Sago is a tree of tropical low lands with high irradiance and humidity, and an average temperature of 26oC. Its natural distribution is confined to SE Asia and nearby Pacific Islands. Aerial and ground surveys conducted in Papua New Guinea show that sago palms grow here till 1200m above sea level. As sago palms grow on a range of soils that vary from the land inundated with water most of the year to drier and less flood prone areas, vegetation types in which they grow vary accordingly. The paper makes an effort to provide a description of these vegetation types. It also discusses the effect of traditional social forestry practices on the distribution of sago palms.

Sago is a staple food in Papua New Guinea, yet its cultivation is not a common practice. The ease with which it grows in the forests of PNG enables the people to meet most of the daily needs of palms from the wild. Locals have planted some palm trees in the past but left them unattended after planting. These so-called cultivated areas acquire a wild appearance after a few years.

Cultivation of this kind has been motivated by either scarcity or the need to bring palms closer to dwelling areas. in order to benefit the large populations living in other remote locations, cultivation of sago needs to be spread to other swamplands and potential sites. To them sago can provide a good supplement towards food and a better substitute to kunai grass or coconut thatch for constructional purposes.

Finally the paper concludes that sago is a vital resource for people of Papua New Guinea. Sago palm as such may not be contributing to the cash economy of the country, but its significance in the subsistence economy can't be ruled out. At present, sago palms are in abundance in the forests of PNG and not much attention has been paid towards its management. However with increasing population, demand for sago palm is steadily rising. Therefore it becomes necessary to develop sustainable management systems for sago palms that will not only rehabilitate some of the unproductive swamps but will provide a sustained supply of sago in many years to come.

Marketing of Non-Timber Forest Products: A Key to Conserve Natural Tropical Forests?

Michel Becker, Antonia Engel
University of Freiburg, Institute of Forest Policy, Markets and Marketing Section, Freiburg, Germany
FAX: 62 251 622100, Email: w.de-jong@cgiar.org

Expanded and improved commercialisation of non-timber forest products (NTFP) will increase cash incomes of rural households in tropical countries, thereby motivating local actors to conserve forests through sustainable management. This expectation has recurrently been raised by environmentalists and development professionals over the past 15 years. But does the very nature of NTFP markets and marketing underpin this expectation? This paper reviews the main features of NTFP markets and marketing based on experiences made in the past and current market trends. Particular attention is given to the role of rural households in the marketing chain and how their economic position could be strengthened.

Notwithstanding the scarcity and erratic nature of global NTFP data, there is evidence that NTFP represent an impressive economic asset in many tropical countries. The overall value of NTFP extracted from tropical forests is estimated at US$ 90 billion per year. The trade in the 150 most significant NTFP alone amounts to around US$ 11 billion per year, with the major part being exported from tropical countries to the northern hemisphere.

Nevertheless, some researchers question the viability of NTFP economies. They conclude from experiences made with individual NTFP traded on international markets, such as rubber or rattan: once NTFP become high value goods in international trade they are believed to suffer from economic pressure to overexploit the resource base, or face competition from plantation products or cheaper substitutes. Thus, it would only be a matter of time until NTFP from natural forests lose their market shares and, consequently, plant extractive economies would disappear.

It may be doubted that substitute-induced market collapse is a distinctive feature of NTFP markets. That products become obsolete should rather be viewed as a typical feature of any commodity traded on whatever market. Marketing and related policies typically aim to extend the life cycle of products and to prevent substitution. If this challenge has not been met in the past concerning important tropical NTFP, this may be understood as a consequence of lacking marketing strategies and poor resource management rather than being a distinctive feature of NTFP markets. It should also be borne in mind that reported examples for substitute-induced market collapse primarily concern international markets while there are numerous examples of NTFP which long have been sold successfully on local and national markets despite the modern substitutes available. Even on international markets declining demand for certain NTFP must not be conclusive, as consumer preferences may shift back to products that had lost significant market shares in the past.

There is evidence that negative examples of extractive economies primarily result from the lack of even basic marketing strategies. This is partly due to low accessibility of adequate market information, in particular as regards demand for NTFP traded on international markets. in addition, actors on NTFP markets face uncertainty when land tenure is vague and, hence, NTFP are open access resources. The development of medium-term marketing strategies is further hampered by the at times ephemeral nature of consumer preferences, poor post-harvest treatment, lacking processing facilities to meet consumer needs, and low investments in customer relations.

At the very beginning of many NTFP marketing chains are rural households. When involved in the mere collection of NTFPs, they typically receive a nominal portion of the final sales price. Their bargaining power tends to be weak and, worse, the poorest among them may be deprived of lucrative NTFP resources by external forces. To change this situation, improved marketing alone is insufficient. Providing extractors with the control over NTFP resources and acknowledging the crucial role NTFP play in rural economies is also indispensable when rural households are to be empowered. Based on such general pre-requisites, specific steps to develop NTFP marketing in favour of rural communities are to be made , *e.g.* encouraging co-operative processing and sale, introducing appropriate market information systems, and promoting the access to promising segments of national or international markets through preferential chains.

Management and production of NTFP and the commercialisation/conservation proposition

Bruce Campbell, Wil de Jong
University of Zimbabwe, Institute of Environmental Studies, Center for International Forestry Research, Harare, Zimbabwe
Email: w.de-jong@cgiar.org

Central in much of the discussion on NTFPs is the proposition that their commercialisation will lead to biodiversity conservation. This proposition has several problems. The theory of the historical cycle of extractive economies predicts that when a NTFP becomes demanded widely, this eventually will lead to its cultivation or the production of substitutes. in addition agricultural transformation theory predicts a diminishing role of NTFP extraction when rural economies expand.

This paper is based on research on local forest management among Dayak farmers, and ribere¤o farmers in Peru and extensive literature review. It concludes that when NTFPs become economically more important, swidden agriculturists who rely on the forest for an important part of their livelihood needs, will produce NTFP through some kind of forest management. As a result, managed forests are common in among many swidden agriculturists. These forests often maintain important levels of species diversity and structure, sometimes similar to the natural forest that they replace. If some NTFPs become the major source of income, intensified production may develop. This will lead to changes in local land use, with consequent impacts on the cover, structure, and floristic composition of the forest. However, in some case this may lead to an increase in forest cover, rather than the opposite.

These findings justify speculations on alternative development options such as estate crop development, as currently is taking place. Oil palm, for instance, originally an NTFP, is currently a prominent plantation crop in Sumatra and Kalimantan, the two largest islands of Indonesia. Especially when local incomes are considered the most important, NTFP development may lead to smallholder production with much less impact on biodiversity, carbon storage, and other environmental features.

These findings suggest that the commercialisation-conservation proposition needs to be broadened to account for changes as described in this paper. Natural forest conservation as opposed to converting for agricultural use is only one effect of NTFP commercialisation. This effect can be expected to occur only under a limited number of circumstances. in other cases, NTFP can be commercialised in a way that it can be produced by smallholders and become an alternative for large-scale estate development. Such NTFP development will also have a beneficial effect on biodiversity and other environmental functions of the forest landscape.

NTFPs and rural poverty alleviation: the economics of scepticism

William Cavendish
Imperial College-Royal School of Mines, T.H.Huxley School, London, United Kingdom
Email: w.de-jong@cgiar.org

Non-timber forest products (NTFPs) have been embraced by the international community as a means of simultaneously promoting the economic development of poor, rural households and of conserving forests and woodlands. This paper uses the perspective of household economic analysis and data results from various sources to suggest that much of this enthusiasm is misplaced.

First, there is nothing special about NTFPs from the perspective of rural households. They are simply goods and services with particular economic characteristics, and their use can only be explained with reference to the constrained economic choices faced by most rural households. The typical rural household is extremely poor; faces very high transactions costs of trading in formal markets and therefore extensive formal market failure thanks to a poor infrastructure; faces considerable production risk against which it is hard to insure; has only partially monetised economic activities; has low levels of education; and has low levels of financial and physical capital.

There is much evidence that poor, rural households rely heavily on NTFPs for economic goods and services, so that these resources are a critical - though often hidden - source of welfare for rural households. However, this heavy reliance on NTFPs is a function of the poverty and economic constraints of rural households rather than free choice. Indeed, it is the economic characteristics of NTFPs that makes them attractive to poor households. NTFPs are usually derived from commons areas and are collected and consumed rather than purchased with cash; as open access goods they are low value and can be consumed by the poor; NTFPs are collected using unskilled labour, in which rural households are abundant; NTFP processing requires low levels of education and physical capital; and NTFP use can help offset production risk. So NTFP economic characteristics match the economic constraints of the rural poor.

In consequence, there will be many problems associated with the commercialisation of NTFPs to drive rural socio-economic development. in particular, there is little evidence that as households get richer they still wish to consume most NTFPs. Most NTFPs are inferior goods so that demand will fall as incomes rise. There are considerable problems overcoming the high transactions costs of trading in NTFPs and the lack of storage facilities for perishable goods. If an NTFP is commercialised, high demand levels have led in the past to rapid extinction of the resource, especially where held under open access, and can trigger the process of resource privatisation. Higher prices for NTFPs will also trigger investment in domestification or the search for technical substitutes.

Non-wood Tree Biomass - a Raw Material of Coming Century

Mauris Daugavietis
Latvian Forest Research Institute "Silava", Rigas str. 111, LV-2169 Salaspils, Latvia
FAX: +(371) 7 901359, Email: maris@silava.lv

The commercial stem wood harvesting is a dominant method of forest utilization today. The utilization of knot wood and small sized items from thinnings for energy is developed only in countries with intensive forest management.

The forest biomass studies show that 5-20 % of tree biomass is a tree foliage (succulent tissues or living part of tree biomass) - i.e., leaves, needles, twigs, flowers, nonlignified shoots, called "loging residues" today. A lot of investigations show a great concentration of biologically active substances and nutritions in the tree foliage and possibilities to utilize it as a raw material for animal feed (mainly broadleave foliage) and for obtaining hight quality natural substances for pharmacy, cosmetics, food industry and other branches of economy (mainly coniferous and some specific broadleave species foliage). The another non-wood part of tree - bark also content many usable substances. A large number of such natural substances urgently needed for insuring of peoples and animals vitality, but we can't obtine its by modern technologies of synthesis. The many of them is founded only in the tree foliage, for example different terpenes, polyprenols a.o., but not founded in agricultural crops and other flora.

The genetic older gymnospermous species contain more specific biologically active substances to compare with angiospermous trees. The risk to decrease the forest productivity by tree foliage removal from forest area simultaneously with final cutting is minimal for boreal forests. The harvesting of tree foliage may be done on the basis of modern tree harvesting technology and technic using in forest industry, for example, "green chips technology" and other. The environmental friendly technologies for tree foliage processing and obtaining more than 30 commercial products are elaborated and tested. The new profitable product lines for replacing synthetic substances in pharmacy, food industry, pesticide industry, fodder and other branches of economy are tested, the market of natural substances is rapidly growing. The most popular today is different solid extracts form tree foliage on the basis of polar and nonpolar solvents as well as concentrates or pure compounds obtained from extracts. The present knowledges about tree foliage and bark chemical composition of *Pinus*, *Abies*, *Pices*, *Betula*, *Ginko*, *Eucaliptus* and other species is a good basis for development of utilization but for many species we need additional investigations. The expierence of different countries show that utilization of non-wood tree biomass, mainly tree foliage, will become a very important part of forest economy, especially in the agroforestry, forest plantations and boreal coniferous forests in the early of 21st century.

A comparison of theories on institution relevant to non-timber forest products development

Wil de Jong
Center for International Forestry Research, P.O. Box 6596 JKPWB, 10065 Jakarta, Indonesia
Tel: 62-251-622622, FAX: 62-251-622100, Email: w.de-jong@cgiar.org

Besides the resource base and markets the institutional environment in which NTFP are collected or produced is of crucial importance for any successful exploitation. Institutions are understood here as property rights, rules of conduct, more formalised regulations and laws, in short instruments that condition behaviour in the economic and social sphere, but also the organisational structures that govern resource use. This paper compares five important theories that relate to institutional issues in the NTFP under situations where NTFP based development is an option to understand their scoop and compatibility, and to understand under which circumstances the framework of a particular theory is the more appropriate one for analysis. These theories are: new institutionalism; common property theory; political ecology theory; new social movements theory; social capital theory.

New Institutionalism theory explains the historical processes of institutions to reduce transaction costs, and so to optimise economic gain for society at large. Common Property theory takes a specific case of tenure, namely common property and explains under what conditions common property will emerge and are viable. On the other hand Political Ecology theory Social Capital theory and New Social Movement theory explain contested access to natural resources, for instance NTFP that have become economically attractive. Political ecology theory describes vagaries of NTFP exploitation for local social groups as part of wider power networks. Social movements theory highlights the processes of formation of these groups and what defines their success in claiming access or local ownership. Social Capital theory explains why groups are successful in organising themselves, why they are successful to build social control mechanisms, or concerted efforts in achieving sustained NTFP based development. These theories, when compared, appear to complement each other as they explain different aspects of the institutional dimensions of NTFP based development processes. New Institutionalism and Common Property theory are closest related as they explain the rules aspects of institutions, being Common Property a more specific case of tenure rules that new Institutionalism explains more broadly. Opposite these two theories are Political Ecology theory and New Social Movements theory that focuses on the actors and their group formation and action. in between these categories is Social Capital theory that explains why groups become successful in building common property regimes, why they are successful in building united efforts to benefit from economic opportunities or engage struggle for rights to resources. Social Capital theory may also explain why previously contesting groups may find common ground and engage in concerted efforts to address mutually identified conflicts of development or environmental problems.

These five theories, when compared, for a large part complement each other in explaining the several processes that take place when NTFP based economies develop. They therefore, are each important when addressing institutional issues in NTFP based development efforts.

Conservation Protection and Sustainable Use of Medicinal Plants

P. L. Gautam, S.P. Raychaudhuri, Neelam Sharma
National Bureau of Plant Genetic Resources, Pusa Campus, 110012 New Delhi, India
Tel: +91-11-5783697, FAX: +91-11-5785619, 5819459, Email: director@nbpgr.delhi.ni.in

Keywords: conservation & protection, genebanks, bioresources, threatened plants, medicinal plants

The last decade has witnessed skyrocketing interest in herbal medicines. At present, 95% collection of medicinal plants is from the wild using unsustainable practices of collection/harvesting. Indiscriminate exploitation of natural resources to fulfil escalating consumer demands besides other anthropogenic activities have led to the decline of natural and wild populations. Current rate of species extinction coupled with inter alia ravages of diseases/insect pests has made conservation of medicinal plants, an urgent activity. There is a global recognition of safe conservation of bioresources of medicinal plants. These resources can be conserved employing holistic approach of amalgamating both in situ and ex situ methods using new emerging technologies to ensure sustainable use.

In situ conservation approach allows for continued and dynamic adaptation of plants to environment. Contrastingly, ex-situ conservation requires maintenance of germplasm outside their original habitat. Plant diversity is being conserved in field gene bank, seed gene bank, in vitro gene bank and cryobank. Among the ex situ methods, rare and curious plants can be conserved as living collection in field genebanks, arboreta, botanical/herbal gardens etc. Conventional conservation of seeds in seed genebanks is the most popular strategy. However, it sometimes poses problems in case of threatened species, as the seeds may be inadequate and/or recalcitrant. in vitro genebanks are increasingly being used as an alternative to conserve such species. Cryopreservation offers the possibility of conserving germplasm under suspended growth for indefinite period in a limited space with minimum inputs. DNA storage also needs to be integrated in conservation programme in a planned manner.

The comprehensive and safe conservation of available diversity including medicinal plants is the major aim of conservation efforts at National Bureau of Plant Genetic Resources (NBPGR). The collection, conservation, documentation and scientific management of the precious biowealth has thus emerged as a priority area. in this endeavour, considering the need to survey enormous genetic resources and their distribution, priorities have been worked out, keeping in view the relative degree of threat. Attention is given to adopt different conservation methodologies available in a complementary way to conserve the collected germplasm.

The precious germplasm has been collected at NBPGR through explorations from different phytogeographical zones of India. The germplasm is collected from forests; villages and herbal gardens in the form of live plants, seeds, fruits and other plant propagules. of these, over 100 species are maintained in pots and under field genebanks at its regional stations. Seed samples of 579 and 220 accessions are conserved in seed genebank and cryobanks, respectively. in vitro techniques have been used as an aid to clonal propagation and conservation especially for threatened species. The application of tissue culture techniques for multiplication and conservation of these plants appears a promising option. Employing these strategies, cultures of a few medicinal plants such as *Kaempferia galanga*, *Rauvolfia serpentina*,*Tylophora indica*, *Picrorhiza kurrooa*, *Rheum spp* and *Gentiana kurroo* have been conserved for varying periods. in vitro repository maintains 60 collections comprising 20 threatened/important species as shoot cultures.

Many important forest medicinal plants like Sandalwood (*Santalum indicum* and *Santalum album*), *Eucalyptus* suffer from infection with *Phytoplasma* (earlier designated as Mycoplasma like organisms, MLOs). Raychhaudhuri and his group worked on 'Spike disease', which has devastated the chief sandal growing areas of South India. Temporary remission of the disease symptoms by tetracycline treatment and electron microscopy confirmed Phytoplasma to be the causative agent. The present paper will elaborate on the above activities.

The significance of NWFP for tropical societies: an analysis of statistical data on NWFP utilization in East and Southern African countries

Wulf Killmann, H. Küstel; Laura. Russo; P. Vantomme; Sven Walter
FAO, Forestry Department, Wood and Non-Wood Products Utilization Branch, Viale delle Terme di Caracalla, 00100 Rome, Italy
FAX: +39-06-570-55618, Email: Wulf.Killmann@fao.org

Accurate, reliable information on non-wood forest products (NWFP) utilization and trade is an essential tool for forest management decision-makers at all levels. in most tropical countries, the current coverage and quality of existing information at a national, sub-regional and regional level is inadequate for policy analysis and decision making.

By compiling national reports on the importance of NWFP in tropical countries, FAO aims to improve the availability and dissemination of statistical data on NWFP. in this effort, the major NWFP are identified by country, and their utilization and source, as well as production system, are described. Key findings are presented in a summary by region.

For countries in East and Southern Africa, preliminary results indicate the following regional patterns: in East Africa, gums and resins, medicinal plants and bee products are the main NWFP; whereas in Southern Africa, edible plants, medicinal plants and bushmeat are the NWFP of major importance.

The analysis of available production and trade data on NWFP revealed that they are often mixed with statistics on agriculture crops and that, although not always easy, a proper segregation between agriculture crops and NWFP is required. Internationally agreed-upon terminology, concepts and definitions on NWFP, combined with improved methodologies for the regular collection of statistical data and for monitoring of NWFP use, are essential for a better understanding of the significance of NWFP to tropical societies.

Peoples Dependence on Forest and the Changing Legal Profile

Neil B. Majumdar
Indian Institute of Forest Management, Post Box # 357, 462 003 Bhopal, India
Tel: 91-0755- 775716, FAX: 91 0755 772878, Email: neil@iifm.org

People in India are dependent on forests for the goods and services produced since time immemorial. Apart from timber poles, and fueldwood which were classically categorised as "major forest produce", the dependence is also and even to a larger extent,on several other produce which were referred as "minor forest produce". Though the nomenclature for the later has been changed in the recent years, as "non timber forest produce" (NTFP), dimension and magnitude of the problems remain unchanged. Present paper opts for two such produce viz., Bamboo and Tendu leaves (*Diospyros melanoxylon*) to elaborate people's dependence and the changing legal profile in the country. As per the Indian Forest Act, the prime act regarding forest, bamboos are classified as timber. Poor forest dwellers use bamboo in the construction of their huts though the other modes of use vary from eating young bamboo rhizome, fencing their field to making mats, baskets and various other artifacts and selling them in the market to earn livelihood. "Nistar rules" (rules for concessional supply of forest produce to the villagers) at many places have provisions for supplying bamboo to the villagers though due to shrinkage of forest resources provisions can hardly be followed.

Tendu leaves on the other hand, are used in the large scale "Bidi" manufacturing process (Bidi is country cigarette prepare by rolling tobacco within the dried tendu leaves) and forest dwellers/villagers come in the picture in this regard, as labourers to collect the leaves from the forests and to sell it to the contractors. As per the Minor Forest Produce (Regulation) Act in most of the cases, trade in tendu leaves is a state monopoly. An amendment to the Wildlife (Protection) Act, in the early nineties has created distinct hardship in the life of the people collecting tendu leaves from the wildlife sanctuary areas. Though National Forest Policy and various Acts did not provide an important status to the NTFPs, various management systems partially recognised its value. in "coppice with reserve (CWR)" system of management, which is an Indian modification of "coppice with standards (CWS)", the need of the local people particularly for NTFPs has been given due weightage.

In the present philosophy of forest management, in the participatory line, people's dependence on NTFPs is being considered as a crucial determinant for the success. Forest Protection Committees (FPCs) constituted by the villagers for protecting and regenerating the forests as per the standing order of the government, have been given the 'usufructary rights' on the NTFPs. However, "Panchayat Extension to the Scheduled Area Act (PESA, 96) empowered 'Gram Sabha' (i.e. village committee) members with the ownership right on the NTFPs. This underlines the conflict between the usufructory rights and the ownership rights being enjoyed respectively by the Forest Protection Committee and the village committee members, in case they are not exactly the same. Forest play an immensely important role in the ecological security of the country. However its contribution as a natural resource being used by the people, most of whom stand below the poverty line, cannot also be undermined. An apt forest policy therefore should maintain a balance.

Strategy for Sustainable NTFP Management in India

Ram Prasad
Indian Institute of Forest Management, Nehru Nagar, PO Box 357, 462003 Bhopal, MP, India
Tel: +91-755-775716, FAX: +91-755-772878, Email: ramprasad@iimb.ren.nic.in

Non-timber Forest Products (NTFP) play increasingly greater role in the social and traditional lifestyle of millions of forest dependent population particularly the tribal, landless, women and other rural poor. in view of increasing realisation for ecological, socio-cultural and economic dimensions of forests, the Sustainable Forest Management has come to be reckoned as most important management innovation for ensuring sustainable development. Similarly, participatory forest management, popularly known as Joint Forest Management in India, is an important forest management intervention to attain the goal of sustainable forest management. and, to ensure successful implementation of Joint Forest Management, flow of benefits through production of Non-timber forest products (NTFP's), offers the best incentives to the participating communities on sustained basis. in order to sustain the interest of the participating communities in forest conservation sustainable NTFP management assumes key role. However, the current NTFP management practices are ecologically and socially unsustainable. This paper attempts to highlight the current management practices and presents strategy for sustainable management of NTFP in India. Although, NTFP's have been providing subsistence to the forest dependent communities since time immemorial, it came into great prominence in the last decade due to preference for natural product based medicines, cosmetics, dyes and chemicals, pesticides, food, fibre etc. Importance of NTFPs as a source of revenue to forest department also increased due to restrictions on timber harvesting for environmental-reasons imposed by Supreme Court of India. Joint Forest Management (JFM) arrangements, that is the management of forest resources by govt forest department and local communities with the explicit understanding for sharing of products (timber and non-timber), responsibilities, control and management decision making. Due to uncertainty in getting benefits from timber harvesting being a long-term proposition, NTFPs for their capacity to yield year round benefit starting from first year of protection is an important incentive to the participating communities. There is thus a need to strengthen this useful links between NTFP management and Joint Forest Management so that the synergy of their linkage can be profitably channelled for the well being of the forests and the dependent communities. Although no precise estimate of the total amount of NTFP extracted from the natural forests is available according to a guestimate, it could vary between 10,000 to 50,000 tons annually providing earnings that runs into billions of rupees each year. About 60 percent of NTFPs go unrecorded and are consumed or bartered by about 15 million people living in and around forests. Large revenue flowing to the state exchequer from NTFPs have given the state the vested interest in marketing the produce with huge costs both to the poor who rely on gathering them for their subsistence needs and to the users of NTFPs. Most of the products are sold in raw form and therefore it is not remunerative to gatherers. After walking long distance and spending several hours the gatherer is able to get less than minimum government prescribed wages. Thus, they try to collect as much as possible to maximise their earning from day's collection. in the process they resort to destructive harvesting. As a result of this many important NTFP species are getting depleted in the natural forests. in several studies it has been shown that processing and value addition at primary collector's level increase the earning from NTFP by 4-5 times. Simple value addition measures such as cleaning, washing, air drying, grading, packing etc., which can be carried out at household and community level, without any investment can also result into remunerative returns to gatherers by 2-3 times. Institutional support for awareness and training for value addition process and marketing can motivate collector's to adopt sustainable harvesting practices. The NTFP gatherers have traditionally been conservationists and in normal case would not resort to destroying the natural resource base that their forefathers protected and worshipped for generations. The middlemen and contractors operating in and around forest areas have been exploiting the gatherers taking the advantage of absence of local level institutions, credit facilities and value addition options. Organising the communities through joint forest management (JFM) offers best option to reduce the exploitation by middlemen and ensure better returns from the collection and sale of NTFP.

Community's interest in sustainable production of NTFP may sustain Joint Forest Management and ensure sustainable development of forests and the people dependent upon them.

NTFPs Pivotal for Sustainable Forest Management to Solve Global Forestry Probelms and Society Needs

Mahabir Prasad Shiva, Alka Shiva
Centre of Minor Forest Products (COMFORPTS), 8, Indirapuram, P.O. Majra, 248 171 Dehradun, India
Tel: +91-135-621302, FAX: +91-135-629936, Email: shivamfp@nde.vsnl.net.in

Human and cattle population explosion, urbanization, land grabbing for agriculture, grazing and industrial development have resulted in sick biodiversity, disturbed ecosystem, depletion of natural resources, environmental pollution and natural calamities. As a result, the very existence of life on earth has become at stake. Since, problems are being addressed by different agencies for a particular strategy in isolation, no headway could be achieved. To meet this global challenge, it is suggested that holistic multi disciplinary integrated approach should be adopted. Forest Management which is still mainly timber dominated should be transformed into Non Timber Forest Products (NTFP) oriented need based sustainable forest management as NTFP species play pivotal role in different forestry programmes, viz., Joint Forest Management (JFM), Joint Rural Development (JRD), Watershed Management, Global Warming, Environmental / Biodiversity Conservation and all society needs.

Understanding the global need, the author conveys how the task of global importance can be implemented by the modern information technology to acquire primary or site information on NTFPs, which in turn may serve as a basic tool to support the forest managers, foresters, policy makers, scientists, entrepreneurs and other user groups for the utilization of Minor Forest Products (MFPs) or Non Timber Forest Products (NTFPs) or Non Wood Forest Products (NWFPs) for socio-economic development as well as for the maintenance of vegetal biodiversity and ecosystem / environmental conservation because lack of information has hither to been the major obstacle to the NTFP oriented forest management.

COMFORPTS is the only institute in India and abroad, specifically and exclusively devoted to the pursuits of NTFP, which has evolved a "Standard NTFP Classification and Documentation Manual" in 26 categories for universal use by Shiva & Mathur (1997). The paper explains how the Manual can be used by India and other countries also in selecting the species of NTFP importance according to their edapho-climatic situations for various purposes.

COMFORPTS is acting now as a Resource Centre for NTFPs and the author is the Contact Person and Dy. Coordinator of IUFRO network for NWFPs with the help of MFP Database evolved by the author.

The Web Site address of COMFORPTS is: http://www.angelfire.com/ma/MinorForestProducts and that of IUFRO is: http://iufro.boku.ac.at "Inventory of Forest Resources for Sustainable Management and Biodiversity Conservation" by Dr. M.P. Shiva, with lists of multipurpose tree species yielding both Timber and Non Timber Forest Products (NTFP) and shrub & herb species of NTFP importance has been published and released in second South & East Asian Countries NTFP Network (SEANN) workshop on 27th October, 1998 by Dr. Barry Deren of the World Bank.

The author has suggested in his paper how Research and Community Development Projects can be executed through indigenous NTFP species by raising mixed crops of multipurpose tree species yielding both wood and NWFPs/NTFPs and shrub and herb species of NTFP importance.

About five propagation methods have already been perfected by the author and his co-workers. A book on "Plant Biodiversity for Sustainable Community Development" by Dr. M.P. Shiva & S.S. Bartwal, has also been published and released in second SEANN workshop on 27th October, 1998 by Dr. Ana Doris Capistrano of The Ford Foundation.

The paper conveys how COMFORPTS can offer expertise globally on the following aspects of NTFPs to tackle forestry problems and society needs.

1. Mechanism for making choice of suitable species based on edapho-climatic conditions including forest types etc.
2. Standardizing propagation methods for massive afforestation on land husbandry programmes, on forests and other vacant lands.
3. Evolving harvesting techniques for optimum productivity and biodiversity conservation.
4. Determining marketing and trade channels for NTFP based enterprises for socio-economic development and equitable distribution of profits particularly to disadvantaged groups of both men and women dwelling in urban, rural and forest areas.

Research for a) Augmenting regeneration of mixed NTFP species of trees, shrubs and herbs for biodiversity conservation and socio-economic development. b) For ensuring increased productivity of NTFPs. c) Marketing research for equitable distribution of profits, upliftment of disadvantaged groups of people; study of marketing channels and price regime; assess and regulate demand and supply of NTFP for enterprises according to trends.

6. Strengthening information for generating training material to create awareness among all user groups.

The overall impact will be sustainable forest management of existing resources with replenishment of naturally regenerating forests and extending man made forests, which would ultimately result in conservation, enrichment of biological diversity and socio-economic development of village community and forest dwellers including tribals globally.

Contributions of NTFP-based economies to development - a conceptual framework between growth and distribution

Jochen Statz
University of Freiburg, Institute of Forest Policy, Markets and Marketing Section, Freiburg, Germany
Email: w.de-jong@cgiar.org

It is widely believed that use and trade of NTFP do contribute to economic development, being both, ecologically and socially sustainable at the same time. Over the last years, many scholars and practitioners have adopted this suggestion. But, as much as being tantalising this thesis is unspecific and lacking conceptual clarity - this explains, in parts, it's widespread support. The conceptual understanding of what development is remains obscure.

The concept of development can be traced through history. in antiquity, development originally had a clearly the character of a procedure of unfolding an idea or an argument. in a larger sense development stood for any unfolding of potentials, generally following a given (but mostly hidden to the observer/audience) finality. Since the eighteenth century, this understanding was translated to human society: mankind as a whole, specific societies or individuals were meant to unwrap their intrinsic potentials, thus fulfilling a prescribed (but not known) agenda established by god or nature. Advances in the natural sciences, especially evolution biology, lead to the recognition that development is not linear, not moving neither nature nor society straight towards a given destination. Development, it became clear, does not have a goal, yet it has a direction. Since its beginnings shortly after World War II, development assistance has followed an end-vision: so called underdeveloped countries were to follow the example of the industrialised world. Economic growth would be the starting point for their take-off. It was believed that once entered this road, any underdeveloped countries would follow a given sequence of steps, ultimately reaching the state of being developed. The primary sector of national economies was seen as the key to ignite development, with agriculture and forestry as key economic activities. This rather simplistic view has been questioned and reconsidered in the political discussion of the last five decades. Today, a consensus has been reached over a set of components that do not serve as goals to development, but rather as a direction for international development assistance. The five key components of development comprise Work, Growth, Participation, Equity, and Independence.

Since UNCED these elements have been complemented by a temporal dimension: only activities that sustain the development potential of a (natural or social) system in the longer run, can be perceived as developments (otherwise contributing to the development of under-development). Development of society is today seen as the process by which endogenous potentials are being unfolded leading to an ever more complex system, without narrowing future options for further changes.

Following the contemporary understanding of development, the benefits and contributions of NTFP-based activities have to be valued not only in terms of economic wealth and growth, but in the light of the other components of development, as well. Interdependencies between contributions attributed to the five elements have to be taken into account. It follows that economic growth does not necessarily lead to development. Growth without distribution can be seen as underdevelopment, as a narrowing of future options to a society. Any assessment of the contributions that the NTFP-based economies make to the development of a society has to take into account potential benefits of all five development dimensions. They need to be valued with their interdependencies and their being sustained over time. So far, the support for the thesis that „use and trade of NTFP favours economic and social development“ is due in parts to it’s vague and thus indisputable conceptual founding.

5.12.00 Sustainable wood industry

Sustainable production of forest products in Southeast Asia: what products and production systems?

Kamis Awang, Suree Bhumibhamon
Universiti Putra Malaysia, Faculty of Forestry, 43400 UPM Serdang, Malaysia
FAX: 943 2509, Email: kamis@admin.upm.edu.my

Keywords: Sustainable production; Forest products; Production systems; Southeast Asia

Forest lands and their associated resources have played significant roles in the socio-economic development of most of the Southeast Asian countries. Much of these forests have either been converted into other land-uses such as agriculture, mining and settlement or disturbed due to harvesting of wood and various other products in support of the forest product industries. Apart from these industries, large proportions of the rural populations of these countries are dependent on the forest resources for their livelihood. The forests supply the basic needs in terms of energy, shelter, food, medicines and water of these rural dwellers.

There are varying degrees of advances in technologies, utilization and market development in these different countries. Sustainable management of these resources will therefore have to take into consideration these different stages of development, and the ecological, economic and social dimensions of the production and other uses. It must adopt a holistic approach and research must be strategic in nature.

Past supplies of forest products have come mainly from the harvesting of the natural forests. Today much of these forests have been exploited or converted into other uses. They are fast diminishing or degraded. However, attempts are being made to put the remaining forests under an appropriate management system with sustainable objectives. Other strategies are also being adopted to meet the expected shortage of supplies due to increased demand following population increases.

The increasing reliance on other production systems is emerging in many of these countries. For example interest in plantations, both on a small or industrial scale, has grown in recent years. However, the number of species used is limited to a few, mainly those with fast growth rates. Likewise, increasingly more products are being produced from community forests or on small farms of individual farmers. Various models of agroforestry practices are in use. Other nontraditional sources of cellulosic materials such as oil palm fibers, bagasse and Hevea wood are also fast becoming important particularly in composite industries.

Similarly, the utilization pattern has evolved from the selective harvesting of a few limited species of only large dimension to a wide range of species including those of small dimension. Improvements in processing technologies and market development have produced new products and opened more opportunities. Solid wood utilization is giving way to composite products. More uses are finding their way for each species. Besides wood, other parts of trees are being more intensively researched for complete utilization. Multipurpose species are becoming increasing popular. The products obtained can be used for subsistence or cash income, hence growing trees on farm is becoming more attractive.

Sustainable Forestry and Wood Production. Common Ground and Conflicts. the Mission of Research Group S5.12.

Jamie Barbour, Andrew H. H. Wong
USDA Forest Service, Pacific Northwest Research Station, P.O. Box 3890, 97213-3890 Portland, OR, USA
Email: jbarbour01@fs.fed.us

Keywords: sustainable forestry, forest products, silviculture, wood

The concept of sustainability in the context of forest management holds a different meaning to almost every group that espouses it. Many of these differences arise because of the varying goals and objectives of those who promote the idea of sustainable forest management. When discussing this topic, the question of "sustainability of what" must be answered prior to reaching a common understanding of goals and objectives.

In general, a sustainable approach to forest management uses new strategies to conserve biodiversity, improve the balance among alternative forest values, and sustain healthy ecosystems. It is often also expected to retain the aesthetic, historic, and spiritual qualities of the land. Various silvicultural techniques may be used to alter the developmental trajectory of existing stands to provide this range of values.

In some cases, management strategies include removing wood as a primary goal. in other cases, wood is removed as a secondary objective during treatments to improve forest health, restore wildlife habitat, create recreational opportunities, mitigate impacts of forest pests, or alter the vegetative mix for increased biodiversity.

Forest management strategies that aim to produce wood on a sustainable basis take many different approaches. A common model is one where the tenets of conservation biology are implemented on parts of the managed landscape, often as a network of reserves, or near reserves, on the areas considered most biologically sensitive, and management for wood occurs on adjacent, less sensitive and often less productive lands. Another less common approach, is to attempt to mix production of wood and other resource values on the same piece of ground under the doctrine of management of ecosystem processes. in these cases, forest managers must either have the trust and confidence of members of the public who advocate sustainable forest management or they must have sufficient autonomy to avoid or ignore public scrutiny.

These sustainable forest management strategies are usually implemented on large landscapes and judged using broad indicators of success. They are, however, implemented on a project-by-project basis often at the stand or watershed level. It is important to be able to link activities at all scales and through time in order to understand the implications of activities at each scale to outcomes at other scales.

The Division 5 Research Group S5.12 Sustainable Production of Forest Products was created in 1998 to: 1) promote research on the sustainable production of wood products; 2) encourage communication between IUFRO Division 5, other IUFRO Divisions, and other organizations that are concerned with sustainable forestry. These goals are described in the context of real and hypothetical examples of production of forest products under sustainable forest management objectives.

The Role of Wood Removals in Sustainable Forest Management in the United States: the Contribution of Federal Land.

Marlin Johnson, Hal Salwasser, Barry L. Bollenbacher
USDA Forest Service, Southwestern Region,
Albuquerque, New Mexico, USA

Keywords: Sustainable forestry, ecosystem management, fire, biomass

Forest ecosystems are dynamic; they do not maintain balance in a "steady state." Sustainability of dynamic ecosystems means that, over the long-term, growth and loss will be about equal (the "loss" can be from human use as well as natural decomposition.) For the past 500 years, the human elements of Earth's ecosystems have not been in steady state; growth has far exceeded loss. That growth has consumed ever-increasing amounts of land, water, energy, crops, wood, and biodiversity. Regardless of desires for sustainable forests, we will not achieve forest sustainability without simultaneously reaching reasonable sustainability in the human component of Earth's ecosystems. Thus, the grand experiment in sustainable forestry cannot stop at the forest border; it must encompass the human enterprise as well.

Conserving and restoring diverse forest ecosystem composition, structure and function while producing wood resources requires an understanding of both the biophysical and socio-economic dimensions of forest management. Among society's desires from forests are diverse opportunities for recreation, clean water from productive aquatic systems, wood, wildlife, fish, livestock forage, and a sense of place coupled with the knowledge that those forests remain healthy, productive, and pleasing to look at. This set of potentially conflicting desires is what constitutes a sustainable forest in the eyes of many Americans. in the United States, many of these social values are reflected in legal mandates, such as Federal and state laws and regulations concerning endangered species, water and air quality, and how citizens may participate in forest decision making. These mandates provide guidance for management of public and, to a more limited extent, private forestlands. in the past four decades, substantial areas of federal forestland has been "set-aside" through reservations for uses and values other than wood removal. These reservations have not been matched by a commensurate reduction in domestic wood consumption, thus, U.S. wood demand and production has shifted to U.S. private lands and forests in other countries. This raises the question of whether U.S. federal forest policies contribute to or perhaps detract from the sustainability of forests and forestry at the global scale. The United States Forest Service manages 31 million hectares of forestland in 42 states, and 73% of the major vegetation types in the country. The USDA Forest Service can play a major role in advancing knowledge about sustainable forest management by using this land to test new ideas. This paper describes part of that role.

