidad y otra de la tabla en espesor deberia estar entre 0,2 cm e 0,5 cm y la diferencia de ancha entre las extrenidades de la tablas entre 0,2 cm y 0,5 cm. La 3ª clase fue dividida en dos sub-clases A y B, siendo que na sub-clase 3A a diferença de espessura y largura entre uma extremidade y otra da tablas deveria ser mayor que 0,5 cm, con corteza ocupando menos de ¼ do longitud de un o ambos lados de la tablas. La sub-clase 3B deberia tener las mismas especificaciones de la sub-clase A, pero con corteza ocupando mas de ¼ de la longitud de un o ambos lados de las tablas.

Después de la clasificación, el nível de calidad fue através de la observación del mayor número de tablas en determinada clase. Do total de 193 tablas analizadas, 38 tablas pertenecierón a la 1º clase (19,69% del total), 26 a la 2º (13,47%), 105 a la 3ºA (54,40%) y 24 a la 3ºB (12,44%).

La evaluación de los resultados mostró claramenta la falta de calidad de la matéria-prima y del proceso de aserrado convencional en aserrraderos de pequeño porte, pues mas de 50% de las tablas fueron clasificadas como de 3ª clase. La inferioridad de calidad puede ser atribuída a los equipamientos y a las técnicas utilizados, además del poco entrenamiento de los operadores.

Se sugiere la utilización de equipamientos y técnicas mas modernas, uso de sierras com dientes menos gruesos y equipamientos com menores desvios de corte, realización de manutención preventiba y adecuada de los equipamientos de las sierras, aserrado de los rollizos con mayores diámetros y longitudes, siendo estos de mejor calidad.

Workplace improvement program for the furniture industry in Malaysia

K. S. Ho
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6342633, FAX: 603-6367753, Email: hoks@frim.gov.my

The furniture industry in Malaysia has played an important role in the country's economic growth. The growth in furniture export is very impressive from RM 171 million in 1989 to over RM 2.8 billion in 1997. There are over 2000 furniture manufacturers in Malaysia, of which over 200 manufacturers are engaged in the export of furniture and the remaining are small- and medium- sized enterprises. Being small- and medium- sized entrepreneurs, they are very busy looking after problems of finance, production and marketing giving them very little time to spare for improving environment of workplace, operational safety and efficiency, motivation and efficiency of workers and their welfare.

A project entitled "Environmental improvements in the wood processing industry" had been funded by Danish Cooperation for Environment and Development (DANCED) and executed by Forest Research Institute Malaysia (FRIM) since October 1996 and ended on October 1998. Under the project there were three main activities viz. 1) clean technology, 2) waste management, and 3) occupational health and safety. It was under the third activity that a workplace improvement program was adopted and introduced to two groups of furniture companies in assisting them to identity and implement areas of possible improvements. The program is based on the Workplace Improvements in Small Enterprises (WISE) methodology developed by the International Labour Office. It aims to demonstrate to entrepreneurs and workers that better working conditions can result in higher productivity and improvements in quality of work. For example, simple measures such as the regular cleaning of the work area and machines, improved lighting or proper storage of materials, can reduce work hazards while upgrading efficiency. Well designed equipment and organisational improvements can increase the efficiency, motivation and capability of employees, while reducing fatigue, strain, absenteeism, and labour turnover.

Activities in the program are oriented in according with the concept of learning by doing and the participation of participants are greatly encouraged through trained facilitators. These activities are outlined and described in this paper. These include visiting participating companies by the program facilitators, workshops to present technical subjects and ideas, and two intermediate periods for preparing action plans and implementing proposed improvements. All these activities were spanned over a period of one month. Follow-up workshops were carried out in 5 - 6 months' time after the completion of the above activities as a mean to monitor the progress of the participants in relation to the implementation of improvements and to provide any technical assistance as needed.

Achievements of the program were highlighted based on the results from the two groups of companies. These are supported with statistics on the planned improvements and also on the improvements that were fully implemented. Examples of improvements are selected to illustrate the situations before and after implementation. These cover areas on material storage and handling, work station design, lighting, productive machine safety, control of hazardous substances, welfare facilities, work organization, ventilation and premises. A reasonable balance between the productivity and occupational health and safety side of the implemented and the planned improvements can be seen from the results of the WISE program.

CT-scanning during drying

Tom Morén, Pär Wiberg
Luleå University of Technology, SE-931 87 Skellefteå, Sweden
Tel: +46 910 585300, FAX: +46 910 58 53 99, Email: tom.moren@tt.luth.se

Wood drying has been studied for several years on a more fundamental level, as well as in more applied projects often in co-operation with the wood working industries. in such projects the objective has often been either to develop fundamental mathematical models for the moisture migration within the wood during drying, or on an applied level, to optimise and construct drying schedules for different wood species and plank dimensions.

A serious drawback in such cases is often the lack of reliable experimental techniques for verifying moisture migration models by in situ measurements of the moisture redistribution. Such techniques should ideally be non-destructive in order not to disturb the drying process. The development of medical CT-scanning technology has made it possible to make high-resolution X-ray images where the X-ray attenuation is converted to a density image by image processing of for instance a cross section of wet wood, or even more interesting, wet wood during drying.

Green wood contains a lot of water; often the weight of the water is more than the weight of the dry wood substance. Most of this water is capillary bound in the sap wood portions of a plank, while approximately 30% of the moisture content is bound in the cell walls by hydrogen bonding. The moisture migration mechanisms are quite different for these phases: The bound water moves mainly with the vapour partial pressure acting as the major driving force, while the capillary water migrates from interior to the surface driven by capillary forces.

If free water is present in the sapwood, the density will be affected in a significant way. This fact makes it possible to use CT-scanning for determining the decrease of density caused by for instance air circulation or micro-wave drying of a piece of wood. The X-ray attenuation values are then transformed into density levels, which in turn can be visualised by adopting image processing which correlates colours to density levels.

Using such CT-scanning technique during drying experiments of green wood, we have been able to show some significant phenomenon that are of major interest for modelling moisture transport in sap wood as well as to reaching a phenomenological understanding of the process. Also, the formation of surface checking and cell collapse can be studied simultaneously.

The conclusions for soft wood of pine and spruce are
- A receding evaporating front develops in green sap wood creating a thin dry shell between the surface and the evaporating front
- The resistance to water flux within green sap wood is little as long as there is capillary contact in the wet portion of the wood
- The heat- and mass transfer flux between the ambient air and the evaporating front controls the drying rate during the capillary regime of drying
- Since heat- and mass transfer controls the drying process in the capillary regime, industrial kiln dryers can be constructed for much higher power input than what is normally the case today. The drying time can thus be dramatically shortened for sap wood planks without causing damage to the wood.

Sawing characteristics and mechanical strength properties of branchwood of *Aningeria robusta* and *Terminalia ivorensis*

Reynolds Okai, Abubakar I. Mohammed
Forestry Research Institute of Ghana, University P. O. Box 63, Kumasi, Ghana
Tel: 233-51-60123, FAX: 233-51-60121, Email: okai@forig.org

Keywords: Branchwood; Sawing characteristics; Lumber yield; Specific gravity; Strength properties

In Ghana, it is estimated that for every tree felled, nearly 50% of the tree volume are left in the forest in the form of branches and stumps. To ensure that timber harvest can be sustained into the future, there is the need to utilise a greater proportion of the total tree volume. in this regard, sawing characteristics and mechanical strength properties of branchwood of *Aningeria robusta* and *Terminalia ivorensis* were determined to clarify the suitability of branchwood as raw material for downstream processing at the wood industries. Sawing tests were then conducted on branchwood of *Aningeria robusta* and *Terminalia ivorensis*. The log length was 2 m and its diameter ranges from 10 cm to 25 cm. The machine used for the log breakdown is a horizontal mobile bandmill. The saw blade (spring set) had the following dimensions: tooth pitch 22 mm, width 30 mm, kerf 1.6 mm, gullet depth 5 mm. The logs were grouped into four diameter classes and sawn into boards of dimensions 25 mm ? 75 mm using live and cant sawing patterns. The surfaces of the sawn lumber were examined for woolly or fuzzy grain, knot, pinworm holes and washboards. They were then graded into first and second grade boards. It was observed that washboards were induced on some of the boards from *Terminalia ivorensis*. There was absence of woolly or fuzzy grain on all the boards from *Aningeria robusta* and *Terminalia ivorensis*. The mean lumber value yields for first grade boards from *Aningeria robusta* and *Terminalia ivorensis* were 25% and 20% respectively, and the mean lumber volume yield was 40% for *Aningeria robusta* and 32% for *Terminalia ivorensis*. Within each diameter class there were no significant differences in lumber yield between live and cant sawing patterns. However, significant differences in lumber yield exist between some of the diameter classes.

The bending strength, modulus of elasticity, compressive strength, tensile strength and shear strength of small clear test specimens of standard dimensions from branchwood of *Aningeria robusta* and *Terminalia ivorensis* were determined. in addition, the moisture contents and nominal specific gravity were also determined. The results of this study indicate that branchwood of *Aningeria robusta* and *Terminalia ivorensis* were more hygroscopic, that is, their green moisture contents based on the oven dry weight were higher than that of their corresponding stemwood. It was observed that the moisture content has an influence on the strength properties. in particular, as the moisture content increased, the strength properties decreased and above the fibre saturation point the strength properties of branchwood did not further decrease but remained constant. It was also observed that the nominal specific gravity of branchwood was higher than the nominal specific gravity of the corresponding stemwood. The specific gravity of the heartwood from a branchwood was higher than the specific gravity of the sapwood whereas for stemwood the reverse occurred, that is, the specific gravity of the sapwood was higher than the specific gravity of the heartwood. Statistically, there were no significant differences between specific gravity of branchwood and stemwood. This indicates that the branches used for the study are not reaction wood or tension wood. The strength properties of the branchwood were slightly less than the strength properties of the corresponding stemwood. Within species, there were no significant differences between strength properties of branchwood and stemwood. However, there were significant differences in strength properties between species. Branchwood of *Aningeria robusta* exhibited the highest strength properties. Judging from the results obtained for lumber yield and strength properties, it is satisfactory to use branchwood of *Aningeria robusta* and *Terminalia ivorensis* as raw material for downstream processing.

Plasma and corona treatments of wood: modification of surface properties

Laurence Podgorski, F. Schambourg, Bruno Chevet, Ludivine Onic, Andre Merlin
CTBA Technical Center for Wood and Furniture, All,e de Boutaut BP 227, 33028 Bordeaux Cedex, France
FAX: +33.556436486, Email: Laurence.Podgorski@ctba.fr

The durability of an outdoor wood-coating system is low, especially when the coating is a stain. The most important degradations come from the dimensional variations of wood which strain the coating and lead to its cracking. Thus the service life of a wood coating system can be increased through different routes:

- improvement of the coating flexibility: it can be obtained by decreasing the glass transition temperature (Tg) below the temperature of use. But in this case the coating is more sensitive to water.

-dimensional stabilization of wood: thermal and chemical treatments (acetylation) are efficient but most of them decrease the wettability of the wood surface and therefore the adhesion of the coating is no more guarantee Surface treatments are convenient either to improve wettability and therefore coating adhesion or to decrease wettability in order to provide an extra protection.

That is why plasma and corona treatments have been applied to wood in two ways:

-the first one consists in improving the wettability of wood surface to increase the coating adhesion especially after a thermal treatment. First experiments consisted in selecting treatment parameters (type of gas, treatment duration, power) leading to better surface characteristics of wood, before and after thermal treatments. Plasma and corona treatments are effective to improve the wettabilty of wood but no improvement of the coating adhesion has been observed.

-the second one consists in decreasing the wettability so that the surface becomes waterproof. Some tests have been performed to deposit thin films (based on ethylene or flourine) by plasma or corona treatments. This kind of deposits can be considered either on bare wood or on coated wood with a low Tg stain, that is to say a stain whose sensitivity against water will be solved thanks to this kind of films. This is the aim of an on-going research programme.

New Opportunities in Forestry for the Woodworking Industry in the Russian Federation

Irina Rykunina
Moscow State University of Forest, Institutskaya-1, 141005 Mytischi, Russia
Tel: +7 095 588 52 21, FAX: +7 095 586 80 12; 7 095 586 91 34, Email: isr@mgul.ac.ru

Since financing for forest operations is presently limited and only 25 percent of the allowable cut is harvested, forestry in the Russian Federation should be more oriented to demands from industry. More than half of the timber harvested in Russia is directed to saw mills. Large-scale saw mills profitably produce chips, but the chip production at small saw mills is not always profitable. Possibilities to increase the chip production are not realistic in the near future because of large investments needed for the further stages of the production process. So the main customers for timber from the forests are saw mills and woodworking enterprises. The number of small saw mills (which produce less than 10 thousand cubic meters of lumber per year) is increasing.
For these smaller mills, it is critical that the quality of raw materials should be strictly determined. The present study was conducted to find some opportunities for the Russian forestry and woodworking industry to work more efficiently under current economic conditions.

Information was obtained from interviews with managers of saw mills, woodworking and forestry enterprises. For one woodworking enterprise, an analysis for profit maximization was done with the help of linear programming methods.

Presently, the importance of wood quality by saw mills and woodworking enterprises has not been stressed. Many forest management approaches, which originated under the old centrally planned system, can produce obstacles for development in the new economic environment. If an enterprise does not take into consideration the features of the present economic system, the enterprise can lose considerable money. There are also some logging technology features which are not favorable for wood quality identification. But on the other hand more and more managers of saw mills and woodworking enterprises have begun to realize that wood quality could be a key factor in making a profit. in the centrally planned economy, forestry was oriented to volume of material and not necessarily to wood quality.

Most timber is harvested in natural forest stands, where wood quality characteristics are more varied in comparison to planted stands. The level of wood quality on a volume basis can be determined by three different quality characteristics: knot-free timber, timber with sound knots, and timber with unsound knot. These quality characteristics are not taken into consideration in the present inventory system. New methods are needed to evaluate timber quality to meet the specific needs of the saw mill.

Performance of Coated Carbide Tools in Cutting Wood-Based Materials (The Effect of Coating Materials and Cutting Speeds on the Wear, Noise and Forces Characteristics of the Coated Carbide Tools)

Wayan Darmawan, Chiaki Tanaka, Hiroshi Usuki, Tadashi Ohtani, Kiminori Sato
Shimane University, Department of Natural Resources, Nishikawatsu 1060, 690-8504 Matsue, Shimane, Japan
Tel: +81-852-32-6562, FAX: +81-852-32-6598, Email: wayandar@hotmail.com

Keywords: coated carbide tool; tool wear; cutting speed; turning; wood-chip cement board

Introduction

Machining wood-based materials such as particleboard or wood-chip cement board causes cutting tools to wear out much faster than machining solid wood. Rapid dulling of cutting edge of steel router bit, saw teeth, or other cutting tolls when machining particleboard is well-known occurrence. Furthermore, the use of tungsten carbide tool, which is widely used in the wood working industry for cutting particleboard is also limited because of relatively high rate of wear. An effort of coating the surfaces of the carbide tool with a hard coating material has been already developed in order to increase the wear resistance of carbide tool.

Experimental procedure

This paper presents the performance of coated carbide tools when turning wood-chip cement board. Coating materials studied were titanium, carbonitride (TiCN), titanium nitride (TiN), chromium nitride (CrN), and titanium aluminumnitride (TiAIN), which were synthesized on the P30 carbide substrate. Cutting tests were performed in turning at cutting speed of 30, 40, 50, and 60m/s and feed of 0.05mm/rev.

Results and discussion

The results of the study that the coated carbide tool provides better performance especially in reducing the progression of tool wear and in retaining lower cutting forces and noise level compared to the uncoated P30 carbide tool at every cutting speed performed. The TiAIN coated carbide tool could be the best in retaining a gradual increase in these values with an increase in cutting speed. Furthermore, the results in Table 1 will suggest that the TiAIN coated carbide tool will provide wider ranges of cutting speed in its application. TheTiCN coated carbide tool was the lowest both in amount of wear and rate of wear cutting speed of 30 m/s, however these values after cutting speed of 50 m/s increase drastically and matched with those of the CrN and TiN coated carbide tools investigated. Therefore, the TiCN coated carbide tool would be suitable to be used only for low cutting speed, by considering that the TiCN coated carbide tool retain hardness at the low cutting speed due to the cutting tool temperature (435°C) fell under its limit oxidation temperature (435°C).

Table 1. The amount of clearance wear (μm) at final length (5 km), the rate of wear of the tools investigated and cutting temperature during cutting at four different cutting speeds

Tools	**Cutting speed (m/S)**			
	30	40	50	60
Uncoated P30 carbide	125 (39.0)	247 (118.0)	289 (167.9)	399 (276.5)
CrN coated carbide	112 (37.3)	228 (112.9)	283 (159.8)	335 (241.5)
TiN coated carbide	90 (35.0)	169 (76.6)	278 (163.3)	324 (242.7)
TiCN coated carbide	76 (24.2)	139 (61.6)	270 (164.5)	343 (276.1)
titian coated carbide	78 (25.7)	83 (33.4)	104 (47.4)	110 (52.2)
Cutting temperature (°C)	435	630	800	1010

Values in the brackets determine the rate of wear.

Both the cutting forces and noise level of the tools investigated increase with an increase in cutting speed, and could show the same behavior during the progression of the tool wear. High cutting forces generated during turning with high cutting speed are probably causes by more wear attained by the tools for the high speed turning. Then, the high noise level for the high cutting speed is probably due to high impact force to be imposed on the cutting tools.