The USDA Forest Service adopted ecosystem management as a guiding philosophy in the early 1990's. Ecosystem management blends the resource needs of people with the protection of wildland environments to sustain diverse, healthy, productive and adaptable ecosystems. Wood utilization under ecosystem management is based on the integration of objectives for fiber production with desired ecosystem conditions at scales ranging from sites to watersheds to landscapes to whole regions of the nation. in one example, natural fire cycles have been disrupted for nearly a century on many national forest lands, especially those in the Interior West. Biomass harvest has also been much less than annual growth for the past 50 years, resulting in increased stand density. These densities cannot be sustained nor can intensive fire be safely returned to these forests without mechanical removal of some of that biomass. Developing economically feasible and socially acceptable silvicultural techniques to restore healthy forest ecosystems, through removal of smaller, under story trees, is the major challenge we face in nearly 17 million hectares of federal forests.

Sustainable Production of Forest Products in Australia

Keywords: Sustainable Forestry, Australia, Montreal Process

The sustainability of production from Australia's forests - especially but not exclusively its native forests - has been a strongly contested issue for the past three decades. Australia's first National Forest Policy Statement in 1992 committed Australia to the goal of sustainable forest management in the context of a broader commitment to ecologically sustainable development. It is being translated from policy to practice by - for the first time in Australia's history - a suite of nationally-coordinated processes consistent with international initiatives. Although progress towards sustainability in forest management far exceeds that in other Australian natural resource sectors, the sustainability of production from Australia's forests remains both contested and challenging.

Over the perhaps 50000 years of their settlement, the land management practices of Australia's aboriginal people - principally their extensive use of fire - altered the distribution of Australia's forests, ecosystem structure, and the forest fauna. The European settlers' displacement of aboriginal people, and their conversion and use of forests, both had profound impacts. The fragmentation and conversion of forests to other uses, and European farming practices have adversely affected for the sustainability of Australian agriculture and its rural landscapes, including their forest and woodland remnants. These impacts have generally been most severe in the widespread broad-acre cropping and grazing regions; it is not yet clear whether production from these ecologically-degraded landscapes can be sustained.

The historical focus, and continuing emphasis, of Australian native forest management has been on the closed forests; their discontinuous continental distribution coincides with the distribution of the majority of Australia's population near the southern and eastern coasts. With the exception of forest-rich Tasmania, the majority of these forests are in public ownership; their principal products and services are biodiversity, recreation, a diversity of wood and non-wood products, and water. Whilst the economic importance of wood production from these forests remains significant, the relative value accorded it by the majority of the Australian population has been progressively diminishing. Continuing community conflict over the management of these forests led, in 1995 the Australian governments to institute a Regional Forest Agreement process, first mooted in the National Forest Policy Statement.

Australia's Regional Forest Agreement process is the first nationally-coordinated attempt to assess the diversity of Australian forest values - economic, environmental and social - and agree forest allocation and management based on this information. Regional Forest Agreements are being negotiated between the Commonwealth and respective State governments for each commercially-important native forest region. The goals of the process are expressed in terms of greater certainty: for biodiversity conservation, based around establishment of a national reserve system with a target of incorporating 15% of the pre-European extent of each forest ecosystem, and around the development of ecologically sustainable forest management regimes in forests outside reserves; for the forest-based industries, based around secure access to resources outside the reserve system; and for indigenous and European heritage, based on explicit recognition of those values in forest allocation and management decisions. Concomitantly, Australia's wood production has been shifting progressively from native to plantation forests. Most existing plantations were established on sites converted from forest; almost all new planting is established on farmland, much in partnership with farmers. This expansion poses both challenges and opportunities for enhancing the sustainability of production.

The Montreal Process is providing the framework for the development of criteria and indicators of sustainable forest management for all Australian forests. The formulation and testing of criteria and indicators are paralleled by the development of Codes of Forest Practice and by institutional reform in which State regulatory and management roles are separated. These measures are relatively well-developed for State forests, but are – with the exception of Tasmania – as yet poorly developed for the increasingly important private forest sector, including its extensive woodlands. Substantial research and implementation challenges remain in improving, monitoring and communicating the sustainability of production from all Australia's forests.

A conjoint analysis of New Zealand consumer preference for environmentally certified forest products

Lucie K. Ozanne, Hugh Bigsby and Christopher Gan
Lincoln University, Commerce Division, Post Box # 84, Canterbury, New Zealand
FAX: 64 3 325-3847, Email: bigsbyh@lincoln.ac.nz

Keywords: Environmental certification, conjoint analysis, cluster analysis, forest products, marketing

One of the major challenges facing the forest products industry over the past ten years has been how to address consumer concerns about the environmental impact of forestry activities. One strategy suggested by the environmental community and some industry groups is to provide certification for forests and the products from those forests where forest management practices meet particular environmental standards. Many concerns have been raised by the industry about the wisdom of companies pursuing certification. A particular question is whether consumers are really interested in certification and in turn, whether they will be willing to bear the additional costs associated with certification activities. A number of studies have examined this issue; however these studies have only looked at consumers making a trade-off between price and environmental certification and have not examined all of the relevant trade-offs consumers may have to make when purchasing certified wood products.

This study was designed to address the question of how consumers value environmental certification when combined with a number of other wood product attributes. The particular example used to look at the relative importance of environmental certification was the purchasing decision for wooden outdoor furniture by New Zealand consumers. The method used in the study was conjoint analysis, a recent development in mathematical psychology that has been applied extensively in the marketing field. Conjoint analysis measures the joint effect of two or more independent variables on the ordering of a dependent variable. in the area of market analysis, it relates the buyer's preferences to a set of pre-specified brand attributes. Using a survey, consumers were asked to rate a label outlining the attributes of a wooden outdoor furniture. Each label had a different set of combinations of attributes, including, price, length of product warranty, the country of origin of the wood, and forest type that the wood came from (plantation-grown versus natural forest). For each attribute, there were two possible values or levels.

For wooden outdoor furniture in New Zealand, the conjoint results indicate that environmental certification ranks highly as a product attribute, but is just one of a number of important product attributes. Other important attributes include the country of origin of the wood, with New Zealand wood being preferred over imported wood, and forest type, with plantation grown wood preferred over wood from a natural forest. Price and length of warranty were less important attributes. Cluster analysis was used to segment the respondents based on the relative importance they attach to each product attribute in the conjoint analysis. The cluster analysis results indicate that there are six market segments with unique furniture attribute preferences in New Zealand. Three segments, comprising 56.4% of the sample, view environmental certification as the most important attribute, preferring certified over uncertified wood. A fourth segment, comprising 16.3% of the sample, indicated that they were most concerned with where the wood was sourced, preferring wood sourced from New Zealand. A fifth segment, comprising 14.8% of the sample, was price sensitive. The sixth segment, making up 12.4% of the sample, indicated that forest type is the most important furniture attribute, preferring wood harvested from plantation forests over natural forests. in terms of profiling these segments, results indicate that common demographic variables, such as age, sex, and education, do not provide a basis of description.

Wood Products Research for the 21st Century in China

Tel: +86-10-62889051, FAX: +86-10-62884229, Email: Chenxh@caf.forestry.ac.cn

Keywords: carbon sequestration, wood supply, China, value-added processing, wood based panels

Wood is wonderful and it is the most important and widely used raw material on earth except water. It is renewable and beautiful, with a high strength to weight ratio, and it is easy to process with low energy consumption. Further more, the growth of wood and wood utilization reduces CO_2 emissions which makes wood an environmentally friendly material. As the economy and population grow, the demand for wood and wood products will also certainly continue to increase. The future of the wood products industry largely depends on the stable supply of wood resources from sustainably managed forests. China holds the potential develop a sustainable wood supply because of its favorable climate, vast land area, and the abundant workforce. Wood currently plays an increasingly important role in the economic and social development in China where the annual consumption of timber (250 million m^3) equals to the sum of that of steel, aluminum and plastic. Further research is, however, needed to support the sustainable development of the wood industry in the 21st century.

The major objective of forestry has shifted from simply supplying timber products to providing multiple functions including ecological, environmental, and social benefits while still supplying timber and timber products. Under this sustainable development principle, the wood products research in China should further develop the cultivation and utilization of industrial plantations environmentally compatible technologies and products that meet the needs of the markets, and to improvement in the competitive capabilities of the forestry and wood products industry.

Many timber-producing countries have restricted or decreased their exports of logs and sawn timber to encourage developed down stream value added wood processing. Malaysia is a good example of a country where the government policy of restructuring for down stream value-added processing has reduced the export of raw logs and primary wood products. These policies will influence the availability of raw material supply for countries like China. It can be concluded that the future of wood products industry in China largely depends on a stable wood supply from sustainably managed forests.

To meet the demand for wood products, the Chinese industry has made remarkable improvements in technology in recent years. This is especially evident in the in the wood based panel industry in 1997, the production of wood based panels in China reached a ranking the 2nd in the world at 16.48 million m^3. As the wood resources available for industrial purposes shift from the natural forests to plantations, the industry needs technical support from research institutions in developing technologies for establishing plantations and utilizing the fast growing and high quality trees from them. Effective value added processing of environmental friendly products requires R&D conducted to address issues specific to the conditions in China. A proposed set of topic areas is as follows: wood properties, wood drying, wood and the environment, wood preservation, wood composites, pulp and paper, economics and policy.

Prospect of Community-Based Ecotourism in the Sundarbans Mangrove Forest in Bangladesh

A. Emran Ali, Tsuchiya Toshiyuki
Iwate University, Faculty of Agriculture, Forest Policy, 3-18-8, Ueda, Morioka, 020-8550 Iwate, Japan
FAX: +81 19 621 6129, Email: toshit@iwate-u.ac.jp

Bangladesh is one of the densely populated country in the world. The economy of the country is mainly dependent on agriculture and the country faces enormous constraints for the development of itself. Sustainable development in Bangladesh needs a strategy which would accelerate economic growth with equitable distribution of benefits across different segments of population without harming the environment. Planned and ecologically sound utilization of natural resources is a prerequisite for sustainable development. The government has taken different policies for sustainable development.

Ecotourism, as a logical component of sustainable development, requires a multidisciplinary approach, careful planning and strict guidelines and regulations that will guarantee sustainable operation. The focus of this paper is on achieving sustainable development objectives through the development of Community-Based Ecotourism in the Sundarbans, the largest mangrove ecosystems in the world, is situated in the southwest coastline of Bangladesh. Sundarbans forest is the natural habitat of the world famous Royal Bengal tiger, spotted deer, crocodiles, jungle fowl, wild boar, lizards, rhesus monkey and an innumerable variety of beautiful birds. Migratory flock of Siberian ducks flying over thousands of sail boats loaded with timber, golpatta (round-leaf), fuel wood honey, shell and fish further add to the serene natural beauty of the Sundarbans. All of these are good potentials for ecotourism development in this area to become a significant revenue and income generator.

According to a survey of ESCAP 500,000 to 600,000 people of local areas directly depend on Sundarbans for their livelihood. The Forestry Department (FD), the government agency, is in charge in management of the forest and forest resources. The FD is established in 1989 and after the creation of FD there is conflict between the FD and local communities. There is also very negligible relationship between the tourists and the local people.

The domestic market for tourism in Bangladesh is very small and largely independent on small unorganized groups. A very low number of foreign tourists arrive to visit Bangladesh and the national tour operators are also very small in number. These indicate that the service sector is not well established in Bangladesh. At present there is little involvement of local communities but there is the potential. Local involvement will be essential if tourism is to meet conservation objectives.

The premise of the present paper is that if properly planned, ecotourism has the potential to generate a reasonable return on investment and offer substantial community benefits. The successful Community-Based Ecotourism initiatives are supported by partnerships between communities and government, non-government and private sectors.

This objective of the paper is to find out the way to develop the relationship between the FD and local communities by using primary data collected from face-to-face interviews with tourists, tour operators, FD and the community people. The community leaders are asked about tourism activities in their area, giving emphasis to the community role in each. It will also examine the possibilities of community-based ecotourism in the Sundarbans area and will try to find out the proper policy for the expansion of ecotourism in Bangladesh.

Planning for recreational forest. Is there an optimal distance to forest

Lisa Hornsten, Peter Fredman
Swedish University of Agricultural Sciences, Department of Forest Management and Products
Box 7060, SE-831 25 Ostersund, Sweden
Tel: +46 (0)18-67 38 19, FAX: +46 (0)18 67 38 00, Email: lisa.hornsten@stek.slu.se

Keywords: forest recreation; visiting frequency; distance; urban

This paper presents a study of the relationship between the time span since a person's last recreational visit to a forest, the size of a municipality and the distance between the place of residence and the closest recreational forest. The study was carried out as a mailed inquiry distributed to 2500 randomly selected Swedish citizens, aged between 16 and 75 years. The response rate was 52 percent.

The time since the last forest visit varies from 0 to 365 days with an uneven distribution largely dominated by low values. The distance to the forest affects the time since last visit. The longer the distance between a residence and the closest recreational forest, the larger the time span since the respondent's last recreational forest visit. When distance exceed 2 km a large increase in time since the last forest visit is observed.

Visiting frequencies is grouped according to respondents' present distance and comparisons are made between groups. For the lower quartiles, i.e. the quartiles where respondents state the shortest time since last visit, visiting frequencies are similar irrespective of distance. For the upper quartiles, however, where respondents state the shortest time since last visit, visiting frequencies increase significantly with the distance to the forest.

Results show fewer forest visits for respondents living in an urban environment compared with those living in a rural context, here defined as municipalities larger than 90,000 and smaller than 5,000 inhabitants, respectively. Also after correction for distance to the closest forest, results show fewer forest visits for respondents living in an urban environment compared with those living in a rural context.

Benefit-based recreational forest management in Corea

Won Sop Shin
Chungbuk National University, School of Forest Resources, 361-763 Cheongju, Korea R.
Tel: +82 431 261 2536, FAX: +82-431-273-2241, Email: wonsop@cbucc.chungbuk.ac.kr

Benefits-based management seeks to provide recreation benefits for recreation participants by managing the physical environments in which recreation occurs. This study investigates the relationship between benefits desired by visitors and the physical, social and managerial characteristics of settings that facilitate realization of recreation benefits. Data were collected from 370 visitors to Sorak-san National Park in the eastern part of the Korean peninsula. Cluster analysis was used to group visitors desired benefits into twelve domains: relationship with nature/scenery, escaping pressure, learning about nature, family togetherness, introspection, exploration, autonomy/achievement, being with friends, leading others, skills/learning, risk taking, and meeting/observing new people. Multiple regression was used to link benefit domains with the characteristics of settings. The social attribute of recreation settings was found to be linked to eight of the ten benefit domains. There were two strong multiple regression correlations:(1) between "relationship with nature /scenery" and the attributes "forest/water", "attractive nature", and "facility/maintenance" (R .40) and (2) between "escaping pressure" and the attributes "attractive nature" and "social" (R.386). The paper discusses how the findings can be used to develop recreation services and marketing strategies to respond to client needs and preferences.

Motorized Access Control as a Wildland Recreation Management Tool: Access Changes and Visitor's Behavior at Daisetsuzan National Park

Keiko Shiratori, Taiichi Ito
Yamanashi Institute of Environmental Sciences
5597 Kenmarubi, Kamiyoshida, Fujiyoshida, 403-0005 Yamanashi, Japan
Tel: +81-555-72-6211, FAX: +81-555-72-6205, Email: shiratori@yies.pref.yamanshi.jp

Keywords: Wildland recreation; Motorized access; Access control; Daisetsuzan National Park

Environmental deterioration triggered by overuse is a common issue in wildland recreation. There are several ways to minimize the problem such as law enforcement and regulation of visitor number. However, these approaches require a certain budget and staff, both of which are often under supply. On the other hand, controlling motorized access to wildlands seems more practical as well as economical, while enhancing the visitor experiences.

In order to clarify the feasibility of the motorized access control method in wildland recreation management, the authors studied the relationship between access improvement and visitor increase at Daisetsuzan National Park, Hokkaido, Japan. This park, with the area of 2,300 km^2 including vast wilderness, is the largest in Japan. Still, previous studies indicate increasing impacts on vegetation and soil erosion. The authors first analyzed visitor statistics since the 1960s when road improvement and tramway service began. Second, with GIS data including the information from previous research results, changes of the walking rigor were evaluated at the major trails. Third, visitor's preferences of hiking routes and opinions on access improvement were analyzed from mountaineering plans submitted in past few years and from on-site surveys to hikers.

First, historic statistics revealed that motorized access improvement rapidly increased the number of visitors to Daisetsuzan area, especially to trailheads at higher altitude with connection to other sightseeing routes. Second, such improvement also changed walking access patterns. Areas required over-night stay disappeared, and day-use areas expanded. Most of core areas of the park with fragile alpine vegetation fall under the category of day-use areas now. Third, almost 70% of visitors come by their own cars and tend to prefer short and easy walks. Such day-use visitors expect more access improvement, while overnighters welcome longer walking access. Fourth, more than 20 % of tramway users mentioned willingness to walk paralleling trails, but those who really walk such trails are very small. This gap between intention and behavior implies that they know more walking give them deeper experiences and other benefits, but cannot resist the temptation of tramways.

From these analyses, we suggest that motorized access should be regulated and walking access enhanced. From the point of nature conservation as well as rich visitor experience, closing mountain roads and suspension of tramway service is ideal. But, we should not ignore local economy. Visitors will walk longer if motorized access is regulated by economic incentives such as higher tramway tickets and introducing parking fees at high seasons. Such extra revenue should be directed to improvement of public transportation service and existing trails. Especially, interpretational activities on trails supported by such fund will enhance the visitor experience. Higher cost may divert some visitors to other areas. Even if the total visitation decreased, increased overnight visitors contribute more to local economy than passing-by day-use visitors. Eventually the impact on the natural environment will be reduced. Thus, motorized access control can be a powerful and effective tool to wildland recreation management.

Recreation monitoring at the Dutch Forest Service

Peter A. M. Visschedijk
Institute for Forestry and Nature Research (IBN-DLO),
Post Box # 20, 6700 AA Wageningen, Netherlands
Tel: +31 317 477713, FAX: +31 317 424988, Email:
p.a.m.visschedijk@ibn.dlo.nl

In 1996 the Institute for Forestry and Nature Research started to develop a system to monitor the recreational use of forests and other grounds owned by the Dutch forest service. The aim was to determine the number of visitors, their activities and the percepted quality. This information provides a valuable management tool for targeting of resources. The systems uses three methods to gather the information:

1. Monitoring vehicle and bicycle use at the sites by using traffic counters with induction loops installed in the road (all year round).
2. Visual counting of visitors at all entrances (on 12 days during the year).
3. Survey of visitors (on 12 days during the year).

When the system is fully implemented their will be a network of 48 sites. All of these will be monitored by using this method once in every 10 years, on average 5 sites a year.

ad. 1 The use of traffic counters enables one to gather information about the number of passing vehicles and bicycles all year round. The counters automatically register the numbers and also provide other details such as date, time and speed. With this information it is possible to see the variation in use throughout the year.

ad. 2 Counting all the site-entrances visually is essential for determining the exact number of visitors. With traffic counters is it impossible to cover the complete site, only cars and bicycles can be counted and you don't know how many people are for instance in the vehicles. in combination with the figures from the traffic counters it is possible to calculate the number of visitors during a certain period of time.

ad. 3 With the visitorsurveys information is gathered among other things about activities, use of facilities, number of visits a year, place of residence, duration of visits and last but not least the percepted quality of the site.

The qualityscore is generated by asking the visitors their opinion about 17 items concerning outdoor recreation. First through 17 thesis about recreation in general in which the visitors are asked about the importance of the items (general importance), in the next question the same thesis are asked in connection with the visited site (verdict). Then the questions are combined, the answers about the site itself are weighted by the answer about the general importance of a certain subject. The next table shows the weightfactors.

		General importance				
		Very unim-portant	Unim-portant	Neutral	Im-portant	Very important
Verdict	Very negative	-1	-2	-4	-6	-8
	Negative	0	-1	-2	-3	-4
	Neutral	0	0	0	0	0
	Positive	0	1	2	3	4
	Very positive	1	2	4	6	8

When an item is being considered as very important by the visitor, then his verdict about the item in the visited can raise a score between -8 and +8. However, when an items is qualified as unimportant then score is between -2 and +2. When an items raises a total average score of more than 1 the quality is qualified as being sufficient.

Since this system of monitoring is only carried out in 48 sites, there was a need to get information about all the other grounds of the Dutch forest service. Since counting is too expensive to be done in all sites, in the sites not covered by the monitoring network visitors are going to be given a questionnaire which they can fill out and send back by mail. Through extrapolation we try to predict the unknown factor, the number of visitors. Test are carried out in 1998 en 1999 and the first results look promising.

6.01.00 Nature experiences and sustainable management of landscapes and recreation resources

Visitors' perceptions on the management of recreation forests - a qualitative case study in southern Finland

Eeva Karjalainen
Finnish Forest Research Institute, Unioninkatu 40 A, 00170 Helsinki, Finland
Tel: + 358 9 85705766, FAX: +358 9 85705717, Email: eeva.karjalainen@metla.fi

Keywords: perceptions, experiences, forest management, recreation areas, qualitative research

The aim of this study was to explore how visitors perceive and experience the management of recreation forests. A recreation forest in southern Finland was chosen for a case study area. This area's primary use is to provide recreation for visitors, and the forests are managed to some extent. There have been conflicts concerning the management of the areas; nature conservationists demand that these forests should be left untouched, while other visitors' needs remain unknown.

A qualitative study was needed to meet the aim of the research, although results do not represent all visitors of the area. During the summer, 1998 a total of 22 visitors were interviewed. The researcher walked together with each visitor a path one kilometer long, and each visitor was allowed to comment freely about the environment. Interviews were audio-recorded and tapes were transcribed. Transcripts were analyzed using a qualitative content analysis.

Visitors were very knowledgeable about forest management and the biological processes going on in nature, as well as the processes caused by humans. They mentioned that trees grow, die, fall down and decay, and different plants and trees fight for living space. Respondents had clear understanding that narrow paths are formed by people walking a certain route, and that these paths would disappear if people did not use them any more.

The following ways of perceiving forest management were identified; aesthetic and experiential perceptions (exploring), safety, possibilities to move, educational perceptions, impacts on nature and economic perceptions. When visitors' perceptions on the paths were studied additional dimensions of perceiving and evaluating were found; social relations, maintenance of the area and the activities one can perform.

Visitors supported the current soft forest management; there are uneven-aged forest stands with many tree species and undergrowth, no clear-cutting, and some of the fallen and dead trees are left. Respondents compared this area to commercial forests and appreciated that there are mixed forests and no large openings in this area. Some visitors also preferred this area to forests in their natural state. They agreed that there could exist small pieces of untouched forests so that people can see how nature develops. Visitors suggested that some of the forest stands should be thinned or appreciated thinned forest sites, because after thinning forests become more spacious and light, and trees have more space to grow. However, some respondents did not like when they saw that trees were cut. in general, visitors thought that logging residue should be removed because it could be used for firewood and it looks ugly. Several respondents thought that dead standing trees and fallen trees belong to nature, while others were worried that dead standing trees could fall over someone.

Application of Sustainable Development Concept to Recreation Resource Management in Forests

Joong Myung Kim
Forestry Research Institute, 207 Chongnyangni, Seoul, Korea R.
Tel: 961-2532, FAX: 961-2530, Email: johnjmkim@hotmail.com

In 1987, the World Commission on Environment and Development broadly defined sustainable development as development that meets the needs of the present without compromising the ability of future generations to meet their own needs and the term became widely adopted within the international community related with economic development and environment conservation. Since then, many argue for the development of sustainable economies as the new guidepost to deal with issues of growth, economic and community development, and environmental protection. The concepts of sustainable development has been incorporated into forest management and it became known as the sustainable forest management. There have been, therefore, many initiatives towards implementing sustainable forest management at the international and regional level. The sets of criteria and indicators have been developed through the initiatives to enhance the awareness and improve the understanding of forest sustainability as well as to specify the fundamental elements of sustainable forest management. in the paper, criteria and indicators for tourism and recreation in forests are discussed as developed by several initiatives for sustainable forest management and in this context recreational forests managed mainly for recreation activities in Korea are analyzed for sustainable forest management. Due to the socio-economic changes in recent years in Korea, demand for recreation and tourism has been steadily increased and thus forest resources play an important role in the provision of various outdoor recreation opportunities to meet recreational needs of the society. The sustainable forest management has become a main goal of forest policy and relevant criteria and indicators have been developed for implementation at the international, national, and forest management unit level. The criteria and indicators on recreation and tourism developed by international initiatives are discussed, including the Montreal and Helsinki Processes. The recreational forests designated and developed for general recreation and tourism in Korea started in 1989 and since then attracted many visitors into forest environments across the country. Based on the specific indicators related to recreation and tourism, the management of recreational forests are discussed in this paper. The number and area of recreational forests has increased up to 60 and over 110 thousand ha, respectively, during the past decade. As of 1997, recreational forests accounted for about 1.71% of total forest land and attracted more than 2.6 million persons accounting for over 5.5% of total population. The facilities in recreational forests, as suggested by an indicator, are discussed and future directions suggested.

The Experience of Forests

John Murray
Edinburgh College of Art/Heriot Watt University, School of Landscape Architecture, Lauriston Place, EH3 9DF
Edinburgh, Scotland
Tel: 0044 131 221 6094, Email: JOHN_M@eca1.cen.eca.ac.uk

This project, commissioned by Simon Bell, The Forestry Commission's Chief Landscape Architect, was undertaken as a pilot study on peoples' experience of forests. Its objective was to contribute, along with other parallel studies, to design theory & applications which relate to the restructuring of production forests for recreational purposes.

The two sites selected for the study were:

1. The Waterfall Walk at the David Marshall Lodge Queen Elizabeth Forest Park near Aberfoyle

2. The Allean Walk near Queen View, Loch Tummel, Pitlochry

In investigating forest experience we wished to tap multisensory experiences (not solely visual) in an unconstrained way. As a consequence the study was in two parts. Firstly, an open ended qualitative and flexible approach was used with minimal intrusion. Walkers were invited to make a self-directed film of their walk (with comments) using a hand held digital camcorder. No guidance was offered other than to film anything of interest or anything which they liked or disliked. The second part of the project was essentially a de-briefing in the form of a short questionnaire. Data was gathered mainly at weekends between the 11th July and 8th August 1998.

The weather was mixed to fine on the walks. The gender split of walkers was approximately 60:40 in favour of men and at each site there were relatively few walkers over 50 years of age. It was of interest that most people had travelled from 10-50 miles in order to go on the walk with relatively few 'locals' i.e. within a 10 mile radius participating.

RESULTS

A total of 37 people participated at both sites.

Video Data

A content analysis of the video data identified 6 general categories of interest. These were:
1. Objects (*e.g.* sculpture, building, waterfalls)
2. Aspects of path (*e.g.* waymarking, surface, width)
3. Views (*e.g.* panoramic, scanning)
4. Human Interest (*e.g.* other people)
5. Flora and Fauna
6. Human Intervention (*e.g.* litter, pylons)

The degree of attention given these categories was estimated from the frequency of stopping points to film each category across both walks.
1. The rank order of stopping point frequency was consistent over both walks
2. Objects had the highest frequency, followed by views. Next were paths, then flora & fauna. The lowest frequency of interest was attached to human activity and interventions.
3. Only 50% of views and 50% of spaces identified by the landscape architect research assistants were found to be of interest to the lay groups.

Questionnaire Data
1) Approximately half the sample went for forest walks more than once every two months.
2) Approximately 40% of walkers had travelled over 50 miles to visit the site, with a further 40% travelling between 10 & 50 miles.
3) Approximately equal numbers of walkers were either with or without children.
4) Nearly all participants reported enjoying the walk experience. Approximately 50% reported the experience as moderately exciting (pleasant and aroused). The other 50% reported the experience as relaxed (pleasant and unaroused)
5) Sight was recorded as the most important of sensory information. Sounds in the forest were ranked second in importance. Most participants were neutral about the role of smells and touch.
6) Most walkers commented that a central function of the walk was to have contact with nature and not be reminded of people. This reinforces the low levels of interest in human activities shown in the video filming.
7) Likes:
a) spatial change clearings & views
b) narrow paths, enclosed by the forest
c) waterfalls/water flora & fauna
Dislikes:
a) crowded places
b) uphill sections & clear felling
c) signs of human intervention

DESIGN IMPLICATIONS

The context data and the stated preferences of the walkers provide some useful information for the design process. One special challenge for designers emerges from this study. The walkers clearly want wayfinding information and facilities (*e.g.* seating, shelters, WC's) to be marked. These are seen as necessities. At the same time the walkers want this information in a way which minimises indications of human intervention. A major function of forest walks appears to enable visitors to get closer to their idea of nature.

Sustainable Management of Natural Resources: Is It Possible at the Urban-Rural Interface?

Joanne M. Westphal
Michigan State University, MI 48824 East Lansing, USA
Tel: (517)353-7880, FAX: (517) 353-0006, Email: westphal@pilot.msu.edu

Keywords: Sustainable Landscapes, Land Use Planning, Urban-Rural Interface

Despite the vast landmass of the United States, resource managers, landscape architects, and planners are becoming increasingly aware of the difficulty in protecting natural resources at the urban-rural interface. Part of the problem stems from the fact that a comprehensive national land use plan has not been forthcoming from the federal government. Thus, state, county, and local government bodies have been left to determine priorities in land use as well as preservation and/or protection strategies for properties under their jurisdiction. Because each of these layers of government has different agenda, oftentimes, a coordinated, effective land use planning effort that could protect natural resources, especially at the urban-rural interface, is impossible to develop.

This paper examines historic land use management tools in the United States from a planning perspective, and it provides insight to the political and economic factors that determine the success or failure of these tools to create and/or enhance sustainable landscapes. Suggestions for alternative land use planning strategies in the face of urban sprawl are provided. A case study using a rapidly growing area in Michigan (USA) will be used to illustrate the need to integrate some of the old planning strategies with the new alternatives to be effective deterrents to uncontrolled growth and lost sustainability of our natural and agricultural landscapes. A brief discussion on how this new approach may be used to overcome some of the governmental barriers of the past will conclude the paper.

Assessment on Recreational Impacts in Malaysian Recreation Forests

Noor Azlin Yahya
FRIM, Urban Forestry Section, Forest Plantation Division, 52109 Kuala Lumpur, Malaysia
FAX: 03- 630-2105, Email: azlin@frim.gov.my

Keywords: Recreation, impacts, eco-tourism

A study was conducted at three Recreation Forests near Kuala Lumpur to assess impacts of recreational activities on the natural resources of the area. This paper mainly reports the results of the study and suggests a management action to be taken.

Recreation Forests in Malaysia are usually scenic forests with rivers where the most popular activities conducted are picnicking, swimming and relaxing under the forest shade. Camping, trekking and photography are also carried out but to a lesser extent. As owner of the Recreation Forests the Forestry Department usually manages the areas. However, some areas are fully or partly privatised where the management of certain facilities or the whole area is given to private concessionaires.

Visitors to Recreation Forests have been shown to in be great numbers especially during weekends and school holidays. Studies showed that visitation to each Recreation Forest often exceeds 100,000 a year. The majority of visitors to the Recreation Forests are the Malays who are also the major ethnic group in Malaysia, from the middle and the lower income group, and with highest education attainment of secondary education.

Impacts of recreational activities on the natural resources of the three Recreation Forests, namely Sungai Chongkak, Lentang and Sungai Tua were assessed for soil and vegetation parameters. From this study it was found that soil compaction is always higher at recreation sites compared to control sites for all three Recreation Forests. For vegetation parameters, it was found that vegetation cover is greater and there are more mother tree species at the control sites. It was also found that, there is a domination of forest species at the control sites, whereas vandalism signs were found to be more common at the recreation sites. The results on soil and vegetation parameters show that areas used for recreational activities are losing their natural conditions whereas similar control areas along the river that was not used by visitors shows better regeneration and in more natural conditions.

Visitor's opinion on problems of the Recreation Forests was also evaluated to assess perceptions on the conditions of the natural resources. Out of several parameters tested, it was found that many visitors to the recreation forests are aware of the litter problem and many perceived it as a big problem. The conditions of tree vandalism and soil erosion are also considered as big problems to visitors.

6.03.00 Forest information services for foresters and society

Using Information Technology to Meet Changing Knowledge Needs in Forestry

Philip Edge, Patricia Neenan, Gillian Petrokofsky and Peter Scott
CAB International, OX10 8DE Wallingford, United Kingdom
Email: cabi@cabi.org

Keywords: information network; electronic publishing; bibliographic database; community of users

At a time when there are fundamental changes in the status of forests, in their perception by the public, and in forest-related environmental issues, there is an unprecedented need for sound decision making in forestry. This has led to a new requirement for knowledge, organized in a way that provides convenient decision support. Information Technology (IT) can greatly facilitate this process. Partnerships of people and organizations with common information needs and a mutually-dependent interest in facilitating information sharing and knowledge management can take advantage of the power of IT to realise their aspirations rapidly and effectively.

Bibliographic databases exemplify the power of IT to render huge volumes of facts accessible as useful information. This can be illustrated by a database, conceived and maintained by cooperative partnerships, containing over half a million abstracts and spanning more than fifty years of the world literature of forest science. It allows access through multiple routes, including CD-ROM and the Internet, and can be built into knowledge bases as required.

IT allows information to be presented to the user in a convenient and friendly way, so that knowledge results. Examples in the forestry context include taxonomic information systems, geographic information systems, and multimedia knowledge tools such as Electronic Compendia. The Forestry Compendium illustrates how varied information sources can be brought together to make a single coherent knowledge base.

The Internet, Intranets, the World Wide Web, CD-ROMs, and email provide unprecedented new opportunities for innovative approaches to meeting the need to conserve knowledge and pass it on. The implementation of electronic publishing and information dissemination presents new challenges in the achievement of efficiency, economy, convenience, and standardization. CABI believes that the Internet provides the medium for the provision of large bodies of related information to 'communities' of users with common needs. The creation of these bodies of information requires CABI to form alliances with and develop collaborations with organizations which can provide information and/or communities of users which complement its own; and create novel information products by combining primary, secondary and tertiary information in innovative ways. Central to Internet resource development is CABI's further belief that the future of information access on the Internet lies in developed networks of interlinked information. Internet sites of bibliographic data, with other information where possible, form platforms which provide the forum for combining with the information of other organizations through linkage. CABI's concept of linkage is that abstracts, structured within a database, provide the navigation to and from full text and other material, thus fulfilling the dual function of a searchable information resource and a powerful mechanism for locating information.

While the Internet is an extremely powerful enabling mechanism, there are still large areas of the developing world where connectivity is limited and access to the Internet is not available. CABI has proposed the establishment of "Knowledge Networks" that comprise moderated exchanges of knowledge using email between established groups of scientists working in a related field. Selected extracts from many of the above resources used for a virtual "community" can also be provided by email to these groups, and discussion papers summarizing the exchanges can be added to the Internet resource for access by a wider audience.

Capacity building through information: the role of international forestry research centres

Michael Hailu, Rita Mustikasari
Center for International Forestry Research, (CIFOR), Jalan CIFOR, Situ Gede, Sindangbarang, 16680 Bogor Barat, Indonesia
Tel: +62(251) 622 622, FAX: +62(251) 622 100, Email: m.hailu@cgiar.org

Keywords: natural resources management; forestry information; agroforestry information; capacity building; networking; international collaboration

The Consultative Group on International Agricultural Research (CGIAR) has largely neglected research on natural resources management until the system recognized the need to address this important area and expanded its membership. in 1991, the CGIAR admitted three centres into its fold, including the International Centre for Research in Agroforestry (ICRAF), and decided to establish the Centre for International Forestry Research (CIFOR). Since this change, a number of networks and system-wide programmes dealing with natural resources management, including forestry, have been launched. These networks and system-wide programmes provide not only a useful mechanism for international research collaboration, but as a major vehicle for information exchange and dissemination. Specialized information systems and services, developed at centres such as ICRAF and CIFOR, provide a useful source of information for network members and other users. Such services include specialized forestry databases, publications, CD-ROMs, modeling and decision support tools, web sites, and library/documentation services. The paper reviews some of these services and highlights their relevance to the forestry research community and explores avenues for enhancing their accessibility.

The paper also explores capacity building in information and its impact on the work of scientists, including foresters. Using the case study of the AfricaLink Project-aimed at providing electronic connectivity to several research networks in Africa-the paper explores problems national scientists encounter due to poor communication facilities and lack of access to relevant and timely information. It demonstrates how a modest effort in providing basic email connectivity-especially in remote research stations-can make a significant difference in enhancing information exchange and research collaboration among network members. The paper concludes by highlighting how the Internet and the World Wide Web can be used to facilitate collaboration and information access for regional and global research networks.

The Rainforest Interpretation Centre - A Contribution to Forest Conservation and Environmental Education in Sabah

Bernadette Joeman, Hilary Macleod & Michael Trockenbrodt
Forest Research Centre, Forestry Department, Post Box # 1407, 90715 Sandakan, Sabah, Malaysia
Tel: +60-89-531522, FAX: +60-89-531068, Email: frc@tm.net.my

Keywords: information centre; extension service; teacher training; rainforest information

The Rainforest Interpretation Centre (RIC) is an Environmental Education facility located within the Sepilok Arboretum, Sandakan, Sabah, Malaysia. The Centre was constructed in 1995 with funds from the Deutsche Gesellschaft für Technische

Zusammenarbeit (GTZ). However, this facility is now run by the Environmental Education Unit of the Forest Research Centre, Sabah Forestry Department.

The RIC houses an exhibition that covers a wide variety of aspects of the rainforest (*e.g.* importance, characteristics, distribution, effects of their destruction) and a collection of artefact displays, ranging from dipterocarp seeds to traditional handicrafts made from forest products. Adjacent to the RIC is a 'Rainforest Walk'. The trail is guided by interpretative boards.

There are two main aims behind the establishment of the Rainforest Interpretation Centre:
- to increase public awareness of the rainforest, its importance and the consequences of its destruction
- to change attitudes and behaviour towards the rainforest and the environment as a whole.

The Environmental Education Programme at the RIC has been divided into three main components:

1. an environmental education component for visiting primary and secondary school groups. The aim of this component is to plan and conduct environmental education programmes for primary and secondary students using the RIC facilities.

2. an environmental education component for in-service and pre-service teachers and teacher educators. The aim of this component is to train teachers to implement environmental education and enable them to plan and conduct their own environmental education programmes at the Rainforest Interpretation Centre.

3. a public awareness component which caters for the general public and tourists. The aim of this component is to produce quality interpretive materials and programmes for the public.

In addition to the target components, there are two supporting components:

- an Environmental Education Resource Collection to establish a resource base for the sustainability of the environmental education programme.

- an Administration and Training component to establish procedures for the running of the programme.

Since the RIC opened for visitors in July 1996, over 3400 tourists have visited the centre. About 20 workshops for teachers and teacher trainers have been conducted. The workshop programmes contain a general introductory lecture on environmental education including the principles and a demonstration of some selected activities that teachers can do with their students. To support the workshops, a training manual for the participants was produced. The manual contains information on environmental education, the Rainforest Interpretation Centre, and sample activities as well as programmes that can be run with students. The main target group is school students for whom half day and full day programmes for both primary and secondary groups are conducted. So far about 50 schools visited the RIC. in many cases the programmes incorporate a visit to the nearby Sepilok Orang Utan Rehabilitation Centre.

The RIC is becoming increasingly popular with schools, tour operators and other visitors. The majority of the visitors is interested and eager to learn. Young students have expressed an increasing degree of awareness and concern about the state of the environment especially the forest. Thus, the RIC and the Environmental Education Programme of the Forestry Department is considered a small, but nevertheless important contribution to forest conservation in Sabah.

Developing an Integrated Protected Area Network (IPAN) System for Biodiversity Conservation: Lessons Learned

Vinod B. Mathur, Pradeep K. Mathur, Vineet Sood
Wildlife Institute of India, Post Box # 18, 248 00248 001
Chandrabani, Dehradun, India
Tel: +91-135-640112 to 115, FAX: +91-135-640117,
Email: vbm@wii.gov.in

Keywords: information system; information technology; resource management; modelling; GIS

With the rapid advancement in the field of Information Technology (IT), natural resource managers have become conscious of the need and utility of developing and managing databases in order to facilitate informed decision making. Likewise, advances in the field of Remote Sensing and Geographical Information System (GIS) technology provide natural resource managers synoptic, repetitive spatio-temporal coverage's for management and monitoring of complex and dynamic landscapes. Realizing the global as well as the national need for developing a rapid, transparent, participatory and informed decision making process in the field of biodiversity conservation, we developed an Integrated Protected Area Network (IPAN) System for the Maharashtra State Forest Department (MFD) India.

A generic approach, capable of evolving solutions in a participatory and transparent manner was adopted in the development of the IPAN system. The IPAN system is 'modular' and 'hierarchical' in nature. There are nine modules viz. (i) Biogeographic Zonation; (ii) Protected Area Resources; (iii) Human Resource Development; (iv) Research and

Monitoring; (v) Tourism and Nature Education; (vi) Finance and Budget; (vii) Supporting Institutions; (viii) Legislative Assembly questions; and (ix) Bibliography. Each module is further divided into several 'sub-modules'. Each sub-module contains information on various 'attributes'. The organization of information follows a 'nested architecture'. The system has a flexibility to increase the number of modules/sub-modules/attributes as per specific needs arising in future.

The IPAN system has been designed to operate at four functional/operational levels of management decision making. The IPAN system software has been developed using Visual Basic 4.0 programming language and is designed to handle both the spatial and aspatial data. The IPAN system provides outputs in a variety of formats viz. (i) tabular statements (ii) graphics, and (iii) maps. Most of these outputs conform to the existing procedures of providing information within the departmental hierarchy and wherever necessary modification have been made to optimize the reporting requirements.

The IPAN system facilitates: (i) storage, retrieval and query of large data sets; (ii) compilation of tabular, periodic statements/returns on staff position, offences, management activities routinely required for regional planning and management; (iii) providing of updated information on Protected Area (PA) resources required for preparation/revision of PA management plans; (iv) monitoring of trends pertaining meteorological variables, vegetation, animal populations, tourism, animal damage compensation, etc; and (v) resource map generation for better visualization, planning and decision making.

The integration of various modules in the IPAN system allows the users to query and generate information *e.g.* determining the visitor carrying capacity and ecotourism potential of a national park; calculation of biotic pressure indices; monitoring of trends in socio-economic dependence of rural communities living adjacent to the protected areas; identification of information gaps by searching the bibliographic database. The paper also summarizes the lessons learned in addressing complex data management issues viz. data custodianship, data validity, value addition and data updation, which would be very useful for handling similar tasks in a developing country situation.

Resource Sharing and Networking amongst Forestry Libraries in India

M. S Pathania
Dr. Y.S. Parmar University of Horticulture and Social Sciences, Library, 173 230 Solan (HP), India
FAX: 91-01792-52242, Email: asc@yspuhf.hp.nic.in

Keywords: library networks; forestry databases, information infrastructure

For undertaking forestry research, carrying out literature searches and information consolidation, the resource sharing and networking is the most appropriate. in a country like India where the resources of most forestry libraries are inadequate and unbalanced, it is extremely important to pool the resources of various libraries together. As such the libraries of various institutes in the country set up by Indian Council of Forestry Research and Education (ICFRE) / Ministry of Environment and Forests and Agricultural Universities imparting forestry education were surveyed.

With the expansion of knowledge, a lot of literature is published and it is not possible for any of the aforesaid libraries to cater to the need of all its users. Several Commissions in India had recommended 6.25 to 10% of the educational budget alloted for expenditure on libraries. But it is disappointing to note that only 1.5% or less is spent on most of the libraries. To-day the effective library co-operation is still on idea plane in India. Only few libraries are developing ways and means to make efforts towards library co-operation. The areas where resource sharing has achieved partial success in India are:
- Inter Library Loan Services
- Co-operative Training
- Book exchange
- Co-operative Library Services (SDI, CAS)

Whereas in areas like Co-operative Acquisition, Co-operative Cataloguing, Co-operative Storage and Technical Processing the initiative is yet to be taken as far as forestry libraries are concerned.

The effectiveness of the system can be had only with the enactment of Library Legislation. It should also provide for finances and the way for conducting library services. in India there is still no agreement on Acquisition Policies, Bibliographical and Standardization procedures of various forestry. in the fact of the problems facing the forestry libraries, resource sharing seems to be the only solution. It is hoped that the use of computers, the modern networking systems, union catalogue and co-operative library services will provide effective resource sharing facilities in the near future. For a successful implementation of resource sharing activities, there is a need of creation of databases by means of computers at various levels. This in turn, may be combined into bigger data-bases of all materials available in participating libraries.

This paper discusses as to how the modern forestry researcher in India is confronted with the literature explosion and the importance of resource sharing and the need for developing an effective network of forestry libraries in India.

Plant resources of South-East Asia (PROSEA)

Elisabeth Philip, M.K.M. Rizal, M.S. Khadijah and M.A.A. Razak
Forest Research Institute Malaysia, 52109 Kuala Lumpur, Malaysia
Email: philip@frim.gov.my

Keywords: plant species; tropical plants, publications, PROSEA databank; handbook

South-East Asia houses one of the biggest remaining complexes of tropical plant diversity. Between 5000 and 10,000 plant species have been described in the course of time as being used by mankind. The information on these plants both old and new is scattered world wide that only scientists could consult a handful. Similarly, the vast amount of vernacular reports by emerging class of local scientists within the region hardly reaches an international audience and often - even colleagues in neighbouring countries.

Hence, an international programme was initiated with the objectives to document and make available the existing wealth of information on plant resources of South-East Asia; to make operational a computerised data bank on plant resources of South-East Asia and to publish the results in an illustrated multi-volume handbook. It is an interdisciplinary project covering the fields of agriculture, horticulture and forestry. A network of offices in six South-East Asian countries has been established to achieve these objectives. see also: http://www.bib.wau.nl/prosea/

The information gathered has been grouped into 20 commodity groups based on their primary uses. The data bank on plant resources has a total of 52,967 records as of 1998. Bibliographies of less accessible (often gray) form the records of this data bank. of these records, edible fruits and nuts and timber trees are the commodity groups with the highest records of more than 8000. More than 8000 species of plants both lower and higher have been covered in the data bank. Plants are also classified based on their conservation status and distribution. Retrieval of information has been made easier with the advent in computer software and CD-ROMs.

Between 1989 and February 1999, twelve commodity groups have been finished and published in 14 volumes; Pulses, Edible fruits and nut, Dye and tannin-producing plants, Forages, Timber trees, Major, Minor and Lesser known timbers, Rattans, Bamboos, Vegetables, non-seed carbohydrate-producing plants, cereals, Auxiliary plants and Essential-oil plants. in total 4602 species have been described, 3592 as major and 1023 as minor. The remaining volumes; medicinal and poisonous plants, spices, vegetable oils and fats, cryptogams, stimulants, fibre plants, plants yielding exudates and ornamental plants will be published between 1999 and 2001.

6.03.02 Forest Terminology: How to get society understand forest terminology

Forest Terminology in relation to Societal Change and Decision Making

John A. Helms
University of California Berkeley, Dept. Environmental Science, Policy, and Management, 145 Mulford Hall, CA 94720-3114 Berkeley, USA
FAX: (510) 643-5438, Email: helms@nature.berkeley.edu

Keywords: Forest terminology, societal change, definitions, on-line dictionary

The last decade has seen dramatic, world-wide changes in the diversity of societal perceptions of the uses, needs, and values of forests. Many societal groups, particularly in the conservation area, are strongly influencing the management and conservation of forests on both publicly- and privately-owned forests.

Forest management is also becoming increasingly diverse. in the United States it encompasses a variety of objectives represented by owners that include private (industrial and non-industrial), public (federal and state), native tribes, and organizations interested in forests as long-term financial investments. One could argue that this diverse set of ownerships represents a broader cross-section of societal needs and values than do the conservation groups.

Given this diversity in needs, uses, and ownership of forests, it is not surprising to find that forest terminology is used inconsistently. Sometimes, as in the case of such terms as sustainability, forest health, and clearcutting, this is probably deliberate to further the objectives of the user. Until recently, existing terminologies were commonly dominated by traditional focus on timber management. To fill the need generated by more diverse objectives and values, current documents are typically accompanied by independently-developed glossaries. Consequently, in the development of public policy and regulation it is common to find that terms are defined differently.

A standard, accepted, on-line dictionary is needed that is used as a basis for all documents, debate, general communication, and policy development. Such a dictionary should probably be developed and maintained by a group of forest terminology specialists representing diverse elements of the broad field of forestry. These experts whould manage the peer review of definitions before incorporation. IUFRO should expand its leadership role in developing a standardized terminology, probably with regional variation of definitions, both nationally and internationally. The great advantage of an electronic dictionary is that it would be readily available and could be constantly updated and revised as terms are introduced or modified. Current issues needing to be resolved include the use of copyrighted definitions that are currently limited to use in the print medium, defining the extent of the field of forestry, and determining the extent of coverage of terms in each of the forest science disciplines.

Proposal of A Multilingual Forest Terminology Database Designed for Western and Non-Western Languages.

Mitsuo Matsumoto
Forest management division, Forestry and Forest Products Research Institute, Post Box # 16 Tsukuba-Norin, 305-8687 Ibaraki, Japan
Tel: +81-298-73-3211, FAX: +81-298-73-3799, Email: machan@ffpri.affrc.go.jp

Keywords: Forest terminology, multilingual terminology database, non-western languages, two-byte code, SilvaVoc-J

SilvaVoc, IUFRO's clearing house for multilingual forest terminology, is working to establish a forest terminology database to be published on the Internet. Non-Western languages such as Japanese, however, have some problems in multilingual databases, and current web browsers have a limited capacity to manage multilingual functions. For example, western computers cannot display Japanese characters correctly on the monitors, because they cannot manage two-byte code and have no Japanese font data.

SilvaVoc-J, which is a partner of SilvaVoc in Japan, developed an experimental system of a multilingual forest terminology database. This system was based on one of the solutions proposed by the author at the IUFRO international workshop "Multilingualism and Expert Cooperation in Forest Terminology" (MEXFT'98). It consists of three functions. The first function is a World Wide Web server, the second a database server, and the third one is a function to convert Japanese characters' fonts to raster images automatically.

The system works as follows. First, a user queries about a term to the Web server from a client computer. Then, the Web server requests to search the term to the database server via Common Gateway Interface (CGI). The database server carries out the search and sends the result to the Web server via CGI. If the result term contains Japanese two-byte characters, it is converted to a raster image on the way to the Web server from the database server. Finally, the Japanese term is displayed as an image in a Web browser on the client computer.

The system does not require Japanese font data and special browsers on client computers. in other words, Japanese characters can be displayed in popular Web browsers such as Netscape Navigator and Microsoft Internet Explorer on any countries' computers. Furthermore, the method is available not only for Japanese characters, but also for characters of other non-Western languages.

Therefore, the system also makes it possible to add other non-western languages to the multilingual forest terminology database.

The experimental system of a multilingual forest terminology database will be demonstrated in the presentation.

Terminology as a way to communicate values. Sustainable forest development: vision of the world in the 21st century

Nerida Puentes Alvarez
Universidad de Pinar del Rio, Pinar del Rio, Cuba
Tel: +082-5032, Email: npuentes@eco.upr.edu.cu

Keywords: Forest terminology, Spanish language, English language, teaching programmes, terminology work, sustainable forest development

Language is a working instrument common to all subject specialists, a working tool and a means for communicating scientific findings.

The objective of the Programme of Foreign Language of the Technical Center of Higher Education is to elaborate versions and summaries of expert materials in Spanish with an adequate usage of the Spanish mother tongue. The educative project as main working document in the three dimensions, the instructive, sociopolitical and extension aspects, serves as a basis for integrating English as a foreign language programme with the other expert programmes.

Facing the challenge of the globalization, the correct usage of the language as a distinctive feature of the national identity and the valorization of linguistic variants are of major concern to the project leaders. The strategy was set to use Terminology as a way to integrate English into other teaching programmes in the University of Pinar del Rio. This strategy consists of several phases, resulting in the integration of the students in research work, sistematic terminology work and in the organization and elaboration of concept systems of the contents of the several subjects. With this strategy the transdisciplinary approach of the English technical language course leads, via sistematic terminology work, to the formation and strenghening of general and professional values which the students need to have as members of a society that has to face the challenges of a new century.

Sustainable forest development as a paradigm to reach sustainability is the perfect conceptual world. Terminology work takes into account the scientific perception of the world through knowledge-generating processes in the construction and permanent reconstruction of the student's "vision of the world". It aims at providing an education which allows to perceive semantic and conceptual features of sustainable forest development. These combined language and subject field teaching programmes are intended to prepare the students to the challenges that they will have to face as future subject specialists.

Sustainable forest development as a paradigm to reach sustainability is the perfect conceptual world. The scientific conception of the world through knowledge generating processes in the construction and permanent reconstruction of the students' "vision of the world" is taken into account in the terminology work to obtain an education which allows to perceive semantic and conceptual features of sustainable forest development and therefore provides a way of action in view of the challenges that the students have to face as future subject specialists.

Coming to Terms with Politicians and Definitions

H. Gyde Lund
Forest Information Services, 8221 Thornwood Ct., VA 20110-4617 Manassas, USA
Tel: +1-703-368-7219, FAX: +1-703-257-1419, Email: gklund@worldnet.att.net

Keywords: Forest terminology, international processes, definitions

Recently there has been a large number of international agreements, conventions and protocols dealing with forest and forestry - especially since the United Nations Conference on Environment and Development (UNCED) in 1992. Politicians and high-level government officials, eager to do the right thing regarding the environment endorsed documents such as the Forestry Principles, the United Nations Framework Convention on Climate Change (UNFCCC), the Convention on Biodiversity (COB), and the recent Kyoto Protocol. Successful accomplishment of these agreements on a global basis requires common understanding and implementation at the national level. However, these agreements often contain terms that are not clearly defined or accepted on a national level. It could be that the endorsers either believed that they were commonly understood or they purposefully left the definitions and interpretations up to the implementing bodies.

To understand the magnitude of definitions in use at the national and international levels, IUFRO 6.03.02, in 1998, undertook studies of some terms associated with the Forestry Principles, Climate Change and Biodiversity Conventions, and the Kyoto Protocol. The studies included a world-wide literature review and internet survey for definitions of such terms as tree, forest, land cover land use, deforestation, afforestation, reforestation, old growth and ancient forest, protected areas, and low forest cover, that appeared to be ambiguous in many of the agreements. For example, the term "forest", key for the implementation of the Kyoto Protocol, may be defined as an administrative unit by one country, a type of land cover by another or a type of land use by yet another. With such diversity in definitions at the national level, it would be very difficult to develop any meaningful statistics at the global level.

How to do Terminology Work in Forestry. Services Offered by IUFRO

Renate Prüller, Michèle Kaennel Dobbertin
IUFRO, Secretariat, Seckendorff-Gudent-Weg 8, 1131 Vienna, Austria
Tel: +43-1-877 0151 ext. 21, FAX: -43-1-877 9355, Email: prueller@forvie.ac.at

Keywords: Forest terminology, co-operation, terminology services

Efficient communication among scientists and with decision makers needs a precise and clear technical language. The network of IUFRO experts in forest science is an immense pool of living expert knowledge. Experts create the terms we use to communicate and thus constitute an ideal partner for IUFRO's services in their attempt to define and make accessible the forest technical language to a wider public.

At a time when English has become the *lingua franca* of science, it is crucial that other languages - and IUFRO has four official languages - keep playing an active role. This broadens the horizon of scientific thinking and knowledge, but also makes unequivocal communication more difficult to achieve.

Vocabularies, glossaries and terminological databases present the technical vocabularies and, if relevant, interpret them for the interested public. The role of forestry experts is to help and assist in this process of explication and definition of their own specialised language, in order to guarantee the high quality and liability of these communication tools.

IUFRO offers services with regard to terminological problems through its Working Party 6.03.02 "Trends in Forest Terminology" and its terminology project SilvaVoc based in the IUFRO Secretariat, which are interrelated and pro-active. Additionally we will show how 6.03.02 and SilvaVoc incorporate IUFRO officeholders in terminology work and illustrate the most important services that are provided by 6.03.02:
- electronic discussion groups
- terminological hotline for telematic-based terminological assistance;

and by SilvaVoc:
- on-line Bibliography of terminological publications in forestry
- terminological database SilvaTerm.

Traditionally IUFRO's role in terminology has been to make people aware of terminological differences. Our approach is therefore based more on descriptive than prescriptive principles, e.g. instead of aiming primarily at recommending definitions, it is our concern to point out differences in the use of the terms. Guidelines for quality forestry terminology projects will be distributed at the IUFRO World Congress.

As globally co-ordinated forest research becomes a priority in the context of sustainable management and global change, the need for concerted action in terminology will increase. Partners from various geographical and institutional backgrounds will have to base their collaboration on common definitions. They will also need to avoid duplicating terminological efforts. Together, WP 6.03.02 and SilvaVoc can significantly contribute to this collective effort by consolidating the network, resources and expertise they have built since 1995.

6.06.00 Research driven by scientists' wish or society's demand?

Scientists and Forest Policy: Roles, Opportunities and Responsibilities

Denver Burns
USDA Forest Service, Rocky Mountain Research Station, 97303 Ft Collins, CO, USA

Within the United States Forest Service, the role and responsibilities of research scientists is widely discussed in terms of decision making for policy and management. The issue is widespread within the national scientific community as scientists come face-to-face with the conflicting demands of unbiased research and moral and ethical considerations to make public their views and value judgments about trends and issues that their work has uncovered. The Forest Service has attempted to draw a clear line between science and value judgments in the policy and management of the Nation's public forested lands.

A successful example of an interaction between universities and forest companies to promote research and development in Brazil: SIF

Laercio Couto, Amaury P de Souza, Antonio J de Oliveira, Antonio S Alipio, Antonio B do Vale, Jos, C Dias Casali
Federal University of Vicosa, Dept of Forestry, Society for Forest Research, 36571-000 Minas Gerais, Brazil
FAX: 55 31 891-2166, Email: lcouto@mail.ufv.br

In 1974, the Department of Forestry - DEF of the Federal University of Vicosa - UFV in Minas Gerais, Brazil, along with five private forest companies founded the Society for Forest Research - SIF a non-profit organization with the objective of promoting research and development in the Brazilian forestry sector. At the same year, the Department of Forestry of that University was also starting its graduate program in Forestry. This fortunate coincidence led to one of the best examples in Brazil of an interaction between the scientific and private sector in the country. Most of the research thesis at Master and Doctorate level in the graduate program of Forestry of UFV were funded and developed at those associated companies. Since its foundation in 1974 SIF has promoted a series of short courses, workshops and international meetings and publishes today Revista µrvore which is considered the best scientific journal in the forestry area in the country. The objective of this paper is to show how an agreement between private forest companies and a federal university can lead to one of the best examples of interaction for forestry research and 6.06.00 Research driven by scientists' wish or society's demand?

Optimizing Societal and Corporate Needs While Delivering Quality Science to Support Forest Policy and Practices

David De Yoe
Ministry of Natural Resources, Ontario Forest Research Institute, Sault Ste. Marie, Ontario, Canada

Aligning science activities to best address ecological sustainability, private sector business objectives, and/or societal demands is a major challenge in research and development (R&D). Forest resource policy makers must account for all three when developing legislation, standards and guidelines to reflect the wide array of multi-sector values. Policy is being increasingly scrutinized to ensure its integrity and relevance. Delivery of quality science to meet sector needs requires 4 major steps: a) identify sector needs (including the scientific community), b) translate those needs into research proposals, c) select of priority R&D projects, and d) ensure the service or product fits the need and is delivered on target.

Ontario is exploring the use of a process to effectively, efficiently and equitably address each of these steps. The procedure includes the use of a values and objectives driven survey of key stakeholders, a protocol for aligning science activities with stakeholder values and objectives, a delivery tracking system to help ensure a good product - need fit, and a performance-based system that guides and supports scientists and specialists to help them meet corporate priorities.

The process uses sophisticated information management and technology to involve senior management at key decision points, optimize the use of human and financial resources, minimize subjectivity and bias in decision-making, and reward scientists and for delivery of quality products and services.

Forestry and Forest Research in Brazil

Vitor Afonso Hoeflich, Arnaldo José de Conto, Erich Schaitza
Universidade Federal do Paran, Embrapa Florestas, Brazil
Tel: 041-3425332, FAX: 041-244-1545, Email: hoeflich@cnpf.embrapa.br

Brazil has an area of 8.5 million km^2 and a population of over 160 million inhabitants. Brazilian GNP was about 750 billion dollars in 1997. Natural forests still cover a large area of Brazil. Although one may list several different forest ecosystems, six of them deserve special mention: the Amazon forest; the Atlantic forest; the "Cerrados"; the "Pantanal"; the "Caatinga"; the "Paran Pine" forest. Brazil has about 6 million hectares of man-made forests, mainly with *Eucalypts* (many different species, the most common one being *E. grandis*) and pines (slash and loblolly pine). These forests were planted mainly from 1966 to 1987 by large companies with tax incentives from Brazilian Government. Today, nearly all wood used for pulp and paper, particleboard and fiberboard comes from these man-made forests. Besides, more than one third of all veneer and plywood comes from pines.

In the last decade, Brazilian government has changed legislation to diminish deforestation and created a large number of conservation units. None of these measures was fully effective as there are no effective law enforcement structures and conservation units need further investments on financial and human resources to work properly. Forest research had an important role in forestry development in the last century, but research institutes are facing problems due to a rather long economic crisis. The early and current story of forestry research in Brazil is presented, and current trends in organizational and tematic aspects are discussed. The weakness of information systems and the need for the strenghtening of networks are key factors to the success of forest research in the country, which is hindered by a steady diminution of funding and to the current process of privatization of public research institutes.

The perspectives of development of forest sector in Brazil are good provided some structural changes occur in the country, increasing competitivity of forest products.

Current Research at the Institute for World Forestry

Jochen Heuveldop
Institute for World Forestry, Federal Research Centre for Forestry and Forest Products
Leuschnerstr. 91, 21027 Hamburg, Germany
Tel: +49-40-739 62 100, FAX: +49-40-739 62 480,
Email: heuveldop@aixh0001.holz.uni-hamburg.de

The mandate of the Institute for World Forestry/Chair of World Forestry is to conduct research on the structure and composition of forests, on their conservation, management, and potential for utilisation. The research is concentrated on the development of strategies to preserve forests and improve their multiple functions, on recultivation of degraded forest lands and on integration of forestry into overall regional development.

According to the research agenda, scientific activities and research projects focus on five key aspects covering tropical and boreal forest types:

Forest Ecosystem Dynamics

Regeneration and growth of trees essentially depend on their genetically programmed capability to adapt to changing site conditions. The knowledge of adaptability, of autecology and site preferences of important tree species is a significant precondition for the planning of environmentally compatible development of forests, and for the rehabilitation of degraded forests. Various projects investigate the autecology of tree species to gain knowledge about their suitability for integration in rehabilitation programmes. Furthermore, plant species diversity is studied to assess the effects of forest management in stands with different harvesting intensities and compared with pristine forest conditions.

Influence of Land Use on Biodiversity

Forests have a key function in determining the distribution and the abundance of many other plant and animal species. Biological diversity is becoming a central criterion for forest management and interdependencies are to be fully understood. Fundamental research topics deal with dispersal of plant diaspores, with browsing and predation and their consequences, with floral ecology and pollination success, as well as with competition. Sustainable management of forests mainly in an international framework also includes the careful utilisation of biological resources, other than timber, for the proper use and treatment of forests as a resource.

Forest Development and Monitoring

As part of the co-ordination and evaluation of the European Assessment on Forest Condition by UN/ECE and EU, a data bank is established. Data on site parameters, soil chemistry, elementary compounds in needles and leaves and the development of the canopy are included. All information is recorded in a time range of 15 to 20 years and is based on several thousands of monitoring points in Europe. The assessment methods of the different monitoring programmes of all participating countries need to be harmonised for interdisciplinary and synoptical analysis.

Silviculture as a Tool for Sustainable Management of Forests and Non-Timber Forest Products

Emphasis is put on research of structure and dynamics of tropical and boreal forest ecosystems as a fundamental prerequisite for the development of silvicultural systems. Concepts for silvicultural operations need to be elaborated and verified. They have to be oriented towards an economic feasibility, to ecological stability and socio-cultural compatibility.

Non-timber forest products play an important role in the sustainable management of tropical forests. Corresponding research concentrates on the production and utilisation of non-wood forest products.

Sustainable Forest Development

At the Conference on Environment and Development in Rio, the Federal Republic of Germany has agreed to implementing the Agenda 21, the environmental action programme for the 21st century. Chapter 11 of this Agenda ('Combating Deforestation') specifies research priorities of forestry research in the tropics. Moreover, Germany signed the Framework Convention on Climate Change in Rio. It obliges Germany to implementing the targets of the convention and to report to the Secretariat of the Conference of the Parties. This convention has meanwhile become national law. Considering Germanys international commitments, the Institute for World Forestry elaborates proposals in the context of harmonisation of diverging views for political decisions to be taken by the Federal Government.

6.06.02 How are innovations applied in sustainable forestry

The practice and prospect of participatory forestry in China

Jinlong Liu
Chinese Academy of Forestry, The Sustainable Forestry Research Centre, 100091 Beijing, China
Tel: 86-10-62889632, FAX: 86-010-62872015, Email: liujl @ rif.forestry.ac.cn

Keywords: Participatory forestry, community forestry, implementation, impacts

In historical review of the philosophy of human development regarding interaction between forests and humans, a transition is occurring from the perception of forests as a resource to recognition of forests as an associate. Humans have stepped into this new stage with difficulty, and participatory forestry can be a brick for paving the way into this new stage of human development. Participatory forestry was introduced to China in the mid-1980s and then fostered by international aid projects. in the past decade, issues raised for study have included policy, indigenous knowledge, gender analysis, conflict resolution, technical improvement and innovation, and training with international technical aid. But studies were limited in the area that has been tested with focus on southwest China. Since the mid-1990s, community forestry projects have been implemented in areas of poverty in the middle and west part of China with international financial aid. The impacts of these projects were analyzed for behavior and attitude changes of various stakeholders related to forests, institutional support for developing participatory forestry, the orientation of objectives, technical improvement and innovation, and extension. The constraints in the development of participatory forestry were analyzed with regard to behaviors and attitudes of outside individuals and institutions, policy and regulation, role of existing institutions, promotion costs, financial agencies, participatory process, and techniques.The decision-making processes, processes for implementation, and impact of the participatory forestry projects were analyzed in comparison to those of the prevailing top-down forestry projects. in regards to the participatory forestry as an emerging philosophy and strategy, many issues related to forestry management were analyzed including land tenure reform, policy and regulation, and decentralization of decision-making. Because of the great variation in natural, economic, social, and cultural conditions and the imbalance of policy reform in different regions, many cases with great variation were provided. This resulted in the important conclusion that cultural, natural, economic, and social conditions should be considered and different nations and regions should find their own way in promoting participatory forestry. Recommendations for forestry policy reform and strategies for project implementation were put forward.

Survey, Assessment, and Analysis of Existing Extension Strategies and Transferred Technologies in the Cordillera Region of the Philippines

Helen A. Maddumba, Jocelyn S. Mapanao
Ecosystems Research and Development Service, Department of Environment and Natural Resources, Cordillera Administration Region, Loakan Road, 2600 Baguio City, Philippines
FAX: 0063-442-4531, Email: erds-car@mozcom. Com

Keywords: extension; technology transfer; information dissemination; technology adoption

The study identified technologies and information that were disseminated through a loan project by the Ecosystems Research and Development Service. Dissemination methods and extension strategies were also identified as basis for formulating an appropriate and effective extension strategy for end-users and the government. Respondents identified one to four types of information and technologies with soil and water conservation measures most widely known in three provinces and tree planting technologies better known in two provinces. Methods used for disseminating information include: lecture, lecture with brochure, training, training and actual demonstration, cross-farm visits, film showing, broadcast, brochure distribution, house-to-house interviews, and meetings. Cross-farm visits occur when a group of farmers in the same area will visit a group of farmers with model farms in another area to learn technologies being adopted in that farm and in turn share their experiences and technologies to this group of farmers.

The most common and preferred method was training with actual demonstration followed by cross-farm visits. These strategies showed high impact and are recommended for introducing technologies and information to this type of client (upland farmers, a majority of which belong to 30-39 age group and have either reached or graduated high school education). Farmer factors that influenced adoption in several provinces included age, sex, civil/marital status, education, household size, experience, farm size, tenure, and membership in organizations. Technology features (profitability, simplicity, practicality, compatibility with tradition,

and low cost inputs), characteristics of extensionists (interest, positive attitude toward their work, and communication skills) and credit facilities were perceived by respondents to have influenced the adoption of the technology and information.

Influencing the Adoption of Forestry Innovations: A Case Example from the United States

Cynthia L. Miner, George H. Stankey
USDA, Forest Service, Pacific Northwest Research Station, P.O. Box 3890, Portland, OR, USA
Tel: 503-808-2135, FAX: 503-808-2130, Email: Stankey_George/r6pnw_seattle@sv2

Keywords: Forestry innovations; information dissemination; technology adoption; research organizations

People come to adopt innovations (new information, concepts, or technologies) through a process of becoming aware of the innovations, deciding to try it, and evaluating as to whether they will continue to use it. Forestry research organizations are in the business of producing innovations, but are increasingly challenged as how to best organize to promote the cycle of innovation adoption, implementation, and evaluation. This paper examines three ways that the Pacific Northwest Research Station, United States Department of Agriculture, Forest Service, promotes adoption of innovations that it has produced: (a) information and technology retrieval, (b) in-person interaction with scientists, and (c) organizational arrangements that emphasize learning. Traditional reliance on hardcopy scientific and technical publications is giving way to an increasing use of electronic information retrieval, including publication, software, and databases. Electronic access has broadened both the types and number of people aware of the station's research. Experiences with scientists include field trips, workshops, training, and some direct participation in research. Although such experiences can be effective in influencing people to try innovations, they are also time-consuming for scientists and involve an opportunity cost in time and resources that could be otherwise directed at research. Finally, the research station has experimented with several organizational arrangements that bring scientists, forest managers, and often citizens together. Such arrangements are innovative and complex, often requiring commitment from two or more organizations. Results have been mixed. Two examples of these arrangements are learning centers and adaptive management areas.

Rehabilitating Cold Deserts through Apropriate Transfer of a Technology Package

Om. Prakas Sharma, K K Raina
Dr. Y.S. Parmar University of Horticulture and Social Sciences, 173 230 (HP) Nauni (Solan), India
Tel: +91-1792-52288, FAX: +91-1792-52242, Email: dext@yspuhf.hp.nic.in

Keywords: technology transfer; extension; participatory processes; cold deserts, sustainable development

The "cold deserts" in India, covering and area of 74,809 km^2, pose a challenge to development because of rugged terrains, isolation, inhospitable climate, and a lack of communication facilities. The development in the region has witnessed a sequence of changes of edaphic, abiotic, and social-economic environment over time and is unfortunately contributing to environmental degradation.

The traditional farming practices are being over shadowed by modern culture without a fresh look at these technological interferences and capital appraisal of their influences on economic prosperity and sustainable development of these hostile regions in perpetuity and commensurate with the cultural heritage. The cold deserts need to be conserved by adopting environment friendly and appropriate development packages. The suggested technology should depend least on internal inputs and aim at intensive farm research to maximize land productivity, resource conservation, and environmental protection, and catalysis of natural ecological development processes.

The transfer of technology package suggested in this paper caters to the needs of the poor and marginal farmers with recognition of innovation for and accountability to these users. It is based on participatory principles which are socially pro-people, that is, economically viable and culturally acceptable. This transfer of technology module will help solve complex problems by blending modern scientific innovation and the traditional expertise developed by the inhabitants for centuries. The suggested appropriate transfer of technology package intervenes into the physical, socio-cultural, agroclimatic, geographic, environmental and different components of soil, water, crops, livestock and resource endowments of the community. Appropriate technology needs to be considered for vegetables, fruits, peas, potato, kuth, saffron, hops, and traditional crops like minor millets, seed production of flowers, grasses, forest plantations, medicinal and aromatic plants, sheep and goat husbandry, fisheries, and management of nomadic grazing. These technologies need to be transferred through the participatory processes and extension education techniques for sustainable development of socio-economic conditions and ecological sustenance of cold deserts.

Adaptation and evaluation of innovative technologies by society: a step towards optimum utilization of forest resources for sustainability and socio-economic development

Diwakar Sinha
Watershed Management Directorate, Indranagar Forest Colony, 248006 Dehradun, Uttar Pradesh, India
Tel: +91-135-724229, FAX: +91-135-620334(attn: Diwakar Sinha), Email: diwakar42@hotmail.com

Keywords: watershed management, technology, adaptation; evaluation; sustainable forest management

Sustainability in forest management is accepted as essential. Optimum utilization of available resources and adaptation of the latest management and innovative technologies are key factors in planning programs for forest management. India is striving to adjust and reorient teaching, training, and project implementation to address the changing focus of forest management. A technology policy statement was formulated to develop indigenous technology and ensure efficient diffusion and adaptation of imported technologies appropriate to national priorities and indigenous resources. The policy statement aims at attaining technical competence and self-reliance with maximum use of indigenous resources. It also aims at using traditional skills and capabilities toward commercial competitiveness.

Several other measures are envisaged to optimize demand on energy and ensure harmony within the environment. in view of the progressive pressure on the environment and natural resources, it was agreed on to give a new thrust toward conservation and sustainable development. To weave environmental considerations into the fabric of national life and the development process, the Government of India adopted the National Conservation Strategy in June 1992. This identified population control and conservation of natural resources including land, water, atmosphere, biodiversity, and biomass as the priority areas needing specific concerted action. These actions would integrate environmental consideration into policies and programs of development in various sectors.

The strategy also highlighted the role of International Cooperation and Systems for strengthening institutional mechanisms, research, and development, mobilization of financial resources, creation of public awareness, and training of professionals.

One of the significant steps in implementing the strategy was launching the National Watershed Development Project for restoration of the ecological balance in rain-fed areas and sustainable biomass production. It focuses on conserving rainwater and topsoil by (1) conservation, upgradation and optimum use of natural endowments in an integrated manner with low cost innovative technology and (2) generating employment for the poor rural communities, directly with farmers and watershed beneficiaries in planning and implementing all projects in the watershed by developing self-help groups.

The Doon Valley Integrated Watershed Management Project has implemented the National Watershed Development Project in Uttar Pradesh, India, with the help of the European Economic Commission since 1993. It includes agriculture, minor irrigation, horticulture, animal husbandry, community participation, soil conservation and forestry. The project now is being implemented in 255 villages covering an area of about 1,854 square kilometers. This paper discusses, reviews, and highlights issues of adaptation and evaluation of technologies, old and new, of the multidisciplinary project, with emphasis on environmental restoration, socio-economic development, and sustainable forest management.

6.06.03 Targeting the real forest managers

Impact of Societal Change On Extension Work in Bavaria

Roland L. Beck, Stefan Schaffner
University of Munich, Faculty of Forest Science, Am Hochanger 13, D-85354 Freising, Germany
Tel: +49-8161-71-4621, FAX: +49-8161-71-4623, Email: beck@forst.uni-muenchen.de

Keywords: Societal change; Extension; Bavaria

So far the focus of state support and forestry extension activities for small scale forest owners in Bavaria has been put on farm forests. The whole system of education, further education and extension for private forestry was and still is adjusted to that type of forest owner. The structural changes in the agricultural sector causes an ongoing abandonment of farm enterprises which lowered the number of managed farms from 472.805 in 1960 to 252.972 in 1997 and extended the number of pure forest enterprises from 46.148 in 1980 to 73.275 in 1997. Therewith the number of forest owners no longer covered by the traditional forest education and further education system increased and will increase further on. Coincidentally the management objectives of these "new" non farm forest owner type changes, at least partially no longer focusing on wood production.

The traditional forestry extension approach in Bavaria to link extension with the financial support of private forestry within the framework of financial funding programs does not seem to be appropriate in the future: The catalog of supported activities generally aims at traditional forest management measures. in addition, due to budget restrictions, the available amount of funds for management activities decreased remarkably since 1990. Therewith the attractiveness to seek extension services will shorten too.