An overview of the light organic solvent preservative (LOSP) treating of *radiata* pine: Modelling of solvent loss, residual solvent composition, and paint adhesion

Bernard Dawson, H. Kroese
Forest Research, Private Bag 3020, Rotorua, New Zealand
Email: bernard.dawson@forestresearch.co.nz

Radiata pine boards were treated with a light organic solvent preservative solution, placed in a randomised manner in a timber stack of five layers and the residual solvent loadings in the boards were monitored over time by measuring weight change. An exponential model was fitted to the residual solvent loading data, expressed as a percent of the initial solvent loading, to allow calculation of solvent loading, at any position in the timber stack at any time, over the 108 day trial period. The exponential model was linearised by a natural log transformation in order to estimate parameters of the involved variables in the model, i.e. time and the x, y and z positions of each board in the timber stack. A stepwise multiple regression procedure was used to select the significant variables in the model. The coefficient of determination (r2) for the fit of the model to the data was 0.88.

Solvent uptake, rates of solvent evaporation and consequent change in the composition of the residual solvent in another set of LOSP treated pine boards were examined. The variability in LOSP uptakes in timber was large and was attributable to the natural heterogeneity of timber.

There was a measurable difference in residual solvent composition in samples taken from the centre and from the outside of treated boards. The solvent composition of samples taken from the boards at various stages of ventilation shows, as expected, a relative increase in the concentration of the higher boiling alkylbenzene components.

The control of residual LOSP solvent content appears to be the single most important factor affecting paint adhesion on *radiata* pine wood and its impact is seen strongly with a paint system combining oil-based and water-based paint layers. Results show the average residual LOSP solvent after ventilation was 51 % of initial uptake at 13 days, 36 % (22 days), 23 % (41 days) and 18 % (92 days). Blocking (sticking together of paint surfaces) was high for the acrylic primer and low for the oil-based primer. Acrylic layers dried rapidly through water evaporation while oil-based paint layers cured slowly through solvent evaporation and paint resin oxidation. Adhesion failure was highest where acrylic undercoats or topcoats were applied over an oil-based primer/undercoat when the initial LOSP solvent uptake was 30 L/m^3 or higher. Adhesion failure, while decreasing 92 days after painting, was still significant.

High-Temperature Drying of Black Spruce for Value-Added Products

Gordon Duplain, Yves Fortin, Pierre Laforest
Université Laval, Departement des sciences du bois et de la Forêt, G1K 7P4 Québec, Canada
FAX: (418) 656-3177, Email: yves.fortin@sbf.ulaval.ca

High-temperature (HT) drying in eastern Canada has been so far mainly applied to softwood lumber used in construction. The lumber is thus dried to an average final moisture content (MC) of about 15% with an allowable fairly large variation in the MC between boards. The export markets for dimension lumber becoming more and more competitive, and because of the imposed quotas on Canadian softwood dimension lumber exported to the US, the lumber industry in eastern Canada is looking for ways to diversify its production. The remanufacture of lumber into value-added products such as doors, furniture and windows appears to be a very attractive alternative. A great proportion of the dimension lumber manufactured in eastern Canada comes from high-temperature kiln dried black spruce (*Picea mariana* Mill.) B.S.P. This species is in general fairly easy to dry although its tends to show severe warp when being dried at MC's below 10%.

The ultimate goal of this project was to develop a HT drying strategy for black spruce lumber with respect to the production of value-added products dried at low moisture contents. The specific objectives were to develop: 1) a HT drying strategy that leads to a final MC of 10% with 90% of the boards between 8 and 12%; 2) a HT drying strategy that minimizes warp and check formation; and 3) a HT drying strategy that minimizes residual stresses and final MC gradients.

Dimension stock of 2.4 m in length and 42 mm x 69 mm in cross-section (2x3) was kiln dried using two different drying schedules and two levels of top-load restraint. Eight matched batches of 182 studs each were dried in a 2.5 m^3 capacity HT steam-heated laboratory kiln. All the required measurements were taken before drying (width, thickness, weight, twist, bow and crook). The same measurements were repeated after drying and the final MC was measured in two locations of each stud with a resistance-type moisture meter. Warp was assessed after planing the lumber to a final size of 38 x 64 mm. A sample of 25 studs was resawn across the thickness and another one across the width into two identical pieces which were measured for warp again. Internal checking was assessed from the resawn face of each of these pieces. Profiles of residual stresses across the thickness were also determined on some of the studs. The results showed that high quality products can be obtained from black spruce dried at low moisture contents by the high-temperature drying process. The drying strategy has, however, to be adapted accordingly and the drying time increased substantially. Presteaming and top-load restraint were shown to be effective ways of controlling warp in both the raw product and the resawn lumber, although a good proportion of the pieces with diagonal grain or spiral grain were affected by internal checking.

Measurement of Internal Features in Logs

Anders Grönlund, Stig Grundberg
Lulea University of Technology, Skelleftea Campus, Skeria 3, S-931 87 Skelleftea , Sweden
Tel: +46 910 585307, FAX: +46 910 585399, Email: anders.Gronlund@tt.luth.se

Today many sawmills strive for an increasing amount of customer adapted products. in a customer adapted production it is crucial to be able to select the right logs for a certain product, i.e. we must be able to predict the properties of the sawn products before the actual sawing operation.

There are several systems used in sawmills for the scanning and automatic grading of logs. These systems use either optical scanners or gamma-ray scanners. The optical scanners used for grading logs measure the log diameter every 10 mm along the log in two or three directions. From these consecutive diameter values new variables such as taper, butt taper and bumpiness are calculated.

With the aid of these new secondary variables, statistical classification algorithms can be developed. The gamma-ray scanner called Tina is principally used in the same way, but Tina is using green density variables together with the outer shape variables for prediction of the internal log quality.

The log-grading scanners described above have so far been more or less focused on normal export grades for commodity products. in the future it is anticipated that the selection of sawn timber for a specific customer will be more and more based on a specific feature or some specific features. in order to be able to measure specific internal features of logs an industrial X-ray LogScanner has been developed. The measurement performance for this X-ray

LogScanner has been studied. The objective with this investigation was to determine if it is possible to develop accurate models for knot volume, knot type, annual ring width and distance between whorls using a LogScanner with two modern industrial X-ray sources. The study was based on simulated signals from the LogScanner.

The study shows that when the different models were tested against a test set the strongest model had a R2 =0.95 (the distance between whorls for Scots pine) and the weakest model R2 = 0.66 (the annual-ring width for the twenty innermost annual rings on Norway spruce). The results indicate that a two-direction X -ray LogScanner can be a good tool for control of a customer adopted production.

Analysing the Efficiency of Norwegian Sawmilling

Anders Qvale Nyrud, Baardsen, S.
University of Norway, Department of Forest Sciences, 270199 P.O. Box 5044, N-1432 Aas, Norway
Email: anders.qvale.nyrud@isf.nlh.no

Norwegian commercial sawmilling consists of about 200 units (5 employees or more). Its annual production amounts to approximately 2.5 million m^3 sawnwood and planed sawnwood, equivalent to a gross value of about NOK 5.6 billion ($ 750 million). Even though the size of the sawmills differ, production ranging from < 10000 m^3 to 140000 m^3 per year, the output is relatively homogenous.

In this paper the efficiency of Norwegian sawmilling will be examined using Data Envelopment Analysis (DEA). By the means of linear programming efficient production units are identified, and, when assuming convexity, an efficient ("best practice") production frontier is fitted. The inefficient units' distances to the frontier are minimized with respect to input saving or production expansion regimes. Thus, corresponding efficient peer units are identified, and the relative efficiency of the units located inside the frontier can be measured.

The analysis will be carried out on an extensive panel data set consisting of 3101 individual sawmill observations over the period 1974-1991. Several input and output variables are available - physical quantities as well as economic measures. The DEA approach is cross-sectional by nature. Using panel data adds the dimension of time to the analysis, making it possible to investigate the development of Norwegian sawmilling (for example technical change and production efficiency) throughout the period. For this purpose, the Malmquist productivity index will be used. This index corresponds to the efficiency measure originally developed by Farell (1957). It distinguishes between technical change and changes in production efficiency.

Production Structure in the Swedish Sawmilling Industry

Anders Roos, Matti Flinkman, Armas Jöppinen, Mats Warensjö
Swedish University of Agricultural Sciences, Department of Forest Management and Products, Post Box # 7054, S-750 07 Uppsala, Sweden
Tel: +46 18 671564, FAX: +46 18 673522, Email: anders.Roos@sh.slu.se

Wood products face market competition from a range of materials, *e.g.* plastic, concrete, steel. These materials are furthermore constantly being improved and adapted for different end-users. On the other hand, wood products have important competitive advantages-especially aesthetical and environmental qualities -- that need to be recognized and better exploited. One way for the sawmilling industry to meet the market challenges is to diversify and adapt the production according to the needs of different customers. This involves for example more drying to orders, length trimming, stress grading, finger jointing, surface treatment-and less bulk production.

For the sawmills this approach requires more efforts and investments in training, computers, drying technology, and other equipment to add more value to the product. in this way a mutually beneficial situation could be reached, where the customers of wood products receive a higher grade good and sawmills -- and the whole forest sector -- receive better prices for their products.

However, more advanced and specialized production can also increase risks as investments increase and niche markets sometimes are rather volatile. Therefore the production structure and market conditions of the sawmilling industry have to be thoroughly analysed in order to allow the industry to identify feasible strategies and to find factors for success. What characterizes, for instance, the technologically advanced sawmill and how do different types of sawmills perform concerning value-adding processes? One step in this analysis is to conduct systematic empirical studies of the sawmilling industry.

In this study, production strategies by Swedish sawmills today are described and analysed. The focus of the study is on input factor use, innovation and value adding processes. We compare different categories of sawmills and describe the most frequent ways to organise the production. Plant level data from 1995 about the Swedish sawmills is used in multivariate statistical analyses.

The results include a description of the general situation of the production structure of the sawmilling sector. Relationships between plant size, ownership, productivity, log handling, saw type, value-adding processes, drying, and computer use are investigated. Moreover, different alternative ways to organise a sawmill today, especially regarding technology adoption and value adding processes, are identified.

The adoption of different value adding processes is fast in the industry. It follows different dimensions, which reflect the technical and the market orientation of the enterprise. Value added shares of the total production depend generally on ownership, location and size of the sawmill.

Still, however, an important share of the sawmills treats only small quantities of lumber in value adding processes. Many sawmills apply 'standard' value adding processes based on planing and extra drying to orders. Smaller groups of sawmills have a more specialized production where the lumber is treated for specific uses.

Sawmills are classified in different strategic types along the axes: size, value added share and labour productivity. A number of strategic groups in the Swedish sawmilling industry can be identified. The implication of the results for the competitiveness of the sawmilling industry will finally be discussed in the presentation.

5.04.00 / 5.05.00 Innovations in wood bonding and utilisation of wood residues

Composting of Furniture Manufacturing Woodwastes and Phenolic-bonded Softwood Plywood Sawdust

Hamid Borazjani, Susan V. Diehl and Harold A. Stewart
Mississippi State University, Forest Products Laboratory, Box 9820, MS 39762 Mississippi State, USA
Tel: 601-325-2116, FAX: 601-325-8126, Email: hborazjani@cfr.MSstate.edu

Two six-month outdoor studies were conducted to evaluate different amendments for composting of furniture woodwastes and sawdust from phenolic-bonded plywood. in the first study, furniture wastes were amended with 5% and 10% horse manure with the unamended wastes as controls. All treatments and controls were replicated three times. Moisture was provided through precipitation and substrates were aerated once or twice weekly. Samples were collected at 30-day intervals and analyzed for pH and toxicity. All treatments showed a significant reduction in dry matter by 180 days. The treatments containing 5% and 10% horse manure showed nearly twice the weight loss as the controls but there was no significant difference between 5% and 10% manure treatments. A reduction in toxicity occurred in all treatments and all treatments maintained neutral pH after 30 days.

In the second study, phenolic-bonded plywood softwood sawdust was amended with 5% chicken manure, 5% cow manure, 5% horse manure, 3% cotton gin trash, and 500 ppm inorganic fertilizer solution with the unamended sawdust as control, and three replications per treatment. Sampling, watering, and aerating was done as described for the first study. All treatments showed a reduction in toxicity and maintained a neutral pH after 30 days. All treatments showed almost double the percentage of weight loss compared to unamended control.

The composted sawdust was also evaluated in a greenhouse study to determine its effect on the growth of row crop plants. Twenty-five percent by weight of the composted sawdust was mixed with potting soil, in which corn, soybean, and cotton seeds were planted. The pots were watered daily and allowed to grow for 55 days. The chicken manure treatment showed no significant difference in mean weight of the plants when compared to potting soil only. Other treatments were comparable to chicken manure, except gin trash, which showed significantly less plant weight compared to the others.

Aspects et tendances concernant l'utilisation des lignosulphonates techniques dans les adhesifs pour l'industrie du bois

Valeriu Petrovici, Daniela Mihai, Valentin Popa
Universiti Transilvania Brasov, B-ul Eroilor 29, 2200 Brasov, Romania
Email: petrovic@unitbv.ro

On connait le fait que la lignine technique est obtenue dans la phase industrielle, comme un sousproduit à la désincrustation alcaline ou acide du bois de résineux ou de feuillus et par la hydrolise de celui-ci dans le milieu acide. Jusqu'à présent, les tentatives de créer une industrie pour valorifier la lignine résiduelle ont eu des succès partiels, pour les produits obtenables, en employant, en général, des quantités réduites de trois types de lignines techniques.

On y ajoute aussi certaines difficultés dans la transformation des lignines, liées à une connaissance insufisante sur la nature et sa structure chimique complexe, la diversité de ses unités structurales, des liées avec les autres composants chimiques du bois et surtout des aspects

économiques concernant la rentabilité de tels procédés.

Partant des considérations de ci-dessus et du fait que ce produit aromatique naturel qu'on isolé du bois, mais qui d'une facon où d'autre revient dans ce même bois, aurait une compatibilité meilleure envers les polymers synthétiques, nous avons étudie quelques posibilités de valorisation sous diverses formes des lignines techniques, comme produits chimiques employés dans le secteur de l'industrialisation du bois. L'emploi de lignosulphonates techniques d'amonium ou du calcium s'est realisé soit sous forme de poussières atomisées, soit sous forme de solution ayant des concentrations variables entre 35-45%.

Dans une prémière catégorie d'expériments ceux-ci ont étè employés comme de simples suppléments dans des adhésifs uréo-formaldéhidiques pour:

la fabrication des panneaux de particules de bois en substituant 25% de l'urée technique pour la couche extérieure ou pour celle de l'intérieure ;

la fabrication des panneaux type sandwich pour les meubles, en substituant intégralement la farine de seigle;

le placage des panneaux pour les meubles, en substituant intégralement ou en proportion de 50% la clorure d'amonium, 50% de l'urée technique et 75% de la farine de seigle.

Dans une autre catégorie d'expériments les mêmes lignosulphonates techniques d'amonium ou de calcium ansi que ceux qu'on à métalliquement complexes avec les cations mentionnés ci-dessus on a utilisé comme substituants en proportion de 15, 20 et 25% du phénol technique, utilisé à la synthèse de la résine phénol-formaldéhidique classique, en obtenant ainsi deux résines phénoliques modifiées:

résine lignin-phénol-formaldéhidique type P pour la fabrication du contre-plaqué pour d'extérieur;

résine lignin-phénol-formaldéhidique type F pour la fabrication des panneaux de fibres de bois.

En partant du lignosulphonate technique d'amonium et de calcium par des modifications chimiques adéquées, on a obtenu aussi deux produits tannants végétaux pour la tannerie et le retannage du cuir.

La lignine de hydrolise acide de la cellolignine en bois de chêne a été utilisée aussi comme un supplément simple à l'adhésif uréo-formaldéhidique pour la fabrication du contre-plaqué pour l'intérieur, en substituant totalement la farine de seigle.

On remarque le fait que dans toutes ces recherches expérimentales, les limites des suppléments de lignines techniques n'ont pas dépassées 20-25% des composants substituées.

Les essais d'augmentation de la proportion de lignine au dessus de ces valeurs n'ont plus conduit à des produits agglomérés ou stratifiés de qualité, ceux-ci présentant des caracteristiques physico-mécaniques inférieures aux éprouvettes témoins.

Pour accroître le degré d'emploi des lignines techniques, y compris dans le domaine des adhésifs pour l'industrie du bois, nous estimons résoudre deux problèmes importants à présent:
la réalisation d'une uniformisation du degré de polydispersion;
l'augmentation de la réactivité chimique des lignines techniques.

Dans la réalisation de tels désidérats il faut conjuguer les efforts de tous les chercheurs scientifiques qui travaillent dans ce domaine, par la réalisation des programmes communs de travail, des échanges d'expérience, des publications et, pourquoi pas, l'organisation d'une rencontre scientifique internationale dédiée à ce sujet.

Adhesive innovation and production of North American glued-wood and related products

Terry Sellers
Mississippi State University, Forest Products Laboratory, Forest and Wildlife Research Center, Box 9820, MS 39762 Mississippi State, USA
Tel: +1 (601) 325-3110, FAX: +1 (601) 325-8126, Email: sellers@fpl.msstate.edu

Based on 1998 estimated m^3 data, about 36% of the wood composites in North America were plywood and laminated veneer lumber products, 29% oriented strand products, 19% particleboards, 6% medium-density fiberboards and 10% a variety of other glued-wood and fiber products. The expanded array of glued-wood products has increased demand for a variety of wood adhesive resins and fostered adhesive systems with enhanced properties. in 1998 in North America, consumption of adhesive resin solids required to bond the glued-wood and related products were estimated to be about 1780 kilotonnes (kt). Considering the percentage of glued-wood products in North America as a basis, the calculated resin solids consumed by country were 1370 kt (77%) for the United States of America (U.S.), 374 kt for Canada (20%) and 36 kt for Mexico (2%).