The classic extension clientele (farmers, wood production oriented forest owners) is also confronted with changes on the customers side: The ongoing concentration process in the wood industry sector in Germany creates new challenges to small scale private forest owners in terms of delivery conditions (just in time production, sufficient volume per harvest etc.) and grading of timber.

Simultaneously forest owners available time for individual forest management is decreasing due to the growing size of the agricultural part of the enterprise in the case of farm forests. Therefore private forest owner organizations or service enterprises will increasingly take over forest management competencies in small scale forests. These "new" forest managers are therewith of growing interest for extension professionals.

The described processes demand the modification of the existing extension praxis in Bavaria in terms of approaches and contents, from a reactive general outline to an extended active extension. A precondition is knowledge on the motivations and attitudes, as well as objectives of the "new" forest owners and managers. Most recent research shows, that the new clientele not necessarily spends less time in their forest but less time with forest work. Absentee owners dedicate up to 70%, farmers at least 90% of their time in the forest to active work. Lack of equipment and less skills also characterizes these new absentee forest owners. 2/3rd hire entrepreneurs for specific forest management activities, 1/5th exclusively. Income generation plays only a minor role, main management strategy becomes to "keep the forest", using concepts from "traditional" to more "close to nature" but also "do nothing".

Forestry Extension in Environment of Political Transition - example of Slovenia

Jurij Begus, Zivan Veselic
Slovenia Forest Service, Vecna pot 2, p.p.71, 1001 Ljubljana, Slovenia
Tel: +386-61-123-54-32, FAX: +386-61-123-53-61, Email: Jurij.Begus@gov.si

Keywords: transition, forestry, Slovenia

The article deals with the conditions raised from the political changes in Central and Eastern Europe. We focused on forestry which in many places went through radical transformation. We are dealing with Slovenia as an example.

The political changes which occurred in Eastern and Central Europe in the last years, seized strongly into every pore of social life. One of the essential matters that went through a radical change, is property. in nature, as well as in social relations, the system of pendulum is present. If in a system we hold one thing on one, extreme side for a long time, the reaction, in the moment of release, will be adverse and more impetuous than it is good for a system. If the rights, arising from private ownership were oppressed for decades, it is logical that the demands of the new, or better "renewed" owners would not always be profitable for the forest. Therefore it is urgent that the interests of singular components of the system (owners, profession, politics, public) are coordinated, because only such coordinated system will work successfully.

Even though the conditions in Slovenia were, and still are, different from the rest of the countries in transition, the basic relation and problems in a society are in its nature similar, if not the same, everywhere. That's why the description of the condition in Slovenia is enough to make an observer get a rough picture of the circumstances, governing in other countries in Central and Eastern Europe.

The main changes, performed in the field of forestry in Slovenia are:
- with the denationalisation process the share of private-owned forests has increased
- the rights and duties of forest owners towards their forests have been strengthened
- a united public forestry service has been set up for all the forests, regardless of ownership
- financing of forestry has been completely changed; because of public meaning of forests, the state finances the public forestry service and the major part of protection works in private forests and it also participates in financing of tending works and maintenance of forest communications.

The united public forestry service assures a more efficient professional guidance of forest development.

The system of forest-management planning has been completely renovated and supported by modern technology of space treating (ortophoto plans, geo-coding of all data about forest and forest space). We are paying a special attention to incorporation of forestry planning into general regional planning in the country, even bigger stress than so far is given to protection of nature and to the highest possible extent the wishes of forest owners, who also participate in forestry planning, are being considered. The public forestry service makes wild-life management plans, too. One of the most important tasks is education of forest owners and the public.

The Forest Bank: An Innovative Program To Manage Forests and Protect Biological Resources On Private Lands

James E. Johnson
Virginia Tech, College of Natural Resources, 324 Cheatham Hall, Mail Code 0324, VA 24061 Blacksburg, USA
Tel: 540-231-7676, FAX: 540-231-7664, Email: jej@vt.edu

Conflicts between the need to harvest and extract timber products and to protect rare, threatened, and endangered biological resources are common throughout the world. in the US such issues have centered around a small number of high profile species such as the spotted owl in the Pacific Northwest and the Louisiana black bear in the South. Often, the critical habitat and species in question reside on large tracts of public land, and the controversy becomes one of public policy. However, across the US, about three fourths of the forest land is owned by private, nonindustrial land owners, and conflicts often become more personal between environmental organizations and private citizens. Recently an environmental organization, The Nature Conservancy, developed a program known as the Forest Bank, and is implementing it in Southwest Virginia as the first test site. The Forest Bank allows for a forest landowner to voluntarily place the value associated with his/her timber rights into the Bank, then withdraw an annuity equal to 3 to 5% of the value of the timber into perpetuity. For example, if a landowner has $100,000 worth of timber, he/she would receive from $3,000 to $5,000 each year. The Nature Conservancy would then take over management of the forest land, and harvest the timber in an environmentally responsible manner. in fact, the harvest of timber by The Nature Conservancy would be essential in order to provide a stream of income to keep the Bank funded at a level high enough to pay the annuities. This presentation focuses on a series of related research projects now being conducted by Virginia Tech in cooperation with The Nature Conservancy. Studies are underway to evaluate the willingness of forest landowners to participate in the program, to determine the impact on individual and community economics, and develop spatial data analysis techniques to relate demographic and economic data with land use patterns and critical habitats on the ground.

Household Livelihood and Labour-Time Use Patterns as Frameworks for Devising Community-based Agroforestry Extension Strategies

Alice A. Kaudia
Kenya Forestry Research Institute, Post Box # 20412, Nairobi, Kenya
Tel: +254-154-32891-3, FAX: +252-154:32844, Email: akaudia@arcc.or.ke or aas@africaonline.co.ke

Since the introduction of the concept of agroforestry and associated practices in the early 1980s, agroforestry projects have adopted conventional extension methods and approaches such as farm visits, group training, and the modified Training and Visit method. Typically, the planning of agroforestry extension activities by extension agencies has not taken into account the local conditions. Consequently, it has been observed that some categories of potential beneficiaries of agroforestry extension services have been sidelined. in addition, adoption of agroforestry technologies, especially in marginal subsistence agricultural areas, has been limited.

Participatory approaches have also been tried since the early 1990's. However, often these approaches continue to be based on operational frameworks of the intervening agencies.

Against the background of the need to devise extension methods that fit into the livelihood strategies of a target community, research was conducted for a period of 7 months in a semi-arid district of Lake Victoria basin in Western Kenya during 1996-97.

One of the objectives of the research was to determine patterns of labor-time use by peasant farmers in this semi-arid area in the context of livelihood strategies. The research identified the types of agroforestry practices that have been most popular with farmers and hence have diffused extensively.

A formal sample survey was conducted in five divisions of the Homa Bay District in Kenya. Three hundred households were interviewed during the months of August to October 1996. Through the interviews, data on the socio-economic background and agroforestry practicing households, and the types of practices that have been adopted were collected. Labor-time use data was collected using the personal recording method. Data sheets were provided to members of the households who reside in the farms for more than six months in a year. Respondents were requested to record all activities done in a day from the time of waking up to the time of retiring to bed. One hundred and ninety-seven members of the sampled households participated in the labor-time - activity component of the research. Records were kept for a 3-5 month time equivalent spread across 7 months. Over 100 different activities were recorded, then grouped into nine broad activity categories. The period of the day when the activities were undertaken and the duration were also summarized. Data was statistically analyzed to determine the proportioning of time between different non-farm and farming activities by members of the surveyed households. The analysis was done to identify differences according to gender and age, as well as the season.

The research has identified the complexity of livelihood strategies of rural peasants and how these complexities have defined households' decisions on allocation of the one scarce resource that is common to households: Labor-time. The diversity of activities and rural households' time constraints require that agroforestry extension agencies devise extension strategies that involve active participation of community members. Research to determine which agroforestry extension methods, which are already being used, can be adapted to circumstances of rural subsistence farmers to enhance dissemination of agroforestry technologies is necessary.

Socio-Economic Implications Affecting Farmers' Participation in Agroforestry Extension Activities in Garhwal Himalaya

M. C. Kukreti, Vinay Kumar
Indian Council of Forestry Research and Education, Kaula Garh Road, 248195 Dehradun, India
FAX: 91-0135-759203, Email: amrish_sharma@hotmail.com

AA study was conducted during 1996 to analyse some of the socio-economic implications affecting farmers' participation in agroforestry extension activities in the villages of Chopariyal Gaon macro watershed of Garhwal Himalaya. Statistical tests revealed that farm size, household size and total number of animals in the household were significantly related to agroforestry participation at the 5% level. Distance travelled for fuelwood collection was negatively significant. Number of days used for fodder collection were not statistically significant. The study recommends that the well being of the poor and powerless can be improved by ecosystem rehabilitation through economically viable and ecologically sound methods, using a ?do it yourself? approach. It has been postulated that application of technologies based on isolated biological, physical and social science research cannot resolve this issue and that a proper understanding of the socio-economic conditions affecting the population is essential. in the model developed using this approach, the village organisations assume responsibility to meet the needs of the community. in addition to policies of consolidating the land use, land tenure and related issues are also addressed to ensure sustainability of both the technology and people's participation The use of conventional methods of policy and management practices, which result in the alienation of local populations from the forest and consequential forest degradation, is abandoned in this approach. The study also recommends that detailed analysis of clientele should be the prerequisite in any agroforestry activity to be undertaken.

The Forestry and Agroforestry Technology Transfer Through Agricultural Technical Assistance Units - A New Approach To Rural Extension

Fernando Ortiz Ramirez
Forestry Research and Promotion National Corp., CONIF, Avda. Circunvalar Nro. 16-20 (detras del Inst. Roosevelt), A.A. 091676 Santaf, de Bogot, Colombia
Tel: 57-1-3417000, FAX: 57-1-3376970, Email: conif2@colomsat.net.co

In the context of community forestry projects participation, planning can be clearly defined as the union between activities realized by the local people and the project staff. The objective is to formulate plans and to choose the best alternative available for implementation. in Colombia, the Forestry Research and Promotion National Corporation (CONIF) and the Ministry of Agriculture and Rural Development (MAG) have implemented an alternative extension methodology entitled "Forestry and Agroforestry Technology Transfer Through Agricultural Technical Assistance Units (TAU's)." With the drug problems in Colombia, the project has also been implemented as an alternative to substitute or replace illegal crops in some Colombian regions. The aim of this project is to achieve high extension agent performance influence in rural households. The main function of the TAU is to give assistance to small farmers. TAU's have the widest cover of the country, because they are associated with the national extension service. This is the first continuous and systematic effort in Colombia to use such units. Through this training proposal, CONIF seeks to provide conceptual information and practical experience on forestry and agroforestry, methodologies to identify and to validate agroforestry practices, and information for the extension agents to design, advise, and support farmers to adopt technology. To ensure that the process is successful and practical, the training proposal has the following characteristics continuous with three phases: 1) theoretical/practical training; 2) learning application; and 3) advising, monitoring, and evaluation systematic with respect to the contents of the training materials, the lecturers, and field trips.

- Responsive to local needs. The project aims to resolve the ecological, economic and social problems related to watersheds, deforestation, erosion, and environmental education.

- Based on human development, the project requires that extension agents be qualified to make decisions, respond to the rural development issues, and to provide alternatives for resolving issues.

- Community participation: Extension agents and farmers work together to identify and prioritize problems, and devise solutions. This allows maximum use of farmer indigenous knowledge.

- Based on research and established technology: The project is supported by the latest research results from ICRAF, CATIE, as well as CONIF in Colombia. Additionally, extension agents can draw information from the Monitoring and Evaluation System and the Forestry and Agroforestry Technical Information System, which operates nationwide.

Searching for a New Paradigm in Sustainable Forest Management: Participatory Forest Management as a Strategy for Forest Conservation and Development in the Tropics

Miyan Rukunuddin Ahmed
University of Chittagong, Institute of Forestry and Environmental Sciences, 4331 Chittagong, Bangladesh
Tel: 880-31-714914, FAX: 880-31-714914, Email: ifescu@globalctg.net (Attention: Dr. Rukun)

Participatory forest management (PFM) is a new field in the arena of forest resources management. It evolves as an innovative approach for forest management and conservation with active involvement of the people for the development of forest and raising socio-economic condition of the community. PFM can be considered as a development program for the poor in the tropical developing countries with mitigating forest resource conservation problems. It has been realized that forest protection is difficult without active involvement and cooperation of local community. PFM can replenish the degraded forests in the tropics and protect existing forest resources from further deterioration through partnership with public agency and community groups. Promotion of people's participation in tropical forest management needs much stimulation and encouragement among the public, trust on forestry administration, and a rigorous overhauling of forestry policy and legislation. It needs community resources mobilization and organization into a successful PFM. PFM can enhance the involvement of local community in forestry activities through which local people change their attitude from destructors to keepers of the forests.

This article will deal with a development of a model for PFM of the tropical forests. Modeling of PFM will include reformulating the policy and legislation; strategy for effective community participation (resources mobilization, community organizing, care and share (stewardship), partnership among public forestry agency, community people/ neighborhood groups, and PVOs/NGOs; incentives and rewards; appropriate technology development and adoption (ATDA); multiple-product forestry practices (honey, wax, deer farming, woodlot, orchard, silvipasture, cash cropping, protected area development, ecotourism, etc.); implementation and evaluation, and research and extension. This article is about how to mobilize resources, organize and involve community people into a body of strong support and action for PFM. Upland people and people around the forests realize the importance of forest in their lives from subsistence to life saving drugs, and they are careful about not to destroying the forest resources base.

Government forest policy should welcome and make provisions for popular participation in forestry planning and management. Reformulating of policies and laws that are necessary for people's active participation, support and recognition of community-based tenurial systems, and strengthening local institutions. The tenurial rights over the land and usufructory rights over the produce should be clearly spelled out in the form of an agreement. This is important to gain confidence of the participants by the government forestry agency in the PFM. Administrative restructuring, foresters' orientation toward community interaction, democratic participation of local community in decision making and implementation in forest management, are some of the important steps that should be taken into consideration. Some of the strategies for PFM in tropical forest management can be (i) establishment of community forest/forest village development, and agroforestry model, (ii) development of protected area, nature reserve, etc. through active participation of the community negotiated on limited access/uses by the community, (iii) ensure use rights of non-timber forest products (NTFP), and marketing development, (iv) tribal/shifting cultivators' rehabilitation/settlement, (v) formation of forest farmers groups/Forest user group, and (vi) encourage equal gender participation, (vii) conflict management, and (viii) community empowerment and control. in this connection, we can cite the examples from India where joint forest management (JFM) was practiced that benefited both the community and the forests; and Nepal where forest user groups (FUG) were organized and involved in participatory forest management and rehabilitation/reforestation of degraded lands.

Conflict Cultures: A Comparative View of Environmental Forest Conflicts in Selected European Countries and Regions of the USA

Eeva Hellström
Finnish Forest Association, Salomonkatu 17 B, FIN-00100 Helsinki, Finland
Tel: +358-9-685 088 12, FAX: +358-9-68508820, Email: eeva.hellstrom@smy.fi

Keywords: Environmental conflict, culture, conflict management, Europe, USA.

Cultural clash is often perceived as an important background to environmental forestry conflicts. Indeed, conflicts usually involve a struggle between sub-cultures of society (*e.g.* those related to rural communities, industrialism, environmentalism). However, cultural aspects of conflicts are in this paper viewed from a significantly broader angle.

Environmental forest conflicts can be viewed as cultural products of the societies in which they occur. Owing to its unique social, political, economic and resource structure, each society has its own cultural way of producing certain types of conflicts and managing them in a certain way. Each country has its own "conflict culture". Only by understanding the conflict culture of a society, may we consciously aim at realising the positive potential of conflicts for social development.

This paper presents the findings of a comparative study of environmental forest conflicts during 1984-95 in seven cases: Finland, France, Germany, Minnesota, Norway, the Pacific Northwest region of USA, and Sweden. The data comprises a total of 210 focused interviews, which are analysed by using Qualitative Comparative Analysis. The analysis provides an understanding of conflict patterns in each of the seven cases, focusing particularly on patterns related to the types of conflict and conflict management, and to the value, policy, market and resource aspects of the conflicts. in comparing whole societies and in examining long time spans, this research fills in a gap in research on forestry conflicts, which has typically focused on the examination of case-specific or country-specific conflicts.

As a result of the analysis, models of conflict cultures and conflict management strategies are presented, and the cases are understood in the light of these models. The model of conflict cultures is based on three dimensional setting where mild vs. intense conflicts, social stability vs. rapid change, and co-operative vs. separative relations are examined in relation to each other.

The models help understand that conflict culture is a dynamic phenomenon. The appearance of conflicts and responses to them change in time within any society. Within this frame, conflict management may be regarded as a conscious effort to constructively influence conflict culture. This view becomes apparent when using the cases to construct a model of conflict management strategies.

Forestry and Stewardship in South-East Asia, with Special Reference to Peninsular Malaysia

Jeyanacar Kathirithamby-Wells
Clare Hall Cambridge, Herschel Road, CB3 9AL Cambridge, Malaysia
FAX: 1953-498121, Email: wells.serendip.@ easynet.co.uk

Key-words: deforestation, biodiversity, tropical forest history

Climate and geography have rendered the task of forestry difficult and complex in the tropics. Early realization of the impact of deforestation on climate and environment made colonial foresters aware that forests afforded services other than the provision of wood and fuel. The rapid expansion of population in Southeast Asia as of the nineteenth century obliged foresters to put in place appropriate legislation to curb indigenous practices of shifting cultivation. The forestry service was much less successful in arresting the loss of forests to plantation agriculture.

After World War II, the challenge to forestry was intensified by Southeast Asia's emergence as a major timber export region. Where previously natural regeneration, long cutting cycles and manual extraction allowed the return of biodiversity, post-War extensification and intensification of logging has threatened the fundamentals of forest stewardship in the tropics. Ironically, it is where the environmental and biological value of forests are highest, such as in the moist tropics of Southeast Asia, that the forester's role has been most challenged by politics and economics. The paper will argue that it is within the context of these processes that global discourse on the ethics of forest conservation and stewardship has evolved.

Human impacts of South American forests. Historical development

Rudi Arno Seitz
Universidade Federal do Parana, Rua Bom Jesus 650, 80.035-010 Curitiba, Brazil
Tel: +55-41-232-9084, FAX: +55-41-253-2332, Email: r.seitz@cce.ufpr.br

Before the discovery by european navigators, South America had a native population well integrated in its environment, using the forests as a natural resource without depletion. The spanish and portuguese colonization during the 300 years after discovery changed little in this situation, as the main human impact was concentrated on the coastal regions, were of course the forests were cleared to provide space for some agricultural activities.

After 1800, as consequence of political changes in Europe, more attention was given to South America. The establishment of local governments brought more economical activities. Also the improvement of colonization of new lands by european settlers caused in the first moment heavy forest destruction. The forest was the enemy, plenty of dangers, wild animals and diseases. and the region had no open grasslands for agriculture. But yet at this time the role of forests as watershed protection was recognized. in the surroundings of the city of Rio de Janeiro the first reforestation action started on coffee plantations, nowadays called "Floresta da Tijuca". Later in this century, the development of steam engines increased the use of wood for energy as well as material for the construction of railroads. But still in most of South America, the forest was a source for special products, like rubber or some special woods. Fortunatelly this extractivism didn't caused much damage to the ecosystem.

At the beginning of the XXth century it was clear for many people that forests should be replanted. The first attempts to plant *Eucalypts* and pines were made in Argentina, Brazil, Chile and other countries. Later, even plantations for rubber tappering (by Henry Ford) were tryed, without success.

Real impact on forests started after World War II. Due to the development of international markets, evolution of better equipment for logging operations and industrial investments (paper mills, iron industry), the pressure on natural forests raised, as well as reforestation for industrial purposes increased. in the 60ties, land clearing for agricultural activities, like soybean plantations or cattle raising promoted a new wave of deforestation, after extraction of the best logs of the forest.

Actually, plantation forestry has high technical and scientific standards in South America. But the management of natural forests remains more or less extractivistic. and after all valuable woods or other products are depleted, land occupation for agricultural purposes is the consequence. International pressure and local interest achieve some results in preserving special tree species (like *Araucaria araucana* in Chile) or even landscapes, like the forests in the coastal mountain range in southeastern Brazil.

6.07.00 Social changes and forests

A Historical Chronology and Impact of Urban Forestry: A Case Study of Kuala Lumpur, Malaysia

Nik Ismail Azlan
MARA Institute of Technology, Department of Landscape Architecture, Malaysia
Email: niara@tm.net.my

Beginning with its founding at the confluence of two rivers, the city of Kuala Lumpur has seen the introduction of several exotic and local forest species planted within the built up areas. Initially some of the existing forest species were left intact as development was very minimal during the early years. When Kuala Lumpur was placed under the British administration several exotic forest species were introduced for their shade and beauty amidst the humidity of the tropical climate. These trees were often planted side by side with the local species especially within the town centre, residential areas, government buildings, club house, parks and greenbelts. Combined with the introduction of flowering shrubs Kuala Lumpur was slowly developed into a conceptual garden city. The wet and humid tropical climate quickened the growth of these urban trees. As Kuala Lumpur developed into a modern city the policy of tree plantings of the colonial era was slowly revised. Unlike architectural buildings of old, these trees could not and did not last long due to neglect and changes in the land use. As more buildings were built some of these trees were cut down, pruned or replaced with tree species that are occupy less growing spaces. This is more apparent after Kuala Lumpur was declared a territory of the Federal Government in 1974. Fortunately Kuala Lumpur City Hall or Dewan Bandaraya Kuala Lumpur (DBKL) undertook a majestic task of transforming the city into a tropical garden city by preserving some of the trees and at the same time introducing new species of trees to suit the needs of the urban environment. Rows and row of trees were planted alongside low and medium sized shrubs for functional and aesthetic purposes. Millions of dollars were allocated for this purpose. Such immense effort has transformed Kual Lumpur into a city of a balanced and healthy environmet for its population. A lot of the city population has benefited from the presence of these trees in so many ways. The economic, social, political, and environmental benefits are discussed. However, such transformation is not without problems but nevertheless Kuala Lumpur has managed to provide a pleasant image to visitors and citizens alike. These problems and solutions are in so many ways similar to other cities throughout the world. The lessons learnt in Kuala Lumpur may be applied to other cities throughout the world.

Learning from Self-Initiated Community Forest Management in Orissa, India

Czech Conroy, Abha Mishra and Ajay Rai
University of Greenwich, Natural Resources Institute, Chatham Maritime, ME4 4TB Chatham Kent, United Kingdom
FAX: 00 44 1634 880066/77, Email: czech.conroy@nri.org

There is growing recognition in tropical countries that safeguarding forests requires the active involvement of local communities, but knowledge of how best to do this is limited. Orissa's extensive experience of community forest management (CFM) provides some valuable lessons and insights regarding: (a) how and why communities manage their forests; and (b) the sustainability of CFM initiatives. The paper discusses the following aspects of CFM in Orissa: (a) the conditions that give rise to the initiation of CFM; (b) the size and nature of the benefits, and how they are distributed among the various sub-groups of a community; (c) the factors affecting its sustainability, including conflicts and their management; and (d) communities' support needs. The principal research activity was a survey, primarily socio-economic, of 43 forest-dependent communities. CFM was examined in the context of people's livelihood systems as a whole, since these can affect the size and nature of any benefits they derive from forest protection, and also their main reasons for deciding to protect. The authors conclude that CFM has made an important contribution to the regeneration and sustainable management of Orissa's forests, and argue that the formal balance of control of forests be shifted further towards communities. They highlight the plurality of institutional and management arrangements that communities have developed, and caution against forest departments imposing a standardised, blueprint approach, as has tended to happen in government Joint Forest Management (JFM) programmes. Several weaknesses are

identified in India's JFM programmes and reforms recommended.

Keywords Community, management, indigenous, sustainability, conflict

The relationship between forest and community in Turkey (after the first general assembly of forest villages)

M. Kurtulus Gürses, Dr. Ali Ozkurt, Suade Arancli
Eastern Mediterranean Forestry Research Institute, Post Box # 18, 33401 Tarsus, Turkey
Tel: 90 (312) 417 91 60, FAX: 90 (312) 417 91 60, Email: Ormanapk@superonline.com

The year of 1998 was the seventy-fifth anniversary of the Republic of Turkey. in this connection, a lot of institutions evaluated their own past activities with the aim of producing more successful policies and conducting more successful activities in the future. So the Ministry of Forestry held "The First General Assembly of Forest Villages". There were those considerations behind the organisation:

Almost all of the forests belong to the government in Turkey. There are 19000 villages in or near forest land and they are called as "forest villages". Almost nine million people live in the forest villages and they are called as "forest villagers". Forest villagers have a hard life and they are also in the lowest income group of the country. As a result of this they frequently commit a crime such as illegal cutting or clearance of forest land. Furthermore, they feel that they are stranger in their own land because of the forests belong to the government and for this reason they do not hesitate to damage forests. It is the proof that there are 130000 forest lawsuit in the courts now. So the Ministry of Forestry is in dispute with forest villagers because of all of these negative conditions. So the first general assembly of forest villagers was held with the aim of improving the dialogue between the Ministry of Forestry and forest villagers and discussing all problems with a great participation. Before the general assembly each regional forestry directorate held meetings with forest villagers. Problems were discussed on the regional basic and delegates that would participate in the assembly were elected in these meetings. Two hundred fifty-five delegates were determined in this manner among forest villagers. Later elected delegates, members of universities, NGO's, experts and high level bureaucrats of the Ministry of Forestry, representatives of the political parties constituted the general assembly. All of the members of the general assembly discussed the problems and general forestry issues during two days in the capital Ankara. in the light of these discussions a declaration was written and declared to people.

More detailed knowledge on the general assembly will be given and its success will be discussed in the paper. Also the paper will have discussion on thought in the declaration.

Lessons learnt from international assistance to forestry?

Reidar Persson
CIFOR, P.O.Box 6506 JKPWB, 100 65 Jakarta, Indonesia
FAX: 62-251-62100, Email: r.persson@cgiar.org

1.6 billion US$ is now reported to be used for "aid (assistance) to forestry". in international fora there is always a request for more assistance. But the assistance given to forestry development so far has not always been successful (instead a lot of failures). How can the resources available for "forestry aid" be used in a more efficient way? If we don't find ways of improving the use of funds we may soon see that the "aid-money" going to forestry will decrease. Recent studies from *e.g.* the World Bank show that there is little relation between assistance and growth. The reason is that assistance has often been given on political grounds. It is also shown that it is difficult to direct funds to a special area (fungibility). If an area is popular among donors the countries can reduce their own funding of this area. If the Government is committed to *e.g.* forestry many economists argue that one can as well give budgetary support. Is it possible and meaningful to try to direct support to forestry? When is it meaningful? What can be done at the sector-level? Problems in the developing countries are often discussed in connection with assistance. The report will take up some of the most important points. There are, however, a lot of problems within the aid-administration itself. What can be done to rectify this? What can be done to change donor behaviour? What can be done to improve delivery mechanisms? One point to analyse is "prerequsites for failure" and "prerequisites for success". Old-timers know a number of things that *e.g.* do not work. But the lessons learnt are not used. Why do we not learn from experience? Decisions taken about "aid" is as said very political. What can be done to better use the knowledge we after all have? Influence politicians? Other points to discuss are objectives of forestry and assistance to forestry. Is it it conservation, alleviation of poverty, "development" or what? It is also necessary to discuss where there are disagreements between different donor-groups. The report will also analyse situations where assistance to forestry seems too difficult to succeed.

One conclusion is most likely that assistance must go from quantity to quality. What can be done to improve quality? Is more support needed to build capacity? Should more resources be invested in planning (e.g.National Forestry Programmes)? Is research one field where more assistance ought to be given? The report aims to summarize the lessons learnt so far and if possible identify measures to improve the present situation in different types of countries. PS. During the last 15 years I have written a number of articles in Swedish where I have summarized the experiences I (and Sida) have gained of assistance to forestry during the last 30 years. in 1998 Sida published an English summary ("From forestry to land husbandry"). This report has arouse a lot of interest. There is evidently a need to discuss these issues at a greater depth than done so far. CIFOR has therefore initiated a research project to learn more about these questions. in late 1999 CIFOR will arrange a meeting to discuss experiences of aid to forestry and ways to improve it. As a background to the meeting a report will be written discussing some of the main issues.

The report proposed to be written for the World Congress 2000 will give a state of the art of the knowledge gained at the time of final writing.

The interaction of change in environment and society: analyzed through some cases in Central America

Kees Prins
CATIE, Costa Rica
Email: prins@computo.catie.ac.cr

The approach of this proposed presentation will be one of environmental sociology: the interaction between (the changes in) society and its bio-physical environment. The first part of the presentation will contain some basic ideas about the societal and environmental changes which have occurred, in the last decades. Some issues are presented which need to be addressed. in the second part these ideas and issues will be illustrated with case studies in Central America. Some guidelines for environmental and social policy will be distilled from the social process and practices analyzed.

General ideas and developments:

Environmental issues are rather new in society and science. 'Environment' and 'Conservation' became global issues, when awareness grew that the natural environment puts its limits to the treadmill of accelerated economic development, and that the future of mankind depends on the proper treatment and maintenance of the natural environment and its resources.

Public awareness rises when a latent problem becomes manifest and its negative effects visible .When material and social problems become manifest and widespread, there, usually, occurs a gradual change of societal values and norms. Ideas of what is worthwhile to aspire at, and what is socially good and bad behavior, are being reshaped.

With changing conceptions, the means and ends of policies also change: What was, initially, stimulated by incentives, at the present is discouraged by fines. Two examples illustrate this rather radical change of ends and means:

Until recently, fiscal and legal incentives in Costa Rica stimulated the conversion of primary forests into pastures and crop land, as forests were seen as a hindrance to development. Currently, the end and trend are opposite: maintaining the woods and reconverting part of the pastures and agriculture land into secondary forests by abolishing former subsidies to live stock production and subsidizing the use of land for forestry.

In the Netherlands the strong promotion of agricultural and livestock intensification, after the second World War, gave way to a policy of enhancing a more ecological way of production, as the negative ecological side effects of the former policy became more manifest: pollution of soil, groundwater, air, acid rain and so on. Now farmers are obliged to take preventive measures (internalizing the externalities) and are sanctioned if they don't comply. On the other hand farmers receive a subsidy if they allow part of their land become fallow.

However, this is not at all a linear process. It implies tensions and insecurity, inherent to a situation of conceptual and social transition. It leads to different types of social reactions and the pace of readjustment to the new situation, is also differential.

In general terms it is crucial to build a strong social base for policies geared at sustainable paths of development, and to find ways and means to reconcile different interests and points of view in society. This has several dimensions:

One crucial aspect is how to bring the interests and behavior of individuals or individual groups in line with the interests of the society at large. This is partly, a matter of internalizing new ideas and values in the conscience through environmental education by parents, school. and others. Nevertheless, the effects of this approach are limited if they are not accompanied by measures directed at economic interests such as internalizing externalities by sanctioning bad environmental behavior and remunerating good one by paying for environmental services.

Another central dimension is how to combine the struggle against poverty with the struggle for conservation and gain the poor as allies for purposes of conservation. The poor will be indifferent, if not hostile, to conservation, if their actual and vital needs are not attended. On the contrary, when their welfare needs are met and they get a stake in conservation for their subsistence and progress, their attitudes and conduct change, and they may become strong supporters of environmental policy, as can be inferred from different concrete cases.

This all has to do with a third basic question: Equity. For measures to be widely accepted, their costs and benefits must be equitatively shared: between groups in society, countries, and generations. It is not equitative and ethical to burden the next generations with the costs of irresponsible, unsustainable economic behavior. But it is not just either to neglect actual social needs of poor groups for the sake of conservation and needs of future generations. It is not effective either. On the other hand, groups and countries which contribute most to national and global environmental problems, should contribute more to their solution and prevention, especially if they are in a better economic position to do so. This is a very weak spot in environmental policy. Their is a general awareness, that environmental problems are global issues which require measures of a global coverage, but their is much less unity about how to share the bill, as illustrated by the problems to put into practice Agenda 21. Some cases to work out and validate aforementioned ideas:

A first case will be the analysis of environmental and social process in the Biosfera Maya in Peten, Guatemala. The original situation can be typified as follows:

Peten has a reputation of a land of nobody. Forests used to be converted into pasture and agricultural land by large and small colonists. (Although Peten was the heart of the Maya civilization, at the present native communities hardly exist in the region any more). Through the so-called agarradas colonists grasp parcels of forests and convert them into agricultural land and pasture. To stop this ongoing process of deforestation, ten years ago the northern part of Peten, still abundant in forests, was declared Biosfera Maya and Area of Conservation. Part of this was for absolute protection, another part was designated for multiple and sustainable use.

The heart of the question is: how to put into practice a policy of conservation in a context characterized by the pressure for land, the illegal exploitation of wood, an individualistic, short term economic behavior and weak social and public institutions; how to build a social basis for the new policy to make it effective; and how to bring about a new relationship between people and environment, in this particular context.

CONAP, the agency in charge of the administration of the Biosfera Maya, initially applied a conservationist biased and control based policy. Families and communities of colonists, inhabiting the same area. try to get a living out of a socio-fisical environment. new to them. Coming from the highland or coastal lowlands, theyïve got an agricultural background and outlook, although adopting some gathering practices of the original inhabitants, as to forest products like chicle, pimiento, xate. Their vision of future.is usually rather short and their knowledge of their new environment limited. The new environmental policy was seen as repressive in state of supporting. The goals of two central actors were divergent. There was originally no common ground to (inter)act upon in a fruitful way. CONAP had a long term perspective, but lacked a social basis and a clear strategy to realize its objectives, while the population had no stake in measures of conservation. So the policy was not effective and even counterproductive.

Nevertheless situations are not static nor are social process linear. New actors and views enter into the social scene. Through its projects in I&D: OLAFO and CATIE-CONAP CATIE started to promote security of tenancy and usufruct of forestry resources as a necessary means to get communities interested in their proper use and management. The legal and institutional framework was readjusted. A new legal institution was created: Concession Forestal Comunitaria. It was adopted and promoted by CONAP, as the most effective way to protect forests, giving the people who live in them, a direct stake in its conservation. The growing interest by the local population reflects itself in the growing quantity of concessions recognized and requested (over 10 in 1998). On the other hand development agencies give orientation and assistance in legal, technical, organizational and economic aspects. It is an incipient process and not yet sufficient in scope and mass to overcome the phenomena (outlined in the foregoing) which traditionally, characterize the region. Nevertheless some first promising effects can already be noticed:

Poverty alleviation provides to be an excellent incentive to get poor people to become conservation minded. People can become excellent guardians of the forests, when they protect their own present and future well being with the maintenance of the forests. Their livelihood becomes more varied and secure. Outlook and behavior change, when given a stake in the conservation of the forests, by entitlement of their use. Their vision broadens and enlarges. People start exploiting their resources having in mind present and future needs. Protecting the forests against fire, illegal cutting and 'agarradas' becomes an intrinsic part of the value orientation and social organization of the communities. New human and social capital is built as well as local institutions for regulating the use and management of resources, with incentives and sanctions, socially accepted, internalized and controlled. A critical mass and social basis is being formed, slowly but surely, essential for implementing policy goals.

In a second case the attention will be focussed on the changes which have occurred in a community of colonists in a land reform program, and within a buffer zone of the Tortuguero National Park in the north east of Costa Rica. in order to earn a reasonable living from their new land, the peasants had to adjust themselves to the limitations and opportunities of their new biophysical environment. in the process a serie of cognitive and organizational changes have occurred as to the way people valorize and manage their resources. Through experimentation and with assistance of Neotropico, a local NGO, peasant families encountered an optimal way of combining their resources and agronomic practices. Forest resources have been integrated in the peasant economy. The people have become environmental minded because it suits their economic and social interests. The case illustrates and analyses how a social group may start interact in a new and fruitful way with its environment and, in the process, changes its vision of space and time.

Some guidelines for policy and action will be abstracted from those process of change and the cases of good practice. Those are highlighted, as there is a need to show ways and means to reach a renewed, fruitful and sustainable relation between society and environment. People being the cause of most environmental problems, must find also ways and means to tackle them in an effective way. Conscience of the scope and complexity of the problems and process of natural degradation, must be accompanied by efforts to find proper answers.

Knowing forest, knowing people, knowing change

Lye Tuck-Po

FAX: 81-75-7537350, Email: tuckpo@cseas.kyoto-u.ac.jp

Historically, one of the challenges in forestry is to holistically integrate the disciplinary expectations, methodologies, and conclusions of the social and natural sciences. Where forestry sciences are directed towards policy-making, there is the added problem of satisfying the needs of the "consumers": governing bodies, conservation authorities, multilateral institutions, and the like. While we can say that genuine progress has been made, especially since UNCED '92, it is also true that the divide has been growing. This is evident in studies of local knowledge. in the drive to meet the demands of both academia and policy, research directions have become increasingly fragmented. On one end of the spectrum is a vast array of highly technical reports (many not even released for public scrutiny) that are grounded in empirical findings of locally specific conditions and problems, but impossible to draw comparative conclusions from. On the other are abstract critiques and analyses that may be illuminating and programmatic but lack practical recommendations for on-the-ground action. in my own research among Malaysian hunter-gatherers, the Batek, another problem comes up: the ideological divide between people who have to live with environmental destruction and those who control it. in the Malaysian popular imagination, there is a great deal of mystification about the "environmental wisdom" and mystical understanding that forest peoples supposedly have: the sort of environmental perception that anthropologists would classify as knowledge of a highly practical and scientific cast. For the broader world, however, this knowledge is merely primitive exotica that apparently can cure everything from marital discord and impotence to cancer and muscle fatigue. Given the power of such mystifications, policy recommendations that might seem logical and natural from the point of view of the forest peoples might be viewed as utopian and idealistic by those in charge. Further, local knowledge, in this instance, is not the objective, isolable body of technical practices that we can "learn from" and transport easily elsewhere. This last is, I suggest, premised strongly on the equally entrenched belief that local peoples and local knowledges do not change without outside intervention; after all, only static ideas can be placed in storage liquid and implanted into other static situations. If we take the contrasting view, that local ideas and local environments have been changing more rapidly than research and policy directions, then the question is: at what level do we find a basis for comparison and developing a multidisciplinary science of resource management? Drawing from the Malaysian context, this paper will review and examine some of these ideological and practical problems and suggest research directions.