In 1998 in North America, particleboards, fiberboards, and decorative and hardwood plywoods were bonded principally with amino resins (1060 kt). The ratio of resin solids consumed by the particleboard and medium-density fiberboard industries was similar to the ratio of production of the two products (76:24) since both industries add a similar amount of resin binder to the respective products. The vast majority of the amino resins are urea-formaldehyde based, however, METLAmine is added for some upgrades. METLAmine-formaldehyde resins in North America are primarily applied in overlay coating applications for wood products. Phenolic additions to amino resins are being explored.

In 1998 in North America, the quantity of phenolic resin solids consumed by the wood composite industries was 568 kt. The phenolics are primary binders for oriented strand products, construction plywood, and laminated veneer lumber. in addition, selective medium-density fiberboards and high-density compressed fiberboards (wet- and dry-process hardboards, including dry-process door skins) are bonded with phenol-formaldehyde (PF) resins, and other engineered lumber products are bonded with phenol-resorcinol-formaldehyde modified resins.

Over the past 15 years in North America, polymeric diphenyl methylene diisocyanate (PMDI) has established an entry into the glued-wood products industry. The consumption of PMDI for these products is estimated to be 90 kt with 90% of this volume being applied as binder in oriented strand panel and lumber products. About 18% of the binder requirements for oriented strand boards (OSB) are estimated to be PMDI with the balance OSB binders being liquid PF and powder PF resins. PMDI resins have been shown to be the preferred binder for agrifiber boards (wheat straw furnish, etc.) unless the agrifiber has been modified by mild chemical and steam pretreatment and fiber bundle refining.

Vinyl compounds (50 kt) for gluing wood in North America are consumed mostly as assembly glues, but some are utilized as adhesives for hardwood plywood and hardwood lumber flooring products (flatbed trailer and railway car flooring). The vinyl may be a homopolymer polyvinyl acetate or an upgraded cross-linked vinyl product. The vinyl upgrades may be based on phenolic, isocyanate or other thermosetting additions to the emulsion polymers.

Excellent historical data, including cost, have been published on many wood-based composites for Canada and the U.S. Substantial research and development on wood adhesives continues in North America, including amine, phenolic, polyurethane, vinyl, soya and accelerator modifications.

The Role of Temperature, Humidity and Fungus On The Adhesion Failure of Alkyd Paint On Timber Substrate

Ahmad Shakri Mat Seman, P.D. Evans
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6342633, Email: shakri@frim.gov.my

During natural weathering opaque paint finishes on wood experience surface discolouration, checking and loss of finish adhesion. These effects are through to be due to the action of complex combinations of weathering factors such as moisture, heat and micro-organisms. The relative importance of each of these factors has not been well defined. The controlled laboratory experiment was then carried out to determine the importance of each of these weathering factors in the adhesion failure of paint on wood.

Painted Kempas (*Koompassia malaccensis* Maing. Ex Benth.) specimens were exposed to controlled environments in which each of the factors, temperature, humidity and fungus exposure, were held at pre-determined, fixed levels. Additional factors investigated were the effects of artificial pre-weathering of substrate and cutting of the paint finish. The ultraviolet light factor was not taken into consideration.

Results showed that a relative humidity had the most deleterious effect on paint adhesion, followed by the presence of the stain fungus. Loss of paint adhesion was further increased when pre-weathered specimens were exposed to a high relative humidity. The presence of a cut on painted wood surfaces increased the deleterious effect of the blue stain fungus on adhesion presumably because it allowed the fungus greater access to the underlying wood.

Application of Industrial Wood Waste for the Development of Multipurposes Glue

Galia Shulga
State Institute of Wood Chemistry, 27 Dzerbenes St., LV 1006 Riga, Latvia
Tel: +371 7 553063, FAX: +371 7 310135, Email: koks@edi.lv

It is known that environmental restrictions put sulfite pulps mills that produce industrial recovering lignin - lignosulfonates (LS), a large-scale wood waste, out of business. At the same time, a chemical modification of LS offers the great opportunities to produce novel polymer products on their basis. in such a way, environmental demands, economic reality and a high efficiency of the biomass conversation might be involved into producing of the multipurpose, environmentally friendly and high quality polymer products.

In this work, we would like to show how it is possible effectively modificate lignosulfonates and what the real applications of the polymer products formed are. Synthesis of lignin-based interpolymer complexes (LIC) is based on the interaction between the oxidized lignins and the water-soluble polymers or oligomers (Shulga et al. 1997). LIC obtaining proceeds, as a rule, in water media at room temperature, normal pressure, and without using of any catalysts. These polymer products exist both in water-containing solvents and a solid state. The main reason of LIC structure stability to the action of different outward factors (pH, elevated temperature, UV-radiation) is conditioned by a cooperative system of the macromolecules coupling that has entropy nature. The nature of linking between LS and synthetic polymer/olygomer can be different: ionic, donor-acceptor, covalent etc.

The established relationships and mechanisms of interpolymer reactions as well as the nature of the interaction with different interfaces have allowed to developed the new glues on the LIC basis with controlled adhesive properties.

LIC-based glues are able to substitute almost 45-55% of UF-resin in the fibres composite materials (Shulga et al .1990). Besides that, it is no any necessity in additional power consumption for their producing at an increased lignin-based glue content. The advantages of the composite materials obtaining are as follows: using of the significantly lower temperature for pressing and drying, no necessity of any curing agent. There are some advantages of the composite materials themselves in comparison with ones obtained with UF-resin such as a higher mechanical strength, a higher hydrophobicity, a significant lower evaluation of formaldehyde during the manufacture and in use as well as a lower cost.

LIC-based glues may be applied as ecologically friendly soil conditioners with pronounced structure-forming and adsorbing properties on sandy soils (Shulga et al. 1998). For their obtaining, the formation of LIC proceeds in the presence of salts of multivalent metals. It allows to approximate LIC-based conditioners to the structure and the properties of soil organic-mineral formations.

The soil structure obtained by LIC application has the important influence upon water-holding capacity, water transport, aeration and heat transfer in soils, and indirectly improves the conditions of the vitality of plants and microorganisms. Owing to structural peculiarities, LIC-based conditioners are capable of cementing the particles of sandy soil and forming a composite polymer-sand coatings, which are able to withstand wind and water erosion and prevent blowing off a fertile layer. Field tests have shown that composite coatings formed reduce the evaporation of moisture from the soil, but at the same time, do not prevent water and air transfer into the soil. Perennial grass seeds germinate easily through composite coatings, forming the turf of a good quality with a thick-branched root system.

An environmental friendly composite made from hydrated lime, pozzolanic material, spent carbon dioxide and reinforced with recycled cellulose fibers

Maruli H. Simatupang
Universiti Sains Malaysia, School of Industrial Technology, Division of Wood, Pulp/Paper and Coating Technology, 11800 Penang, Malaysia
FAX: 60 4 65 65 326, Email: humala@pd.jaring.my

The reasons why asbestos fibers reinforced cement composites are still used in many developing and less industrialized countries are briefly elaborated. A new kind of cellulose reinforced laboratory board was developed as possible alternative for non-compressed asbestos cement panels. *Pinus radiata* kraft cellulose (PKF), recycled newspaper (RNF) or oil palm trunk soda fibers (OPF) were used as reinforcement. The binder consist of slaked lime and ground rice husk ask (RHA) or pulverized-fuel ash (PFA), also designated as fly ash. The web was formed by mixing the reinforcement and the binder mixture with water and dewatering the slurry. It was then compacted by vacuum and pressure. The still soft board was placed in a pressure vessel. Pressurized carbon dioxide was introduced after vacuum treatment. The gas reacted with slaked lime to form calcium carbonate, which gave the panel its early strength properties. If the carbonated panel is cured in a moist cubicle for 14-28 days the uncarbonated slaked lime reacts with RHA or PFA to form calcium silicate hydrate. This binder contributed significantly to the ultimate strength properties and improved the moisture resistance and dimensional stability. The parameters influencing carbonation were examined. It was feasible to use a mixed gas with 15% carbon dioxide content. Such carbon dioxide enriched gases are emitted from thermal power stations fired with coal or liquid fuel, at calcination of lime stone or magnesite and in the fermentation industry. Carbon dioxide is one of the main green-house gases. in the new process this gas is recycled. The technological properties of the novel board are compared with those of asbestos-free commercial panels.

Utilization of residues at sawmills, plywood mills, and precut factories in Japan

Tsutomu Takano, Kohji Murata, and Katsumi Nishimura
Forestry and Forest Products Research Institute, P. O. Box 16 Tsukuba Norin Kenkyu Danchi, 305-8687 Tsukuba, Japan
FAX: +81-298-73-3798, Email: ttakano@ffpri.affrc.go.jp

Japanese total timber consumption was 110 million cubic meters in 1997. of total timber are 44 % for sawn lumber, 40 % for pulp and papers, 14 % for plywood. We investigated how many residues were remained and how the residues were utilized at sawmills, plywood mills, and precut factories. of the residues at the sawmills, 10 % was bark, 20 % was slab, and 14 % was sawdust. The bark is utilized as fuel, livestock bedding, and fertilizer. The slab is utilized for manufacturing pulp chip. The sawdust is utilized as fuel, livestock bedding, fertilizer, and culture ground of mushrooms. Less than 10 % of the residues at the sawmills was thrown away or thrown into fire.

Plywood recovery was 64 %, and main kind of residues at plywood mill was green veneers (25 %), dry veneers (24 %), cores (16 %), and plywood edges (13 %). 76 % of the residues was used as boiler fuel for veneer drier and hot?press, and 20 % of the residues was reused as wood chips for particle board, MDF, fiber board, or fuel. Only 1.5 % of the residues, which contained 95 % of bark was thrown away or thrown into fire. Precut means machining of timber joints of building members for Japanese traditional wooden houses (post and beam construction) at a factory (precut factory) instead of hand cutting by a carpenter. We machined about 20 million cubic meters of timber at the precut factories in 1997. Five percents of odd, 0.5 % of sawdust, and 1 % of chip were generated from the total timber machined at the precut factories. The odd is utilized for manufacturing pulp chip, small size lumber, and glue laminated lumber. The sawdust and chip were utilized as livestock bedding and fuel. in Japan, almost the residues at the sawmills, plywood mills and precut factories are effectively utilized.

Production Technology and Advantages of Environment Protective Fibreboard

Cao Zhongrong
Research Institute of Wood Industry, Chinese Academy of Forestry, 100091 Beijing, China
Tel: +86 10 62889424, FAX: +86 10 62881937, Email: caozr@wood.forestry.ac.cn

In order to meet the requirement of environmental protection, the production of environment protective wood based panels will become a development trend. This paper introduces the production technology and advantages of environment protective fiberboard. On proper conditions, environment protective high density fiberboard (S2S HDF) can be produced, on the general dry-process hardboard or medium density fiberboard (MDF) production line, without adhesive and change of equipment.

The production process of environment protective fiberboard is as follows:

Raw materials - chipping - screening - refining (-wax addition) - fiber drying - forming - prepressing - cross- cut - loading - hot pressing - unloading - trimming - stacking - inspecting and grading - product storage.

The results studied show that the hot-pressing technique is the main key to produce environment protective fiberboard. The technological parameter of hot-pressing includes a temperature of 190 ~ 200°C and a pressure of 4.0 ~ 5.4 Mpa. The pressing time depends on the thickness of board to be made and wood species. Generally, the pressing time for each one millimeter board thickness does not exceed one minute.

After completing a technology study on the manufacture of environment protective fiberboard at the laboratory, a pilot-scale trail was conducted on the MDF production line with an annual capacity of 10000 cubic meter to examine further technological parameter obtained by a series of technology experiments and determine the physical mechanical properties of the commercial environment protective fiberboard is suitable and feasible.

5.05.00 Composite and reconstituted products

The wood- based composite industry in Chile: a general overview

Aldo Ballerini
Universidad del Bio-Bio, Relaciones Internacionales, Casilla 5-C, Concepción, Chile
Tel: (56-41)26 12 61, FAX: (56-41)31 67 37, Email: aballeri@apolo.dci.ubiobio.cl

The wood-based composite industry in Chile has been playing a mayor role, in the forest product sector during the last 10 years. Growth has averaged 15% per year based on the volume produce. There is an installed capacity of 1.28 million cubic meters within 19 mills, which are producing particleboard, medium density fiberboard (MDF), hardboard, plywood and veneers. The Chilean wood-based composite industry is very dynamic, and is currently investing in other Latin American countries: Argentina, Brazil and Venezuela, to produce particleboard and MDF. in addition, several new plants are projected for the next five years.

The Chilean market account for 64% of the total panel products produced. The remaining 36% is exported mainly to Europe, America and Asia. Current and future new plantations in Chile assume the availability of commercial timber, which suggest significant increase of the panel sector over the next 10 years.

Developments in Composite Research and Industrial Manufacture of Composite in Japan

Shuichi Kawai
Kyoto University, Wood Research Institute, Uji, 611-0011 Kyoto, Japan
Tel: +81-774-38-3673, FAX: +81-774-38-3678, Email: skawai.@kuwri.kyoto-u.ac.jp

Recent developments in the research on wood composite products and their applications in the industrial manufacture in Japan are being reviewed. Engineered wood products are playing an increasingly important role in timber constructions; glulam and laminated veneer lumber (LVL) are now widely accepted as timber construction members, and are already produced commercially by using domestic softwood species. Structural panels such as plywood and oriented strandboard (OSB) are often used, even as Japanese conventional post & beam housing structures for bearing wall panels. Medium density fiberboard (MDF) is used dominantly as a base panel for secondary processing.

More reliable and higher performance wood composite products are being developed by aligning the elements along the fiber direction; a cylindrical LVL made of helically wound veneer tapes provides a bio-mimetic structure of wood cell and proves to exhibit high bending performance despite its light weight. in panel products, an advanced OSB is manufactured with thin strands in order to achieve improved surface properties, dimensional stability and mechanical properties. This advanced OSB is now in the process of being produced on a commercial scale. High performance oriented MDF with long lignocellulosic fibers is now being developed, whereas vertically oriented fiberboard with an ultra low density has been marketed as a substitute to the foam plastic materials. A new technology for producing high-performance cement bonded particleboard by using rapid curing process of either super-critical fluid or gaseous state of carbon dioxide is now under development.

Currently, new concepts of zero-emission and recycling processes have been introduced to support the sustainable utilization of wood resources. New processing technology to convert forest residues, non-wood lignocellulosic materials, agricultural wastes, and recycled wood into new types of lumber and panel composite products is necessary to ensure sustainable utilization of the existing forest resources.

Jute Composite By Resin Transfer Moulding -A New Techno Economically Viable Product

M. Sarkar, A. Mandal, A.K. Rana, K. Jayachandran
Indian Jute Industries' Research Association, 17, Taratola Road, 700 088 Calcutta, India
Tel: +(033) 401 4615/17 - 20, FAX: +(033) 401 4621/4298, Email: ijira@cal.vsnl.net.in

Various forms of jute reinforcement alone and alongwith glass were used successfully to reinforce composites moulded following Resin Transfer Moulding process using Unsaturated Polyester Resin as the matrix. Products include panels, chair seats, trays, angles, etc. Properties of these types of composites were evaluated. Advantages of using jute reinforcement include reduction of costs, lowering of density and the use of an environmentally friendly, renewable, reinforcement. The lower mechanical properties of jute composites could be compromised where higher mechanical properties of high value glass reinforced composites are not justified. Commercial viability of resin transfer moulded jute composites has been established from techno-economic feasibility studies.

Wood Modification Towards Practical Application: An European Perspective

Joris van Acker
SHR Timber Research, Wildekamp 1c, NL-6704 AT Wageningen, Netherlands
Tel: +31-317-425422, FAX: +31-317-425783, Email: shr@bart.nl

During decades, efforts are made by research organisations and industries to develop wood modification methods. Most of the efforts, however, were done on laboratory scale and never reached practical application. Whereas the research in the 1960's and 70's mainly concentrated to the US and Japan, during the last decades different European research and development programmes were directed to wood modification. Main goal in most of these programmes was the search of environmental acceptable modification chemicals and reactions with potentials for the European wood industries. As outcome of these efforts, the last few years some of the developed methods were yet introduced to practice or under pilot scale evaluation. This paper will give an overview on these technologies. State-of-art, problems and challenges will be discussed, for solid wood modification as well as composites modification treatments.

Wood/polymer composites - a state-of-the art review

John Youngquist
USDA Forest Service Forest Products Laboratory, One Gifford Pinchot Drive, Wisconsin 53705 Madison, USA

Interest has burgeoned in combining wood and other raw materials, such as plastics, into composite products with unique properties and cost benefits. The primary impetus for developing such products has come from one or more of the following reasons:

- Reducing material costs by combining a lower cost material (acting as a filler or extender) with an expensive material.
- Developing products that can utilize recycled materials and be recyclable in themselves.
- Produce composite products that exhibit specific properties that are superior to those of the component materials alone.

Composites made from wood and other materials create enormous opportunities to match product performance to end-use requirements.

The use of lignocellulosic materials with thermosetting polymeric materials, like phenol- or urea-formaldehyde, in the production of composites has a long history. The use of lignocellulosics with thermoplastics, however, is a more recent innovation. Broadly defined, a thermoplastic softens when heated and hardens when cooled. Thermoplastics selected for use with lignocellulosics must melt or soften at or below the degradation point of the lignocellulosic component, normally 200oC. These thermoplastics include polypropylene, polystyrene, vinyls, and low- and high-density polyethylenes.