6.11.01 Forest Resources and Human Welfare in Developing Countries

An investigation on the forest worker's health in Turkey

Halis Hulusi Acar, Habip Eroglu
Blacksea Technical University, Faculty of Forestry, Department of Forest Engineering, 61080 Trabzon, Turkey
Tel: +90-462-325-3223, FAX: 00 90 462 3257499, Email: hlsacar@risc01.ktu.edu.tr

Forest areas in Turkey are generally located on the mountainously region. Therefore, forest labour is affected by the shape and conditions of the field. Forest workers in Turkey generally work during the spring, summer and autumn. Most of the forest workers are tentative and seasonal forest workers and rest of them are permanent workers. Approximately, there are 30 thousand forest workers in Turkey. These workers have task on logging, cutting, skidding and transport the logs.

The demand to the forest labour has been getting decrease because of forest workers' health problem, unsatisfied payment, high risks of getting injured and their hard working conditions. These unwanted conditions are affected negatively forest workers productivity. The % 99 of the forest areas in Turkey are managed by government and the most of the workers are male. in this study, the general forest workmanship in Turkey, especially the production and fire workmen's positions are exhibited. Furthermore the health problems investigated that are seen in these works. This study have done over workers who work at Directorate of Yusufeli, Serik and Iskenderun Forest Enterprise.

The workers are chose randomly and the questionnaire forms which are prepared before filled by the conversation one to one with workers. First of all, the workers are classified into groups according to their ages; 15-30, 30-45 and older than 45. So that to obtain the integrity of questionnaire and asking the questions belong to same topic, the general topics are determined. This general topics are worker's social economic position, health position and the effects causing health problems. The result of questionnaire evaluated by statistical methods. For this the simple statistical methods are used. For evaluated at least 30 worker are referenced. When the findings evaluated generally the production and fire workers are consisted of males. When this two kind of group compared the blood pressure of fire workers are more normal then the production workers. The diseases having ache-pain can be seen at production workers more then fire workers but these diseases changes according to climate properties. Generally the production workers have more backaches according to fire workers but fire workers have more arm and leg aches than the production workers. When the worker's habits observed, it is seen that two group have a high percent of habit of smoke and alcohol. According to evaluation, the forestry workmanship that is done in Turkey is doing as a obligation of economic results, it is not an optimal branches. The work conditions have very negative conditions according to be uneconomic and sociologic way. From the standpoint of health evaluation results, in the forestry workmanship, the diseases having ache-pain diseases such as nervousness, fatigue and insomnia, the other diseases; bronchitis-flue, eczema, itching can be counted. in this point, heavy work, lack of feedings and clothing and other negative work conditions performs. According to this, the rules below must be applicated to improve the forest workmanship in Turkey; to organize periodically health services for workers and mobile health crew, work organization, work place discipline, worker psychology, and education of workers, these topics must be improved.

Land allocation programs in Vietnam: from a view point of the H'mong peoples in northwestern mountainous region

Makoto Inoue, Miho Omatsu
The University of Tokyo, Graduate School of Agricultural and Life Sciences, 1-1-1, Yayoi, Bunkyou-ku, 113-8657 Tokyo, Japan
FAX: +81-3-5689-7252, Email: *Pinus*@fr.a.u-tokyo.ac.jp

1. Background

Under the "DoiMoi" policy or economical renovation policy, the Vietnamese government has been driving forward the land allocation programs since 1993. The rights to use the national land are granted to individuals, cooperatives, armies, national enterprises and private companies, etc. The forestland is further divided into three categories: "special use forests" such as national parks, "conservation forests" where watershed management, etc. are applied, and "production forests" for the purpose of produce timber and non-timber forest products (NTFPs).

2. Objectives

1) to clarify the gaps and conflicts between the land category of the governmental program and traditional land category perceived by the people.

2) to consider the impact of the program to the livelihood of the people

3. Method of field survey

Four hamlets were selected as research sites in SonLa province where the ratio of forest coverage is the lowest (9%) in Vietnam. Main ethnic Group in the hamlets is the H'mong. We interviewed some leaders of each hamlet and thirteen households. Furthermore we listed NTFPs which were utilized by the people.

4. Customary land and forest utilization by the H'mong

The people have been making their livelihood by practicing swidden agriculture with ox plows of which main crops were upland rice and maize. They classify the fallow land into three based on a succession stage: "Pa Lau" or the grass land 1-2 years after harvest, "Pa HayCau" or Bush 3-4 years after harvest, and "Pa Dong" or secondary forest more than 5years after harvest.

The forests were prohibited from cutting tree customary. The forests were categorized into three: "Rung Ma" or cemetery forest, "Rung Tuoi" or old forest, "Rung SuoiNuoc" or water catchment forest.

Our survey showed that they collected around 60 species of NFTPs not only on the natural forest but also on the fallow, etc.

5. Gaps between the governmental programs and actual condition of land/forest utilization

Under the governmental programs, the land for swidden agriculture is divided into agricultural land and unused land that is prohibited from cultivating. The problem is that most of the fallow lands are classified as unused land and the people are forbidden to cultivate the fallow land. The gap is generated from the difference in the perception of agricultural land between the government and the H'mong The H'mong regard the fallow land covered with grass, bush, and forest as swidden land or farm land: the government does not regard them as farmland.

6. Conclusion

It is obvious that the area of the arable land for the people is reduced, fallow period is shortened, food production decreases, and the welfare of the people is lowered. Even though the program will have an effect on increasing the forest coverage area, it seems to be necessary to revise it in terms of the livelihood of the local people.

Forest resources and human welfare in Himalaya: the contribution of commercial medicinal plants

Carsten Smith Olsen and Nirmal K. Bhattarai
Royal Veterinary and Agricultural University,
Department of Economics and Natural Resources,
Rolighedsvej 23, 1958 Frederiksberg C, Denmark

Keywords: Rural livelihoods; income generation; non-timber forest products; trade; Nepal

Recent studies indicate that the annual trade in medicinal plants from the Himalaya amounts to thousands of tonnes of roots, rhizomes, tubers, fruits, leaves, etc. The annual value of the trade is worth millions of USD. The medicinal plants are collected by rural households in forests and other vegetation types throughout the Himalaya; hundreds of species are harvested and sold to traders in order to increase household incomes. The paper briefly introduces forest resources in Nepal Himalaya and how they contribute to improved human welfare in rural communities. The main aim of the paper is to document the economic importance of commercial medicinal plants to rural households in Nepal. In each of Nepal's five development regions, three districts were chosen for data collection; in each region one district was chosen in each of the three main physiographic zones (Terai, Middle Hills, and High Mountains). Thus, field work was conducted in 15 districts; a total of 636 collectors were interviewed in 92 groups. Results detail the number of households involved in commercial collection; estimate contribution of collection to household economies; and analyses collector net margins compared to wholesale prices in the main markets in India. Discussion focuses on identification of realistic interventions that may increase rural collectors' income from medicinal plant collection.

Russian and Chinese Forest Economies in Transition: A Comparative Analysis

Matti Palo, Dr. Maxim Lobovikov, M.Sc.Yaoqi Zhang
Finnish Forest Research Institute (METLA), Unioninkatu 40 A, FIN-00170 Helsinki, Finland
Tel: +358 9 857051, FAX: +358 9 85705 717, Email: Matti.Palo@metla.fi

Keywords: economic reforms, privatization, forestry, economic development, China, Russia

Transition of a great number of countries from central planning of economic development to a more reasonable combination of planning and market economy is no doubt the most prominent phenomena in the world economy at the edge of the third millennium. The success or fault of this movement will likely be crucial factor for the future performance and development of the world economy society and environment.

Russia and China are the most prominent instances of the countries in transition. They count altogether for 21% of the total land area, 24% of the population, 26% of the forest land and 25% of the forest inventory. Meanwhile the share of both countries in the world gross product does not exceed 4%.

Forest sector issues are not to be treated separately from the rest of the economy. During the 1950s with the technical help from the former Soviet Union took on the Soviet model of economic organization in the forest sector, which is proved to be inefficient since the 1970s. China started economic reforms in forest sector earlier and advanced further than Russia. Several reasons cause China chose gradual transition rather than a radical changes. Russia used the "shock therapy" despite the desperate attempts of the former authorities to take smother economic curse.

The average annual production growth of 10% in China during the recent decade made up a steady growth of roundwood output and forestation. Forestry development also has greatly helped the economic growth, particularly the rural areas where the economy greatly depends in forests. Non-timber production and ecotourism have become important parts of forestry sector. For the same time Russia lost 2/3 of the pre-reform level of roundwood yield. China started successful decentralization and privatization of the collective-owned and state-owned forests. Russia by so far has no experience in this respect. in general economic reforms in China were more successful, advanced and less painful than that in Russia. But major political change in China seem still to be ahead. Environmental regulations are as well lag behind the economic growth. That became evident in 1998 during the disastrous floods of Changjiang river caused suffering to 200 million population.

The experience of China and Russia cannot be entirely compatible due to the discrepancies in the socioeconomic and resource conditions of the two countries. One third of the Chinese forest area is represented by plantations, whereas natural forest absolutely dominate in Russian landscape. Nevertheless the comparison of the two countries clusters transformation yields few major conclusions.

1) It is argued that there is no sustainable forestry without adequate privatization. Fair competition between contractors is the crucial condition of fair pricing the forest resources. When private parcels are intermixed with public forest tracts as in Scandinavia the price references could be easily taken from the private sector.

2) Analysis of Russia and Chinese experiences may be not sufficient to tell whether the gradual transformation in more preferable than shock therapy. Straight parallels are barely reliable due to the difference in historic development and contemporary situation. But the experience learned is very deductive for the other countries in transition.

3) Political stabilization seems to be a crucial factor for the economic growth.

Russia and China are both facing similar problems of poor economic performance especially in the public sector, unfair revenue distribution, environmental pollution, poverty and widespread corruption. Impartial analysis of the reforms in the Russian and Chinese forest clusters is to help to cope with the problems which are still far behind the final resolution.

The Contribution of Cassiavera (*Cinnamomum burmanii*) in Improving the Environment Quality and Society Welfare in Indonesia

Eulis Retnowati
Forest and Nature Conservation Research and Development Center, FORDA
Jl. Gunung Batu, PO BOX 165, Bogor, Indonesia
Tel: +62-251-325111, FAX: +62-251-325111, Email: slitbang@bogor.indo.net.id

Indonesia is the greatest country in contributing Cassiavera (*Cinnamomum burmanii*) in the world. The export of this commodity is about 40,000 ton/year.

In a district in West Sumatera, Cassiavera contributing 41.66 % of the total income, and decreasing the soil erosion from 26.46 ton/has/year in an open area to be 14.25 ton/ha/year under Cassiavera stands. Cultivation is mostly as community forest.

Alternated Rows Harvesting can improve the role of Cassiavera as a conservation plant in a critical land.

6.11.01 Poverty and management of forest resources

Pauvreté et gestion des ressources renouvelables dans les pays en developpement: les liaisons dangereuses?

Alain Bertrand, Didier Babin, Jacques Weber
CIRAD-Forêt, Campus international de Baillarguet, BP 5035 Montpellier, France
FAX: 334 67 59 37 33, Email: alain.bertrand@cirad.fr

La pauvreté est un phénomène social total, à la fois économique social et culturel. Pour un individu, ou un groupe social il se traduit par la dépossession de son présent, de son futur, de son identité, voire de soi-même, c'est à dire par une exclusion. La pauvreté frappe sous des formes diverses le plus grand nombre des pays en développement et est considérée comme la cause majeure de dégradation de l'ensemble des ressources renouvelables de la planète au premier rang desquelles figurent les ressources forestières.

La pauvreté qui se combine généralement à diverses formes d'insécurité, conduit à une mobilité des hommes et à l'accès libre de fait aux ressources renouvelables. Dans les pays en développement les ressources renouvelables et en particulier les forêts sont un des principaux moyens de survie des pauvres. Ceux-ci sont contraints à une pluriactivité continue: tout ce qui peut se vendre se collecte. Le lien entre pauvreté, insécurité alimentaire et exploitation des ressources renouvelables apparaît tellement fort que les organisations internationales considèrent la commercialisation des produits de cueillette comme un indicateur fiable des situations de disette alimentaire voire de famine. L'exploitation des ressources renouvelables échoit le plus souvent aux femmes et aux enfants et constituent pour ces catégories de la population une tâche harassante et très mal rémunérée.

La mondialisation de l'économie et le développement rapide des droits de propriété sur la diversité biologique, seront-ils des facteurs supplémentaires d'extension et d'approfondissement de la pauvreté, ou au contraire, seront-ils mis en place au niveau international de façon à constituer un moyen efficace d'éradiquer la pauvreté rurale dans les pays en développement? La même question se pose à propos des droits d'émission et de stockage du carbone définis après la conférence de Kyoto.

La transformation des modes de gestion des ressources naturelles et en particulier des forêts peut-elle être un moyen efficace d'aider les pauvres des pays en développement à sortir de leur misère ? Par le passé les politiques forestières d'exclusion des populations rurales de la gestion locale de leurs ressources forestières a constitué indéniablement un facteur d'extension de la pauvreté. Divers exemples montrent que la gestion locale contractuelle des ressources renouvelables constitue à la fois :

• une porte d'entrée efficace vers le développement local,

• un moyen de limiter, voire d'inverser, les dégradations des ressources renouvelables résultant de la pauvreté,

• un moyen de sécurisation et de sortie de l'exclusion pour les pauvres des pays en développement.

Fuelwood dependency

Ananda Bhandari, Robert C. Albricht
ITC, Forest Science Division, c/o Min Raj Panday 15/252 Pakanajol, Kathmandu, Nepal
Tel: 00977 - (0)1 - 429235, Email: albricht@itc.nl
website

In rural areas of Nepal most of the rural population have traditionally depended on forest resources to fulfil their basic energy needs for domestic purposes. As a case study the Shivapuri Watershed and Wildlife Reserve (SWWR) was selected to examine the nature of dependence on protected forest resources. People living in and around the SWWR were legally excluded from their traditional access to the forest after the area was declared a reserve in 1984. in spite of a two meter high stone boundary wall and active forest guards patrolling the reserve boundary the people living in the buffer zone surrounding SWWR continue to risk fines and imprisonment to enter the reserve to collect forest products to meet their basic needs.

This study was undertaken to determine the degree of dependency on forest resources inside the SWWR for fuelwood collection and consumption by the surrounding villagers and assess the factors affecting the dependency. The research was confined to two sample villages of the Baluwa and Nayapati Village Development Committees of the Kathmandu district in the southern buffer zone area of the SWWR (Fig. 1&2).

Systematic sampling was applied to select the sample households within the villages. Topographic maps, aerial photographs and knowledge of local people were used to pinpoint the selected households. An open questionnaire method followed by informal discussion was used to determine the number of energy consuming activities for domestic purposes. The amount of fuelwood consumed for each cooking activity was determined by user estimation and validated by direct measurement. Pieces of fuelwood from each household's woodpile were randomly selected to determine the origin of the fuelwood which was subsequently validated during field visits with local people and forestry staff.

The results show that about 40% of the fuelwood collected in the study area for domestic energy requirements comes from the SWWR with the rest coming from private woodlots (58%) and government forests (2%) (Fig. 3). There was no significant relationship between daily per capita fuelwood consumption and distance of households from the forest (Fig. 4). The socio-economic condition of the people and their ethnicity however, were found to be important factors determining the level of dependency on the reserve forest.

In the study area two main social classes were identified: the elite and the poor, divided along caste lines. The Brahmin and Chhetri castes comprise the elite group while the latter is comprised of Magar, Tamang and Newar castes. The more well off group has in general a higher social and economic status, more private land holdings, higher education and smaller family size. These socio-economic factors are reflected in the dependency level on the reserve forest with the elite collecting less than 30% of their fuelwood from the SWWR and the poor collecting over 70% of their fuelwood from the SWWR (Fig. 5). A further analysis of the proportion of fuelwood collected from the reserve forest for each social group revealed a distinct difference in the nature of the dependence between the two groups with the poor having a markedly higher level of dependence on the reserve forest than the elite group (Fig. 6). Although Figure 5 shows a decreasing trend in dependence for both groups as distance to the reserve increases neither trend was statistically significant. The most important factor determining dependency of households on reserve forest in the SWWR buffer zone is the socio-economic condition of the people, not horizontal distance to the forest.

The socio-economic values of sustainable mangrove forest management: the Matang Mangroves in Malaysia

Lim Hin Fui, Mohd. Parid Mamat
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603-6365687, Email: limhf@frim.gov.my

The socio-economic value generated from a forest is an important factor deciding its sustainable management. This is precisely the case of the Matang Mangrove Forest Reserve (MMFR), covering 40,151 ha in Malaysia. For about a hundred years, the commercial socio-economic activities (i.e. forestry and fishery) taking place within the MMFR ecosystem have sustained the utilisation of mangroves in its natural environment. The utilisation of the MMFR resources includes development of human settlements, timber harvesting, fishery activities, development of aquaculture and eco-tourism.

The sustainable management of Mangrove resources has resulted in the development of about 27 permanent coastal settlements. The MMFR ecosystem provides the resources, which meet the needs of local communities within the mangrove area as well as settlements on the landward side of the mainland. Mangrove ecosystem sustains two types of settlements, varying in size from a few hundred to a few thousand residents near MMFR. The sustainable management of the MMFR since 1902 has brought about local development, which supports local livelihood. Villagers in its vicinity are involved in fishing, forestry and other related activities. Local communities depend on the mangrove resources in meeting their daily subsistence needs. The mangrove resources also meet subsistence needs (food and medicine) and generate cash income for local population. It has been estimated that the MMFR meets the subsistence needs of 8,000 individuals comprising mangrove workers, their spouses and children.

The mangrove forest produces timber sustainably and is recognised as important spawning, nursery and habitat areas for many economically important species of finfish and prawns. The mangrove water ways and mud banks are suitable for aquaculture development. in monetary terms, the timber products (charcoal, poles, firewood) are expected to generate an annual income of about RM22 million for the 1990-1999 period. The values of non-timber products were RM84 million (marine fish, prawn and shellfish in 1994), RM17 million (cockle culture in 1995) and RM1.3 million (finfish cage culture in 1992). in terms of employment, the timber harvesting/processing industry creates employment for between 1,008 and 1,680 local people. There were about 2,039 fishermen living near mangrove areas in 1994. Mangrove harvesting/processing generated an average monthly income of between RM776 and RM964 per worker in 1997. On the other hand, a fisherman earned between RM934 and RM2,700 a month in 1997.

The role of research and development (R & D) has contributed much to the successful sustainable management of the MMFR. The R & D activities began in Matang since its preservation as early as 1906 and it plays an important role in the drawing up of working plans, which are revised until the present day. These working plans lay the strong foundation in outlining the various management aspects of sustainable management: management objectives, classification of forest type by function, best management option, the rotation, allocation of coupes, silviculture system, silviculture operations, silviculture improvement, reforestation efforts, control of operations, monitoring and supervision. To further enhance R & D activities, research and sample plots were set up to test and develop best practices in the management and silviculture of the MMFR.

The implication from the successful sustainable utilisation of the MMFR is that it is essential to highlight the socio-economic benefits of a mangrove ecosystem. Enhancing R & D efforts in these aspects would contribute much to the sustainable development of the mangroves. It is seeing beyond the timber value that the overall mangrove ecosystem could be sustainably utilised and managed.

Sustainable Management of Community Based Forests through Credit in India

M. S. Haque
NABARD A-5/24, NABARD Nagar, Thakur Complex, 400101 Mumbai, India
Tel: +91-22-8879838, FAX: +91-22-4938699, Email: nasreen@giasbma.vsnl.net.in

Collaboration between villagers and Government in community based resource management specially forests, started in India in the beginning of twentieth century, but the present type of Joint Forest Management (JFM) grew out of experiences at Arabari in West Bengal and Sukhomajri in Haryana in the 1970s. The National Forest Policy of 1988, the Government of India guidelines of June 1990 and the State Government's orders on JFM are all positive steps to benefit the forest communities in particular and rural people in general. It has been estimated by Forest Survey of India, that there are 34 million ha degraded forest lands. At present, there are 35,000 Forest Protection Committees (FPCs) in India who are protecting and managing seven million ha. forests under JFM. If we assume that only one million ha land is protected under JFM the annual fund requirement would be Rs.15,000 million based on a cost estimate of Rs.15,000/- per ha (1 US $ = Rs.43/- - February, 1999). Budgetary allocation for Forestry Sector is less than 1% and there is no likelihood of increase in future. It is, therefore, necessary to involve institutional credit to sustain JFM movement for sustainable management of India's forests. It may be mentioned that NABARD/Banks are funding forestry projects implemented by Forest Development Corporations. However, so far, no JFM project has been funded by any financial institution in India.

A study undertaken by NABARD in andhra Pradesh indicated that it might not be difficult to channelise bank credit to FPCs. Certain institutional arrangements are necessary including Government guarantee and legislation. Studies further indicated that there are three types of JFM activities that may be bankable, viz. Sal (*Shorea robusta*), Teak (*Tectona grandis*) and Bamboo species. It has been estimated that with an investment of Rs.15,000/- per ha, a return of Rs. 1,20,000/- is possible by sale of poles and other Non Timber Forest Products (NTFPs) in 8-10 years. The major expenditure for protection and management of forests under JFM is for payment of wages to the watchers. Bank loan with interest can be repaid within 8-10 years leaving a surplus that can be reinvested and or shared by FPCs. The intermediate yield of grass within 6 months of protection will also be available for sharing among FPC members.

JFM is a complex system involving ecological, economic, social institutional and political aspects. Hence, financial package for JFM projects is different than traditional Forestry projects. Thus, the working out of modalities of financing JFM projects is essential. For this, research on the incentives, cost and benefits for local communities, collecting data from several sites under a variety of ecological and social conditions and the biological relationships and production function of timber, NTFPs and other products are necessary. The economic sustainability and institutional implication of JFM approach need also to be studied. The effort by NABARD might be able to formulate few models for financing JFM projects in near future. The aspirations of the rural people have been raised too high by adopting JFM in all the states. Failure to channelise fund to the system would not only degrade the forests further but would also create social unrest, hence, require serious attention both from Government and the financing institutions. We are sure that in near future, banks would be in a position to fund JFM projects for their Sustainable Management through Credit.

Dependence of Local People on Protected Forests

M. I. L. Katigula, Michael K. McCall, Robert Albricht
Catchment Forestry Office Tanga Region, P.O. Box 1449, Tanga, Tanzania
Email: usambara@twiga.com

The Government of Tanzania is intensifying efforts to conserve the biodiversity-rich and ecologically-sensitive East Usambara forests in Muheza District in Tanga Region. The government's current strategy is to apply regulatory forest policy instruments that do not recognise the dependence of the adjacent local communities on the protected forests as their major source of non-timber forest products (NTFPs).

This research assessed the use of NTFPs by local people living in four villages - Bamba, Churwa, Mhinduro and Segoma - that surround a block of three protected forests in the East Usambaras - the Bamba, Segoma and Kwamgumi Forest Reserves.

A participatory data collection approach using mainly rapid rural appraisal techniques, such as semi-structured interviews, was applied to elicit information on NTFP utilisation and other socio-economic factors. A global positioning system was used to locate NTFP collection sites in the protected forests. Subsequently these spatial data were processed using a GIS to produce maps showing the NTFP collection sites.

The results of this study indicate that, despite government efforts to protect and conserve natural forests in East Usambara through regulatory instruments, local people still enter the forest illegally and extract forest products; the primary reason being to extract NTFPs for their livelihood needs and for cultural services. Evidence of local people's use of NTFPs and their dependence on the protected forests as sources, is clear from the fact that they can identify a total of 378 species or types of NTFPs classifiable into seven purposes -: as medicines, foods, construction materials, fuelwood, water, seasonal agricultural indicators, and worshipping sites. More than 54% of the identified species are obtained only from the protected forests, which implies a high level of people's dependence on them. The relationships between villagers and the protected forests are found to be dependent on whether there are alternative sources of NTFPs, and/or whether there are substitute products which are accessible to and affordable by the villagers.

Local people respond to the current restrictive management approach by opting for secretive access and NTFP collection measures, and one result is an over-utilised 'ring' on the periphery of the protected forests.

The attitudes of local people towards the protected forests as sources of NTFPs are generally positive, indicating the importance of the forests to them. However, their attitudes towards the forest guards as managers of the protected forests are generally strongly negative, and accompanied by conflict indicators, such as 24 court cases (1993-1997) concerning NTFP use.

The findings lead this study to recommend to the government to revise the Forest Ordinance, especially Part V Section 15, that gives directives on the protection of forests and forest produce. For the government's forest management approach to be effective at an operational level, a collaborative management approach is recommended that would involve local people in planning implementation, control and monitoring activities in forests adjacent to them, which would bring benefits to both local stakeholders and the government. It is the dependence by forest-adjacent communities on protected forests as sources of NTFPs which gives the opportunities for collaborative management strategies that should lead towards more successful conservation.

Further studies are recommended on the assessment of forest capacity to supply various NTFPs at a sustained level and on the need to determine and set NTFP extraction levels. Future studies should monitor the sustainability of any utilisation levels set for the villages and forests.

The Impact of Industrial Plantation Forest Establishment on Socio-Economic Condition of Local People

Sri Suharti
Forest and Natural Conservation Research and Development Centre, Jl.Gunung Batu 5, Po.Box 165, Bogor, Indonesia
FAX: 62-251-325111; 62-251-315222, Email: Maryadi@usim.or.id

The demand for industrial wood in Indonesia in the year 2000 is projected to be 80 million m^3 per year. As the current annual increment of production forest is estimated to be only 30 million m^3, Government of Indonesia is trying to develop a major expansion of industrial plantation forest. The target is to establish 6.2 million Ha of plantation forest.

The establishment of plantation forest in a particular area would directly or indirectly involve and influence local people living in and around it. It is expected that positive impacts would be accepted by those people, hence some benefits from the establishment of the plantations would be gainned by the people. The reality however is not always so, since benefits received by the people depend on how far they are allowed to involve in plantations forest establishment. Whereas the degree of involvement of those people in the plantation depends on the awareness of the company of the importance of involving local people in the activities and how much the company is willing to devote some of their benefits and transfer it to local people surrounding it.

In Indonesia, there are two different forms of industrial plantation forest which is expected would possibly increase the opportunity of the people to participate in forest plantation forest activities i.e inter cropping-Industrial Plantation Forest model and Transmigration-Industrial Plantation Forest model. By participating in the plantation, local people get a chance not only working as labour but also an opportunity to grow food crops in between trees. A study in two forest concession (HPH PT. Yayang and HPH PT. Hutan Kintap) in South Kalimantan province found that the establishment of plantation forest increased people's income by 17,5 % and 19 % respectively. Those activities also give a chance to the people to get some other incentives such as extension, provision of infrastructure and social facilities in their village. Subsequently in PT. Inhutani V (State Forest Enterprise) allowing farmers to grow rice, corn and other food coops under rubber plantation for three years could increase their income by almost double. The production of rice in the area is even relatively high, on the average could reach 3.5 tones of unhulled dry rice.

The objective of this paper is to give an overview about the impacts of plantation forest establishment on socio-economic condition of local people surrounding it in some areas of Indonesia. The information presented here has been gathered from several research studies and literature.

Extraction of Non-timber Forest Products and the Tribal Economy - A study in south India

S. Suryaprakash, M.R. Girish
University of Agricultural Sciences, Department of Agricultural Economics, 560 065 Bangalore, India
Email: surya@uasblr.kar.nic.in

Man and forest have been having a close relationship from time immemorial. With the growth of civilization and with the develop0ment of agriculture and industry, man's dependence on forest has decreased. Yet, there are certain societies who have been living in forests for ages and who invariably continue to depend on forests. The non-timber forest products (NTFP) have been the main stay of forest tribals, sustaining their livelihood. in the recent past, medicinal and industrial demand for NTFP have created the value-in-exchange for NTFP, which were hitherto had only value-in use to the tribals. With increasing restrictions on timber harvest, NTFP constitute a large share of the value of forest products extracted. Lately, the NTFP have been contributing a great deal to the productive employment and household income of tribals. This is more so the case in respect of tribals residing in the interior forests. The special feature of NTFP collection by the tribals is that it facilitates the participation of all the members of the household irrespective of sex and age unlike other economic avocations available to them. in fact, NTFP collection is the only source of employment to the aged and children. This paper is based on a study conducted in the bio-diversity rich western ghat forest area of southern India. Apart from being a major contributor to the non-cash income of tribal households, the NTFP collection accounts for nearly half the cash income of the household. While some non-timber forest products are collected exclusively for home consumption, some other products as for the market only. The rest of the products are, however, collected both domestic use and for the market. This gives a clear indication that inspite of commercialisation of NTFP, they continue to dominate the household consumption basket of the tribal households. The men members of the tribal household collect a large share of a majority of NTFP than women. However, the employment contribution of women to the NTFP collection and processing is more than that of the men in a household. Being the forest dwellers for ages, the tribals are supposed to have property rights (though not explicit) over the NTFP. However, the State assigns the monopoly rights of NTFP extraction for major NTFP to registered forest contractors on tender basis. Thus, in reality, the tribals extract

NTFP for which the contractor offers a price, in lieu of wage. The NTFP collectors are to `sell' the notified NTFP to the authorized contractor alone. The monopoly rights assigned to the forest contractor thus come ion the way of the tribals getting a reasonable price for the NTFP extracted by them. Many a times, the daily earnings from NTFP extraction would be far lower than the wages the tribal receives from hiring out his labour to the Forest department.

6.11.04 Bridging the gap between monetary and non-monetary valuation of environmental amenities

Spatial analysis in economic evaluation of landscape management

Esa Arola, Penttinen, Markku
Forest Development Center Tapio, Soidinkuja 4, FIN-00700 Helsinki, Finland
Tel: +358 9 156 21, FAX: +358 9 156 2232, Email: esa.arola@tapio.mailnet.fi

Keywords: GIS; forest management planning; spatial analysis; economic evaluation; multiple use

The roundwood sales decisions of non-industrial private forest (NIPF) owners produce more than 80% of the roundwood supply, as well as creating potential landscape and biodiversity losses in Finland. Sustainable forestry has been essential, and regeneration has been required by the forest law for nearly 100 years. However, the new legislation protecting biodiversity, and the quality and certification requirements have restricted the owner's freedom to manage his/her property. This has raised concerns among forest owners that their income will suffer through greater regulatory intervention under the new laws, silvicultural recommendations, and other restrictions.

Traditionally, Finnish forest management planning (FMP) and practices have sought to attain (i) sustainable wood production that would assure the availability of raw wood for industry. Where possible, (ii) increasing the volume of growing stock was a secondary goal. Nowadays, the emphasis in FMP is being placed not only on timber production but also on landscape, recreation, and biodiversity. The institutional framework includes the new forest and nature conservation laws, silvicultural recommendations, quality requirements and certification according to PEFC (Pan-European Forest Certification) or the FSC (Forest Stewardship Council). However, from the individual forest owner's point of view, maintaining biological diversity poses a dilemma. While it may add recreational value to the area, it may also mean a loss of income to the owner.

The purpose of this research is to describe an approach which incorporates the economic impact on the NIPF owner caused by these requirements of the FMP system, and to create a method and a program supported by a geographical information system (GIS) to implement this. The method is based on the combination of a GIS and an FMP system that generates several treatment schedules for compartments and selects optimal schedule combinations using linear programming.

The GIS is used to impose silvicultural treatment restrictions on the compartments and to create management zones (MZ) (= a group of compartments). The MZ is based on the production potential of the area, the preferences of the forest owner, the preferences of the local people and the requirements set by society. The GIS is also used to collect and formulate preferences so that the planning problem can be solved in the FMP system. Finally, the GIS program is used in the analysis of the alternative forest management plans.

Trade-Offs between Recreation Benefits in the Preferences for Managing Recreation Areas

Paula Horne
Finnish Forest Research Institute, Unioninkatu 40 A, SF-00170 Helsinki, Finland
Tel: 358-9-857-05-717, FAX: +358-9-857 05 717, Email: Paula.Horne@metla.fi

Keywords: recreation, biodiversity, public preferences, choice experiment method

Preferences of a group of visitors for recreation environment may be incompatible. Some visitors favor natural state of forests with low level of management intensity, while some prefer easily passable forest environment for recreation. Also a single visitor may have contradictory preferences, on one hand wishing for easily passable even-aged stands, on the other hand asking for conservation of biodiversity. The heterogeneity of the public's preferences for forest environment, and their confusion about the concepts and relations of different benefits complicate management planning. in order to evaluate public preferences for forest management of recreation areas, the benefits of recreation experience can be divided into attributes that reflect the public notion of what constitutes the recreation environment. The study area of Nuuksio lake plain with five municipal recreation areas and a national park can be viewed as a system of spatial units whose manager faces an option of choosing varying levels of intensity in their management.

This study examines the preferences of the general public for management of recreation areas. It approaches the problem by focusing on the interrelations and trade-offs between forest benefits, namely biodiversity, the cost of management and scenery, as stated by the preferences of visitors in municipal recreation forests. in this method, monetary values are given by the trade-offs between the cost of management and other attributes. For example, changes in scenery are being valued by the elasticity of foregone biodiversity richness.

The study applied the choice experiment method that is consistent with random utility theory as well as offers a wide range of information on benefit trade-offs. The multinomial logit model is used to analyse multi-attribute choices. A Hicksian welfare measure is estimated from discrete choice data following a theory developed for discrete choice models. Observing the choices made and connecting the different attribute levels to monetary changes enables derivation of welfare measures.

The survey is administered in a questionnaire format on-site at the study areas. The questionnaire contains the choice experiment, attitude and background questions. A special focus is on revealing the respondent's attitudes towards biodiversity conservation and forest management. Respondents are grouped according to their attitudes using factor analysis and those groups will be used as explanatory variables. Respondents are instructed to choose the best management regime from each choice set of three alternatives. Each alternative is presented using a map of the five recreation areas and the Nuuksio National Park. The alternatives present different combinations of management options in the five areas. The different sceneries are illustrated using pictures of forest featuring two age groups. Each alternative regime is also given a biodiversity level and the associated cost of management.

Methods and Defects of Value Assessment of Forest Environmental Resources in China

Zhiyong Li
Chinese Academy of Forestry, Forestry Policy Research Division, 100091 Beijing, China
Tel: 86-10-62889019, FAX: 86-10-62884229, Email: zyli@caf.forestry.ac.cn

Keywords: sustainable forestry, forest valuation

The common goal of society is to implement sustainable development so that both a sustainable economy and environment is achieved. Sustainable forestry is an important part of achieving this goal. This research points out that sustainable forestry will be the dominant theme in forestry development around the world. Research on the value of forest environmental resources is both necessary and important for forest environmental management in China. Forest ecology projects have important implications for public welfare, especially to the extent that such projects insure the sustainability of forest benefits.

There are evident theoretic defects or limitations in the existing methods of environmental economics, which are based on traditional economics. We applied these approaches in valuing forest resources in China. The paper describes the main methods of forest environmental resource valuation, including forest value classification and the main assessment methods. It then analyzes three conceptual and theoretic defects of those methods and two mis-uses in the application of those methods, including the mis-use of static and dynamic measures, and the mis-use of substitution of benefit measures for function measures. Finally, the paper discusses three questions: (1) what kind of research and and policy development would be useful in integrating forest environmental resources, which are never considered as scarce resources, into modern social and economic systems? (2) Should environmental resources accounting be complementary to SNA and MPS, or a principal part? (3) Have the the limitations of environmental economics research method retarded the development of environmental economics itself, as well as limited the application and extension of research achievements in social and economic development?

Based on the discussion of the questions mentioned above, the paper points out that research on the methods and defects of forest environmental economy will be helpful for developing an improved theoretical framework for valuation of forest environmental resources in China, and also provide useful information for developing policies to insure the sustainable management of these resources The purpose of research in this field is is to provide theory and methods that can be used to develop a modern Chinese forestry for the 21st century.

Non-Monetary Valuation of Non-Market Environmental Goods and Services

George Peterson
USDA Forest Service, Rocky Mountain Research Station, 3825 East Mulberry, 80524 Fort Collins, Colorado, USA
Tel: 970-295-5963, FAX: 970-295-5959, Email: gpeterson/rmrs@fs.fed.us

Keywords: non-monetary valuation, environmental psychology, market research

The nature of many environmental goods and services is such that market prices fail to measure their value. The results of economic analyses of policy decisions that involve such goods will therefore be incomplete and biased without monetary valuation of the non-market components. The state-of-the-art of monetary valuation is imperfect and controversial, however, and effective application of available methods is often too expensive or infeasible. and, even if valid and complete, monetary economic analysis does not represent the full spectrum of human values associated with environmental goods and services. Complementary non-monetary valuation methods can contribute important and useful information to policy decision analyses, both to correct biases in economic analysis caused by incomplete monetary valuation and to represent those values that lie outside the domain of monetary economics. in this paper we identify the alternative methods available, discuss and compare their relative merits and applications, and explore the research frontiers of non-monetary valuation. The alternative approaches include (1) environmental psychology and psychometric measurement, (2) social survey research, (3) market research methods, (4) structured small-group decision procedures, (5) derived valuation based on scientific analysis of human dependence on things removed from direct human consumption, and (6) techniques for direct public involvement in the policy decision process. The paper integrates these various approaches into a comprehensive framework for non-monetary non-market valuation.

Measurement of attitudes and beliefs in contingent valuation as a preference construction tool in the case of forest quality

Eija Pouta, Mika Rekola
University of Helsinki, Department of Forest Economics, Post Box # 2400014, Helsinki, Finland
Tel: +358 (9)0 191 7728, FAX: +358 (9)0 191 7729, Email: eija.pouta@helsinki.fi

Keywords: contingent valuation, forest regeneration cuttings, beliefs

In a contingent valuation (CV) study a sample of people is asked about their willingness-to-pay (WTP) for non-market goods or services in order to measure environmental benefits or costs in monetary terms. in a CV study respondents are expected to state their preferences concerning the good to be valued. The assumptions concerning the completeness of preferences and the rationality of decision makers have been criticized in the valuation literature. Several reasons for inconsistency and incompleteness of preferences have been discussed, such as respondents having conflicting values, uncertainty about his or her own values, or the complexity of the choice situation. For example, it has been suggested that protest responses and "don't know"-responses reflect respondents' frustration with a situation where a demanding choice must be made, but no tools are provided to help make the choice. in this study, attitude and belief measurement is offered to the survey respondent as a tool to form preferences about forest quality.

The attitude-behavior framework can be seen as a series of hypotheses, linking behavior to behavioral intentions, and secondly, linking behavioral intention to attitude, which is a function of salient beliefs about the attitude-object. Each salient belief links the object to an attribute or to an outcome of the behavior in question. The attitude is determined by the strength of these beliefs and evaluations associated with the attributes concerning behavior. in a WTP question, the behavior under consideration is whether to support a proposed policy that provides an environmental good, given a specified expense. in contingent valuation studies, the attitude-behavior framework has been used as a model that explains behavior. However, the multi-attribute structure of the model is very close to multi-attribute utility theoretical aids of decision making. By expressing their beliefs and attitudes concerning the attitude object, respondents also construct their preferences about the choice setting.

The valuation of non-market benefits of forests provides an excellent case to test the effect of attitude and belief measurement. The data come from a contingent valuation survey in a case of forest regeneration cuttings in Finland. A mail survey sample of about one thousand respondents chose between two forest regeneration practice alternatives: a) status quo management or b) environmentally oriented forest regeneration. Alternative (b) included an expense for the respondent's household. Half of the respondents went through belief and attitude questions regarding both alternatives, while the other half did not participate in the belief or attitude measurement. in this paper we test the effect of this preference construction tool on the item response rate of the WTP question and on the WTP itself. The WTP was estimated using a logit model of dichotomous choice. in addition, two different treatments of decision complexity were formed by varying the number of attributes in the alternatives. The perceived decision confidence of respondents was also measured and compared between the treatments.

Preference construction treatment decreased the number of responses. This was the case especially when the alternatives in choice setting had only some attributes. The treatment had some effect on dichotomous choice. When the choice setting was simple, the treatment increased the number of supporters of the environmentally oriented cutting. Also, in the logit model of dichotomous choice, belief questions increased the probability of choosing an environmental alternative. Including preference construction treatment in the model improved the performance of the model somewhat significantly. Belief and attitude questions decreased the perceived decision confidence, especially when the education level of the respondent was low. It seems evident that responding to belief questions about the good reminds respondents of the dimensions of the choice which they otherwise would not have considered. in this way the choice becomes more complicated and the respondent perceives uncertainty. On the other hand, this raises the question of the response quality in dichotomus choice in general. Should the CV-questionnaire guarantee that respondents deliberate all dimensions of the choice equally? Furthermore, how should we deal with the group of respondents who are more confused after screening dimensions?

Evaluating the Impact of Farm Woodlands on the Landscape: a Case of Blending Perspectives

Colin Price
School of Agricultural and Forest Sciences, University of Wales, Bangor, Gwynedd LL57 2UW, United Kingdom
Tel.: 44-1248-382454 / 382281 / 351098 Fax: 44-1248-354997
Email: c.price@bangor.ac.uk

Several disciplines bring their own perspectives on valuation to aesthetics. Landscape architects enunciate descriptive principles for design and arrangement of landscape elements. Planners quantify the relative merit of landscapes seen holistically. Perceptual psychologists analyse individuals' responses to landscapes. Economists do not consider landscape as fundamentally different from other public goods, so incline to value it by their willingness to pay criterion. Using this, they may seek to displace the contributions of other disciplines: hedonic pricing attempts directly to place a cash value on landscape elements; contingent valuation of a given landscape change condenses citizen preferences with consumer purchasing decisions; but both methods suffer disabling weaknesses. It is more constructive to integrate the insights of other disciplines than to compete with them. By such a combined process a farm woodlands programme in Wales has been evaluated. Hypothetical planting schemes were designed for representative landscapes, using received design principles. A single assessor evaluated, subjectively, impact on landscape quality, judgements being calibrated by reference to a larger assessor group. Landscape change was given a monetary scale via recorded differential willingness to pay for travel to Welsh landscapes of different quality. The resulting value of aesthetic gain was similar to the expected cost of the programme.

6.11.07 Social Dimensions of Forest Protection (Africa, Europe, North America)

Collaborative Forest Fire Management Strategies in Ghana

Viktor Agyeman, Asare, A.B., Orgle, T.K. and Gronow, J.
Forestry Research Institute of Ghana, University Box 63, Kumasi, Ghana
FAX: 233-51-60121, Email: forig@africaonline.com.gh

Fire is currently the most important cause of deforestation and forest degradation in Ghana. The severe drought and fires which occurred in 1983 and 1987 exacerbated by indiscriminate logging in some of the affected reserves have resulted in the conversion of forests from generally aggrading ecosystems to systems of progressive degradation. During the past 15 years, wildfires in Ghana have resulted in an annual loss of approximately 3% of Gross Domestic Product (GDP) during the past 15 years through destruction of forests, agricultural lands and property. in 1993, the total area of forest reserves in the high forest zone affected by fire was estimated at 0.917 million hectares, more than half the total area of reserved forest.

Wildfires in Ghana are mainly anthropogenic in origin. The major human activities that can lead to uncontrolled fires include, charcoal burning, palm-wine tapping, slash and burn system of farmland preparation and hunting. in order to prevent further environmental degradation resulting from wildfires, the Government of Ghana initiated a collaborative forest fire management (CFFM) programme aimed at mobilising local community support for wildfire prevention, detection communication and control.

The CFFM approach recognises that successful wildlife prevention and control programmes need to be developed and implemented in partnership with local communities. The CFFM system aims to improve management of natural resources and increase the flow of benefits from forest lands to the local land-owning community as an incentive for increased participation in forest and wildfire management.

The paper describes the key elements of the evolving CFFM strategy including the use of a learning process approach to guide the overall development of the programme and various field activities including consultation, needs assessment, investigation and consensus building. The progress made up to date in the implementation of CFFM strategies including the establishment of green fire breaks are outlined. The paper concludes with a comparative assessment of the classical wildfire management approach, involving the Forest and Fire Service Organisations, and the collaborative approach involving forest users including local communities.

An Economic Analysis of Residential Nonconsumptive Wildlife Recreation Expenditures in the United States

Yeong-Nain Chi, Ferdinand F. Wirth, Jack Coburn Isaacs, E. Jane Luzar
National I-Lan Institute of Technology, Department of Forestry, I-Lan, China-Taipeh
Email: ynchi@ccmail.ilantech.edu.tw

This study utilized cross-sectional data obtained from the 1991 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation to analyze individual's annual expenditures of nonconsumptive wildlife recreation in the United States. Residential nonconsumptive wildlife recreation is defined as a person who participates in a recreation activity less than one mile from home with the specific intent of observing, photographing, and feeding wildlife.

In the process of selecting an appropriate model most consistent with consumer behavior associated with nonconsumptive wildlife recreation, the tobit model and the double hurdle model for the residential expenditure model were evaluated. Based on the likelihood ratio test result, the double hurdle model fit the data much better than the tobit model.

The empirical results from the residential expenditure model indicated that income, age, gender, education, wildlife category (such as birds, mammals, and insects), visiting public parks or natural areas, maintaining natural areas for fish or wildlife, and planting around home for fish or wildlife had a significant effect on residential nonconsumptive wildlife recreation expenditures.

An individual's annual expenditures were predicted to increase $0.00006938 for every $1.00 of income growth, increase $0.3029 when participants are middle-age individuals, increase $2.6054 when participants are male, increase $2.6649 with increases in educational status, increase $11.3563 when observing birds, increase $4.6485 when observing mammals, increase $4.0757 when observing insects, increase $7.8431 when participants visit public parks or natural areas, increase $5.8571 when participants maintain natural areas for fish or wildlife, and increase $6.6430 when participants plant around home for fish or wildlife.

The results in this study provide insight into determinants of residential nonconsumptive wildlife recreation expenditures which can be used for planning and decision making purposes for nonconsumptive wildlife management. This study also provides guidance in the choice of empirical model for use in this type of expenditure analysis. Together, these results provide a rigorous analysis

Improving Forest Management Practices in Quebec (Canada) Through a Social Learning Process

Marc André Cote, Luc Bouthillier
University, Laval, G1K 7P4 Quebec City, Quebec, Canada
FAX: +1 418 656 3177, Email: mac@moncourrier.com

To develop a truly sustainable approach to decision making in forest management, a model is needed to facilitate collaborative decision-making between different parties with widely varying objectives. The task is to transform the dialogue between stakeholders into a collective learning process that will permit the forest manager to find new solutions to current problems; solutions to which forest users hold the key. The goal of this research project was to create a social learning process 1) between stakeholders and forest managers in which the stakeholders informed the forest decision makers about ways to improve forest management and 2) between stakeholders and researchers in which the stakeholders expressed their needs to the researchers.

A mechanism of social learning was developed for the management of 400 000 hectares area held by the corporation Cartons Saint-Laurent, in Quebec, Canada. An initial round table involved representatives of the following organizations: Native people, regional counties, town council, wildlife management associations, hunting and fishing associations, Ministries of Natural Resources Wildlife, and Environment ministries, forest contractors, local business associations, country cottage owners, and snowmobile association. A second round table involved researchers from three universities conducting research projects in forestry, sociology, economics, geography, and biology. Two project managers serves as the link between these two round tables. The stakeholders and their areas of expertise were identified and these are being used to determine the issues for the Cartons Saint-Laurent forest management area. All stakeholders shared their knowledge in order to develop new alternatives that may improve forest management.

To date, this social learning experience has showed that new interactions between the stakeholders resulted in the development of new information networks. Moreover, the identification of areas of expertise and skills of stakeholders helped to develop a practical partnership where everyone had something to contribute to improve forest management practices. For example, involving the researchers helped to direct their projects towards stakeholders' needs and concerns, and involving the wildlife stakeholders helped to increase the forest manager's knowledge on this issue.

However, the success of our experience depended primarily on a preliminary stage in which the process was carefully planned and designed with the involvement of all stakeholders. This preliminary stage helped us to develop several mechanisms of social learning to suit the different parties involved. For example, Native people and snowmobilers did not have the same concerns and thus did not wish to be involved the same way.

The imputability of interested parties involved in the process, the proliferation of public participation initiatives in a same region, and property rights were issues raised during the process that still have to be addressed. Nevertheless, this approach of public participation could be used by forest managers wishing to initiate a certification process for a given territory.

Institutional Impediments to Conservation and Management of Forested Dispersal Zones Adjoining Protected Areas: Some East Africa Examples

James Legilisho-Kiyiapi
The Centre for Wildlife Management Studies, Post Box # 47272, Nairobi, Kenya
Tel: 254-150-22278, FAX: 254-150-22106, Email: jkiyiapi@net2000ke.com

The multiple uses of forests means that forest management is often constrained by a variety of factors. The traditional timber-oriented forest management was relatively simple in that the goal was to maximize timber production by manipulating the forest system in favour of selected commercially important species. Recent shifts in forest resource conservation and management paradigms embracing participatory and whole-system approaches present rather complex and difficult forest management scenarios. Nowhere is this complexity more real than in Sub-Saharan Africa where a broad spectrum of colonial and post-colonial land and resource tenure regimes exist and where rapid social change threatens to destroy communal forest resource ownership systems.

Participatory natural resource management present challenges within the scientific and social domain: scientific in that technical solutions are needed to deal with the forest ecosystem based management, and social in that we need to define relevant management entities and formulate supporting policy and legislation. in East Africa as in other parts of the world, forest management problems seem to revolve around the increasing human-resource interactions in or close to protected area systems. Whilst the delimiting of protected areas (e.g., National Forest Reserves and Parks) in most African countries in 1940-50s, following European and North American models achieved some reasonable natural resource conservation goals, continual conservation of these resources is no longer possible without the support of surrounding local populations. This derives from an historical alienation of local populations from resources and perpetual inequitable distribution of benefits from these areas. Equally central, are weak institutional mechanisms in place to address management issues. The sectoral nature of regulatory government agencies (e.g., one agency responsible for forest and another for wildlife resources) means that different policies and laws often apply even when ecological requirements would demand otherwise.

Given the socio-economic conditions of communities adjacent to forest-protected areas, conservation solutions must seek to maximize the mix of economic benefits derived these sites. This will involve a landscape-level ecological characterization and site specific analyses of rural livelihoods towards land/resource-use zoning. Effective involvement of local communities entails a clear understanding of what constitutes 'a community' and existing local structures within the broader context of resource conservation and rural development partners. A pragmatic approach to creation of local community institutions is demonstrated using examples drawn from the Maasai Mara National Game Reserves and the Tsavo-Amboseli ecosystems in southwestern Kenya.

Keywords: Protected areas, dispersal zones, resource continuum, adjoining communities

Community based bioprospecting of *Mondia whytei* indigenous plant as income generating activity in Western region of Kenya

Kefri Muguga and Mukonyi Watai
Kenya Forestry Research Institute, Post Box # 20412, Nairobi, Kenya
Tel: 0154 - 32891/2/3, FAX: 0154 32844, Email: kefri@arce.or.ke

Bioprospecting for non-timber-forest-products (NTFP) by involving the rural communities has been seen as alternative in salvaging deteriorating environment, alleviating poverty and enhancing economies of most countries (1) NTFPs are a source of phytomedicines, social and spiritual fulfilment to most rural communities and urban dwellers in the world (2) A study carried on ethnobotanical survey of medicinal plants and trade potentials of NTFPs established that they play an important role in Kenya's economy generating about US$ 40 million annually (3) About 70% NTFPs in Kenya's are from natural ecosystems and not on farms. Most of them are of plant origin, few derived from animals. These NTFPs are used as constituent of main products. The constrains of NTFPs bioprospecting in Kenya are: no date on status of NTFPs scarcity of scientific information like bioactive ingredients, forest clearing and unsuitable exploitation has reduced biodiversity, production and marketing not clearly established, no direct link to rural income. A community based research carried out by Kenya forestry research institute to alleviate poverty and conserve the environment through bioprospe3cting of a locally valued plant species *Mondia whytei* has been a success. (4). The communities are domesticating this species through agro-forestry systems and their income base has broadened. Bioprospecting of this plant species is a good example of how benefit can be return to communities, custodians of biodiversity and how it can be an incentive to environment conservation.

6.11.07 Social Dimensions of Forest Protection (Asia)

Indigenous Technologies for Sustainable Resource Management in Indian Cold Deserts

Prem Kumar Khosla, K.K. Raina
Himachal Pradesh Agricultural University, 176 062 Palampur, Himachal Pradesh, India
Tel: 91-1894-30522, FAX: 0091-1894-30511, Email: vc@hpkv.hp.nic.in; atul@hpkv.hp.nic.in

The Indian Cold Deserts located in North Western Himalayan Region, covering 74,809 m^2 area, pose a greater development challenge due to rugged terrains, isolation, inhospitable climate and lack of communication facilities. These areas are ecologically varied and biologically diverse, unique systems. These are further characterised by subzero winter temperature (-40°C to 20 °C) annual precipitation less than 30 cm. Shrubs and perennial herbs form the dominant vegetation. A variety of biotic, abiotic, ecophysiologic and socio-poltical factors restrict the economic growth of the region. There are inadequate sources of livelihood with agro-pastoralisum forming the main source of the income. Farming is traditionally practised without any marketing facilities.

Institutions related to economic development are either missing ore are too weak. Nomadic grazing is practised for meeting the requirement of wool and milk. Poor communication network is further leading to isolation. Collection of medicinal herbs is also practised for meeting the cash requirements. There is over exploitation of certain herbaceous flora by the pharmaceutical agencies. Natural vegetation is mostly herbaceous *Thymus, Medicago, Trifolium, Anemone, Potentila, Epilobium, Verbena, Alluim, Aconitum, Delphenium, Aquilegia, Primula, Geranium, Polygonum* and *Cannabis* are the dominant herbal species. Common shrub species are *Hippophae, Myricaria, Ephedra, Artemesia, Rosa, Astragalus, Caraga* and *Salix*. in addition manmade forests are found along the river banks rivulets, and nallahas comprising mostly of poplars, willows, *Hippolhae spp.* and *Myricaria spp*. Excessive harvesting of natural and plantation trees for energy requirements during freezing winters is a common scenario. Inspite of harsh living conditions, inhabitants of Cold Deserts have sustained them over a period of time. They have rich knowledge concerning their environment and natural resources, including crops and livestock. This traditional knowledge is acquired through generational experience and is flexible to the needs of the natives. The sustainability of village ecosystems is ensured through indigenous resource management. The identification of these traditional technologies are packaged through intervention into physical, socio-cultural, environmental and different components of soil, water, crop, livestock and other resource endowments of the community. The documentation of indigenous techologies will help in conservation of rich traditional knowledge, hitherto practised, but now the most threatened due to cultural mixing and opening up of communication systems. It will also give an insight to know more critically the scientific bases for superstitions which are being followed by people for sustainable management of resources and improving crop and animal productivity. It also opens the scope for scientific explanations are not available till date. The paper includes the detailed account of indigenous technologies with particular reference to the age old knowledge on the use of herbs for the treatment of human and cattle ailments. The judicial use of local flora for pharmaceutical purposes can also form the basis for commercial enterprenurship.

The Development of Community Forest in Improving the Environmental Qualitay and Society Welfare in Indonesia

Eulis Retnowati
Forest and Nature Conservation Research and Development Center, FORDA
Jl. Gunung Batu, PO BOX 165, Bogor, Indonesia
Tel: +62-251-325111, FAX: +62-251-325111, Email: slitbang@bogor.indo.net.id

In Indonesia, Community Forest Policy is described in the Basic Forestry Act No.5 of l967. in order to develop Community Forest, the government has carried out various ways.

In the Year 1995, the Community Forest in a district in Central Jawa contributed 29,76 % of the total income, and decreased soil erosion.

Some important aspects needed to encourage more farmers to involve in Community Forest activity are the establishment of forest farmer groups, Cooperation of forest farmer groups for wood marketing, and partnership between farmers and the owner of the wood industry.

Sociocultural and political aspects of biodiversity conservation: Implications for Sustainable Forest Management in a Tropical Timber Production Forests in the Philippines

Lucrecio L. Rebugio
UPLB College of Forestry and Natural Resources
College, P.O. Box # 132, Laguna, Philippines
Tel: 63-49-536-3996, FAX: 63-49-536-3206, Email: llreb@laguna.net

The study was conducted to provide relevant social data for the formulation of a socially relevant, equitable and acceptable Sustainable Forest Management and Biodiversity Conservation Plan of the Surigao Development Corporation (SUDECOR) area in Surigao del Sur, Philippines and to address the concerns with respect to the rights of indigenous peoples and tenured migrants in the area. The sociocultural part was specifically aimed at identifying the actors/stakeholders in forest resources management, and at determining how people and communities regarded and used forest resources, how they viewed forest biodiversity and biodiversity conservation and how they perceived SUDECOR. The political analysis on the other hand sought to assess the political environment of forest production and biodiversity conservation in the Project area. Specifically it was aimed at analyzing the effectiveness, influence and importance of various organizations from the communities viewpoint; gender division of labor and decision-making; the ethnic and class relations and the relation between SUDECOR and indigenous communities in the concession area. Data were gathered mainly through focus group discussions (FGD) and interviews with selected groups and key individual informants (KI) conducted in the SUDECOR timber concession area and surrounding communities. Based on the results of the study nine (9) socio-economic and political strategies for sustaininable forest management were proposed, namely: 1) mutual respect for their rights and recognition of corresponding responsibilities by both the SUDECOR and the affected indigenous cultural communities; 2) creation and establishment of a field level consultative body as a mechanism for participation among affected stakeholders; 3) provision of stable livelihood communities; 4) protection and conservation of floral and faunal species which are endangered and useful for the communities depending on the resource; 5) assessment of indigenous resource conservation practices and integration of relevant ones in the sustainable management plan; 6) institutionalization of benefit sharing scheme for community participation in sustainable forest management; 7) formulation and implementation of an information, education and communication (IEC) program supportive of the project; 8) provision of other extension services; and 9) creation of an IEC and/or community relations office within SUDECOR.

The Increase of Community Participation in Forest Management through Development of Social Forestry Program in Indonesia

Sri Suharti
Forest and Natural Conservation Research and Development Centre, Jl.Gunung Batu 5, Po.Box 165, Bogor, Indonesia
FAX: 62-251-325111; 62-251-315222, Email: Maryadi@usim.or.id

In the last few years there is a tendency of a change towards new forest management system in which people's participation becomes the focus of attention. This concept has several different names such as community forest based management, collaborative forest management, joint Forest Management and Social Forestry. Three main principles are applied in this new forest management system i.e 1) Local people need to be involved in forest management activities; 2) Local people have legal rights and obligations to participate in forest management activities; 3) There is a need to actively involve local people in deciding activities developed to guarantee forest management system which is economically feasible, socially adaptable and ecologically sound.

To anticipate those tendency, Government of Indonesia (GOI) c.q Ministry of Forestry and Estate (MOFE) has developed several programs with the main purpose to rationalize and empower the life of local people living near and around the forest area and to increase active participation of the people in forest management activities. There are various forms of Social Forestry program in Indonesia i.e. PMDH forest (Village Development Program), Community Forestry, Mixed Farming Timber Estate, Transmigration Timber Estate, Small scale Private Forest, etc.

The research on community participation in forest management through social forestry program establishment was conducted to learn how could the program increase and facilitate community participation and describe how far and in what activities local people could participate in forest management activities in some area of Indonesia. Some case studies presented in the paper focus on what the local people receive and how they react offer establishment of those programs. The information presented here has been gathered from several research studies and literature.

The results showed that from time to time there are dynamics in Social Forestry program development. Begin from the first time when the program was introduced, it showed there is a change of intention where professional foresters who mostly in the past think they know more and have the right more over forest resources start to change their mind. Now they realize that local people have also the right to be involved in forest management activities. Furthermore, active participation of the people in forest management activities has also an important role in determining the success of sustainable forest management. Top-down approach as the only method applied in program establishment now is gradually left. The new introduced method, PRA (Participatory Rural Appraisal) start to be used widely in designing alternative activities in Social Forestry program. The degree of community participation depend on the concessionaires (as executor); the GOI c.q MOFE (as supervisor and evaluator) and the local community themselves.

6.12.03 Sustainable land use as precondition for sustainable forestry

Sustainable Land Use and Sustainable Forestry

Hans Essmann, Stefanie Linser
University of Freiburg, Institute of Forest Policy, Bertoldstr. 17, D-79085 Freiburg, Germany
Tel: +49-761-203-3724, FAX: +49-761-203-3705, Email: essmann@ruf.uni-freiburg.de

The Rio Conference 1992 declared "sustainable development" as one of its central concepts and deemed it as a guideline for all future activities. The model of sustainable development represents a concept which seeks to reconcile people's social and economic needs with the long-term conservation of natural living conditions. This does not mean that protection of the environment should be subordinate to economic and social factors; instead, it should be an integral component of development. in fact, in chapter 9 of AGENDA 21, the signatory states pledged to manage natural and environmental commodities in a sustainable manner so that they could be utilized now and in the future. A comprehensive form of sustainable trade should also mean that, among other things, any types of ecologically damaging and resource-wasting land use are to be avoided. in order to reach the objective of sustainable land use, the "implementation of policies and programs that will discourage inappropriate and polluting land-use practices and promote sustainable utilization of terrestrial and marine resources" (AGENDA 21, section 9.21 b) should be initiated. From our point of view there seemed to be no doubt that at a long run sustainable forestry is feasable only in the frame of the sustainability of the overall land use. From the authors point of view there seemed to be no doubt that in the long run sustainable foresty is only feasable in the frame of sustainability of the overall land use. Orientated on the Driving Forces-State-Response Model of the OECD (Organization of Economic Co-Operation and Development) criteria and indicators for the assessment of sustainability of land use have been developed and are presented in the paper. Additionally, orientating on some of the criteria discussed and agreed to at the Third Ministerial Conference on the Protection of Forests in Europe in Lisbon (1998) indicators for the assessment of sustainablity of land use in forestry as a small step of the realisation of sustainable forest management has been developed. For verification of the selected criteria and indicators, the "Naturpark Südlicher Schwarzwald" (Nature Park Southern Black Forest), established in February 1999, has been chosen. The parc area of around 300.000 hectares represents all existing conflicts between the different land users as there are agriculture, forestry, tourism & recreation, trade, industrial & private housing settlements as well as nature conservation. C&I are supposed to enable and rationalise political decisions concerning land use in general and forestry in particular with regard to sustainability.

New Challenges for the Forest Sector to Contribute to Rural Development in Europe

Pentti Hyttinen, Anssi Niskanen and Andreas Ottitsch
European Forest Institute (EFI), Torikatu 34, FIN - 80100 Joensuu, Finland
Tel: +358-13-2520235, FAX: +358-13-124393, Email: Pentti.Hyttinen@efi.fi

Rural areas across Europe are facing more rapid emigration than ever before. Due to the diminishing prospects for financially feasible agriculture, and the lack of supplementing sources of income, rural areas are characterised by high unemployment, narrow occupational base and poor job creation. The vicious circle of rural underdevelopment is feeding itself - low work opportunities result in increasing emigration, decreased tax revenues, which in turn, decrease investments to infrastructure. The result is a loss of attractiveness of rural regions for human resources.

The main challenge for the forest sector in supporting rural development is to find counter-measures to break the vicious circle. Rural areas of Europe are becoming more and more just sources of timber with no processing industries. Higher and especially more innovative utilisation of existing wood and non-wood forest resources would contribute to rural development by increasing employment opportunities, and raise the economic benefits obtained from the forests.

The challenges of the forest sector in contributing to the vitality of rural areas in Europe have been extensively examined by the authors. This paper presents the major findings of the potentials and practices in utilising local forest resources for high value added production, and discusses how forest-based income and employment could be increased.

Among the main findings regarding the prevailing situation is that the correlation between forest resources and employment is very weak. Employment per unit of processed wood is highest in those countries, which feature a higher concentration of population and closeness to markets, which attracts more refined stages of processing industries. The main consumers of forest products are situated in the large urban agglomerations, whereas the main producers and exporters are in regions and countries with an overall rural structure. It is therefore obvious, that strategies aimed at increasing the potential for the forest sector cannot concentrate on regional consumption alone, but that the main task lies in connecting rural producers and urban consumers. Today's development of communication infrastructure and transportation logistics provide useful tools also for the forest sector for linking up rural and urban areas. One such example is the on-line marketing of forest products and services.

Ownership fragmentation and absentee ownership are an increasing problem in mobilising forest resource for income and employment, since in many rural areas average forest plot areas are well below any economic significance for the owner. To tackle this problem, various forms of co-operative forest management activities have been developed, which provide labour for those who remain in the regions, as well as income for the forest owners who do not live at or near their land anymore.

At the processing side, much of the hope is put especially on small and medium-scale (SM) mechanical wood industries. The reasons for the optimism are obvious. The required investments are often rather modest, and the restrictions of economy of scale are not that substantial than in mass-scale pulp and paper industries. Businesses in SM industries may start up on mainly local and regional markets, which makes their business easy to manage. Exploration of export-opportunities has also been a successful factor for the development of many SM industries. in this respect, investments in staff qualifications have proven essential.

The development of services is also seen among the opportunities to create forest related income and employment. Tourism is usually named among the chief potentials, but other options exist as well. Examples are visible, where employment also has been created through conservation activities such as the carrying out of traditional management methods in the interest of landscape aesthetic. One of the chief problems here is the development of appropriate transactions mechanisms to direct income from these activities to rural regions rather than extra-regional actors.

Today, the forest sector employs 3.2 million people in Europe, and undoubtedly has increasing importance in rural development issues in the 3rd millennium.

Change of forest region seen from the land use

Tetsuro Sakai, XiaoMeng Sun
Kyoto University, Graduate School of Infomatics, 606-8501 Kyoto, Japan
Tel: +86-753-3134, FAX: +86-753-3138, Email: sakai@i.kyoto-u.ac.jp

In the last century, the total amount of forest area in Japan has remained fixed at a ratio of about 70%. However, there have been large changes in land. It is important to understand the characteristics of the forest area to have sustainable use of forest. It is also important to understand whether changes in forest areas have been caused by societal and economic developments. We attempt to explain geographical features of the forest area and changes in land use in Japan.

We obtained the data for land use and geographical information from the 2km mesh land use data provided by UNEP/GRID-Tsukuba and the 50m mesh altitude data provided by GSI (Geographical Survey Institute). The former are made from the topographical maps of three periods: circa 1900, circa 1950 and circa 1985. Land use types are classified into 31 categories, including urban agricultural, and forest uses. The 50m mesh altitude data consists of the altitude in spots of equal length and width based on 1/25000 topographical maps of GSI. First, inclination and slope azimuth were calculated at each grid location using the altitude data of the four neighboring grid locations. Thus, a database of landform information containing inclination, slope azimuth, and altitude value was constructed. Next, the average and dispersion statistics, the maximum, and the minimum altitudes and inclinations and the average and dispersion statistic of the slope azimuth of the 2-km meshes were calculated using the landform information of the 50 m meshes.

Forest area comprises 2/3 of all land in Japan in 1990, 1950, and 1985. The next largest category of land use is agriculture at about 17% of total land area. The key points of land use change between 1900 and 1985 are as follows. The total amount of forest area did not change. Land devoted to agricultural use hardly increased. Land devoted to urban use increased rapidly after World War II, whereas land devoted to other uses declined rapidly. Land use in 75% of the total area saw no change, whereas 13% was changed by 1950 and 16% by 1985. Most land use changes consist of 1) changes from forest use to other use, 2) changes from forest use to agricultural use, 3) changes from agricultural use to urban use, and 4) changes from agricultural use to forest use.

As altitude increases and inclination becomes steeper, land use tends not to change. For altitudes less than 200 m, much area is diverted from forest area, whereas from 200-400 m, much land is diverted to forest area. For inclinations less than 10%, much area is diverted from forest area, whereas for inclinations of 20-50%, much area is diverted to forest areas. The forest area has increased on land of higher altitudes and inclinations. The largest such increase is at altitudes of 300-699 m and inclinations of 30-49%. Land devoted to other use has diminished. The largest such drop is at altitudes of 100-499 m and inclinations of 20-49%. We conclude that changes of land use depend on characteristics of geography.

In forest areas, the broadleaf tree woods have decreased whereas the mixed woods have increased. in area devoted to broadleaf tree and conifer woods, the average altitude increased and the average inclination became steeper. However, for mixed woods, the average altitude decreased and the average inclination became gentler. The cause is artificial wood development since 1950. The artificial woods area became 10 millions ha.

Some Notes About Shifting Cultivation, Problem and its Alternative Solution in Indonesia. A case study in HPH PT. Hutan Kintap, South Kalimantan.

Sri Suharti
Forest and Natural Conservation Research and Development Centre, Jl.Gunung Batu 5, Po.Box 165, Bogor, Indonesia
FAX: 62-251-325111; 62-251-315222, Email: Maryadi@usim.or.id

Shifting cultivation is an example of a traditional land-use system, which is often in conflict with the management of the forest. in Indonesia, shifting cultivation has been practised in almost all of the island. in the areas where the native fertility of the soil has been high, or man/land ratio has become high due to population growth, this system has changed to more intensive land use ones.

Numerous interrelated factors like the increase of population growth, rising demand for land for commercial exploitation and immigration of landless poor and refuges from other regions are generating the deteriorated and migratory shifting cultivation spread in many regions. This often causes the degradation of natural vegetation and soil resources and other environmental problems.

These processes induce an extension of shifting cultivation to new areas and a gradual impoverishment of resources. This spiral process of land degradation and rural poverty does not only create much human suffering, but also results in the loss of natural resource, which otherwise would be used for generating development activities.

In the early 1970's, there were various attempts had been tried in Indonesia to diminish the expansion of shifting cultivation through the development of several resettlement and not resettlement programs. Two example of resettlement programs are HPH Bina Desa, now called PMDH program (Forest Village Community Development Program) and Tumpangsari program (inter cropping program). The target was 500,000 shifting cultivation hourseholds should be rationalized in every five years. in fact however, at the end of 1988, there were only 123,470 families that could be resettled, disregarding that a substantial amount of them has left.

The research on shifting cultivation and its control in South Kalimantan with a case study in HPH PT. Hutan Kintap was carried out to investigate what factors motivate the people to practise shifting cultivation and how far the programs developed in the area could improve the living condition of shifting cultivator household in terms of better socio-economic condition and the increase of self reliance of the people. The results show that there are several factors underlying the people to practise shifting cultivation, some of them are need of land for crop cultivation, limited job opportunities, lack of skill and knowledge, low wage, tradition, etc. The two programs established in the area have not satisfied its participants. As a result many participants still practise shifting cultivation and even leave the program. in order to overcome the problem some adaptation and modifications of the program should be done or otherwise a new program should be established to replace the less appropriate program developed before.

Crossing traditional boundaries: The role of social and psychological parameters in interdisciplinary landscape analysis projects

Christine H. Jakobsen
University of Idaho, Department of Resource Recreation and Tourism, ID 83844 Moscow, USA
FAX: 208 885 6226, Email: morg2148@novell.uidaho.edu

The issues we face in contemporary natural resource planning and management are complex. The continued development and use of the resources stresses biological and social systems and raises problems that transcend traditional boundaries between disciplines. No single institution or discipline is equipped to manage or indeed is expected to have the full competence to solve the complex problems. Collaboration through integration of perspectives between the different disciplines may be the only way to successfully complete this task. It is crucial to our ability to cope with this challenge that we improve our understanding of the elements and processes involved in integration of perspectives across those boundaries. The results presented here come from two research project with similar objectives, to develop ways to integrate findings across disciplinary and organizational boundaries: The assessment phase of the North American Interior Columbia River Basin Ecosystem Management Project (primary data) and the Danish Boundaries in the Landscape (secondary data). Researchers have theorized about interdisciplinary collaboration processes but few studies look at concrete projects, such as the ones compared in this paper. Three levels of boundaries emerged from the data: Individual-based boundaries that precipitate barriers and appear to be bridged by facilitators between individuals; Group-based boundaries with related barriers and facilitators of collaboration between groups in the projects; and Organization-based boundaries that induce barriers and facilitators to collaboration between participating organizations. Comparison of the two research projects revealed a set of similar barriers to collaboration across different boundaries in the two western cultures.

6.13.00 The response of law to changing social demands on forests and the environment

Forest Legislation in Developing Countries: Emerging Trends and Persisting Dilemmas

Lawrence C. Christy, Ali Mekouar and Jon Lindsay
FAO, FAO Legal Office, via delle Terme di Caracalla, 00100 Rome, Italy
Tel: 39-06-5705-3216, FAX: 39-06-5705-4408, Email: lawrence.christy@fao.org

Recent years have witnessed a significant acceleration in the revision of forest-related laws in developing countries. Not surprisingly, the results of these law reform efforts have been extremely varied. They have taken place within the context of vastly different legal and political traditions, reflecting a wide range of economic, ecological and social variables. It is possible, nevertheless, to identify several trends that have achieved prominence in forestry laws over the last decade. Drawing upon the experience of FAO's Development Law Service, this paper will report on several inter-related clusters of issues in which a reorientation of national forest laws is evident:

- Local forest management. Increasing attention has been devoted to enhancing the legal capacity of local people to manage forests on which they depend, through the introduction of community-based management arrangements, decentralisation of forestry institutions and innovative tenurial instruments. - Private sector involvement. Efforts to stimulate private sector investment in sustainable forestry has resulted in a variety of legislative efforts to reduce the most common constraints, such as overly restrictive or cumbersome regulatory regimes and unsuitable land tenure arrangements. New approaches to contracting services and monitoring performance are finding their way into legislation.

- Environment and sustainable management. Laws increasingly focus explicitly on the environmental functions of forests, imposing new planning and inventory provisions closely tied to biodiversity and other environmental considerations, EIA and management planning.

- Accountability and law compliance. New legislative approaches have emerged to attempt to deal with several factors which have traditionally undermined the enforceability of forest laws, including corruption. Increasingly laws include a greater emphasis on transparency in government forest policy and management, better public access to information and public input into decision-making and improved penalty provisions.

- Institutional restructuring. There have been new experiments with the redesign of government forestry institutions, with the splitting of regulatory and management functions into separate bodies, and new approaches to the financing of operations.

In each of these areas, there have been important conceptual advances, and a variety of interesting legislative techniques have been crafted. At the same time, many of the recent laws show evidence of a profound ambivalence within governments about the appropriate direction and velocity of reform in the forestry sector. and indeed, efforts to create legal frameworks that reflect a balanced appreciation of the multiple dimensions of forestry have brought to the forefront legal and policy dilemmas that have vastly complicated the jobs of lawmakers.

Impacts of Environmental Legislation on Forest Management Practices in Chile

E. Gallardo Gallardo
Corporacion Nacional Forestal, Avd Bulnes No 285 of 601, Santiago, Chile
Tel: +56 2 6966677, FAX: +56 2 6954788, Email: conaf1@iusanet.cl

Este país ubicado en el extremo sur de américa, reconoce durante el siglo XX que recién termina dos esfuerzos legislativos tendientes a conservar y a desarrollar nuestros recursos forestales: en 1925 con la ley de bosques, aún vigente y en 1974 con la ley de Fomento Forestal, ambas con diversas modificaciones.

La primera con un marcado carácter proteccionista y de preservación, entre otras medidas, reguló la corta de bosques nativos en áreas de protección y el uso del fuego en terrenos de aptitud preferentemente forestal y la segunda impulsó fuertemente el proceso de forestación y reguló la corta o aprovechamiento obligando a reforestar una superficie igual, a lo menos, a la cortada o explotada conforme a un plan de manejo previamente aprobado por la administración forestal.

A estos dos textos de jerarquía legal debe sumarse algunos instrumentos internacionales ratificados como "ley de la República" referidos a la protección y comercio de la flora y la fauna y sobre conservación de la diversidad biológica y una profusa regulación reglamentaria de protección de especies y áreas silvestres protegidas, legislación toda fuertemente patrimonialista, sectorial y sin una visión ecosistémica o ambiental propiamente tal.

Sólo en 1994, después de más de 20 años de la Conferencia de las Naciones Unidas sobre el Medio Ambiente Humano de 1972 y la Conferencia sobre Ambiente y Desarrollo de 1992, y la fuerte presión del comercio internacional, en Chile con el carácter de "ley marco", se aprobó la Ley sobre Bases Generales del Medio Ambiente que vino a legislar con sentido global y sistémico, incorporando la dimensión ambiental en todas las actividades del quehacer nacional, entre ellas, la actividad forestal. Esta ley recoge y desarrolla los principios de prevención, realismo y gradualidad con que el gobierno impulsó su política ambiental a partir de 1990, destinada a proteger el medio ambiente, preservar la naturaleza y a conservar el patrimonio ambiental.