Markets for these hybrid composites have expanded in the past 6 years to include a host of consumer products, components for the automobile industry, packaging materials, and now, products designed for building applications.

This paper reviews technologies used to produce these materials, reports on recent research accomplishments in the field, and provides a detailed review of products now on the market or being developed for commercial application. A look to the future will also be included in this review.

5.06.00 Properties and utilization of tropical woods

Wooden school furniture for underdeveloped and developing countries

Carl Eckelman, Eva Haviarova, Hui Zui, and Jorge Acuna
Purdue University, 1200 Forest Products Bldg., IN 47907-1200 West Lafayette, USA
Tel: (765) 494-3635, FAX: (765) 496-1344, Email: ehaviar@fnr.purdue.edu

Keywords: school furniture, underdeveloped, developing countries, plantation thinnings, wood residues, cottage industries.

In many underdeveloped and developing regions of the world, school furniture is poorly designed, of low quality, and often unfit for school use, yet it is costly and consumes a disproportionate share of limited educational budgets. This situation need not continue. Our research indicates that attractive, well-designed, durable, maintenance-free furniture can be produced from locally available woody materials including plantation thinnings and semi-processed materials such as pallet deck boards by local industry. Only the simplest machining and joinery processes are required to construct the furniture. Cost of the furniture is generally less than that of competing products, yet performance tests indicate that the furniture produced is several times more durable than furniture currently in use.

Production techniques vary from those best-suited to cottage industries to those more appropriate for small factories in more developed areas. Small stems can be converted into squares or dowels that are subsequently cut into furniture parts, or the stems can be converted into small strips that are subsequently used to fabricate individual furniture parts or entire frames. Curved laminated construction can be used when woods can be easily steam bent. Creep bending with simple jigs can also be used to form parts with sharp corners and straight sides. Green bending can be used to form parts with mild bends such as seat and back slats. Simple chemical bending with household ammonia may also be used to form extreme bends in the ends of such items as seat slats.

Cross lap laminated construction can be used with those woods in which only short lengths of clear wood can be obtained or which have poor bending characteristics. This method of construction produces strong, durable, geometrically accurate frames with very simple equipment.

Round mortise and tenon construction provides a simple yet strong and reliable method of connecting members and side frames together. Round tenons may be produced on a conventional wood lathe or they may be cut with a simple hole saw.

In conclusion, preliminary results indicate that sturdy, well-designed school furniture can be produced from small woody stems and other wood residues by a variety of production processes -- some best suited to cottage industries, others to more developed industries. Thus, school furniture and the accompanying production processes can be matched to the level of development of essentially any interested country. Finally, none of the processes involved in the construction of the frames are inherently costly so that attractive, sturdy, easily maintained furniture can be produced at modest cost in any developing country.

Acacia mangium An Alternative Timber Building Material: A Case Study

Hamdan Husain
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, FAX: +603-6367753, Email: dann@frim.gov.my

Keywords: glue laminated-*Acacia mangium*, alternative building material, engineered components

The diminishing supply of timber from natural forests due to increasing demand for forest products has stimulated interest in forest plantations. Natural forest takes considerable time to rejuvenate and compensatory forest plantations are seen as alternatives to fulfill the needs of sustainability. Among the fast growing tree species promoted in Malaysia is *Acacia mangium*. *A. mangium* plantations now cover some 80% of the total forest plantation areas (51,745 ha.) in Peninsular Malaysia. General aspects of research on this timber have been conducted but records and proper documentation on its potential usage are still lacking.

In order to assess the suitability of using *A. mangium* for construction, a house was built in 1998. The objective was to analyse the utilisation of *A. mangium* as a building material taking into account the preparation of raw material, drying and preservative treatment, timber engineering aspects and construction. This will be followed by monitoring the in-service performance to determine its performance under local environmental conditions. Special attention will be focussed on the structural performance of the engineered components. The economic aspects of the project will however not be discussed in this paper.

Logs of 1.8m and 2.4m lengths were obtained from 13 year-old thinnings. Owing to the inherent presence of heart rots in the logs, care was taken to exclude or minimize them when obtaining the sawn timber. The timbers were conditioned to about 10-12 percent and then cross-cut, planned, finger jointed and glue-laminated with PRF to obtain the required lengths for the construction. Each stage of production of the glue laminated members was monitored although it was not possible to strictly adhere to the established regimes in preparation of the material.

Various problems encountered during the preparation of the components and construction are discussed. However, the project has indicated the potential of using *A. mangium* as building components. Being able to control the sawing of the logs and the use of smaller size logs will help to optimise utilisation of the timber. The performance of the house constructed will be monitored and the data collected will contribute towards information on the use of plantation grown timbers for construction.

***Eucalypts* from South America: a sustainable raw material in the international market for solid wood products**

Erich Gomes Schaitza, Antonio R. Higa, Admir Lopes Mora, Jose Carlos Duarte Pereira
National Centre of Forestry Research, CP319, 83411-000 Colombo, Brazil
Tel: 55 +41 766 1313, FAX: 55 41 1276, Email: erich@cnpf.embrapa.br

South American countries, specially Brazil, Chile and Argentina, have a large experience in the production of *Eucalyptus* pulp and charcoal, but the use of *Eucalypts* as solid wood was somewhat limited to small companies. in the last years, due to a reduction in the offer of woods tradicionally used by sawmills and plywood industries, consumption of *Eucalypts* has been graddually increasing.

As this region has 4-5 million hectares of high productivity eucalypt plantation, it is expected that once *Eucalypts* solid wood establishes a domestic market and production scale grows, *Eucalypts* products will also be sold to the international market. Some large companies from Brazil as Aracruz, Klabin, CAF and Flosul are operating or will start to operate new saw mills using *Eucalypts*.

The same process is occurring in Argentina, Chile, Paraguay and Uruguay. *Eucalypts* wood present a series of problems for solid wood industry as it has a very strong tendency to log splitting, board splitting and warping during sawing process and collapse during drying.

Research on eucalypt wood properties and tree breeding has followed the same trend of its utilization, i.e. most early research was focoused on pulping and heat properties and only lately problems related to eucalypt solid wood production were seriously considered. Currently, utilization of eucalypt wood as sawn timber, specially the control of growth stresses through silviculture and genetic breeding and development of sawing and drying techniques are considered as a key point for forest research.

Lignin, cellulose and extrative contents and specific gravity are some traits usually considered by genetic improvement programs when final product was pulp or charcoal which are not of real importance when solid wood is considered, and log splitting, warping, shrinkage and collapse have been introduced as new variables of the breeding process.

This paper discusses the following topics:

- Current trends in reforestation in Latin America, with a special focous in Brazil is presented together and changes in the silviculture of *Eucalypts* required to meet solid wood industry requirements;

- Impacts of eucalypt plantations in Brazil;

- Wood quality for solid wood of E. *grandis*, *E. dunnii, E. urograndis, E. pilularis, E. saligna* planted in Brazil;

- Perspectives of using log splitting, board splitting, warping, shrinkage and collapse in breeding programs of eucalyps for solid wood, with basis on the analysis of *Eucalyptus pilularis, E. grandis, E. deanei* provenance and progeny combined tests, clones of *urograndis* hybrid and open populations of *E. dunnii and E. deanei*;

- Market possibilities of solid products of the main *Eucalypts* planted in Brazil based on a comparison of their wood quality and machining properties with that of tradicional tropical woods.

Selection of Pulpwood for Plantation Development for Pulp and Paper Making in Tropical Countrys - the case of Ghana

Daniel Sekyere
Forestry Research Institute of Ghana, Post Box # 63, UST Kumasi, Ghana
Tel: +233-51-60123, FAX: 233 - 51 - 60121, Email: dsekyere@forig.org

Keywords: Selection, pulpwood, plantation *Musanga cecropiodes*, hardwood

An indication is given of ways in which wood species with properties suitable for pulp and paper manufacture can be selected. Before any such selection can be undertaken it is essential to know just what are the desirable characteristics from the pulp and paper aspect.

The present study was conducted on *Musanga cecropiodes* to determine the desirable properties and their influence, namely: longer than average fibre length, Runkel ratio less than 1, average basic density, low extractive content, low lignin content and suitable hemicellulose content. in addition to these the pulp characteristics were also determined.

Musanga cecropiodes was obtained from experimental plots in Kumasi, Ghana. The sample was debarked and sawn into discs of approximately 18mm thickness and then split along the grain with a knife to give a chip size of approximately 18 x 18 x 6mm. A portion of chips prepared for pulping was ground in a Wiley-Mill.

Chemical analyses were made on wood meal which passed a BS 40 mesh sieve (425µm) but retained on a BS 60 mesh sieve (250µm). For the chemical analyses an extractive: free sample of wood meal was prepared by successive extraction with alcohol/benzene, alcohol and water. The following analyses were also carried out: cellulose, acid insoluble lignin, 1% sodium hydroxide and hot water.

Preparation for fibre measurements were made according to Franklin's (1945) method. For the measurement one hundred fibres were made.

For the pulping trials chip samples (600gm) were weighed and placed in a 15 litre digester with internal electric heat exchanger. This digester slow but constant rotation when in operation. The cooking conditions adopted were the following:
Active alkaline (%) - 15, 16.5 and 17.5
Sulphidity (%) - 25
Time at maximum temperature (mins) - 90
Cooling time (mins) - 15
Wood to liquor ratio - 1.5
Maximum temperature (°C) - 170

The cooked chips were washed off black liquor and broken up in a disc refiner with a clearance of 0.5mm. The yield of pulp was determined by the dilution method. The physical characteristics of the pulp were determined by preparing sheets from the pulp in a British sheet mould. The sheets of approximately $60gm/m^2$ were tested after conditioning at 65% relative humidity. The following tests were made: Tensile index, tear index, burst index and Canadian Standards Freeness.

The results indicate that the density of *Musanga cecropiodes* 320 kg/m^3 oven dry weight/green volume was lower than that for some hardwoods, such as birch, beech and *Eucalyptus* commonly used for pulp; but similar to others, such as poplars and aspens. Fibres were slender (24.11µm) and thin-walled (3.00µm) and consequently flexible. Thus *Musanga cecropiodes* with Runkel ratio of 0.32 and co-efficient of flexibility of 0.75 stands out as having good fibre structure suited for pulp and paper-making. A high co-efficient of flexibility, like a low Runkel ratio is desirable in a fibre because this leaves a thin-wall material which is suitable for strong inter-fibre bonding in paper sheets.

The cellulose content of 53.7% for the species indicates that the pulp yield will be high. Compared with values usually found in temperate hardwoods used for pulp, the alcohol-benzene solubility (3.70%) and 1% Na0H solubility (13.1%) were average.

Using 15% active alkali for sulphate cook, a maximum temperature of 170°C with 1 hour to reach and 1 hours at that temperature *Musanga cecropiodes* yielded 55% pulp with a kappa number of 28.2. The burst strength of 6.8 $kPam^2g^{-1}$ and tensile index of 115 $mNm^2\ g^{-1}$ for a hardwood paper sheet of basis weight 60 gm-2 form at a pulp freeness of (Canadian Standard Freeness, C.S.F) 300 reported for M. cecropiodes are very remarkable paper strength properties for a hardwood whose average fibre length is 1.25mm. However, the tear index of 4.1 $mNm^2\ g^{-1}$ recorded for the species was low.

The fibre dimensions, chemical analyses and pulp evaluations show that it is possible to produce pulp from *M. cecropiodes* and that there is a need to study its silviculture for plantation development for the species for use as source of pulpwood.

Eucalypts, according to some literature reports, render the soil infertile after some period. This is attributed to the excessive intake of water from the soil which later on renders the soil unsuitable for cultivation of other species. To overcome this and other problems associated with introduction of exotic species emphasis should be placed on local wood species with characteristics similar to our superior to *Eucalypts*. One of such species is *Musanga cecropiodes*. *Musanga cecropiodes* is a tree species which grows in West Africa Central Africa and East Africa and extends to Angola. Its natural growth is very prolific. It is a small to medium -sized tree up to 90 feet high and has a girth of over 6ft at full maturity.

For pulp and paper plantation established species of fast growing species should be considered. Some of the other important characteristics to be considered include:
(i) fast growing species for economic plantation
(ii) longer than average fibre length
(iii) Rynkel ratio less than 1
(iv) average basic density
(v) low extractive content
(vi) higher than average cellulose content
(vii) low lignin content
(viii) suitable hemicellulose content

The features listed above indicate clearly that the anatomy of raw material as well as its chemical composition must be carefully considered in a plywood plantation establishment.

These various features which are the most desirable will depend largely on the product to be manufactured but for all products, long fibres high proportion of fibres in the wood volume, low extractive content, high cellulose content and low lignin are the most valuable characteristics.

Musanga cecropiodes as a tropical hardwood species satisfies most of the features listed and should be encouraged to be used for plantation establishment, especially in developing tropical countries for use as a

Woods from mediterranean and subtropical dry areas: possible uses besides fuel and charcoal

Bernard Thibaut
CIRAD-Forêt, Maison de la technologie, 73, Rue Jean-Francois Breton, BP. 5035, 34032 Montpellier, Cedex 1, France
Tel: 33.4.67.61.44.97, FAX: 33.4.67.61.57.25, Email: bernard.thibaut@cirad.fr

Due both to climatic and human historical reasons, mediterranean and subtropical dry forest ecosystems are today rather poor, with low standing volume per hectare and mostly small diameter trees.

More often the demand in these countries is high both for energy and for wood material dedicated to a lot of domestic uses: tools, furniture, small carpentry, poles, .

Although the information about these woods are few in the classical wood data banks, most of them have interesting basic properties like fine grain, aestetical aspect, high hardness, high natural durability, so they can fit lots of uses for the local communities.

Besides the need for more information on these species, there is also a huge need of specific technology dedicated to small diameter logs.

After a short review of main dry forest species with their specific properties and of today available technologies in sawing or peeling and of today available technologies in sawing or peeling small diameter trees, a possible way of value added wood small industries as by product of fuel wood activity is looked at.

5.06.02 Quality teak timber from plantations

Non-destructive techniques for wood quality assessment of plantation-grown teak

Henri Bailleres, Patrick Y. Durand
CIRAD-Forêt, Maison de la Technologie, 73 rue J.F. Breton BP5035, 34032 Montpellier Cedex 1, France
Tel: +33 4 67 61 44 51, FAX: +33 4 67 61 57 25, Email: Henri.bailleres@cirad.fr

Keywords: *Tectona grandis*: Plantation wood; Quality, Technological properties

Teak (*Tectona grandis* L.f.), because of its outstanding technological properties, is one of the most preferred tropical timber in the world. For this reason and due to the depletion of its natural stands, teak is increasingly coming from plantations of much shorter rotations. It would therefore be of interest to determine whether the wood quality is similar when it comes from natural forests and plantations. After defining the method of wood quality assessment, results from the literature and from the teak wood research programme of CIRAD-Forêt indicate significant between- and within-tree variations in plantation-grown teak.

This need for assessing wood quality of plantation-grown teak has led CIRAD-Forêt to develop its own methodology and non-destructive techniques on standing trees, which are presented hereafter. The methodological options proposed here are specifically focused on teak, taking into account its financial value, its specificity in terms of colour and high oleoresin and chemical extractive content. But, basically, the same methodology could be applied to other plantation tree species, after some key adjustments (e.g.: in spectrocolorimetry or NIR spectroscopy calibration as described hereafter).

A new promising but more sophisticated technique, currently explored by Cirad-Forêt, is presented here, is fully justified by the high market price of teak wood as well as the high investments required for teak plantation establishment and maintenance.

Technology Packages for Quality Wood Products of Teak Plantations: Challenges and Promises for the 21st Century

K. M. Bhat
Kerala Forest Research Institute, Wood Science Division, 680 653 Peechi, India
Tel: +91 487 282037, FAX: +91 487 282249 (Offi) / 282205, Email: kmbhat@kfri.org

Keywords: Sustainable forest management; Tropical hardwood; Industry; Marketing; Regional network

Teak (*Tectona grandis* L.f.) appears to have the greatest potential as a hardwood for sustainable forest management (SFM) in the tropics to meet market demands for quality products in the new millennium. With an estimated area exceeding 3 million ha extending over almost all the tropical countries, teak - the world's most versatile and outstanding timber- accounts for 75% of high quality tropical hardwood plantations. Undoubtedly, it stands to gain as a product from new technologies and has a proven record of being managed successfully to the fastest growing economies. However, the current situation of teak producer countries calls for intervention of more appropriate rather than the traditional technologies in the production-processing-market linkage through research/ technology transfer/ training programmes. Forecasting the future trends in demand-supply, price and marketing system of small dimensional (SD) timber resource of teak plantations is a prerequisite for evolving suitable technology packages for the 21st century.

The challenges of plantation technology for increasing export market include genetic improvement, novel biotechnology as well as high input site management (shorter rotation, fertilisation, irrigation, wide spacing/thinning, pruning, etc.) practices that can modify tree form and wood. The newly developing technology packages should aim at:
- Improved log form (straight cylindrical bole with higher proportion of heartwood and desired dimensions) by minimising timber defects (bole taper, log crookedness, fluting/buttressing, proportion of knots, sapwood, tension wood, etc.)
- desired wood figure (colour, grain, texture)
- more durable and stronger juvenile wood with more uniform distribution of properties.

Optimising technologies to a great variety and combination of situations of producer countries will be another challenge for significant gains in processing (conversion, solar drying and preservation with environmentally acceptable methods) efficiency and utilisation of small dimensional timbers (SD). They also include utilisation of thinnings and SD materials for the manufacture of value-added products such as finger-jointed structures (acceptable to architects and building designers), decorative veneer, panel/composite products, furniture components, handicrafts/ toys/ souvenirs as well as potential new products to meet societal needs. Revisions of grading rules and evolving industrial codes of conduct are necessary for internal quality control and to assure the quality products as labelled commodities of SFM.

The new promises of recent teak wood research programmes include:
- The productivity of short rotation teak plantations is significantly high with mean annual increment of 10-20 m^3/ha.
- Without altering timber strength, plantation managers can now aim at producing larger diameter logs with greater yield (larger cylinder) of naturally durable heartwood per tree by accelerating tree growth with judicious fertiliser application/genetic inputs.
- Teak can produce the timber of optimum strength in relatively short rotations of 21 years.
- Fast growing provenance's/clones of superior genotypes can be selected for teak management without reducing wood specific gravity.
- Wider rings of fast grown teak generally yield higher proportion of more uniform Lakewood with greater percentage of fibres, making the timber more resistant to weathering/biodeterioration.
- Newly emerging processing technologies allow the use of smaller and younger trees.

Effective Regional / international networking, among the newly established institutions such as TEAKNET, IUFRO 5.06.02 (Teak Wood Working Party) and TEAK 2000, is suggested to pool the limited available resources for sharing technology/expertise that would avoid the duplication of wasteful efforts.

Quality Tropical Hardwood Sub-Sector in Crisis

Raymond M. Keogh
TEAK 2000, 27 Loreto Grange, Bray County Wicklow, Ireland
Tel: + 353-1-2864697, FAX: + 353-1-2861188, Email: rmkeogh@teak2000.iol.ie

Keywords: Tropical hardwood; Sustainable Forest Management; Carbon sequestration; TEAK 2000

The greatest challenge of the 21st century is to find ways to achieve sustainable development. This is the wider canvas against which forestry must be viewed in future. To achieve sustainable forestry development it is imperative that the resource we hand on must be able to satisfy the widest range of needs conceivable so that the ability of future generations to meet their own needs is not compromised.

Unfortunately, an aspect of forestry that has been neglected is growing, on a sustainable basis, of quality tropical hardwoods. The paper shows that the sub-sector is far from sustainable - it is in deep crisis. Almost all of the supply of high grade tropical hardwoods originate from deforestation and degradation.

It will be difficult to bring sufficient areas of tropical forests under sustainable management to supply present and future needs. This is partly because management systems in natural forests, designed to supply timber, have had variable levels of successes. Most of these have been abandoned or are only applied on a minor scale. However, natural tropical forests have the potential to sustain, not only the output of timber, but a wide range of goods and services.

The annual allowable timber cut must, therefore, take into consideration the effects on the sustainable output of other goods and services and thus the allowable cut is less than the volume which could be removed if only timber had to be considered. Defining allowable cut, therefore, is a contentious issue and a spectrum of opinions have arisen, depending on viewpoints from a wide range of disciplines. Some conservationists question the wisdom of logging natural tropical forests that are not under immediate threat. Creating conditions for increased access may heighten the risk of destruction.

The level of disagreement around the subject of natural forest management and conservation demonstrates that we are on the slopes of a very steep learning curve and it may be some time before we know whether or not it is possible to manage tropical forests in perpetuity outside traditional methods.

Therefore supplementary sources of sustainable hardwoods will have to be found or extreme shortages are inevitable. Substitution may provide a partial solution but is an admission that a balanced output from forests as a whole is not possible. This is totally counter to most definitions of sustainable forest development. Besides, shortages will put increasing pressure on remaining sources and could lead to further deforestation. Supplementary sources may be developed by creating quality hardwood plantations and these could assist in the shift - in part or whole - from natural harvesting to domestic cultivation.

However, quality hardwood plantations experience considerable disadvantages compared to short rotation, high volume softwood and fast growing broadleaf species.

A solution is to discriminate positively in favour of quality hardwoods. One simple but effective way to achieve this is to allow advanced economies gain carbon credits in developing countries within the Kyoto Protocol, specifically and exclusively for planting quality tropical hardwoods.

A new initiative, TEAK 2000, has been designed to find ways of solving the present crisis in practical ways on the ground.

Fungal decay resistance of Brazilian-grown teak in soil-bed assay

Peter B. Laming, R. Sierra-Alvarez
Wageningen Agricultural University, Division of Wood Science, Sub-Dept. Forestry, Post Box # 324, 6700 Ah Wageningen, Netherlands
Tel: +31 317 478078, FAX: +31 317 483542, Email: peter.laming@hk.bosb.wau.nl

Keywords: *Tectona grandis*; Juvenile wood, Soft rot fungi; Natural durability; Soil exposure.

Teak (*Tectona grandis* L.f.) is one of the world's best known and most valuable timber. Generally, the heartwood of mature teak trees is graded as very durable. As experienced in field tests, teak has high reputation for its resistance to attack by wood-destroying fungi in ground contact.

Being native of South-eastern Asia (India, Myanmar, Thailand) and being planted extensively in many other tropical areas, the existing plantations in Brazil, the Southern part of the state of Mato Grosso near Caceres, are relatively less known. Data on the resistance to fungal decay of teak grown in Latin-America, especially Brazil are very scarce. For different reasons it is important to gain thorough knowledge about the natural durability of the wood from young plantation teak trees.

The natural durability of Brazilian-grown relatively young teak trees was investigated based on the methodology of the modified European pre-standard ENV 807-Test 2 (CEN 1993). The protocol is based on implementation of test procedures under soil-bed test conditions which promote soft rot decay. Mass and static bending (modulus of rupture and Young's modulus) losses were determined at periodical intervals of exposure in the soil-bed.

Material was investigated from three trees: two 22 year-old- and one 14 year-old-teak tree. The tests were conducted on heartwood and sapwood samples. Wood sampling was carried out in such a way that specimens of the same age were drawn from the different logs. By doing so, material was obtained from the real juvenile period of growth of the trees, viz. one age limit was at a few growth rings from the pith; the other age limit is formed by the last growth rings in the sapwood. in the two elder trees, two other sample locations provided material: one from the growth rings situated half-way, and the other in the outer zone of the heartwood. in the younger tree the half-way position in the growth ring was omitted.

The preliminary results demonstrate that teak from the middle West region of Brazil, grown in irregularly distributed trial plots of planted teak trees, shows fungal decay resistance comparable to that of naturally grown material in Asia. These findings enable a good and reliable relevant prognosis on aspects of the natural durability of the teak growing on the neighboring plantations.

The heartwood halfway its width and just bordering the sapwood in 22 year- old teak trees was ranked in the highest durability class (class 1). Heartwood from a younger tree (14 year- old) was also found to display high decay resistance (class 2). Even the first formed heartwood around the pith showed, in all trees, high decay resistance (class 2). To a certain extent it is surprising to record that the sapwood material was ranked in class 3 (moderately resistant to fungal attack). The high durability of Brazilian teak suggests that it can be confidently assigned the practical end-uses under the conditions of exposure involving high risk of fungal attack.

Cytological characteristics of heartwood formation in teak (*Tectona grandis* L. f.)

Todashi Nobuchi, Yuuko Higashikawa, Yusuf. S. Hadi, Wasrin Syafii, Togar L. Tobing
Kyoto University, Faculty of Agriculture, 606-8502 Kyoto, Japan
Email: nobuchi@kais.kyoto-u.ac.jp

Keywords: Heartwood formation, ray parenchyma cell, living wood fiber, starch grain, lipid droplet.

Teak (*Tectona grandis* L.) is one of the popular tree species planted in tropical countries. The characteristics of teak heartwood are considered to be the most significant factors that influence the high grade of wood quality. in this report, therefore, radial changes of cell contents from cambium to pith were cytologically observed. General characteristics relating to heartwood formation such as sapwood width, growth/annual ring, and wood color were also investigated. To understand the waxy nature of wood, chemical experiment was carried out.

Two plantation sites of different meteorological conditions especially of rainfall in Indonesia were selected. The plantations were located in Cepu (Central Java) which has relatively a dry season and Sukabumi (West Java), where precipitation in dry season is rather abundant. The age groups of sampled trees included 5, 25, and 80 years in Cepu while they were 21, 26, 36 years in Sukabumi. After felling, disks were collected from two different positions of the tree trunk representing tree base and clear bole height. One part of the radial strips in a disk was fixed with 3% glutaraldehyde for the cytological observations. Radial sections cut using sliding microtome were stained with Sudan IV, Nile blue for lipid droplets and I2KI for starch grains. Part of small wood blocks was embedded in Epoxy resin for the investigation especially of "living wood fiber". Transverse sections were also prepared to investigate growth/annual ring structure. The color of sapwood and heartwood was measured by a colorimeter (Nippon Denshoku Co. Ltd.). Wood powder was extracted with chloroform-methanol to evaluate the total amount of lipids.

Sapwood widths remained more or less constant in two vertical positions of the tree trunk in both the plantation sites. Except for the young 5-year-old trees, the sapwood widths remained almost same at the lower part of the trunk in all selected age groups of the trees. in the cytological observation, ray and axial parenchyma cells in the outer part of sapwood showed greater amount of starch grains as a reserve substance. To the direction of inner sapwood the amount of starch grains decreased. Coupled with the decrease of starch grains, lipid droplets gradually increased towards heartwood region. in addition to parenchyma cells, wood fibers contained both starch grains and lipid droplets in the sapwood. These fibers were considered to be "living wood fibers". in the heartwood, ray and axial parenchyma cells as well as fibers showed no trace of starch grains. The amount of lipid droplets, on the other hand, was higher in the heartwood. Between the two plantation sites, there were no significant differences in cytological features.

Chloroform-methanol extractives showed about 5 and 8% of extractive content in sapwood and heartwood respectively. Lipids were found as the major components of the extractives, which appeared to be responsible for the waxy nature of teak wood. The samples from Cepu showed more distinct growth ring boundaries than those collected from Sukabumi. The former had large sized pores as characteristics of "ring porous wood". The growth ring structure had the influence of rainfall in each site. From the measurements of a*, b*, L*, it was clarified that sample from Cepu had more yellowish brown heartwood while that from Sukabumi had dark brown color.

Based on the above results, the characteristics of heartwood were discussed in relation to wood formation in teak.

Growth Stresses and Some Wood Quality Attributes in Planted Teak

Takashi Okuyama, H.Yamamoto, I. Wahyudi, Y.S. Hadi and K.M.Bhat
Nagoya University, School of Agricultural Sciences, 464-8601 Nagoya, Japan

Keywords: Teak; Growth rate; Wood quality; Growth stress; Girdling

The tropical man-made forest has been recognized to achieve the global environmental stability by way of carbon sink as well as by the sustainable supply of forest resources. Increase in the teak forest aiming at timber production rises the value of tropical man-made forest and realizes the above objectives. Natural old-growth teak is widely accepted as a high grade timber because of its desired colour and luster, moderate wood density, high dimensional stability and good processing properties. However the trade of natural teak is being prohibited with some exceptions. in order to promote timber production in fast growing teak plantations, assessment on the qualities of planted teak in relation to the growth conditions is important to maximize the potential of the trees by genetic improvement as well as silvicultural control.

This paper discusses some of the results of our on-going research program that aims to elucidate the relationship between growth rate of planted teak and the wood qualities including growth stress. in addition, the effects of girdling treatment on the qualities of teak were investigated as well. Released strain caused by growth stresses was measured in teak stands in Central Java in Indonesia while some wood properties were compared between the plantations of Indonesia and India.

- Annual increment in diameter as taken from the count of growth rings showed that the diameter increased linearly up to 30 years. The diameter range of 30-year-old plantation grown trees was 30-50 cm in India in contrast to 15-25 cm for the same age stands of mountain sites in Indonesia. Teak from India with a dbh range of 45-88 cm at 60 years still continued its growth, while that in Indonesia of 16-34 cm dbh at 38 years did not show decline in growth.

- The relationship between the heartwood ratio (HR%) and the stem radius (R cm) is represented by two linear lines. For the younger stands with less than 10 cm dbh the value is HR = 9.2R while HR = 0.31 R + 84.0 was obtained for the older stands of 38-65 years with a radius of greater than 10 cm. That is, the heartwood ratio rapidly increases to 90% at the diameter of 15-20 cm during younger age.

- The density increased towards the bark by 5-6 cm from pith and then stabilized at the age 10 -12 years. On the other hand, the microfibril angle decreased towards bark until 10-12 years. From these observations, it is expected that the planted teak matures around 10-12 years. The density of 5-year-old fertilized teak in India was greater than the non-fertilized ones in spite of a faster increase in diameter in the former.

5.07.00 Energy and chemicals from forest biomass

Bioenergy production potential from Australia's forests, its contribution to greenhouse targets and developments in conversion

Paul Fung, M.U.F. Kirschbaum, R.J. Raison and C. Stucley
CSIRO Forestry and Forest Products, Private Bag 10, Clayton South MDC, 3169 Vic, Australia
Tel: +61-3-95452222, FAX: +613 9545 2448, Email: Paul.Fung@ffp.csiro.au

Australia is highly dependent on fossil fuels for energy. Under the Kyoto Protocol, Australia was one of only three industrialised nations allowed to increase its greenhouse emissions by 2010 to 108% of 1990 emissions. This represents a major reduction as estimates for "business as usual" suggest emissions would rise to 128% of 1990 net emissions. The Australian Government has announced various measures to reduce Australia's emissions to meet the agreed Kyoto target. One initiative is a mandatory target for electricity retailers to source an additional 2% of electricity from renewables by 2010. With limited opportunities to expand other renewable sources, namely wind and hydro-power, and with technological and cost limitations on photovoltaics, wood has a potential to make an important contribution to both renewable energy supply and greenhouse gas mitigation by sequestering carbon in the wood of living trees. Energy from wood can be greenhouse neutral. Australia's consumption of energy was about 3,000 petajoules annually (PJ/y) producing carbon dioxide emissions of 275 million tonnes (Mt/y).

Of the 23 million cubic metres (Mm^3) of wood harvested from Australia's forests in 1996, the production of wood products, accounted for 15 Mm^3. The remaining residual wood of some 8 Mm^3 would be a potential source of bioenergy. There are also more than 3 Mm^3 of harvesting residues in the form of defective stems and branches which could be recovered. Significant areas of native vegetation are still being cleared from woodlands for conversion to grazing or cropping. The amount of unutilised wood was measured at 38 Mt (dry). in addition, there is on-going clearing of regrowth as part of normal grazing, which provides further resources. There are also opportunities to expand thinning programs in commercial forests to improve the quality of the growing stock to produce bioenergy from the young wood. These opportunities have not yet been quantified. Another major forest biomass resource, currently unquantified, is forest litter consisting of branches, twigs, leaves and bark. The quantity of this material is large and very rough preliminary estimates put it as high as 90 Mt (DW) yr^{-1}. When this material accumulates on the forest floor it can become a forest fire hazard. Even excluding forest litter and potential thinnings, the combined available bioenergy resources have a primary energy potential of 870 PJ/y of which 97 PJ/y is currently being used for energy purposes for domestic heating, cooking and industrial energy applications. The uncommitted wood could potentially supply 26% of Australia's primary energy needs.

New plantations are offering opportunities for carbon sinks and already, this has spawned a fledgling market for carbon futures trading. There is a national vision to treble the area of plantations to 3 Mha by the year 2020 - much of this will be private farm forestry for multiple benefits including greenhouse gas mitigation. Some of this wood could be used for bioenergy, and such markets could facilitate forest expansion. With expected growth rates for new plantations averaging 20 m^3/ha/y, this is equivalent to sequestration of about 20 t/ha/y of carbon dioxide. Thus one million ha of plantation could potentially sequester 7% of the national annual carbon dioxide emission.

To convert wood to energy, there are a number of technologies available or under development. These are classed into combustion, carbonisation, gasification and liquid fuels. Technologies in combustion are well developed using packed bed, fluidised bed and suspension combustion systems. Small to large systems are commercially available for home heating of several kW to large-scale industrial boilers up to 60 MW for process heat or power generation through a conventional steam cycle. Technology for charcoal making is mainly based on primitive, low-cost batch kilns that are labour intensive where cheap labour is available. Large-scale mechanised systems are used where there is a large production of wood feedstocks. in one efficient system the volatiles of carbonisation are burnt to recover energy for process heating and power generation. Gasification technologies have been commercially developed for heat production. Small-scale gasification technology is under development that should offer efficient electricity generation. Gas turbines are providing prospects of high efficiency. There is some interest in ethanol production by cellulose hydrolysis in Australia. Fast pyrolysis has been the centre of development attention in Europe to produce pyrolysis oil to run boilers and even diesel power plants. Some activity in this area is also commencing in Australia for chemicals.

With the availability of a large biofuel resource and emerging technology to make efficient use of it, wood as biofuel has enormous potential to contribute to Australia's energy supply and reduce net Greenhouse gas emissions.

The Use of Fuelwood for Energy in Rural Areas

Hoi Why Kong
Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, FAX: +603-6367753, Email: hoiwk@frim.gov.my

Fuelwood such as rubber (*Hevea brasiliensis*) is the dominant source of energy for many rural industries in Malaysia. Almost 85% of the energy source for numerous medium-scale industries such as for the smoking of rubbersheets, curing of tobacco leaves, firing of bricks and the drying of foodstuff comes from fuelwood. This paper therefore attempts to highlight some of the problems faced by these industries such as the lack of technical and scientific knowledge to improve existing energy conversion systems and the availability of fuelwood at competitive prices. It also focuses on the role of R & D institutions towards overcoming these problems through better process heat production such as gasification and improved heat exchanger systems. Special attention is focused on ways to reduce the specific fuelwood consumption (SFC) through better drying regime, better insulation technique and improved front furnace control. The technical and economic appropriateness of these measures in terms of combined energy savings and pay-back period for one of the system is discussed.