La creación legal de diversos instrumentos de gestión ambiental, entre ellos, la obligación, para los proyectos de desarrollo o explotación forestales de gran magnitud, de someterse, antes de su ejecución, al Sistema de Evaluación de Impacto Ambiental, ya ha producido y producirá en el futuro como consecuencia la posibilidad de prever, predecir, identificar e interpretar anticipadamente el o los impactos ambientales que dichos proyectos o actividades forestales provocarán a los recursos ambientales asociados como comunidades humanas, suelos, aguas, aire, fauna y paisaje, permitiendo que en su etapa de diseño se identifique y se describa la o las acciones que el titular ejecutará para impedir o minimizar sus efectos significativamente adversos.

En consecuencia, el país entra al siglo XXI con la esperanza que aún es tiempo para revertir la etapa de destrucción y deterioro de nuestros recursos forestales, y ,a través de su manejo sostenible y sustentable, poder satisfacer las necesidades actuales pero asegurando al mismo tiempo la satisafacción de las necesidades de las generaciones del porvenir.

The Effect of the Federal Estate Tax on Non-industrial Forest Ecosystems in the United States.

J. Greene, Bullard, St; Cushing, T.; Beauvais, T
USDA Forest Service, Southern Research Station,
Lousiana New Orleans, USA

Anecdotal evidence indicates that the federal estate tax has a disproportionately large, adverse effect on transfers of forest land estates and contributes to the fragmentation and conversion of forest ecosystems. The Mississippi State University, College of Forest Resources, and the USDA Forest Service, Southern Research Station, are cooperating in a study to measure the magnitude of the effect of the federal estate tax on non industrial forestlands and other rural land holdings. Data for the study were collected using mailed questionnaires. Members of the American Tree Farm System, the National Woodland Owners Association, and a nationwide sample of rural landowners were surveyed. Study findings include: 1) Over one-half of nonindustrial forestland owners (53%) held assets valued above the threshold amount for the federal estate tax; 2) Over one-third of forestland estates (36%) incurred the federal estate tax (this is roughly 20 times the rate for the U.S. population in general); 3) Forestland and timber typically accounted for nearly one-half (45%) of the owner's estate; 4) Only about one in three forestland estates (32%) qualified for the "special use" valuation provisions, and only one in four (25%) elected to use them; and 5) About two-thirds of forestland owners (65%) sought the help of a financial or forestry professional to plan their estate. of the estates that owed a federal estate tax, about one-third (35%) needed to sell timber or land to pay part or all of the tax. in nearly every case where timber was sold, the sale was without regard for local market conditions or the forest management plan. in a large fraction of the cases where land was sold, the land was converted to another, more developed use. These last findings are based on small sample sizes and need to be confirmed by additional research. Nonetheless, their implications for forested ecosystems and for tax policy are clear.

Forest and Environmental Law Developments in European Countries with Economies in Transition

Peter Herbst
Wulfenstrasse 15, A-9500 Villach, Austria
Tel: +43 4242 52471, FAX: +43 4242 264048, Email: hp@net4you.co.at

Keywords: Forest Law, Environmental Law, Central Europe, Eastern Europe, European Countries with Economies in Transition

In 1998 and 1999, two International Meetings on "Experiences with new forest and environmental laws in European countries with economies in transition" were held in Ossiach, Austria, both organised by IUFRO 6.13.00, the forest law and environmental legislation subject group, and supported by the Austrian Ministry of Agriculture and Forestry. Eighteen different nations were represented in at least one of both meetings.

The most extensive part of both meetings comprised of sessions on the legal situation in European countries with economies in transition; the whole range of possible stages of development of forest law and environmental legislation as well as problems concerning implementation and administration were covered by oral presentations and discussions.

By means of the moderation method, impending problems and topics were collected, selected according to their relevance to the participants, and discussed.

Highest priority was given by the participants to
- Harmonisation of Forest and Environmental Legislation; ranging from basic conflicts between forestry and environment to necessary harmonisation processes and needs due to international commitments.
- Private Forests; rights and obligations of private owners, training and participatory management, the owners/authority relationship were discussed, in order to find suitable legal arrangements.
- Financing; comprising sources, problems and incentives.
- Protected Areas; national parks, management and financing.

Other topics of relevance were Governance and Participation (Forest Policy), Public Forest Administration and Management, Forests Functions as well as Privatization of Forests.

Papers presented during both meetings have been published as follows:

Schmithüsen, Franz; Herbst, Peter; Le Master, Dennis, Eds., 1999: Experiences with New Forest and Environmental Laws in European Countries with Economies in Transition. Proceedings of the International Symposium Jointly Organized by the IUFRO Research Group 61300 and the Austrian Federal Ministry of Agriculture and Forestry, Ossiach, June 1998. Forstwissenschaftliche Beiträge der Professur Forstpolitik und Forstökonomie der ETH Zürich, Vol. 21, 1999. 142 pp.

Schmithüsen, Franz; Iselin, Georg; Herbst, Peter, Eds, 2000: Challenges in Implementing Forest and Environmental Legislation in European Countries with Economies in Transition. Proceedings of the Second International Symposium Jointly Organized by the IUFRO Research Group 61300 and the Austrian Federal Ministry of Agriculture and Forestry, Ossiach, September 1999. Forstwissenschaftliche Beiträge der Professur Forstpolitik und Forstökonomie der ETH Zürich, Vol. 23, 2000. 111 pp.

Certification and nature conservation regulation

Ullrich Klins
Universität München, Faculty of Forest Science, Am Hochanger 13, D-85354 Freising, Germany
Tel: +49 8161 -71-4627, FAX: +49 8161 -71-4623,
Email: klins@forst.uni-muenchen.de

Pluralism, neocorporalism, participation and integration are terms, which have significantly gained in popularity since the early Seventies. The forest industry is increasingly faced with societies demands for protection and recreation areas, demands which conflict with forest owners (commercial) interests respectivly forest owners property rights, their competence and legitimacy.

Thus the question arises, in what way is influence exerted on forestry. This will be presented using the situation in Germany as an example. When considering the legal situation, it can be observed that the legal framework regarding forestry can be considered to be quite well established. in the (immediate) future there will be no changes or no significant changes in this respect. This is also true for other parliamentary decisions in the field of forestry, since a sufficiently strong lobby of agriculture and forest interest groups is active in parliament itself as well as in parliamentary specialized committees. Thus, influence is exerted on forestry by structures outside parliament. Therefore, the following dynamic structures are being studied:
- developments regarding forests on an international level (*e.g.* conferences in Rio, Helsinki, regulations within the framework of the European Union, etc.)
- changes in the field of nature conservation law, particularly in the area of regulations
- processes on the private economic level *e.g.* with regard to certification

While most of the developments on an international level - at least in the forestry sector - do not involve any important changes for German forestry, interesting trends can be observed in the field of nature conservation regulations and on the private economic level. Nature Conservation Regulations

The example of protected areas shows that there are slow but significant shifts in competence, which effect forestry. The following reasons can be stated:

1) Legal frames are solidified by regulations which are not decided on by parliaments but rather by a forum of specialists such as ministries or other state offices, in other words they get directly submitted to

the state governments. For example in the case of a proposal made by a nature preservation authority, an intervention by agriculture or forest lobbies is less possible.

2) Specific regulations are required for each protected area. This means that only a few forest owners' rights are affected. Up to now foresters have often failed to act against these regulations collectively, resulting in there having been no real resistance against the individual regulations.

3) Forest management has a rather negative image among the population compared to people's associations with forest and wood. Accordingly, a large portion of the population is of the opinion that more forest areas should be protected. Environmental groups are considered more competent in this respect than foresters.

In this way nature preservation authorities are able to make regulations in accordance with their interests on the basis of laws decided by parliament. For example a higher degree of restrictions has already been achieved in landscape protection areas, i.e. forest management becomes more difficult in these areas.

"External determination" - a case study of certification

Environmental groups, trade unions and distributors demand a certification of forests according to the principles and criteria of Forest Stewardship Council (FSC). The impact of these groups on forestry as seen in Germany seems to be stronger than foresters have expected. The forestry, especially private forest owners fear "external determination", which would result in a public interference in their autonomy of forest management. Consequently the debate about certification was dominated by emotionally and ideologically plagued arguments and "false" information. Dated perceptions and pictures of antagonism, known from the discussion "environmental conservation versus forest management", re-emerged. in this study the interests, ideologies and opinions of key players, the differing contribution of their power, given regulations and in addition to this communication strategies of the players and their strategic behaviour within networks will be presented.

Strategies

Thus it poses the question, what possibilities exist, with which the forestry can steer or exert an influence on the momentary discussion processes - and to what extent. The interests and demands of social groups and the resulting consequences are not or only partially recognized by many representatives of the forest industry. The lack of recognition is due to foresters having been able to manage their forests with relative autonomy within the framework of the political administrative system. There has also been no recognition at which level and with which methods environmental groups are acting during a political process. Therefore in the last part of the study the question as to which strategies enable the forest industry to reach a consensus with social interest groups and the support of the public will be discussed.

Selection of Policy Tools in the Context of Multilevel Policy Networks

Dennis C. Le Master
Purdue University, Department of Forestry and Natural Forestry
1159 Forestry Building, Indiana 47907-1159 West Lafayette, USA
Tel: +1 317 4943591, FAX: +1 317 4940409, Email: dclmstr@forest1.jnr.purdue.edu

Merlo and Paveri argued in a paper given during the XI World Forestry Congress that a "substantial lack of attention to, or ignorance of, forest policy tools, not to mention the policy tools mix.. ." is apparent. For example, many policy analysts seem unaware that constitutional, democratic, mixed-capitalist states are actually quite limited in what policy tools or mechanisms they can apply, even when government intervention in markets for forest goods and services is viewed as desirable. Forest policy tools can be divided into two general kinds: market facilitation tools, those that facilitate the functioning of markets, and market intervention tools, those that modify the functioning of markets. Market facilitation tools include (1) information gathering and dissemination, (2) public education, (3) technical information, and (4) research. Market intervention tools are (1) insurance programs, (2) resource protection programs (from disease epidemics, insect infestations, and fire), (3) land management planning, (4) regulation and prohibition, (5) taxation or subsidization programs, (6) land trusts for amenity, recreation, conservation, or other values, and (7) public ownership or production of goods and services. They differ substantially in their relative effectiveness, cost, social and ideological acceptance, and difficulty in administration. No single tool or combination of tools is uniquely effective in addressing public policy problems in forestry. Schmithuesen observes that "A substantial expansion of international law on the environment and (economic) development has taken place during the last twenty years," and today forest and environmental policy must "be seen within the context of multilevel policy networks." International treaties, conventions, and agreements are comparable to domestic laws regulating human behavior and activities. The agent for implementation-the nation state-is the same and will continue to be in the foreseeable future, for no supranational organization has any corresponding power. Similarly, forest policy tools are the same for implementation of international policies as for domestic policies. Hence, international treaties, conventions, and agreements will be as effective as the policy tool (or policy tools mix) selected by the signatory nation states, including its subsequent administration.

Legal Implications of Forest Certification Programs: An Overview

E. Meidinger
State University of New York at Buffalo, Buffalo, NY, United States
Email: eemeid@buffalo.edu

Forest certification programs typically define the environmental standards that forest enterprises must meet and also establish organizational mechanisms for achieving and certifying compliance. They thus bear a striking resemblance to government regulatory programs. Yet, because of their apparently voluntary and autonomous nature, certification programs are often conceptualized as separate and distinct from law. in fact, however, that certification systems are deeply intertwined with law. First, they use legal mechanisms to organize themselves, and often cite the possibility of intensified legal regulation to attract participants. Second, they can have a significant influence on governmental policies, and on the content and implementation of legal rules.

This paper reviews the primary ways in which certification systems are likely to influence legal systems and vice versa, using North American legal systems as the primary basis of analysis. It finds, among other things, that:

1. Certification standards and implementation mechanisms have not been formally adopted by most North American legal systems.

2. Legal systems seem likely to incorporate certification standards in many informal ways, such as adoption of best management practices definitions in environmental regulatory law, tort law, and even information regulation and financial regulation.

3. Regulatory officials are likely to treat certification as an indicator of good practice in many cases, and may reduce scrutiny on certified firms. A few states have enacted statutes giving certified firms special treatment, and some judges have mandated certification as a remedy for regulatory noncompliance.

4. A number of state and local government agencies have subjected the forested lands they manage to non-governmental certification.

5. If certification programs continue to grow in importance they are likely to be subjected to regulation by national and international legal systems. Such regulation may include the substance and procedures of certification, as well the qualifications of certifiers.

6. International trade law will also have considerable influence on the development and effectiveness of certification systems.

7. Over time, certification systems may bring significant changes to the institutional mechanisms through which societies deliberate about and adopt governing policies. The debate about the legitimacy of such developments is only beginning.

Forest Related International Legal Instruments

Franz Schmithüsen
ETH, Department of Forest and Wood Sciences, 8092 Zürich, Switzerland
Tel: +41 1 6323217, FAX: +41 1 6321110, Email: schmithuesen@fowi.ethz.ch

Keywords: International Legal Instruments; Environmental Protection; Sustainable Forest Management; Rural Development; Nature and Landscape Conservation.

The commitments of international forest-related legal instruments are initiated by national governments, which negotiate the framework of co-operation. An increasing range of world-wide, continental and regional processes involving multilateral and supranational entities form at present the international system. in part, they develop their own political and institutional dynamic; in part, they emanate from the work of UN agencies. International and supra-national treaties, conventions and agreements reflect primarily global or continental concerns. They have, however, immediate consequences for the development of rural areas, from which the problems originate and where the solutions and developments chances are to be looked for.

Empirical research on the evaluation of the impacts of existing multi-level legislative networks and on the successes and failures, which result from them, are of considerable interest. Major issues are the relevance, the implementation possibilities and the effective contributions of their various regulations to sustainable resource utilisation in a given area. Since international and supranational legal instruments rely to a large extent on implementation by national and sub-national public services, non-governmental organisations and a large number of land-users, the distribution of competencies, financial and administrative arrangements, and decision making procedures need particular attention. Acceptance and commitment of land owners, local entities, and public opinion are important research issues. The same refers to shifts of responsibilities to the private sector, to bargaining processes and to contractual arrangements.

Implications of the Federal Income Tax for Private Forest Ecosystems in the United States

William C. Siegel
USDA Forest Service, Forest Resource Law and Economics
9110 Hermitage Place, Lousiana 70113 River Ridge, USA
Tel: +1 504 737 0583, FAX: +1 504 737 1074, Email: wcsieg@aol.com

Keywords: Income Tax, Sustainable Forestry, Ecosystem Management.

Changing social demands in the United States in recent years have resulted in greater emphasis being placed on ecosystem management, environmental protection and enhanced stewardship with respect to private forest lands. These concerns are implicitly included in the move to sustainable forest management on private ownerships. The federal income tax is an important component of this changing scene. Set out in the Internal Revenue Code, this tax has been in place in the United States since 1913. Forest landowners are subject to the federal income tax as are all other citizens. Numerous sections of the Code apply specifically to forests and timber; other provisions apply in general terms. The major components of the federal income tax applicable to private forests were examined in terms of their potential and actual contributions to enhancement of sustainable management on private forest ecosystems. It was concluded that some provisions lend little to and actually discourage enhanced stewardship, but that others are making significant contributions. Recent failed attempts at legislative change are discussed. The paper concludes with further recommendations for change which would enable the federal income tax to become a more forceful policy instrument for encouraging sustainable forestry on private timberlands.

The Role of Forest Land Tax Programmes in Promoting Ecosystem Management in the United States

Jeffrey C. Stier, Clendenning, J. G.
University of Wisconsin-Madison, Department of Forest Ecology & Management
1630 Linden Drive, 53706 Madison, USA
Tel: 608-262-3976, FAX: 608-262-9922, Email: jcstier@facstaff.wisc.edu

In the paper we examine if and how existing U.S. preferential property tax programs for forestland are used as policy instruments to promote ecosystem management on private lands. A comprehensive summary of the objectives, structure, and effects of existing tax programs has been compiled with an examination of the manner in which these programs impede or facilitate ecosystem management. No existing program incorporates objectives of ecosystem management explicitly into their program statement, but numerous programs have incorporated, either explicitly and implicitly, program goals and management objectives that have commonly been identified as characteristics of ecosystem management. We conclude that preferential property tax programs can play a limited but important role in incorporating principles of ecosystem management on private forestlands. However, because of the inherent complexities of forestland ownerships, forest management and ecosystem management, no one policy instrument can be expected to address all of the relevant issues, objectives and conflicts. Rather, the solution is more likely to lie in an array of policy instruments that complement and interact with each other.

Research Issues Related to Environmental Restrictions and Financial Compensation Measures in Forestry

Stefan Wagner
Beethovenstr. 3, D-86150 Augsburg, Germany
Tel: +49 821 155679, FAX: +49 821 159570, Email: riwa.augsburg@t-online.de

Keywords: Environmental Legislation; Financial Compensation Measures; Comparative Laws

Forestry worldwide is confronted with a constantly rising number of laws and regulations, especially in the field or nature, land and water protection. As opposed to former times, these provisions no longer aim just for the preservation of a few particular areas, but also for comprehensive and large-scale environment protection as well as for the compensation of impacts. Consequently the possibilities to restrict the management and utilization of forests have increased as well. This development almost inevitably leads to conflicts with forestry interests, making financial compensation measures a bare necessity.

Within the framework of a research project, the questions and issues related to recent environment protection legislation and its impact on forestry in Germany will be subject to legal scrutiny and a comparative analysis of the legal situations in France, Poland and the U.S. Both, Germany and France, are subject to the jurisdiction and legislation of the European Union, yet the conditions for the conversion of European to national law differ greatly for instance with regard to the form of government and the stuctures of forest ownership. Environmental laws in the U.S. have been passed on the grounds of the Common Law System, finding trailblazing solutions for conflicts with agricultural and forest management, such as the purchase of land, the separation of priority cultivation concepts, and the strict territorial jurisdiction of state and federal authorities. Poland, as most East-European countries, is currently in a state of political, enonomic, and social transition on its way to integration into the EU. in the early 1990ies, these countries mostly adopted environmental laws modeled after the West-European fashion. Meanwhile, these laws are being revised and amended on the bases of the previous experiences.

The empirical part of the project will cover an examination of the range and performance of the laws by an analysis of precedences, literature and by expert interviews. of particular interest will be the question, whether the legal provisions on financial compensation measures serve their purpose as control mechanisms in the conflict between environment protection and forestry. For the main objective of the laws is to regulate conflicts and balance diverging social interests. Keeping this in mind, the following issues shall be discussed:

- Do the legal facts deviate from the framework of environment protection laws and why-

- Are deficits the consequence of indistinct legislation or of the wrong (or non-existent) application of the laws?

- in how far have solutions been found in general practice to reconcile environment protection and forestry that have not been provided by the law; especially financial compensation measures, such as financial incentives, compensation payments, contractual agreements?

The results of these two research phases will then lead to suggestions for the future execution of those environment protection laws which are of particular importance for forestry. They will constitute the basis of the discussion about the necessity and adequacy of the utilization of forests for national and international legal environment protection measures.

The International Discourses on Sustainable Development and Sustainable Forest Management - Their Relevance for Modernising Forest Laws

Gerhard Weiss
University of Agricultural Sciences, Institute of Forest Sector Policy and Economics
Gregor Mendel-Strasse 33, A-1180 Vienna, Austria
Tel: +43-1-47654-4405, FAX: +43-1-47654-4407, Email: weiss@edv1.boku.ac.at

Since the 1980's, forest management is discussed politically on a world-wide level and under the premises of "sustainability". This discourse on sustainable forest management is related to the international discourse on "sustainable development". Sustainable development is the dominating discourse on environmental politics since the report of the World Commission on Environment and Development, Our Common Future, was published in 1987. It incorporates the goals of ecological protection, economic growth, social justice, and intergenerational equity - locally and globally, immediately and in perpetuity.

One declared - but failed - aim of the UN Conference for Environment and Development in Rio de Janeiro in the year 1992 (UNCED) was to agree on a World Forest Convention. The negotiations resulted only in a vaguely formulated and non-binding Statement of Forest Principles. The principles of sustainable management, conservation and sustainable development of all types of forests was furthermore included in Chapter 11 "Combating Deforestation" of Agenda 21. Any interpretations of the overall goals and principles of sustainable development inevitably incorporates value decisions. The results of ongoing political processes are driven by the values, interests, knowledge and relative negotiation power of political actors. As no objective definition of "sustainability" can exist the task is rather to define the procedures how sustainable development is to be interpreted.

Various initiatives for elaborating criteria and indicators for sustainable forest management have been started after Rio, among others the Pan-European Process for the Protection of Forests in Europe. These criteria and indicators are biased towards quantitative economic and ecological aspects. Social and cultural aspects are mostly neglected. The same bias even can be observed in the criteria-and-indicators-list elaborated by the Amazon Co-operation Treaty. This bias of criteria-and-indicators-lists towards interests of established administrations and powerful lobbies of industries can be explained by the fact that the generating process takes place in established policy-making systems favouring already powerful groups. The instrument of criteria and indicators in itself is a technocratic tool. Besides of the production of criteria and indicators no efforts are made to change procedures or to address underlying causes of forest loss.

Traditional forest policy-making systems are usually dominated by industry-related interest groups. The challenge of ecological modernisation – which is valid for forest management just like for our society as a whole – is a restructuring of procedures and institutions. Within the discourse of sustainable forest management, for instance, participatory processes in policy-making are demanded. The modernisation of forest laws can only be called successful, if an institutional change is achieved, which balances the power of interest groups. Social and ecological goals will only be considered besides of economic goals if respective interest groups are included in the policy-making process.

Endangered Species Regulations and Timber Harvesting: The Case of Red Cockaded Woodpeckers

Daowei Zhang
Auburn University, School of Forestry, Alabama 36849-5418 Auburn, USA
Tel: 334-844-1067, FAX: 334-844-1084, Email: zhang@forestry.auburn.edu

This paper presents a theoretical framework and empirical evidence on the relationship between regulatory uncertainty induced by the possible invasion of an endangered species-the Red-Cockaded Woodpecker (RCW)-and timber harvesting. Timber harvesting probability and methods in a large number of mature private forests are assessed using a forest production model based on the conventional theory of capital. The empirical results indicate that landowners whose forests are close to a known RCW habitat have a high propensity to cut timber and use a clear-cut method. All these behaviors may be to achieve one apparent objective: destruction or foreclosure of potential RCW habitat quickly and before the Endangered Species Act (ESA) comes into force. This means that ESA and other regulations have given landowners perverse economic incentives and induced actions that they would otherwise not have and that are detrimental to the full recovery of endangered species. The results have implications for future reforms in environmental regulations.

6.14.00 Urban forestry

State of the art of research and knowledge on urban forestry in the USA

John Dwyer, Gary Watson, David Nowak
USDA Forest Service, 845 Chicago Avenue, Suite 225, IL 600202-2357 Evanston, USA
Tel: 847-866-9311, FAX: 847-866-9506, Email: jdwyer/nc@fs.fed.us

Urban forestry research promises to continue to be an integral part of the growth and development of forestry in urban and urbanizing areas of the United States. The future is expected to bring increased emphasis on research in support of the care of trees and other plants, ecological restoration, and comprehensive and adaptive management across the landscape. Particular emphasis will be needed on research to guide new developments in the comprehensive health of urban vegetation; ecological restoration techniques; resource inventory and monitoring; dialogue among forest resource owners, managers, and uses; collaboration among agencies and groups; understanding of how forest configurations influence forest use and benefits; knowledge about urban forest health; and dissemination of information about urban forests and their management. It is the integration of the landscape, ecological, and tree/plant-care research that will provide for the comprehensive and adaptive management needed to sustain urban forest structure, health, and benefits over the long term.

Keywords: urban, forest, arboriculture, landscape, collaboration.

Effects of fragmentation and trampling on the vegetation of Forests in Finland

Irja Löfström, Minna Malmivaara and Ilkka Vanha-Majamaa
Finnish Forest Research Institute, Post Box # 18, FIN-01301 Vantaa, Finland
FAX: +358 9 8570 5569, Email: irja.lofstrom@metla.fi

In Finland, about 80% of urban green areas are forests with natural forest vegetation. Participation in outdoor recreation is active and urban forests are the main environment for these activities. According to the Finnish law, citizens can use forests freely for recreation.

The growth of the urban population has resulted in the fragmentation and increased recreational pressure, *e.g.* trampling in these urban forests. The small size and isolation of remaining forest patches result in decreased biodiversity. When trampling is intense and persistent, the most wear-sensitive species will die leading to the disappearance of the humus layer and risk of soil erosion.

Preliminary results about the effects of fragmentation and trampling on the understorey vegetation of urban forests are presented.

Urban forest stands of varying size (1-1600 ha) were chosen for the study in the greater Helsinki area. Within these areas, mesic spruce (*Picea abies*) dominated forest stands of the Vaccinium myrtillus type, and drier pine (*Pinus sylvestris*) dominated Vaccinium vitis-idaea type stands over 80-years-old were examined, and biotope mapped was undertaken regardless of the size or level of wear in 1999. The total number of inventoried biotopes was 52. Biotope mapping was based on the understorey vegetation. For measuring environmental variables and monitoring the effects of fragmentation and trampling, one or two circular sample plots (radius 5.64 m), were located in the biotopes, depending on the size of the biotope (0.01-3.14 ha). Sample plots were located so that the minimum distance to the edge of forest was 30 meters. Dominant height, stem volume and basal area of trees and number of stems per hectare were calculated. The percentage cover of field and ground layer vegetation was inventoried in four 1 m^2 sub-plots located in each sample plot. in addition path area per biotope area was measured and the number of residents within a 1 km and 2 km radius of each biotope were used as measures of recreation pressure.

Both site types were affected by trampling in a similar manner. With an increasing number of residents, the cover of ground vegetation decreased and the amount of unofficial paths increased. The cover of ground vegetation and dwarf shrubs was the highest when recreation pressure was the lowest. The mean total cover of ground vegetation in the areas studied was 65%. When the number of residents within 2 km radius is > 20 000, ground vegetation cover falls below the mean of 65% (R^2=0.25). Cover decreases about one percentage per 1000 persons. The size of the forest patch in relation to the number of recreationists is one of the main factors affecting species cover and composition.

Soil moisture variations and availability in tree-pits in urban Hong Kong

C.Y. Jim
The University of Hong Kong, Department of Geography and Geology, Pokfulam Road, Hong Kong, China
Tel: +852-2859-7020, FAX: +852-2559-8994, Email: hragjcy@hkucc.hku.hk

Urban areas of Hong Kong are characterized by pervasively high-density and high-rise development with meagre niches left for amenity vegetation. Suitable sites for ground planting is particularly limited at roadsides where the narrow pavement and proliferation of underground utilities often preclude trees. The use of tree planters or containers provides possibilities to insert greenery in locations where above-ground space is adequate but soil volume is restricted. They can also be installed on building podiums, rooftops and indoor habitats such as building foyers and shopping malls. Hitherto few studies have been conducted on planter soils, and none has been attempted in the humid tropical cities. This research attempts to evaluate systematically the quality of planter soils in Hong Kong with special reference to their moisture status in relation to tree growth. A stratified random sampling procedure was adopted to select 12 planters in a dense built-up district, three each from four categories defined by planter geometry, for detailed assessment. With 300 cm width and 60 cm depth as division lines, they are classified as narrow shallow (NS), narrow deep (ND), wide shallow (WS) and wide deep (WD). Vertical holes were opened in each sampled planter with an auger and lined with a PVC pipe of 5.18 cm internal diameter with sealed bottom and an openable top lid. A Time Domain Reflectometry (TDR) miniature moisture probe was lowered into the access tube to monitor gravimetric soil moisture at depth intervals of 5 cm once every two weeks for one year (June 1998 to May 1999). Soil samples were collected in topsoil and subsoil layers to analyze selected physical and chemical properties. The soil mix is mainly composed of local decomposed granite amended with organic matter which is usually peat moss. Most soils have high stone contents of 30-40 per cent, high proportion of sand from 77-87 per cent, with all samples falling into the extremely coarse loamy sand textural class. Bulk density, which is closely related to porosity, has an average value of 1.72 Mg/m^3 which indicates poor structure and compaction down to an average of 33 per cent total porosity. Topsoil, despite the presence of more organic matter, tends to be more compacted and less porous than subsoil. The lack of organic matter and high sand content are unfavourable to soil structure formation and maintenance. The sand, however, could maintain a relatively high proportion of air capacity (AC) pores over 60 µm diameter which serve adequately infiltration, drainage and aeration. There is nevertheless a shortage of medium available water (AW) pore in the 0.2-60 µm diameter range.

Moisture content follows closely the rainfall regime with marked seasonal variations between the dry and the wet periods. Moisture content increases with depth in most planters. The occurrence of layering (lithologic discontinuity) in some planters retards the downward movement of moisture, resulting in water perched in the topsoil and hence less available in the subsoil. The less compacted subsoil of some planters manages to store more moisture, and this phenomenon is conspicuous in deep planters. Waterlogging sometimes occurs in the subsoil when rainfall supply is abundant in the wet season. Drain holes where present are often blocked and are ineffective in shedding excess water. The lower portion of the planters is beset by excessive water accumulation in the wet season. Shaded planters have more water and subdue temporal fluctuations, indicating the importance of moisture extraction through evapotranspiration. The implications on soil water management and planter design for urban tree planting are explored.

State-of-the-art of Research and Knowledge on Urban Forests and Trees in Europe

Kjell Nilsson, Cecil C. Konijnendijk and Thomas B. Randrup
Danish Forest and Landscape Research Institute, Hoersholm Kongevej 11, DK-2970 Hoersholm, Denmark
Tel: +45-45 76 32 00, FAX: +45-45 76 32 33, Email: kjn@fsl.dk

More than two thirds of the total European population live in urban areas, and the number and share of urban dwellers is still growing. Thus the quality of the urban environment is becoming of increasing importance for larger groups of people. Trees and woodlands as main elements of the urban landscape play a major role in providing good urban living, working and leisure environments. As a result, the planning, design, establishment and management of urban trees and woodlands has asked for more attention. However, sustainable management and development of urban tree and forest resources have to be supported by specific research, sound expertise and education. Until now, European research and education related to urban trees and forests have been limited and fragmented, and a wide range of researchers and professionals from various disciplines have been involved, including forestry, landscape architecture, horticulture, biology, sociology, urban planning and other. This means that a better overview and more coordination of research and education at the European level may prove to be highly beneficial.

This paper is based upon a review of research and knowledge on urban forests and trees in Europe. The review has been carried out during 1999 and 2000 at the Danish Forest and Landscape Research Institute with the support of the European Cooperation in the field of Scientific and Technical Research (COST). The aim of the comparative study has been to make a general review of ongoing research and higher education on urban forests and trees in Europe. The concept of urban forestry, defined as the planning, design, establishment and management of trees and forest stands with amenity values, situated in or near urban areas, has served as a theoretical basis for the study.

For the purpose of the review, scientific and higher educational institutes in Europe dealing with urban forests and trees were identified. By means of country studies largely carried out by national urban forestry experts, the state-of-the-art of European urban forestry research has been described in a comparative way. Emphasis has been on identifying institutes and main research themes. in addition, insight in attention given to urban forests and trees within higher education was analysed via case-study reports and a survey. For this purpose, focus has been on higher education within the fields of forestry, horticulture and landscape architecture.

By comparatively analysing both urban forestry research and education at the European level, similarities and differences, as well as major developments and needs in European urban forestry have been identified. The results of the study, which will be widely distributed, may provide a useful base for the development and coordination of urban forestry related research and education in Europe. This paper focuses on more strategic-level aspects (in terms of urban forest and tree functions, policies, forms) that have emerged from the study.

An Analysis of Green Space Management Strategies in Metro Manila

Armando Manito Palijon
College of Forestry and Natural Resources
UPLB College, Institute of Renewable Natural Resources, 403 Laguna, Philippines
Tel:. (063) 049-536-5305, FAX: 63-049-536-3206,
Email: armp@mudspring.uplb.edu.ph

Management strategies focused on the street and park green spaces in cities and municipalities of Metro Manila, namely: Manila, Makati, Mandaluyong, Pasig and Quezon City were analysed.

Information on the biophysical, social and political conditions, management capabilities and practices for street and park green spaces on each site were gathered through survey and interview. The influence of these variables on the performance or success of the green space management as reflected in the conditions or status of trees in either street or park green spaces was determined.

Street and park green spaces of the cities and municipalities studied have varying biophysical conditions that are influencing growth and development of urban plants.

The public is higher aware of the importance of greening, activities and of the usefulness and disadvantages of having urban trees. Only few have actually participated in the greening activities but majority are willing to participate if given the opportunity.

Political atmosphere is only fairly supportive f the greening activities and other environmental issue and concerns, though some municipalities have already initiated greening activities. Legislation of greening ordinances is not given much attention.

Greening offices in the cities and municipalities are already installed. Some are permanent while others are still quasi in nature. Some are well equipped in terms of manpower, financial and technological resources while others still need to build up their capabilities. Each of the cities and municipalities has its own greening goal and objectives and has developed its own cultural management strategies. However, their practices need some improvements.

Monetary Valuation of Urban Forest Amenities: Possibilities and Constraints

Liisa Tyrväinen
University of Joensuu, Faculty of Forestry, c/o Metla,
P.O. Box 18, FIN-01301 Vantaa, Finland

liisa.tyrvainen@metla.fi

Most of the values attached to urban forests are non-priced environmental benefits. Urban development projects often decrease the amenity values of green spaces, which should be taken into consideration in planning. Today land-use planning procedures do not include systematic assessment of urban forest benefits and therefore, quantitative information on residents' valuations is needed.

This paper discusses the possibilities to value urban forest benefits in monetary terms and the application possibilities of such information in land-use planning. The paper sums up European research experience from two economic valuation methods, hedonic pricing and contingent valuation in the field of urban forestry. Furthermore, recent research results of empirical studies conducted in Finland in are presented.

The hedonic pricing method examines external benefits and costs associated with housing. Research results show that people pay for urban forest benefits through house prices. However, measuring and selecting proper variables to describe amenity benefits in house price models is problematic. in recent empirical applications a view to and proximity of urban forest are shown to increase apartment prices in hedonic models.

in contingent valuation method people are asked directly what they are willing to pay for provision of green spaces. Although the economic estimates are based on hypothetical valuations, the method enables valuation of larger range of urban forest benefits than the hedonic method. Recent survey results show that majority of the residents' are willing to pay for the use of urban recreation areas, but also for other amenity benefits of green areas.

The main use of valuation methods is economic evaluation of the impact of urban land-use plans and the evaluation of profitability of urban greening projects. The value of an urban forest capitalized in property prices can for example be calculated by using hedonic price models. The results of case studies show that management of urban forests for amenity benefits is profitable in economic terms. Furthermore, the results suggest that a limit can be found where condensing town structure, i.e. building on green areas, is not worth from the point of view of the society if the losses of green space benefits are taken into account.

6.15.00 Reconsidering study objectives and teaching methods

Information Technology in Forestry Education and its Role in Enhancing Flexible and Distance Education

Cris Brack
Australian National University, School of Resource Management and Environmental Studies - Dept Forestry
ACT 0200 Canberra, Australia
Tel: +61 6 2492579, FAX: +61 6 2490746, Email:
cris.brack@anu.edu.au

Computers and other Instructional or Information Technologies (IT) have been gaining importance in forestry education since the 1970's. The role of this IT has progressed from improving the efficiency of operations (eg automating common administrative procedures) through to changing the way things are taught and learnt and even what is taught and learnt.

Early examples of IT include word processor packages and databases that make it easier to update teaching materials and student records. IT that supports the reliable transfer of digital documents and other files - including file-servers and early examples of the Internet - allowed increased and more flexible access to traditional teaching resources during the 1980's. The 1990's saw the increasing use of presentation technology that allows academics and teachers to explore new ways of recording and showing information. This presentation IT includes digital slide shows, animations, digitised sound and movies, etc. In the 1990's another major emphasis was IT designed to enhance communication between individuals and within groups. This technology includes e-mail, bulletin boards and chat rooms and is being incorporated into many examples of flexible teaching to enhance the communication between students, teachers and other stakeholders. The world-wide-web (www) networks now allows the integration of many of these technologies by imposing a consistent protocol and standard of communication and digital information transfer. Currently there is an increasing interest in organisations who are integrating the administrative and teaching functions of these ITs into holistic packages.

The IT is being used to support teaching in different ways. These different ways may allow students to learn more effectively and in more flexible styles. This flexibility may also allow forest education and further learning to be available to stakeholders who are not able to attend traditional teaching campuses, ie distance education and open learning students. The IT is also used to increase the efficiency in teaching, where efficiency may be measured as increased output (more graduates) for less input (less time spent by academics, etc.)

This State of Knowledge Report will review some of the reasons that IT has been introduced into forestry education. The review will include examples of IT that have been introduced and how the curriculum and student learning changed as a consequence. Some examples of quantitative feedback from students to IT and its role in teaching and learning is included from case studies at the Australian National University. The Report will also cover examples and the reported strengths and weaknesses of flexible teaching and learning, including distance education, that utilises this IT.

Groping along in designing a new subject: participatory resource management

Marlene Buchy
ANU, Forestry Department, ACT 0200 Canberra, Australia
Tel: 62 49 35 34., FAX: 62 49 07 46, Email: marlene.buchy@anu.edu.au

Keywords: Participatory resource management, Forestry curriculum, Rural sociology, Conflict resolution

The introduction of this new subject, Participatory resource management (PRM), in the forestry curriculum is due to a greater emphasis on management in the forestry profession as well as increasing recognition of the value of interdisciplinarity. The recognition of PRM as a worthwhile academic subject also stems from its growing popularity amongst overseas Aid funding bodies as well as students and hence its capacity to attract viable student numbers at undergraduate and postgraduate levels.

Although there is a considerable body of literature concerned with theory and application of participatory concepts and principles in natural resource management (especially within the context of development and sustainable agriculture), the subject has only recently been taught as an academic subject as part of an university degree. The design of the course draws heavily on the practice and implementation of participatory processes within the professional practice rather than on a theory from which a professional practice is derived.

The subject itself borrows heavily from other fields: social sciences - including rural sociology, history, development and gender studies - and management - including conflict resolution, communication and group dynamics and education.

The challenges of the course are the effective introduction and integration of a social science type approach into a biophysical science curriculum, as well as to promote and foster an attitudinal change and a paradigm shift within the professional practice.