Public Perceptions to Wood in Energy Production - Does the Environment Matter?

Ritva Toivonen, Liisa Tahvanainen
Pellervo Economic Research Institute (PTT), Eerikinkatu 28, FIN-00180 Helsinki, Finland
Tel: +358-(0)9-3488844, FAX: +358-(0)9-34888500, Email: ritva.toivonen@ptt.fi

The Kyoto Agreement and energy related atmospheric emissions have been among the main topics in international environmental discussion lately. Common understanding is that emissions need to be reduced in order to preserve the environment. It can be assumed that consumers' interest towards bioenergy has increased due to the general concern about environment. But only a minor share of consumers are willing to pay a price premium for environmental product characteristics, and there is limited knowledge about other factors influencing the potential demand of bioenergy, such as consumers attitudes and interest toward bioenergy. This information is, however, of vital importance for promotion and thus development of bioenergy markets.

This study is conducted to describe consumers opinions and expectations related with energy, in particular wood based bioenergy, in Finland. The data for the study was collected in late spring 1997 through a mail survey to 1 200 households in three regions in Finland: an urban region in Southern Finland, and a small town and a rural municipality in Eastern Finland. A structured questionnaire was used, and 400 questionnaires were sent to each region. Response rate was 44 % and thus the data consisted of 524 accepted answers of consumers of age between 18 to 70. The data was analysed using multivariate statistical methods: factor analysis and discriminant analysis.

The results show that Finnish consumers emphasise safety as one of the most important characteristics in energy production. On average, consumers preferred that solar energy, wind power and wood based energy should be increased in Finland's energy supply in the future.

Consumers' demographic background seems to be linked with different energy attitudes. Persons being in high decisive roles in the society emphasise low priced energy as necessary for economic growth but they emphasise environment less than others. in contrast, high education and living in urban area seemed to be connected with more than average concern on environment. Female and young consumers were the most willing to reduce their standard of living and compromise the general economic growth in order to reduce harmful environmental impacts of energy production. Low energy price and continuing use of fossil fuels or nuclear power were seen necessary for economic growth most often by male and relatively aged consumers and those in high professional positions.

Consumers in rural areas regarded domesticity and low price somewhat more important in energy choices than consumers in urban areas.

Overall, price seems to be a very important criteria in consumers' energy choices. But most consumers assume that they would change to use "green" electricity if this would be available without extra cost in comparison to other alternatives. About half of respondents think that they would choose "green" electricity also if the price is a few percents above other alternatives.

Even though the results of this study are limited to three regions in Finland, it can be assumed that Finnish consumers, on average, would like to see increasing use of biofuels in energy production, and a few might even pay a small premium in energy price for this. But probably increase in price competitiveness is still needed before bioenergy production grows in large scale. However, environment can be expected to matter in energy choices: Bioenergy may reach considerable market share as soon as it becomes fairly price competitive and is available for the majority of consumers. Currently there may be special market segments for bioenergy even with some price premium. The general preference of renewable energy sources gives also a reason to assume that consumers might support society's investments in bioenergy.

5.07.01 Fundamentals of wood carbonization

Effluent gas analysis as a tool for studying wood carbonisation processes

M. A. Connor, D. C. Shallcross
University of Melbourne, Department of Chemical Engineering, Vic. 3052 Parkville, Australia
Tel: +61-3-83446631, FAX: +61 3 9344 4153, Email: m.connor@chemeng.unimelb.edu.au

Wood carbonisation, or charcoal-making, is an ancient process. Historically, its main use was in the recovery of metals from their ores. This remains its most important use today; however, charcoal also finds widespread use as an urban fuel and in specialised applications such as silicon metal production.

Charcoal is produced by a variety of techniques. The efficiency with which these convert wood into charcoal varies widely. The most efficient approach would appear to be thermal decomposition under pressure, a technique developed recently at the University of Hawaii. Retorts are also comparatively efficient. However, both these approaches require a level of technical sophistication beyond the reach of many small to medium scale charcoal producers. For these producers, kilns are likely to remain the predominant means of charcoal production.

Whilst some of the smaller kilns are decidedly inefficient, some of the more established designs perform quite well. Undoubtedly the present designs of such kilns and current operating practices are the result of much hard won practical experience and a good deal of on-site research and development work. However, it now appears as if further gains in efficiency are most likely to come from a better understanding of carbonisation process fundamentals. These fundamentals, as they relate to a charcoal kiln, can be divided into two groups. There are the microscale processes, or the processes that occur within or adjacent to individual wood pieces. Then there are the macroscale processes, i.e. the fluid flow, heat and mass transfer and reaction processes that occur in and around the stack of wood as it slowly decomposes into charcoal.

There has been considerable research undertaken into the processes occurring within individual wood pieces during carbonisation. Since these normally occur in the absence of air, methods for the study of these pyrolytic decomposition processes usually involve maintaining the wood pieces under study in an inert gas environment. Following the process of decomposition is usually done by thermogravimetry, which has the disadvantage that it sheds little light on the chemical changes occurring in the wood. It is possible to study the off-gases from the pyrolytic decomposition process using sophisticated instrumentation employing one or more mass spectrometers. Such instruments provide a wealth of information but the costs are high.

An alternative and more affordable effluent gas analysis approach is being tested at the University of Melbourne. in this approach, a mixture of sand and the material under study is heated at a constant rate in a controlled flow of some oxidising gas, usually dry air. The O_2, CO_2 and CO content of the effluent gas is measured. Experience to date has shown that the levels of these components exhibit peaks and troughs that appear closely related to the decomposition peaks identified using thermogravimetry. in addition, information can be obtained on the rate of evolution of carbon and other elements at different stages along the heating process. With the addition of instrumentation to measure the moisture content of the exit gases, the above technique should yield quite detailed information on the types of chemical changes occurring at different points along the decomposition pathway.

To date this technique has been used solely to obtain information on the processes that occur within individual decomposing particles. However, the conditions in the reactor where the wood or other biomass is heated have a number of similarities to conditions in the wood stack of a charcoal kiln during the preliminary heating stage, when air is being admitted. It would seem possible that the effluent gas analysis technique can be used to obtain information related to this phase of charcoal kiln operation, and the prospects for doing this are examined.

Keywords: Analysis; carbonisation; charcoal; gas; pyrolysis; wood.

Energetic valorisation of wood wastes and by-products by staged pyrolysis

W. Quirino, A. Donnot, E. Mougel, A. Zoulalian
Université Henri Poincare - Nancy I, LERMAB - Equipe Genie des Procedes, BP 239 Vandoeuvre les Nancy, 54506 Nancy, France
Tel: 33.383.91.20.57, FAX: 33.383.91.21.02, Email: zoulalia@lermab.u-nancy.fr

New European regulations will forbid the disposal of wood wastes (waste wood from demolition, framing, packing, pallets, etc.) or wood processing wastes (particleboards, wood composites, varnished and painted woods, etc.). in these wastes wood is associated with other, different materials (glues, paints, preservatives, paper, etc.). Their recycling is not always feasible and presently the preferred method for their disposal is energetic valorisation. This last option can be achieved in two ways, by direct combustion or by pyrolysis in the absence of oxygen; both approaches yield a solid and a gas phase, both fuels.

The direct combustion route produces a large volume of hot flue gas containing not only the main products of wood combustion (CO_2, H2O) but also several undesirable pollutants such as nitrogen oxides (NO_x), volatile organic compounds, and volatile metals (mercury, lead, etc.). The most recent European Community accord on environmental preservation requires that the combustion gases should be treated before their release to the atmosphere. The volume of gas to be treated is significant but it can be decreased if the energetic valorisation process is split into two or more stages.

For several complex wood wastes, the thermal degradation of the materials present in association with the wood (urea-formaldehyde resin, polyurethane varnish, etc.) takes place at temperatures different from the ones at which wood constituents degrade. So, by operating at temperatures between 250°C and 280°C, it was possible to achieve substantial degradation of the urea-formaldehyde resin (53%), while at the same temperature level only 20% of the wood was degraded. As the volume of gases produced at this temperature level is limited (30% of the total possible), treatment of these gases to remove pollutants is economically more feasible. Moreover, the solid residue obtained is practically free of polluting elements. Similar approaches have been used for two other wood additives, polyurethane varnish and preservatives based on chrome, copper and arsenic salts.

In this paper only the pyrolysis of wood wastes associated with UF resin is considered. The optimal conditions for their treatment by pyrolysis are given, specifying the compositions of the gas phase and the solid residues. After that, the pyrolysis stages are modelled in order to get relevant kinetic models that can be used to design an industrial pyrolytic unit.

Destructive distillation of wood

Ernesto O. Sanabria, José Paz
Universidad Nacional del Nord Este, Comandante Fernandez No 755, 3700 Chaco Pcia. Roque Saenz Pena, Argentina
FAX: +54 - 3732 - 420137, Email: josepaz@fai.unne.edu.ar

Keywords: Distillation of wood; *Aspidosperma quebracho-blanco*; Pyrolysis; Charcoal; Fixed carbon

The charcoal that is produced in the Province of Chaco, Argentina comes mainly from wastes from sawmills and carpenter's shops. This charcoal is made from different species such as: *Aspidosperma quebracho-blanco, Schinopsis balansae, Astronium balansae, Patagonula americana, Prosopis sp*, etc.

The species *Aspidosperma quebracho-blanco* is the most abundant in the region of Parque Chaqueno and the charcoal, which comes from it, is the best paid in the market. The production of charcoal from this species is made in typical kilns, like the ones used in the building industry, with a charcoal yield of an approximately 25 % and a fixed carbon content of 74 %, both percentages on a dry basis.

Because of the above mentioned, the purpose of this paper is to propose a more efficient alternative for the use *Aspidosperma quebracho-blanco*, namely producing charcoal by destructive distillation.

To do so, charcoal was produced from *Aspidosperma quebracho-blanco* through destructive distillation. This raw material, which came from waste from sawmills of the whole province, was processed in a Destructive Distillation Pilot Plant which has a vertical retort, with enough room for 50 kg of wood, with indirect heating; an air condenser and a cross-current water one, a multiple temperature meter connected to a thermocouple type "K".

The destructive distillations were made according to a Central Composites Design for heating rate between 60 °C/h and 120 °C/h and final carbonisation temperature between 450°C and 550 °C.

The wastes used for the destructive distillation and the charcoal obtained from it were analysed under specific Argentine Institute of Material Rationalisation (IRAM) standards.

The results obtained show a charcoal yield of approximately a 48 % by weight and a fixed carbon yield of greater than 82 %, both calculated on a dry basis. To sum up, the charcoal yield, on a dry basis, produced from wastes by destructive distillation of the species *Aspidosperma quebracho-blanco* is enlarged in a 49 % as regards the typical kilns, operating at a heating rate of 60 °C/h and with a final carbonisation temperature of 450 °C. The fixed carbon yield, on a dry basis, achieved through dry distillation of wood wastes under conditions leading to greatest weight yield, was 83,9%. This is 13 % greater than the corresponding figure for conventional kilns.

5.08.00 Production and utilization of bamboo and related species. Challenges for the new millenium

Increasing the Service Life of Bamboo

Rajamoney Gnanaharan
Kerala Forest Research Institute, 680 653 Peechi, India
Tel: +91 487 78 2037, FAX: +91 487 78 2249, Email: libkfri@md2.vsnl.net.in

Bamboo is one of the fastest growing plants in the plant kingdom. Bamboo clumps can be established in 5-6 years from the time of planting. Culms reach maturity in about three years. Once the clumps are established mature culms can be harvested every year. Bamboo, because of the fibrous root system, is well-known for its soil binding property. The potential of eco-friendly bamboo for various applications is now being realized throughout the world. Unlike some timbers which are naturally durable because of the presence of toxic chemicals, any species of bamboo is naturally non-durable. in South and Southeast Asian countries, where bamboo grows naturally there is a 'bamboo culture'. Bamboo is referred as 'poor man's timber' and for centuries has been meeting the society's need for low value products like mats, baskets, agricultural implements, constructional material (scaffolding, rafters), etc. Most of these products could afford to be replaced after a short use. However, to ensure sustainable availability of bamboo resource to meet the society's needs, the service life of bamboo should be increased. Whether bamboo is used as 'poor man's timber' or as value-added products for various applications like furniture, building components like flooring, trusses, etc., treatment with preservative chemicals becomes essential.

Depending on moisture condition of bamboo (in green or air-dry); hazard condition of application (in ground contact, out-of-ground contact exposed or under cover); method of treatment (pressure or non-pressure) and type of material (in round form, split form or slivers), different preservative chemicals are suggested. This paper reviews critically the advantages and disadvantages of the different treatment techniques available (like sap displacement, steeping, hot-and-cold, pressure impregnation, etc.) and the different preservative chemicals (coal tar creosote, copper-chrome-arsenate, boric acid, sodium pentachloro phenoxide, etc). Also, the traditional methods evolved in different bamboo using countries for providing protection to bamboo are also critically reviewed.

Bamboo as a housing material

Jules J.A. Janssen
Eindhoven University of Technology, B/CO, P.O. box 513, NL 5600 Eindhoven, Netherlands
Tel: +31.40. 247 29 48, FAX: +31.40.243 85 75, Email: J.J.A.Janssen@bwk.tue.nl

Bamboo has been a valuable material for housing for centuries. The tradition shows many good examples how people could solve their own need for housing and other type of building. Unfortunately also many examples can be seen of short durability, lack of resistance to disasters, etc. Here results of applied scientific research and good engineering practice can improve the use of bamboo towards a proper engineering material with a status equal to recognised materials like steel, concrete, brickwork and timber. Local traditional knowledge is limited to the region of origin; this knowledge cannot be transferred to a different region or climate. A knowledge based system as a decision support during the design process can improve this considerably. Standardisation of test methods can improve the level of testing in local laboratories, and can allow the comparison of test results from all over the world. Next to such an international standard, a manual with simple and clear explanations about how to do tests can be a great help for laboratory staff. For engineers and architects, national building codes are lacking with respect to bamboo as a building material. An international model for national building codes might be helpful. The said documents will be treated in the paper, as well as simple handbooks for field practitioners.

Self help will remain very important in housing, not only to save costs but also to be sure about the involvement of the future inhabitants. This self help can be supported with a balanced aid by prefabricated and industrialised housing systems. Evidently, joints are the key problem, but a considerable progress can be seen. in modern bamboo housing, not only full bamboo culms are being used, but also sawn or split bamboo strips, and panels made of bamboo. Roofs mainly are supported by trusses, in which field considerable development towards good engineering applications will be reported.

Houses have to be resistant against disasters like earthquakes and hurricanes. Applied scientific research has made good progress; evaluation reports made after disasters give also guidelines for improvement. Emergency shelter, or prefabricated or by self help, is also an aspect of bamboo housing related to disasters. The paper will highlight the said items.

China Bamboo Industry: Comparison Study on Socio-economics, Marketing and Policy in Some Main Production Areas

Fu Maoyi, Yang Xiaosheng, Zhong Maogong, R. Manuel Perez, B. Belcher and Liu Can
Research Institute of Subtropical Forestry, CAF, 73# Daqiao Road, 31400 Fuyang Zhejiang, China
Tel: 0086-571-3310001, FAX: 0086-571-3341304, Email: risf@fyptt.zjpta.net.cn

China bamboo industry is now contributing USD 1.5 billion annually to its economy development. For its clear understanding and further development in the region and the world, a cooperative project among two Chinese institutions, CIFOR and INBAR was laid out recently. From east coast to south-west marginal areas of China, totally 500 farmer families, 69 factories and 77 traders, which are located in 6 main bamboo production counties with various levels of intensive management for bamboos, have been surveyed. Based on data assessment and analyses, the production-to-consumption system has been made, the partaking main bodies in bamboo sector and their systems, major running departments and their interests/conflicts with the partaking main bodies and the running mechanism of activities have also been identified. It is found that bamboo sector is really important to farmer's and county's economy in all main production areas, particularly to the potential target groups such as poverty rural people and disadvantaged group, for the income from which can occupy more than 60% of their total family incomes. The socio-economic environment of bamboo sector's development, such as policy, marketing mechanism and scientific technology, is described, from which both problems/constraints and potential/opportunities faced to the local farmer, factory manager, trader and government officer are

identified and discussed. Finally, the main measures which could overcome those problems and constrains for leading to sustainable bamboo sector are put forward for discussion.

Bamboo Aesthetics: New Dimensions of Form and Function

Raja Fuziah, Bte Raja Tun Uda
Crafts Council of Malaysia, c/o B-12/2 Jalan Selaman 1, 68000 Ampang, Malaysia
Tel: +6 03 4703145, FAX: +6 03 4703146, Email: sariayu@po.jaring.my

Bamboo Aesthetics: New Dimensions of Form and Function introduces a brief historical glimpse of the rich tradition of bamboo craftsmanship in Malaysia and in the region. It describes how bamboo, as an indigenous raw material, has had an immense impact on the economic, social and cultural life of the community, the artisans and the craft industry. It also highlights the influence of bamboo on the development of concepts and design issues related to the world of interior design and its imaginative and creative application and usage in the design of living spaces of modern homes and institutions. To illustrate this, a special collection of images (slides) will be presented to illustrate the variety and diversity of its form and function that has evolved in the last hundred years. It would include the use of bamboo as a traditional and contemporary product.

The paper will also discuss the areas of concern and issues relating to bamboo as a material, the use of technology and tools, design development and socio-cultural factors that have contributed to this process. More importantly, the primary concern is to focus on the plan for the future use of bamboo: to explore how bamboo as a vital source of indigenous raw material to the craft industry could be sustained: to ascertain how efforts in research and development, product development, promotion and marketing of bamboo products could be further enhanced.

Finally, in the context of the spirit of cooperation, it would be essential to explore and determine a strategy, direction and methodology which could foster regional as well as international collaboration for the development of bamboo for the future. In this context, what programmes, initiatives and incentives for example, should be developed to encourage a greater effort in tapping the potential usage of bamboo within the next five years. Suggestions will be offered with a view to develop specific proposals and recommendations at this discussion of international gathering.

Bamboo as raw material for wood processing in Europe

Joris van Acker, de Vos, Joris, De Guyter, Sigrid and Stevens, Marc
SHR Timber Research, Wildekamp 1c, NL-6704 AT Wageningen, Netherlands
Tel: +31-317-425422, FAX: +31-317-425783, Email: shr@bart.nl

Bamboos are endemic in all parts of the world except in Europe where they did not survive the last glacial period. The most northern natural distribution limit is the North of China, corresponding to the latitude of south of Europe. Since the first introduction of Bamboo in Europe (1827), about 400 different genotypes have been imported. The actual annual production of bamboo plants in Europe is estimated in millions units nearly exclusively for ornamental purposes. Europe is technologically more advanced in areas like micro-propagation and the selection of superior genotypes of bamboo. The bamboo plant producers envisage at long term the industrial transformation of bamboo.

Co-ordinated by the industry a group of research institutes and universities have been working on the evaluation of bamboo as a large-scale crop to be used as alternative raw material for wood processing industry in Europe. Some 10 different bamboo species, mainly of the genus *Phyllostachys* were selected and evaluated on their production and adaptation parameters in plantations representative for western and southern Europe. From additional research work on harvesting techniques and corresponding crop management systems it seemed that bamboo has potential as an alternative crop for the agricultural sector in Europe.

Growing bamboo, taking into account the European economic structures, is however not feasible without major industrial applications. Within the framework of the research project called 'Bamboo for Europe' financed by the European Commission both production criteria and market potential were taken into consideration. The goal of this project was to consider the use of bamboo as alternative raw material to wood however without changing wood processing. It is generally accepted that at this moment no industry in Europe will invest in processing techniques specific for bamboo. Furthermore labour costs in Europe do not allow input of extra manpower in production processes.

Different industrial uses were considered, tested and evaluated. The possibilities for large-scale utilisation of bamboo as additional or alternative raw material for the wood processing industry range from low quality commodities to highly developed

engineered products. The main areas for potential use in industrial wood processing techniques in Europe are particleboard, medium density fibreboard and laminated products. Although several production problems needed to be solved and some limitation have to be taken into account, it can be stated that the wood processing technology can use bamboo. The successful introduction of bamboo in Europe as alternative crop for the agricultural sector will need the additional support from European policy makers. The result of this research proves however that the forest sector could well profit from an alliance with the agricultural sector in producing additional high quality lignocellulosic raw material.

Properties of Exterior Grade Particleboard from Bamboo: Influence of Age, Particle Size and Wax Addition

Jalaluddin Harun, Jamaludin Kasim, Abd Latif Mohmod & Mohd Nor Yusof
University PUTRA Malaysia (UPM), Faculty of Forestry, Serdang, 43400 UPM, Selangor, Malaysia
Tel: 603-9486101 ext 2411, FAX: 603-9483745, Email: Jalal@forr.upm.edu.my

In the study of exterior grade particleboard from bamboo, homogenous and three-layered METLAmine urea-formaldehyde particleboards were produced. For the homogenous board, the effect of age was found to affect the board properties significantly but since the differences between actual mean values were rather small, it can be assumed that the particles from any age group are suitable for particleboard manufacture. The increase in resin content was observed to be accompanied by a significant increase in the mechanical strength, reduction in water absorption and thickness swelling properties. By varying the particle sizes, the mechanical and physical properties behaved significantly different. Wax used significantly increased the water resistance but reduced the mechanical properties. For the three-layered particleboard, the mechanical properties and dimensional stability of the sample were found to decrease with the increment of core particle sizes. Wax addition, on the other hand, increased the board stability towards water exposure but decreased the mechanical characteristics. Comparison between homogenous and the three-layered board were also discussed in this paper.

Bamboo Silvicultural Theory and Practice in China - Review and Prospect

Yiping Lou, Xiao Jianghua, Fu Maoyi, & Sheng Weitong
International Network for Bamboo and Rattan, Natural Resources and Ecological Applications, Branch Box 155, P. O. Box 9799, 100101 Beijing, China

China has a long tradition of cultivating bamboo resources and using the resources as materials for housing, tools, furniture, pulping, medicines, and foods. in China modern cultivation theory and technical practices started in late of 1950's. Based on the research progress in bamboo atonomy, resource inventory and zoning, biology, physiology, and ecology, a systematic bamboo silviculture has been developed, which includes theory and technology of bamboo seedling propagation, afforestation and high-yielding cultivation and management obviously characterized by Chinese features. These bamboo silvicultural theory and technology have greatly promoted resource cultivation and management, in which bamboo productivity has been greatly raised. The achievements and development of silvicultural theories and practices in China are unique in forest silviculture in the world. of the bamboo silvicultural theory and technology, the high-yielding cultivation theory and technology to improve stand productivity is a very important component. Based on the research findings in experimental trials in comparison between technical practices, the technical prescriptions on control of bamboo community structure and soil management have been developed. From late of 1950's to 1970's, the theoretical research and practices were concentrated on improvement techniques for low-yielding stands aiming at raising productivity of low-yielding natural bamboo forests, in which the techniques progressed and were implemented slowly. in 1980's, a high-yielding cultivation technical system, to achieve high-yielding products in edible shoots and timbers, have largely progressed and been implemented in extension practices. in 1990's, a high-yielding technical system on high-yielding, good-quality, high-benefits with oriented cultivation goals and techniques, in terms of principles of forest management by categories, have been developed and implemented in a large scale, in which bamboo forests are managed in 13 types of 4 categories such as timber-producing stands, shoot-producing stands, ecological maintenance stands, as well as landscaping and reservation stands, to exploit the potential of bamboo forests in economic, ecological and social benefits.

By the brief review of the bamboo silvicultural theory and technical practices in the past 40 years in China, it is found that there are many limitations in existing silvicultural theory and technology and some important issues should be addressed to meet the increasingly demand for bamboo resources and ecologically sustainable management in the coming new century.

Firstly, the limitations exit in theoretical foundation of forming present high-yielding cultivation techniques, which are mainly characterized by lack of understanding of the unique mechanism on bamboo self-crowed generation and propagation and bamboo physiological integrity in culm-rhizome systems in synthesis, consumption, transportation, and storage of nutrients and physiological matters, which results in lack of control mechanism of bamboo stand productivity. The future research should aim at simulating and modeling physio-ecological process to control productivity process at a mechanic level. Secondly, the existing techniques have a poor capacity to control productivity process-based at quantitative level. As a fact, existing techniques were based on the experimental trials, which lacks of modeling and controlling management techniques based on growth and yield simulating models with emphasis on quantitative relation in/between well-organized rhizome-culm systems. The future research should aim at simulating and modeling dynamic growth and yield and management models reflecting the impacts of management practices. Thirdly, there is no quantitative site evaluation and classification and the evaluation of capacity and potential for bamboo forests which has no secondary meristem growth in diameter and height once they matured in relative short months. The future research in this aspect should aim at matching site with management practices for specific management-oriented goals. Fourthly, future research should aim at the maintenance of long-term site productivity to overcome the negative impacts of existing silvicultural practices on sustainable site productivity and to rehabilitate degraded site. Fifthly, the existing silvicultural practices produce some negative impacts on the function of conserving water and soil of bamboo forests. The future research should aim at develop a technical system to a achieve harmoniously the economic, ecological and social benefits from managed bamboo forests.

Studies On Fertilizer Requirement of Culm Cuttings, Seedlings and Cultivated Stands of Bamboo (*Dendrocalamus hamiltonii* L. Munro)

Harsh Nayyar
COA, Himachal Pradesh Agricultural University,
Department of Agroforestry & Environment, 176 062
Palampur, India
FAX: 91-1894-30511, Email: atul@hpkv.hp.nic.in

DendroCalamus hamiltonii L.Munro is a versatile bamboo of Hilly state of India, Himachal Pradesh. The planting material is a major limitation in its rapid multiplication and plantation. Organised nurseries and plantations are extremely rare hence awareness in their management is lacking which restricts the potential bamboo productivity in the State which otherwise has least area under bamboo plantation among other States of India. We are involved in raising its planting material through various vegetative methods and supplying the same to foresters. An organised plantation has also been raised in about 25 ha of wasteland, which acts as a source of resource material for its further propagation. in separate experiments, fertilizer requirements of juvenile culm cuttings, transplanted saplings, seedlings and cultivated stands of local bamboo "Maggar" were investigated to improve its productivity. Single nodal juvenile cuttings (I-year old) of uniform size (5.0 cm) and age were planted in March in the field in 3 replications in a field plot size of 1.0m x 0.30m. Nitrogen as urea was applied in different doses viz. 3.0(N1),6.0(N_2),9.0(N3) and 12.0g(N4) per culm cutting in combination with 5.0(P1) and 10.0 g (P2) of phosphorous as single super phosphate(SSP). Nitrogen was applied as half dose during planting and another half at rhizogenesis stage. SSP was applied as single dose at the time of planting. The days to sprouting of these cuttings was reduced by all the treatments over the control but the reduction was most significant with N2P2, N2P1, N3P1, N3P2, N4P1 and N4P2 treatments. These treatments were, however, insignificantly different from each other. Days to rooting was significantly reduced over the control by N1P2, N2P2, N2P1, N3P1, N3P2, N4P1 and N4P2treatments. Out of these treatments, N3P2 was most observed to be most effective. The days to rhizogenesis were reduced significantly over the control by N3P1, N3P2, N4P1 and N4P2 treatments and N3P2 was found to be most effective among these. The differences among these were, however, insignificant.The rooting % was increased significantly over the control by N2P1, N3P1, N3P2, N4P1 and N4P2 treatments. N3P2 and N4P2 caused maximum rooting among all the treatments though the differences between them were insignificant.Though all the treatments increased the sprouting % but the increase was non-significant. N1P1 was particularly effective but the difference from the control and other treatments was insignificant.A significant increase in survival % over the control was observed with N3P2, N4P1 and N4P2 treatments while other treatments resulted in insignificant increase in survival %.The saplings generated from cuttings were transplanted in the field in subsequent year in March and fertilizer doses were applied as Farm yard manure @ 5 Kg/pit/sapling(T1), FYM+15 g N+10g P+5g (T2), FYM+30 g N+20g P+10g K(T3), FYM+45 g N+30g P+15g K(T4), FYM+60 g N+40g P+20g K(T5).A significant increase in tiller height was observed over the control with T3, T4 and T5 treatments with T3 as the most effective one. T3, T4 and T5 resulted in significant increase in internode length over the control. T3 caused maximum and significant increase among these treatments. T4 resulted in a significant increase in the no. of tillers over the control. Adult clumps of uniform age and dimensions were selected for the experiment and fertilizer doses were applied as Farm yard manure 10 Kg/Clump (T1) FYM+100 g N+ 50 g P+25g K (T2), FYM+200 g N+100 g P+50 g K (T3), FYM+300 g N+150 g P+75 g K (T4). A significant increase in the production of new culms was observed with T4 over the control while other treatments caused a non significant increase over the control. Internode length and culm height were increased significantly by application of T4 in comparison to control. A significant increase in culm girth was observed with T2 over the control while the other treatments caused a non significant increase. The no. of nodes was increased significantly over the control by application of T2, T3 and T4. Among these T4 was observed to be the most effective treatment.

5.09.00 Tree ring analysis

Dendroecology of *Fagus grandifolia* var. *mexicana*, a beech species growing in an extinct volcano in Mexico

Margaret Devall, Guadalupe Williams-Linera
USDA Forest Service, Center for Bottomland Hardwood Research, P.O. Box 227, MS 38776 Stoneville, USA
Tel: 601/686-3161, FAX: 601/686-3195, Email: mdevall/srs_stoneville@fs.fed.us

Fagus grandiflora var. mexicana has a very restricted distribution in the montane cloud forests of Mexico. It occurs in five small stands in addition to the population we studied, which is the southernmost *Fagus* forest in the world, at Acatlan in the state of Veracruz. This stand is inside the crater of a volcano with a conical shape and very steep slopes. On the rim and inside the volcano, *Fagus* is the only canopy species, while it is codominant with *Quercus* spp. on the edge of the crater. Few saplings are present in the forest, but seedlings occur. The volcano is in a valley that is almost completely deforested; even the flanks of the volcano have been converted into cornfields and pastures.

We collected cores from the *Fagus* population at Acatlan. We prepared the cores using standard dendrochronological techniques and developed mean chronologies for the cores from the crater, top and rim of the volcano. We examined the individual chronologies for periods of suppression and release. We analyzed the chronology from the crater with temperature and precipitation data from nearby Xalapa, Veracruz, recorded since 1920. We screened all possible climate models by computing least-squares regressions of the standardized chronology against all the climate variables, and then fitted climate models to the beech chronology. We also collected seedlings, counted their bud scars, then cut several disks from the base of each one and counted the rings.

The oldest core from the crater dated to 1877. The oldest trees were growing in the crater, and it appears that the beech trees spread from the top to the rim of the volcano. The cores were taken at DBH so the trees are likely older than our samples. The seedlings we collected were 16-46 cm in height and had as many as 13 rings and bud scars. Current February mean temperature and February and July precipitation of the previous year were the best predictors of growth of the *Fagus* population in the crater, but the variation explained in the chronology was only 16% ($R2=0.16$, $p.=0.006$). Similar results have been obtained by other researchers for *Fagus* spp. in other parts of the world. Apparently growth of beech is affected more by other factors than by variation in precipitation and temperature. The individual chronologies showed that the trees experienced long periods of unrestrained growth with fewer periods of suppression than *Fagus* spp. that have been studied in other areas.

We will discuss the arrival, establishment and permanence of *Fagus* in the volcano. We will consider periods of growth and suppression in the individual chronologies, and the factors that influence ringwidth of the trees. We will compare growth of trees in this population with that of other *Fagus* populations.

Interregional comparison of long-term growth variability, growth responses and growth controlling climatic forcings in Finland using millennial chronologies of Scots pine

Markus Lindholm, Matti Eronen, Mauri Timonen, Jouko Meriläinen
Saima Centre for Environmental Sciences, Linnank. 11, FIN-57130 Savonlinna, Finland
Tel: +358-15-575 9856, Email: markus.lindholm@joensuu.fi

The number of tree-ring chronologies built in Finland is increasing as research interest is spreading from the open canopies of the northern forest limit to the closed and more complicated stand structures of the south. We have built ring-width chronologies of Scots pine for the northern and southern parts of the boreal forest belt, covering the last 7500 and 1300 years respectively. The present work focuses on long, high-resolution climatic proxies during the Holocene. These records provide *e.g.* an indication of natural, pre-anthropogenic climate variability, either singly at specific geographical locations or in combination on continental and perhaps even hemispheric scales. We have applied means of measuring the strength of the common 'signal' both within and between the two millennial chronologies. in addition we have estimated chronology reliability, as Expressed Population Signal, and as a function of time. Overall correlation between the two chronologies, over the last millennia, is 0.32, and significant at the 0.01 level, when both chronologies were standardised the same way, using 67 % n splines. The present work shows evidence that a common climatic forcing influences the northern and southern pine stands. Interestingly, the signals show opposite features as well, which is evidence for growth inversions, caused possibly by climatic inversions. During some periods, growth conditions seem to have been favorable in the south, while they have been unfavorable in the north.

Using various response function approaches, we have confirmed that growing season temperatures govern the growth rates of northern pines. We have also demonstrated that towards south, tree-growth becomes less effected by temperatures, and more effected by *e.g.* precipitation. Going from the north to the south, the variability of radial growth clearly decreases, and the variance of ring-width series becomes smaller.

The spectral densities of the northern and southern chronologies were also compared as functions of frequency, viz. cycles per year. Very generally, there is more periodic behaviour in the north than in the south in high, medium, as well as lower frequencies. in the north there are concentrations of variance clearly evident corresponding roughly to periods of 2.5, 3, 4, 11, and over 33 years. in the south the peaks in spectral density occur at about 3.3, 5, and 10 years. A most remarkable feature of the two chronologies is their remarkable spectral dissimilarity. However, the two chronologies vary similarly around several pointer years, *e.g.* 1050, 1075, 1210, 1350, 1395, 1550, 1770, and 1840.

The periodicity of growth of tropical trees for dendrochronological studies: the genus *Cedrela*

Mario Tomazello, Paulo Cesar Botosso, Claudio Sergio Lisi
Universidade de St. Paulo, Departamento de Ciencias Florestais, ESALQ, St. Paulo, Brazil
Email: mtomazel@carpa.ciagri.usp.br

The genus *Cedrela* is constituted by 7 species widely distributed in the tropical and subtropical american forests. Three of them occur in Brazil: *C. odorata*, the amazonian forest's cedar; *C. fissilis*, the dry land forest's cedar and *C. angustifolia*, the atlantic forest's cedar. Among the tropical genera, *Cedrela* is potentially one of the most important for dendrochronological studies.

In the present paper, some aspects related to the growth periodicity of these species and *C. lilloi*, which occurs in Argentina, are discussed with emphasis in research done in America Latina. Results refering to the phenological rhythm (leaf fall and flush, flowering and fruiting), seasonality of cambial activity by dendrometer measurements and cambial marking are shown and related to climatic conditions, mainly rainfall. Descriptions on the microscopic wood structure of these species of *Cedrela* are also presented. The appearance and nature of the growth rings show distinct and well-defined annual growth rings, which are delimited by a thick band of initial parenchyma partly including the wide earlywood vessels forming a semi-ring-porous probably arised in the beginning of rainy season. The X-ray densitometry analysis of the intra and inter growth ring density variations normally showed that the minimum density values were coincident with the initial parenchyma bands, marking precisely the growth ring boundary. The growth ring analysis on cross section of the disc taken from the base of the trunk allowed the dating and growth rate determination of *Cedrela odorata* trees.

Dendroclimatic network throughout Russia

E. A. Vaganov
Institute of Forest, Siberian Branch, Russian Academy of Sciences, 660036 Krasnoyarsk, Russia
FAX: (3912) 433686, Email: evag@ifor.krasnoyarsk.su

There are several main purposes of establishing dendroclimatic network over whole Siberia: 1)creating of dense net of sites to design the long tree-ring width and density chronologies for analysis of tree growth response to climate change at local, regional and global scales; 2)quantitative reconstruction of temperature and precipitation variation in different parts of Siberia based on tree-rings and dendroclimatic zonation of territory; 3)using statistical and simulation models which describe the relations between tree growth and climate in evaluation of net primary productivity of wood component of ecosystem and carbon budget both at regional and global levels; 4)comparison of supra-long temperature variations during several last millennia of the Holocene inferred from tree-rings with other indirect indicators of temperature change; 5)to extract the tree growth response due to anthropogenic changes from natural ones.

Dendrochronological material was collected from more than 240 sites in Siberia. The densest network covered the Subarctic (64 sites), Middle Siberia (Enisey meridian)(52 sites), Altai mountains (22 sites), steppe zone in Buryatia (18 sites), the region around Lake Baikal (28 sites). The oldest living trees (*Larix cajanderi*) which own age reaches 850-880 years were found in the low part of the Indigirka river. Most of the tree-ring chronologies based on living trees has a length between 300 and 850 years. For some remarkable sites with abundant dead and subfossil wood the chronologies with length more than 2000 years were built. These sites are located in subarctic region (lowland of the Taz and Indigirka rivers, Eastern Taymir) and in timberline of the Altay mountains. in addition to tree-ring width the tracheid radial size and wood density chronologies were measured which allows to analyse the tree growth response to climate change with high resolution in time (seasonal, monthly).

In Subarctic the main climatic factor affecting radial tree growth is the early summer temperature. The synchrony of the year-to-year tree-ring variations in different parts of Subarctic was used for dendroclimatic zonation of subarctic belt and 6 subdivisions were revealed with common interannual variations of summer temperature anomalies. Analysis of supra-long chronologies clearly shows the coherence of long-term temperature and tree growth changes in different parts of Siberian Subarctic. That long-term change agrees well with temperature changes in the northern hemisphere inferred from other indirect sources (as for example, from Greenland ice cores) and shows the constant appearance of cycles with 180, 76-78, 22 and 11 years length. For instance, tree growth increases during the Medieval Warm Period (900-1200 A.D.) as well as in the middle of the current century.

At a regional level there is a regularity in tree growth response to climate along the temperature gradient from northern timberline to steppe zone in Middle Siberia. Limiting effect of the early summer temperature in northern taiga is replaced by effect of winter precipitation (negative) and June temperature in middle taiga, and spring precipitation (positive) and early summer temperature (negative) in the forest-steppe transition zone. But the conditions at the beginning and in the first part of a season (soil moisture and temperature) play the key role for annual radial tree growth and wood productivity along the meridional transect. This conclusion was also tested using statistical and simulation models. The high relationship between limiting factors and tree growth allows to reconstruct summer temperature, winter or spring precipitation based on regional tree-ring chronologies. The reconstructions reveal weak positive trend in summer temperature in Subarctic during the last century and clear decreasing summer temperature and increasing winter precipitation in the middle taiga of Central Siberia. If such trends relate with documented warming in the northern hemisphere it means that at the regional scale climate changes show their own regularities and tree growth responds to regional combination of temperature and moisture more than to the global trends.

Dendrochronological data are used to evaluate the long-term basal area increment of trees in different parts of Siberia. Only in Subarctic the long-term changes of basal area increment correlate well with the northern hemisphere temperature, but in the more southern areas of Siberian taiga they do not. So, in the first approximation the annual primary productivity of wood component of forest ecosystem doesn’t increase due to global warming trend but depends more on regional changes of temperature and precipitation. The same results were obtained from the reconstructed fire history in different taiga zones using absolutely dated fire scars and tree-ring chronologies. in the northern taiga the fire frequency agrees well with summer temperature changes (similarly both at the regional and global scale), but in the middle taiga the fire frequency is determined more by moisture changes and during the last several centuries completely disagree with northern hemisphere temperature changes. The ways how tree-ring data use in carbon cycle models of forest ecosystems are discussed.

How useful are wood anatomical features in tree-ring analyses?

Rupert Wimmer
University of Agricultural Sciences, Institute of Botany, Gregor Mendelstrasse 33, A-1180 Vienna, Austria
Email: Wimmer@mail.boku.ac.at

The most frequently used variable in tree-ring studies is ring width, including that of the earlywood and latewood separately, as well as the relative proportions of the two zones. Other studies include tracheid dimensions in softwoods or vessel size and arrangement in hardwoods. Wood density profiles have been frequently measured in softwoods and also in hardwoods. Most studies consider usually a narrow selection of tree ring features rather than comparative studies using a large set of features; this research, however, includes 16 anatomical parameters measured in dated tree ring series from twenty spruce trees from the Eastern Ore Mountains, Germany. .The purpose was to show differences in climate sensitivity inferred from the tree rings features, as well as possible effects of features upon wood properties.

Ring width and latewood proportion did not show significance relationships to monthly climatic data, whereas maximum density, latewood cell wall percentage in latewood density both were highly correlated to temperature and precipitation. The climatic signals expressed in resin duct density, ray height, tracheid length and microfibrillar angles were less pronounced and therefore only of limited importance. of 16 tree ring parameters, densitometry - as an indirect measure of xylem anatomy - seems to have the greatest potential to indicate climatic conditions.

5.10.00 Forest products marketing

Environmental activity and timber certification in marketing of forest products

Jari Kärnä and H. Juslin
University of Helsinki, Department of Forest Economics, Post Box # 24, FIN-00014 Helsinki, Finland
Tel: +358 9 1917736, FAX: +358 9 1917729, Email: jari.karna@helsinki.fi

Keywords: Environmental marketing, Timber certification, Marketing of forest products

Environmental and social concerns in the society will set new challenges for companies. in this new age of environmental consumerism, products are being evaluated not only on performance or price, but on the social responsibility of manufacturers. This may create strategic marketing opportunities for manufacturers who can demonstrate strong environmental performance. However, marketers may feel unsure how environmental issues should be integrated into traditional marketing. One specific and currently topical issue for forestry industry is the potential of timber certification as tool of environmental marketing. Implementation of timber certification could be considered as an example of marketing function that could be a reflection from environmentally oriented strategic decisions.

The purpose of the study is to describe and compare how environmental issues are emphasised in the marketing planning of European forest related industry. The countries surveyed are Finland, Germany, Sweden and the UK. Theoretically, the concept of environmental marketing was examined.

The cross-sectional data for the study was collected by using standardised personal interviews with sample size ca.100 in all countries. The Finnish, German and UK data was conducted in 1997 in the context of an EC-FAIR research project on potential of timber certification. Equivalent data from Sweden was collected in autumn 1998 in order to get another big European producer of forest products for comparison. The industries / marketing channels surveyed were the following: Pulp and paper industry, Sawmills and panels, Joinery and other secondary wood processing, Marketing channel intermediaries, and Paper buyers. A special measure instrument was constructed by using multivariate methods to assess environmental activity of the industries of each country. The summated scale was done by focusing how environmental issues are emphasised in three hierarchical decision levels of marketing: strategic, structural and functional level. The validity of the scale was tested by examining its relationship with the importance of timber certification in marketing. Thus, the potential of timber certification as a marketing tool was assessed.

Most of the European forest industries are relatively well prepared for integrating environmental issues in their marketing. Environmental issues are central in the marketing strategies of the European forest industries. On the other hand, it must be said that they are not the most central ones. Integrating environmental issues in marketing planning is not a genuine proactive strategic decision. The industry has been forced to do it. The development of integrating environmental issues into marketing planning could be even deeper if genuine environmental responsibility is regarded important.

The companies also regard timber certification as a necessary tool for marketing of forest products. The results show that the level of environmental activity varies between countries and industry sectors. Finland seems to be the country where environmental issues are emphasised most in marketing of forest products. in the UK these issues were emphasised less than in the other countries. From the industry sectors, pulp and paper industry seems to be the most active in environmental issues. Generally, two thirds of the forest industries in all countries thought that a widely used certification system is needed. However, German forest industry had most reservations towards certification. Regarding the importance of certification as marketing tool, the level of greenness of the companies seems to have significantly more explanatory power compared to the background factors such as country or industry sector. The more environmentally active the companies are the more important marketing tool they regard certification.

The Development of an Effective Marketing Communications Network for Successful Technology Transfer: An Empirical Study Based on the Diffusion of Portable Timber Bridge Technology

Robert Smith, Ren-Jye Shiau
Virginia Tech, Department of Wood Science and Forest Products, 1650 Ramble Road, 24061 Blacksburg, VA, USA
Tel: 540-231-9759, FAX: 540-231-8868, Email: bobsmith24061@yahoo.com

Keywords: IUFRO; Technology transfer; Communication channels; Timber bridges, and Marketing

The ability to use scientific or engineering advances (new technologies) to meet market needs has become a primary business success factor. New technology is also a major factor influencing growth and productivity within a firm. However, the forces that lead to technological innovation are not always from within. Often a company receives technology push from outside sources. However, the transfer process is not always smooth. Public sector research represents an important source of technology. in the major Western industrial countries, government and university research organizations account for over 40 percent of the national research and development (R&D) expenditures. However, many technology transfer efforts between public (federal government) and private sectors have been disappointing.

Like all businesses, government organizations buy, sell, provide, and deliver ideas, services, and goods. Government organizations today face limited funding and personnel. But they must grapple with growing needs for their services. Public organizations often find it necessary to seek help from other organizations and individuals to achieve their objectives. in the case of diffusion of government-sponsored innovations, it is challenging to find parties who can facilitate technology transfer, and once the parties are identified, elicit the necessary assistance from them. Numerous research efforts have been conducted on the technology transfer efforts between government-sponsored innovation and private sectors. However when researchers try to gain an understanding of the efforts, they primarily look for end-results and tend to neglect the information flows and communication processes that lead to these results.

The Wood in Transportation Program, USDA Forest Service, has put considerable effort in transferring timber bridge technology to the private sector. However, much of these efforts have focused upon permanent timber bridge structures for highways or pedestrian use. Another potential large market may exist for portable timber bridges for use in forestry and logging operations. and little research has been conducted on how to facilitate technology transfer to the target users (loggers).

The main goal of this study was to evaluate information flow through the entire communication channel to logging operations and identify key intermediaries who can help the USDA Forest Service - WIT Program facilitate effective technology transfer. This study utilized a unique backward-trace method to gain an understanding of how innovations (portable timber bridge technology) are diffused. The research consisted of the following steps to attain the final goal of developing strategies to successfully diffuse portable timber bridge technology from public research sectors to private sectors. First, the research evaluated how the end-users (loggers) receive information, why they prefer certain channel(s) to others, and how they make decisions to use or not use technology from developers (WIT). Second, the intermediaries were identified by loggers and were evaluated on how they receive information from technology developers; how they evaluate the information; how they currently promote; and diffuse ideas or innovations. Finally, the technology developers were evaluated on how they currently promote and diffuse ideas or innovations. Upon analysis of the network of information flows, a strategic marketing plan for successful transfer of portable timber bridge technology was developed.

Method For Forecasting Demand and Profitability of Wood Products On Market - Wood Product Analysis

Jussi Virtanen
Helsinki University of Technology, Laboratory of Wood Technology, Post Box # 5100, 02015 Helsinki, Finland
Tel: +35894514268, FAX: +358-9-4514277, Email: Jussi.Virtanen@hut.fi

Keywords: wood, wood products, demand, demand analysis, profitability, profitablity analysis, forecasting, forecasting demand, quality, quality estimation, price, price estimation

The research aims at developing a method for forecasting wood product specifications, amounts, qualites, and prices.

The method opens an opportunity to analyze profitability, competitiveness, and strategic position on market for wood products, e.g windows, doors, and other wood construction products. The method enables reseach scientists and companies to estimate future's wood product volumes, product specifications as well as to create products' price estimates. The method combines product's technical specifications and market factors related to product competitiveness. This kind of wood product analysis model has never before been developed. The goal for this research project is closely linked with total goal of adding value for products of wood industry.

In the first phase we have chosen a group of wood products and created a method of definition for all needed product properties. The choice of the wood products is based on the specific needs of the wood product industry as well as the computer model the wood product analysis is closely linked with. The wood product analysis covers a wide range of products of solid wood, engineered wood as well as products of pulp and paper industries. However, in the first phase we have studied products like windows, doors, various glued wood products, panels and different components of wood housing products. The method for wood product analysis has been created with a perspective of gaining advantage of computer optimization modelling and economical analysis, which are closely linked with this area of research. For instance a process of designing new wood products for a new customer group will sig-nificantly benefit of this kind of method.

In the second phase we have collected detailed source information of various wood products for the analysis. This started with a litterature analysis, databases as well as material given by research organisations and companies. Besides we collect information by interviews from product and market areas, which are essential for wood product competitiveness.

In the third phase we develop a method for forecasting wood product specifications, amounts, qualites, and prices. The use of this method combines product qualities, costs, volumes, and other factors related to product competitiveness. Likewise this method can be used in a new way to seek new value added products or product specifications for a company. This forecasting method for instance helps a company or other user of this method to define a potential position for a wood product on markets, which opens a new information decision level for wood product development and investments.

The Internet: Implications for Business Practices in the Forest Products Industry

Richard Vlosky, Rene, Fontenot, Lydia Blalock
Louisiana State University, School of Forestry, Wildlife, and Fisheries, Rm. 227, LA 70803 Baton Rouge, USA
Tel: (225) 388-4527, FAX: (225) 388-4251, Email: vlosky@lsu.edu

Keywords: Internet, forest products, eBusiness, North America

eBusiness is the application of Internet-based technologies for conducting business. eBusiness offers revolutionary tools for business development and management. Through the Internet, many barriers that were once roadblocks to new markets, resources and competitive positioning can be reduced or even eliminated. in addition, the Internet levels the playing field by allowing small companies to be as visible and accessible as the largest companies. Although businesses vary greatly, along with their depth of participation on the Internet, their goals are often the same: to find new customers; new sources of profit; and new ways of doing business in a global marketplace. Technology, while important, is not the limiting factor in eBusiness. What is difficult is managing the changes in business strategies and internal corporate processes that must take place for a company to take advantage of eBusiness.

eBusiness was studied in the context of the forest products industry in the United States and Canada. One thousand solid wood products and 300 pulp and paper companies were surveyed. The sample frames included the top 100 companies (by production volume) in each sector (solid wood products, pulp and paper). The remaining companies sampled were randomly selected from the population.

Overall, respondents were asked to discuss their current or planned eBusiness strategies and the impacts that have on dealings with customers and suppliers. Specifically, the study objectives were to: Examine the current and future uses of eBusiness in the industry and to identify how the forest products industry is investing in and leveraging eBusiness.

Mail questionnaires were used to conduct the study. A list of questions was generated for the survey instrument drawing from constructs and measures developed by the researcher in previous studies or adapted from other sources. The survey was reviewed and revised by the researcher, a pre-testing sample of five companies and the research client. An iterative process resulted in the final instrument.

Results indicate that 40 percent of respondent companies are conducting some type of eBusiness. Implementation of eBusiness by respondents has taken place in the recent past. Nearly ninety percent of respondents developed eBusiness in the past three years. Earlier implementation (before 1996) was done by larger companies, typically lead adopters of technology. The primary reason respondents implemented eBusiness was as part of an overall corporate strategy (mean of 3.5 on a 5-point Likert scale of agreement). These technologies are well-planned activities that are meshed into the corporate fabric as opposed to being independent or non-integrated. Second, and the only other reason ranked above neutral (3.0 on the 5-point scale), was the goal of retaining customers. Respondents registered a number of general concerns they have about conducting eBusiness with concern about security of information ranking highest.

Companies seek products, processes, and technologies that add value to their offerings in an effort to become or remain competitive in the marketplace. Firms that consistently deliver superior benefits are highly valued by business partners. This also helps to establish, develop and maintain strong relationships. eBusiness is one means for developing such a competitive advantage.

Spontaneous occurrence of sago palms (*Metroxylon*) in the swamp forests of Papua New Guinea has created vast reserves of this natural resource in the country. The world's largest contiguous swamps and forests of sago palms are found in Papua New Guinea. These forests cover an estimated area of one million hectares spread over different provinces. The people of Papua New Guinea consider sago socially important as they use it extensively on special occasions, rituals and feasts. It constitutes a staple food and an essential building material. Sago forms the backbone of rural economies in many provinces. There are numerous ways in which sago palm has become a part of people's daily life. Unfortunately, forestry literature of this country often lacks mention of sago palm as a resource.

There are five species under the genus *Metroxylon*, of which two occur in PNG. *M. Sagu* is found on the main land and *M. Solomonense* grows on the Bougainville and Solomon Islands. Both species vary considerably in general characteristics as well as growth habit. Locals consider *M. Solomonense* a better yielding species that is easier to work with. While the paper discusses the biological and ecological differences between the two species, it also highlights some reasons why there has been no effort to cultivate *M. Solomonense* on the mainland.