In this paper, based on personal experience in 2 academic institutions, student's feed back and the appropriate body of literature, I propose to relate and reflect on this experience.

Forests in Geographic Information Systems at the Graduate School, University of Helsinki, Department of Forest Resource Management

Markus Holopainen, Jouko Laasasenaho
University of Helsinki, Department of Forest Resource Management, Post Box # 24, FIN-00014 Helsinki, Finland
Tel: 358-9-191 7675, Email: markus.holopainen@helsinki.fi

Keywords: Educational program, Modular curriculum, GIS, Forest mapping

Geographic information systems (GIS) and remote sensing technology have revolutionized forest mapping in 1990's. Mapping has been changed from individual measurements to the combination of multisource GIS information. These new technologies, however, bring along several drawbacks and problems which should be solved or improved in the near future, *e.g.* effective combination of multiscale and multisource numerical data, effective acquisition of accurate GIS data, co-operation between various organizations, and a lack of GIS specialists in both forest research and practice.

In order to develop the use of GIS in Finnish forestry, the Forests in Geographic Information Systems Graduate School was established in the University of Helsinki, Department of Forest Resource Management in May 1998. in the first year, 15 researchers were chosen for admission to the school, which is financed by the Finnish Foresters Foundation, the Finnish Ministry of Agriculture and Forestry, and the Academy of Finland. Postgraduate studies can be pursued in the University of Helsinki, University of Joensuu, or in the Helsinki University of Technology.

The Graduate School will improve facilities for managing forests with the aid of rapidly developing computer technology and geographic information systems (GIS), developing methods for and training specialists in research, education and practice. The main objectives of the school are:

- To initiate an educational program in the fields of forestry, photogrammetry, remote sensing, and geoinformatics.

- To increase cooperation among those interested in GIS research and the use of GIS both in Finland and abroad.

- To develop GIS applications for use in forestry and the environmental sciences.

The Graduate School is linked with other GIS and remote-sensing research in Finland. in addition to the universities, numerous other organizations are participating in the program, *e.g.* the Finnish Forest Research Institute, the National Land Survey of Finland, Kehitt„miskeskus Tapio, the Finnish Forest and Park Service, VTT Automation, and Metsäteho Oy.

Professor Jeremy Fried from the University of Michigan was employed in 1998 for a year by the University of Helsinki as a GIS specialist and teacher. The establishment of a Graduate School and professor Fried's appointment provided an opportunity to create a new GIS curriculum within a department of Forest Resource Management. A defining objective of this curriculum was a flexible structure whereby students with different GIS backgrounds, disciplinary interests both related and unrelated to forestry, and varying amounts of available study time and learning objectives could all be accommodated. Towards this end, a highly modular curriculum was developed consisting of seven courses. Courses were presented using a variety of instructional approaches. Theoretical content was presented primarily via lectures and readings, with questions and discussion encouraged. Software expertise was developed through more than 80 hours of intensive, hands-on, instructor guided and self-guided laboratory exercises using various ESRI and other GIS related products. All courses shared a common web site for distribution of assignments and data, posting of links to GIS resources, and posting of lecture notes and seminar schedules. Although there have been previous efforts to provide GIS training in Finland before, this curriculum appears to have been one of the most comprehensive undertaking to date, and should form an excellent starting point for future efforts of this kind.

Reconsidering objectives and methods for education in forestry: the case of Kenya

Jane Kiragu
Moi University, Chepkoilel Campus, P.O. Box 1125, Eldoret, Kenya
Tel: +254 321-63101, Email: muphy@net2000ke.com

Keywords: Forestry curriculum, Forest policy, Communication, Teaching methods, Field orientation

People in the developing countries wholly depend on the forests for almost all their daily needs. This mainly includes shelter, food, medicine, fuelwood, fodder for livestock among other uses.

As the populations increase, the natural forests decrease, thus making it impossible for the people to meet their daily needs from the forests. Therefore new survival mechanisms have to be found in order to minimize the human pressure on existing forests. To halt the present demise of the forests and improve the society's well-being, a lot is required. This should mainly be through change of forest policy objectives and forestry curricula in their higher institutions of learning Sustainable conservation of forest has for a long time been the major objective of Kenyan forest policy. However, persistent outcry from the citizens, has forced the government to adopt new forest policies objectives published in 1994 in the Kenya Forestry Master plan (KFMP), 1995-2020, where not only the natural forests but also the individual farms are included in the aim of increasing the forest and tree cover of the country. Also arid and semi-arid afforestation is taken into consideration. This will ensure an increasing supply of forest products and services for meeting the basic needs of present and future generations and for enhancing the role of forestry in socio-economic development.

With the recent change in policy objectives, it also entails changes in the forest curriculum both at the technical and professional institutions, so as to have well trained staff to implement the said objectives. The forestry curriculum should change from production forestry to participatory forestry at all levels. Courses which are more land-user oriented should be given more weight, for example, agroforestry, social forestry, soil & water conservation, arid land afforestation. Other courses such as communication techniques should be continued into the 2nd, 3rd and 4th years at BSc. level.

The teaching methods used should change from class-room oriented to field oriented. The teaching institutions should set up demonstration plots in all ecological zones so as to convince the farmers that whatever they know is practical and can be done in the areas in question.

This paper will try to look into the present forest policy objective and the changes required in the forestry curriculum and the methods used in teaching forestry in the Kenyan institutions. It will also try to propose changes required in the teaching methods.

Scenario for Higher Forest Work Efficiency and Safety in Countries With Economies in Transition

Ivan Martinic
University of Zagreb, Faculty of Forestry, Svetosimunska 25, HR -10 000 Zagreb, Croatia
Tel: +385 1 230 22 88, FAX: +385 1 218 616, Email: ivan.martinic@kr.tel.hr

Forest work in countries with economies in transition is characterised by severe economic conditions, increasing gap between such countries and developed ones, low work efficiency and continuous fluctuation of workers. Low forest work efficiency is also affected by low training level of forest workers and numerous accidents at work. The analyses of the quality of work as well as a survey of causes of injuries showed serious deficiency of the traditional system of training. More then half of all injuries proved to have been caused by insufficient mastering of work techniques and due to not observing work safety regulations. At the same time it was also noticed that the mentors of practical training had been negligent.

This paper shows the scenario for the possible development of work techniques of forest workers in Croatia, one of middle-European countries with economies in transition. The new concept schedules periodical assessment (at six-month intervals) of forest workers by a FWT (Forest Work Techniques) questionnaire. The assessment would be carried out during regular work and it would consist of 20 elements including work preparation, performing work operations, handling and maintenance of equipment and tools and working dynamics.

In felling and wood working operations, the following elements would be assessed:

a) during felling: preparation for felling, establishment and checking of felling direction, supporting felling direction, preparing undercuts, determination of final cut height, the look of felling crest

b) during limbing and transverse cutting: body posture, chain saw movement, limbing quality, transverse cutting technique, use of measuring band, bucking accuracy

c) in handling tools: adjustment of chain saw engine, chain sharpening, use of other tools

d) time-table and duration of breaks, usage of personal protection kit.

In accordance with the results of the assessment, the workers would get the adequate QG (Quality Group) index and they would consequently be classified in the appropriate payment classes, which would apply until the next assessment. The difference between payment classes would range from 10 to 15 %.

For each quality group adequate training programs would continually be going on aimed at correcting and developing their work techniques starting with the analyses of most common irregularities and improprieties, including written and video information, field demonstrations and several-day training with a mentor. After passing their exam and being granted the certificate, training mentors are supposed to go through licence certification at two-year intervals.

Such approach would by all means improve the quality of work and lower the number of injuries as well as the frequency of professional diseases. It would also increase the efficiency and proficiency of forest work. On the other hand, the possibility of higher payment for better work quality would make workers more satisfied and this would bring to a more positive selection among forest workers.

It is expected that during the period of 2 to 3 years, more then 80% of workers could be classified into two high-quality groups.

Looking for Articulation in Professionals' Training: The case of the forestry occupational family

Jaime Millan, Barbara Hinton, Marilú Rioseco G.
Universidad de Concepcion, Facultad de Ciencias Forestales, Casilla 154-C, Correo 3, Concepcion, Chile
Tel: 41-204936, FAX: +56-41-26004, Email: jmillan@udec.cl

Keywords: Occupational hierarchy, Educational development, Forestry curriculum, Competency, Chile

Economic development in many countries has been quite accelerated in recent decades. However, educational development sometimes does not run parallel to economic development, as has been the case in Chile. This presents a problem because the production sector does not have a readily available labor force required to support the economic growth, mainly because the skills, competencies and behaviors required by our advanced, technological, information-based society have outpaced our ability to provide training within our existing structures and systems. There are many production sectors, like the forestry one, whose development requires professionals from different levels working in teams. Because of their work characteristics, they can be thought of as an occupational family. in these cases, it is necessary that articulated training be planned, to allow these teams to work in an efficient and structured manner. in this paper, we propose a model that describes how to arrive to an occupational hierarchy based upon articulation of different professional levels in the forestry occupational family, which includes engineers, technologists and qualified forestry workers.

The model is a competency-based model, which is based upon the determination of the skills, knowledge, and attitudes that students should be able to demonstrate after completion of a program of study. Training of each individual group of professionals, who are located at different levels of an occupational hierarchy, should facilitate the development of required competencies, so that they can act with efficiency and effectiveness in their own field. Seen in such a perspective, the training process of a professional cannot be planned without considering globally all other professionals who belong to a same occupational family. Besides this, the process as a whole cannot overlook the relationships with other related occupational families. This means that articulation, both vertically and horizontally, is essential to professional training in an occupational family.

The model seeks to find an occupational hierarchy based on competencies required in the work place. A first phase of the model is the characterization of employers and the characterization of professionals. in our case, employers are forestry industries and forestry companies or organizations; professionals are forestry engineers and forestry technicians who have been trained at different educational levels. After this, an occupational inventory is developed. The model includes also a phase where forestry occupational positions are clustered according to responsibilities and tasks identified through a preliminary on site survey and a questionnaire.

Characterization of professionals considers the professional position or job and the tasks they fulfil. Through this it is possible to assign each professional to a certain level given by the responsibilities that are inherent to the position or job, and to a certain responsibility level, given by the complexity of the tasks he has to carry out due to his position. Once this characterization is done, tasks are grouped so as to conduct a preliminary tasks inventory, that is complemented through on site interviews Through content analysis of actions inherent to each position or job and of tasks fulfilled by the professionals, and through consideration of different types of companies together with the diversity level of their activities, it was possible to structure different groups of professionals, which later on could give rise to hierarchical levels of the occupation.

Ethnoforestry re-examined: Global status of indigenous knowledge on forestry management

Deep Narayan Pandey
Indian Institute of Forest Management, Indian Forest Service, Post Box # 357, 462 003 Nehru Nagar, Bhopal, India
Tel: 91-755-775716, FAX: +91 755 772878, Email: deeppandey@mailcity.com

Keywords: Equity of Knowledge, Ethnoforestry, Indigenous knowledge on Forests, Tropical Forestry.

Ethnoforestry is defined as a continued practice of creation, conservation, management and use of forest resources, through customary ways, by local communities. This paper examines the world-wide status of ethnoforestry research based on a literature review. It also discusses examples from the field work carried out in India.

Ethnoforestry is classified into Protection Ethnoforestry, Plantation Ethnoforestry and Ethnoagroforestry. Protection provided by local communities to habitats are classified as protection ethnoforestry. Traditional methods of regeneration of livelihood species by people are classified as plantation ethnoforestry. These include direct sowing, bamboo rhizome planting, cutting, nursing of wildlings and closures. Traditional methods of growing trees and crops in farmlands are described here as Ethnoagroforestry.

Availability of vast research on ethnobotany notwithstanding, unfortunately, ethnoforestry has been, mostly, a missing knowledge in global forestry research, documentation and planning. Non-availability of written material in the subject is definitely the result of monumental neglect of local knowledge on forests by foresters in general and so-called scientific forestry scholarship in particular. Drawing on the primary research material from India, the related global research reviewed in this paper throws some light on the operational part of local knowledge on forests. Studies from India, Brazil, Nepal, Ecuador, China, Vietnam and African continent are examined.

Indigenous knowledge on forest management is crucial because of various reasons. Erosion and extinction of cultural diversity and indigenous knowledge is threatening the society. Inadequacy and unsuitability of classical forest management strategies require the help of indigenous knowledge to overcome the crisis of deforestation.

Philosophy of sustainability is ingrained in the traditional ecological knowledge. International ethics and legal obligations of the nations, and voices of the indigenous peoples themselves requires that foresters must take help of indigenous knowledge. The discipline is bound to deliver vital and incomparably significant results for the future of World Forestry. Ethnoforestry alone can ensure the equity of knowledge between village communities and the scientific forestry community. It will stop exploitation supported by the scientific community. Equity of knowledge alone can, ultimately, make the forestry sustainable. Community forestry requires local low cost options to regenerate degraded forests. Sharing of costs of high input regeneration could hamper people's initiative. Only ethnoforestry can provide location-specific solutions. Local knowledge is easily transmitted, used by a large section of the society, does not require costly consultancy, and thus, minimises possibility of corruption.

Data from the plantations carried out in Rajasthan, India, have demonstrated that indigenous knowledge on forests can reduce the cost of tropical afforestation up to 25 percent of the total expenditure. Economizing world's tropical forest plantations through Ethnoforestry is a distinct possibility.

Exploring alternatives for distance education in forestry

Mark Reed
Oregon State University, Forestry Media Center, 248 Peavy Hall, 97331 Corvallis, OR, USA
Tel: +1-541-737-1345, FAX: +1-541-737-3759, Email: reedm@ccmail.orst.edu

Keywords: Lifelong learning, Internet, Forestry course, Continuing education, Extension

The boundary between formal higher education, and lifelong learning through a variety of alternative channels, is rapidly blurring. Learners demand instruction in a place and at a time convenient for them. Universities' response to this demand initially focused on live transmission of lectures and audio feedback from groups of students at remote sites. Opportunities for distant students to participate individually and asynchronously are rapidly increasing. Many courses can now be taken entirely over the Internet, while others can be viewed at home on videotape.

The College of Forestry at Oregon State University (OSU) has a reputation for high-quality forestry education. Notable characteristics include small class size, hands-on learning, extensive use of convenient field laboratories, and close personal interaction with instructors and peers. The College is actively exploring several initiatives in distance education (DE).

Administrators and instructors are presented with several challenges in developing DE. Technological hurdles must be overcome. Standards for communication networks are quickly evolving. Computer software for designing and implementing DE is still in its infancy, and most successful applications are purpose-built. in addition to content mastery, DE requires specialized expertise from computer programmers, network engineers, graphic artists, and audiovisual producers. Another concern is the cost of designing new instruction and providing new infrastructure. Some experienced practitioners estimate that developing a DE course requires five to ten times as much labor as a traditional course. A DE classroom can cost hundreds of thousands of US dollars, and students must be equipped with PCs, VCRs and other devices. Budgets are stretched, and because many new students are needed to justify these additional costs, competition between universities is rapidly intensifying.

Perhaps most importantly, educators are questioning how to maintain high-quality personalized instruction. Distant students expect to be provided with convenient access to learning resources, meaningful hands-on experience, peer interaction, and timely feedback on their efforts. They also expect to be able to guide and shape their own learning experience to a greater degree than do traditional students.

One direction for DE at OSU involves adaptation of existing curricula. For example, a forestry course which has been taught on campus for ten years was recently incorporated into a new DE degree program in natural resources. in order to make it accessible to students enrolled at remote locations, lectures were videotaped and the majority of course content was posted on the World Wide Web. Students communicated with one another, turned in assignments to the instructor, and went on "virtual field trips," using the Internet. Initial responses from students using the new technologies are mostly favorable.

Another direction at OSU involves creation of new infrastructure and curriculum to meet the needs of nontraditional students. For decades, working professionals have come to campus for continuing (further) education, but the focus is now shifting to bringing instruction to the workplace. in one example, a professor of silviculture on campus and an extension agent working 300km away collaborated on a course in uneven-age management. Students on campus, all forestry graduate students, attended lectures in a classroom television studio, and went on local field laboratories led by the professor. Students at the remote site, all professional foresters, watched lectures on videotape, questioned the professor via periodic teleconferences, and were led by the extension agent on field laboratories in their own region. A majority of the distant students indicated that they were satisfied with the experience and would be willing to take another DE class in the future.

Role of Forestry Education in India for Sustainable Management of Tropical Forests

R. N. Sehgal, PK Khoala
Dr. Y.S. Parmar University of Horticulture and Social Sciences, Dept. Tree Improvement, 173 230 Solan, HP, India
FAX: 91-1792-52242, Email: tgri@spuhf.hp.nic.in

Keywords: Forestry curriculum, Social sciences, National forests management, Extension

Forestry education in India, ever since its inception remained as a package deal to train forestry practitioners required for the management of national forests. The aim has been to provide forest administrators to govern and manage the state owned forests which form 93 per cent of the total forested area. Forestry education, research and extension in India had been a preserve of the Federal and State Forest Services till 1985 when the Indian Council of Agricultural Research (ICAR) stepped in to introduce graduation programmes in forestry in six Agricultural Universities. The starting of forestry degree programmes in the universities was more or less a consequence of the general awareness to environment and forestry related problems. The media played a very active role in highlighting the problems of deforestation, wasteland formation, development activities to the detriment of forests, environment etc. During 1985, a high level committee in the Ministry of Environment and Forests, GOI, discussed the lack of trained manpower for executing various programmes in forestry and the projections clearly showed that this lack of manpower would continue well beyond the Eighth Five Year Plan.

To generate the desired manpower in forestry the training set-up in Indian Forest Colleges was found to be inadequate and hence the state Agricultural Universities were requested to start Bachelor programme in Forestry. To improve faculty resources about 80 senior teachers from the discipline of plant breeding, agronomy, horticulture etc. were trained in US Land Grant Universities for one year through a USAID funded program. Their main aim was to study a few related courses in forestry at BSc., MSc. and PhD. level and to see the functioning and integration of department of forestry in the College of Agriculture. This was a very useful programme and within a span of 2-3 years each new department of forestry had 2 to 4 trained teachers to teach basic courses in forestry. At this stage it would be worthwhile if the individual universities decided on building up faculty and research capabilities in all disciplines of forestry *e.g.* silviculture, management, agroforestry, tree breeding, social forestry, forest products and utilisation, forest protection.

In general, all the universities which started BSc. (Forestry) programmes in 1985 formulated their curricula on the basis of guidelines provided by the ICAR with only minor modifications. Some of the courses which lacked in the training package of State and Indian Forest Services trainees are biotechnology, microbiology, computer science, biochemistry, forest tribology and anthropology, meteorology and climatology, forestry extension, ergonomics, forest ecology and biodiversity, tree improvement and seed technology, etc. The forestry component slightly varies from university to university but social sciences find a prominent place in the curriculum, mainly because social forestry and agroforestry oriented personnel are in demand. It is very important that the universities specialise their teaching and research programmes in different areas related with afforestation, land use and wastelands managements, social and agroforestry , forest based industries, forest management, non-conventional energy resources, natural resources and biodiversity so that we have enough suitable manpower in the coming years for achieving sustainable management of the tropical and sub-tropical forest wealth of our country.

Improving forestry education through participatory curriculum development. A case study from Vietnam

Peter Taylor
Social Forestry Support Programme, Helvetas, GPO Box 81, Hanoi, Vietnam
Tel: +844 8329833, FAX: +844 8329834, Email: sfsp.pt@hn.vnn.vn

Keywords: Forestry curriculum, Participation, Social forestry, Extension

In many countries throughout the world, forestry practices are undergoing a major reorientation. A new and different type of forestry is emerging, creating a requirement for a different set of skills, knowledge and attitudes in those persons who must deal effectively with the demands from farmers and rural people, as well as from other interest groups such as environmentalists. Whereas much forestry training has until recently been strongly technology based, there is now a need to build an interdisciplinary capacity in many foresters and extensionists, encouraging an understanding of social principles and processes. The focus will no longer be on uniformity and technology; forestry training programmes need to become more relevant and flexible; diverse and yet well integrated. A wide range of stakeholders will emerge with different interests in what forestry education can achieve. The beliefs and values of some stakeholders may accelerate the change process, whilst others may deter innovations and new developments. The possibility for successful outcomes in the development of forestry education is enhanced, however, through approaches which increase participation of different stakeholders in meaningful ways. It is recognised that there are a number of constraints to stakeholder participation. Even so, a participatory approach to curriculum development should lead to increased opportunities for networking, negotiations and reflection by groups and individuals, including those who are normally marginalised, and a greater chance of successful, sustainable outcomes from the curriculum development process.

Participatory curriculum development (PCD) has been used in a number of contexts and regions of the world, particularly in the areas of agricultural and forestry education. This approach is not new, in that there are many instances of attempts to increase participation in the curriculum development process. During the 1990's however, greater effort has been made to articulate and advocate the basic principles and methods which can support PCD, and to share and disseminate experiences and outcomes more widely. PCD seems, on existing evidence, to have the potential to bring about improvements in both the quality and the effectiveness of university forestry education and training programmes in a context of dynamic change.

The paper explains the PCD approach, which begins with a detailed stakeholder analysis, followed by the identification of meaningful roles and responsibilities for different stakeholders. A series of interlinked steps for curriculum planning, implementation and evaluation is then outlined. The precise organisation and operationalisation of these steps is determined by the context and by the intervention of different stakeholders. This creates a continuous, dynamic, flexible process, with learning as the guiding principle for development.

A case study of the Social Forestry Support Programme with five university forestry faculties in Vietnam is then presented. The paper describes the PCD approach, the focus of which is primarily the development of social forestry education and training programmes, but also the review and revision of Vietnamese forestry degree programmes in general. It explains the process by which curriculum development is based upon systematic learning from the experiences and views of farmers at grassroots level, as well as from teachers, students, extensionists, project staff and other stakeholders at local and national level, and even from regional networks and organisations.

Some constraints affecting the PCD process are discussed, as well as a number of opportunities which have emerged during the programme in Vietnam. The current status of curriculum development activities in the programme are presented, along with plans for future collaboration and involvement of stakeholders. in conclusion the paper advocates the further dissemination of experiences with the PCD approach in order to achieve a wider support for its application in forestry education at local, national and regional level. Ultimately, this should contribute to an improvement of the quality, ownership and impact of forestry education and training for a wide range of target groups and institutions.

6.16.00 Modelling forest managers environmental decisions

Using forest sector models for environmental decision making in the United States

Ralph J. Alig
USDA Forest Science, Pacific North West Research Station, 3200 SW Jefferson Way, OR 97331 Corvallis, USA
FAX: (541) 750-7329, Email: aligr@ccmail.orst.edu

Supplies of goods and services in the forestry and agricultural sectors are affected by land use changes, investment in land management, and policies. We examine environmental and socio-economic impacts in the United States of three different types of policies using model results from the Timber Assessment Market Model (TAMM) and the Forest and Agriculture Sector Model (FASOM). We look at policy scenarios pertaining to: 1) land-use pressures; 2) increased protection for wildlife habitat on public lands; and 3) climate change. With respect to analyzing policy scenarios, use of the TAMM and FASOM models can be complementary. As described in another paper at this Congress (Alig et al., Session 4.02.07), the TAMM system of models links product and stumpage markets and provides projections that are based largely on behaviorial tendencies as reflected by historical observations. The intertemporal optimization framework of FASOM allows ready examination of adjustments or responses to policies that may fall outside the historical range of observations. Investigating the sensitivity of FASOM projections to a range of different assumptions, as under additional scenarios, can be a useful form of policy analysis. This allows examination of different assumptions about supply conditions for land and capital, including the flexibility of the simulated market system to adapt to changes over time and across scenarios. Both models have been used to examine a number of different scenarios, including private responses to reduced public timber harvest, recycling of wastepaper, tree planting for carbon sequestration, and impacts from global climate change.

With regard to land-use pressures, model results indicate that access to additional land as potential afforestation investments provides additional private investment flexibility in market simulations. This may include non-traditional activities on agricultural land such as biomass and short rotation woody crop production and tree planting as part of adaptation activities in response to global change. Next, reductions in timber harvests on public lands for additional wildlife habitat protection may result in having some of the largest environmental and economic impacts occur in regions outside of which the public timberlands are concentrated. However, shifts in intertemporal patterns of private forest investment may act to reduce the price and harvest impacts of public harvest changes over time. Model results for mitigation strategies to address climate change concerns indicate the potential for leakage. Leakage may take place when policy-driven afforestation by the forest sector leads to some market-driven compensating conversion of forestland elsewhere to agricultural use. Another manifestation would be crowding out of investment within the forest sector. Forests created to sequester carbon would enhance future timber supply and decrease anticipated future timber prices. The lower prices may crowd out some forests that would have otherwise have been established in the absence of the policy. With an intertemporal model, lower timber prices may also cause some owners to harvest sooner and invest back in lower intensity management forests or convert to alternative land uses. The ownership tenure system in the United States makes private land use change a potential important determinant of the forest carbon budget, and projections of forest carbon sequestration are sensitive to assumptions about factor supply (e.g., inelastic supply of land within a sector). Costs of the mix of and land transfers and management inputs can vary notably with the type of forest carbon target, including timing and level.

A System of Short Term Forecasting for the Finnish Forest Sector (MESU)

Lauri Hetemäki, Riitta Hänninen and Anne Toppinen
Finnish Forest Research Institute, Unioninkatu 40 A, FIN-00170 Helsinki, Finland
FAX: +358 9 8570 5717, Email: Lauri.Hetemaki@metla.fi

This paper presents a synthesis of the System of Short Term Forecasting for the Finnish Forest Sector (MESU). As its name indicates, the purpose of MESU is to make forecasts for and analysis of the Finnish forest sector. It has become increasingly important to be able to analyse changes in forest sector business cycles. This is, for example, due to the liberalization and globalisation of forest products markets. in addition, the forming of EMU and the launching of euro-currency will affect Finnish forest industry's main export markets. Part of the MESU-system has already been utilized in practice for helping the Finnish Forest Research Institute to make forecasts for the Finnish Forest Sector Economic Outlook (an annual publication).

The use of the MESU-system allows to make assessments in which the development of Finnish forest products export markets and the adjustments of Finnish roundwood markets are analyzed consistently. It is a hierarchical, demand-led system consisting of three parts (models). First, the demand for forest products in the major export countries is forecasted using a consumption function model. in the second stage, these forecasts are inserted as exogenous information in the next stage, the export market model, which determines the Finnish forest products exports. in the third stage, the forecasts from the export market model are, in turn, inserted in to the roundwood market model, which determines the forecasts for roundwood demand and prices. This paper will demonstrate the MESU-system by an example. Particularly, we analyse how the changes in the demand for sawnwood in Germany affect the demand for Finnish sawnwood exports and, in turn, the demand and prices for sawlogs in Finland. The theoretical framework of the system is based on economic theory and the empirical model is based on quarterly time series data from 1980-1997. As far as we are aware, MESU is a first attempt to build a short-term forecasting system, which links the demand for forest products to roundwood markets using econometric models and modern time-series methods. However, the theoretical and methodological framework of the MESU-system is general, and similar modelling approach could be applied to other countries as well.

The role of forest sector models to support environmental and forest sector decision making in the Nordic countries

Birger Solberg, Risto Seppälä
Agricultural University of Norway, Department of Forest Sciences, Aas, Norway
Tel: +358 9 8570 5330, FAX: +358 9 8570 5717, Email: birger.solberg@isf.nlh.no

Keywords: forest sector analysis, modelling, experiences, Finland, Norway

The paper gives an overview of forest sector modelling in Finland and Norway and how it has been used in environmental and forest sector decision making. Strong and weak points with the application of these kind of models are discussed, and improvements of the present situation are analyzed. Till now rather few analyses have been performed related to environmental problems, as most of the modelling efforts have dealt primarily with supply and demand of roundwood and forest industry products. One major obstacle in both countries has been that decision makers have an uncomplete understanding of the basic mechanisms of the models, and thus have been sceptic in using them. However, there have also been positive experiences about collaboration with decision makers, in particular in Finland where various stakeholders have been involved, but also in Norway where the central government has been the main user.

6.16.00 Example of forest sector issues

Forest Sector Analysis for Macro Economic Development of Osun and Ayo States, Nigeria

Busuyi Olasina Agbeja
University of Ibadan, Dept. Forestry Resources Management, Ibadan, Nigeria

The study was carried out for a period of 24 months between July, 1996 and June, 1998. The exercise centred on an evaluation of critical elements of growth and economic development of teak plantation establishments *e.g.* volume production exploitation and regeneration ratios, optimum labour requirements and socio-economic impacts of activities dependent on the forests.The cumulative data were analysed using various tools,such as Smalian`s formula, Gross Margin Analyses, Discounted Cash Flow Analysis Net Present Value (NPV), Benefit -Cost Ratio (B/S) and Economic Rate of Return (ERR), Sensitivity Analysis, Production Efficiency Model, Optimum Labour Demand Model, Bar Charts and Simple percentages. Current forestry contributions of Osun and Oyo States were evaluated and feasible development strategies which would enhance sustained forestry sector of the two states to the gross domestic product (GDP) of the country were outlined. The results showed that the volumes per hectare of teak stand were insignificant (P>0.05) with 782.8 m^3 per hectare in a 21-year -old teak plantation in Ago-Owu forest reserve and 215.8 m^3 per hectare in an 18-year-old teak plantation in Gambari forest reserve. The NPV of N236,128.5, B/C of 12.9 and ERR of 33 percent (where NPV = 0) were signification higher (P<0.05) per hectare of taungya teak plantation in Ago-Owu forest reserve using a discount factor of 10 percent than the NPV of N233,214.0,B/C of 12.7 and Err of 31 percent (where NPV = 0) per hectare of direct teak plantation in Ago-Owu forest reserve.The NPV of N113,206.3, B/C of 6.2 and ERR of 30 percent (where NPV = 0) were significantly higher (P<0.05) per hectare of taungua teak stand at Gambari forest reserve than the NPV of N110,355.5, B/C of 6.0 and ERR of 28 percent (where NPV = 0) per hectare of direct teak plantation in Gambari forest reserve. The NPV and B/C were significantly sensitive (P<0.05) to increase in discount factor of 20, 25 and 30 percent in the two reserves.The production efficiency model per km^3 from 1992 tto 1997 showed that Marginal Products (MPs) of 1.6 for labour in exploitation activity were positive (P0.05) at Ago Owu and Shasha while MPs of -0.1 and -0.1 were negative (P>0.05) at Ago-Owu and Shasha forest reserve. in Gambari forest reserve, the MPs of 0.1 and 0.02 in exploitation and regeneration were both positive at decreasing rate (P<0,005) while the MPs of -0.04 and -0.1 were negative (P>0.05) in exploitation and regeneration at Ijaiye forest reserve. The optimum labour demand models indicated that Ago-Owu, Shasha, Gambari and Ijaiye forest reserves required 25 forestry staff, 17 forestry staff,6 forestry staff and 7 forestry staff respectively from 1992 to 1997. In Osun State, from 1992 to 1997, the forestry department generated N107,574,642.5 out of the total revenue of N271,348,554.8 realized by the Ministry of Agriculture. The percentage contribution of forestry department in six years was 39.6 percent. On the other hand, in Oyo State, from 1992 to 1997, forestry department generated N39,830,073,3 out of the total revenue of N112,320,149,8 realized by the Ministry of Agriculture. The forestry contribution in six years was 35.5 percent. in all these study locations, the respondents complained bitterly about the poor investment on rural infrastructural facilities.For instance, 90, 87.5, 80 and 75 percent respectively of the respondents in Ago-Owu, Shasha, Gambari and Ijaiye forest reserves affirmed that infrastructural facilities were grossly inadequate. The study therefore revealed economic efficiency of land use practices, positive labour efficiency in exploitation and negative labour efficiency in regeneration, under-employment of government employees in all forest stations, substantial and increasing annual revenue generation by forestry services and poor socio-economic impacts of forest operations on rural wellbeing. Forestry development strategies were developed. in particular, commmunal participations in plannning and management processes were identified as a critical strategy for significant improvement of forest sectoral contributions to the national economy.

Mandatory Biodiversity Conservation: Competitiveness versus Green Image Effects

Erkki Koskela, Markku Ollikainen
University of Helsinki, Department of Economics, Post Box # 54, FIN-00014 Helsinki, Finland
FAX: +358-9-191887, Email: Erkki.Koskela@Helsinki.fi

Mandatory biodiversity conservation in forestry is usually thought to decrease harvesting possibilities, raise timber price and weaken competitiveness of the domestic forest industry. If however biodiversity conservation leads consumers to view products as being higher quality, the resulting "green image" increases demand for domestic woods products. This paper studies the effects of mandatory biodiversity conservation by modeling the behavior of the domestic economy as a two-stage game. in the first stage the forest industry and the forest owners' association bargain about timber price, while in the second stage the domestic industry determines output in a Cournot rivalry with the foreign forest industry. in the absence of green image a binding biodiversity conservation requirement will increase the reservation price of timber for forest owners' association and thereby timber price. International competitiveness of the domestic forest industry weakens and its market share falls. If the green image is strong enough competitiveness effect may be more than compensated by increased demand in which case the profits of domestic forest industry may go up. Assuming the competitive timber market, where timber price is determined by equality of demand and supply, does not change these conclusions. A welfare analysis is carried out by assuming that the government maximizes the sum of producers' and consumers' surplus and accounts for the valuation of biodiversity.

Ways to sustainable forest management in the Mari El Republic of Russia

Eldar Kurbanov, Anna Tikina
Russia

Much has been said on sustainable development and sustainability lately. Governments in many countries try to introduce this concept into national policies and combine the economic growth with environmental issues. However, this is not performed in all regions equally, *e.g.* at the level of the Mari El Republic this idea has not found its realisation. This article is aimed at analysing the possibility of introduction of sustainability concept and sustainable forest management into the policy of the republic.

Describing the forest fund of Mari El republic in general terms, statistic states that the total area of the forest sector of the republic is equal to 1210 thousand hectare and the area covered with forests is 1095 thousand hectare. The total wood stock reaches 170 mill m^3, among them 40 mill. m^3 being for the stock of mature and decline forest ecosystems. The vegetation composition of the republic is determined by the natural conditions of the territory. The main resource of the republic is forest that covers about 52% of the territory.

In order to highlight the main sides and main drawbacks of the Mari El forestry it is possible to fulfil a comparison of the forestry policy analysis as well as the analysis of the current situation in the forest sector of Finland and the Mari El republic. It is possible to compare the two institutions because of their almost similar nature conditions and environment. However, Finland can be taken as an example of a country with significant experience of sustainable forest management. This is why a non-favourable comparison will be able to demonstrate the lack of sustainability in Mari El forestry. To find the way out of the current situation in the Mari El forest sector it is necessary to investigate how forest policy of the republic differs from the policy of the countries with the positive experience of sustainable forest management (*e.g.* Finland). This is why a short comparison of the main directions of forestry policies is presented here in the form of Table 2.

Table2. Comparison of Finnish and Mari El forestry policies.

Features	Finland	The Mari El republic
1. Aim at sustainability	Y	Y
2. Multi-functional approach to the use of forest resources	Y	N
3.Bias to economic forest function	N	Y
4.Forest protection:		
a) against fires	Y	Y
b) against pest and disease	Y	Y
c) against air pollution	Y	N
5. Afforestation	Y	Y/N[1]
6.Biodiversity conservation	Y	N
7.Main forest ownership pattern	private	State
8.Existence of a forest information system	Y	N
9.Exceeding felling (more than increment)	N	N[2]
10.Consideration of local peculiarities	Y	Y
11.Protection of landscape beauty	Y	Y/N[3]
12.Forest certification	Y	N
13.Different types of protected areas	Y	Y
14.Mono-culture plantations	N[4]	Y
15.Public participation in forestry activities and policymaking	Y	N
16.Best available methods and technologies	Y	N
17.Violations of forest legislation	N	Y

The differences between the policies can be explained by the contrast in economic situations in both Finland and Mari El, as well as by the difference in the source of funding (in case of the Mari El republic funding is influenced by federal donations). Though biologically the countries are mostly alike (the same plant species can be found in both) and forests consistute main natural resources in both regions, the difference in the economic development, as well as the former bias to military and heavy industry in the Mari El republic can explain the difference and negative sides of forestry policy and management.

Possible amendments to improve the situation in the Mari El republic can include the following measures:
- Introduction of multi-functional forest use and receiving benefits from different forest resources
- financing of activities by taking part in the international grant projects and valuation of all possible forest products
- further introduction of reforestation and afforestation
- investigation and introduction of the methods of forest sustainable use, criteria and indicators of sustainable forest management
- forestry education and professional training
- regulation on control and punitive measures against the violation of norms
- improvement in access to information, creation of policy information systems
- raising of local community awareness and stimulation of their participation in decision-making

To conclude, it is possible to point out that sustainable forest management has not been implemented into the forest sector of the Mari El republic and the current situation in forestry is far from being satisfactory. However, there is a way out of these conditions by introducing changes in the forest policy, and the changes should meet the latest international requirements and be sufficient for sustainable forest management.

Geographical price systems in the timber market

Erik Tromborg, Solberg, Birger
Statskog Ressursdata as P.O. BOX 2, 3601 Kongsberg, Norway
Tel: (+47) 32 77 14 38, FAX: (+47) 32 77 14 02, Email: erik.tromborg@ressursdata.no

Concentration of the forest industry and the spatial distribution of forests imply that transportation costs are important in the timber market. A spatial forest sector model based on partial equilibrium is developed in order to analyse regional implications of a change from uniform roadside prices to uniform non-discriminatory millgate prices for pulpwood in Norway. Uniform millgate prices implied regional differences in roadside pulpwood prices up to 25% compared to the uniform roadside prices. Factors influencing the geographical price system in the timber market are outlined. It is concluded that spatial price discrimination is likely in a pulpwood market with a limited number of buyers.

Ecological Economic Problems of Achieving Sustainable Forestry in Transitional Countries

Yuriy Y. Tunytsya, Taras Y. Tunytsya
Ukrainian State University of Forestry and Wood Technology, 103 Gen. Chuprinki str., 290057 Lviv, Ukraine
Tel: +380-322-35-24-11, FAX: +380-322-97-17-65, Email: ukrdltu@forest.lviv.ua

The main condition for achieving sustainable forestry is to overcome contradictions between ecological and economical systems. Such contradictions occur as the economical and ecological interests seem to be not compatible at first sight. But if one studies the issue more thoroughly, it will turn out that the co-ordination of current economic interests with long-term ecological imperatives is quite possible.

The achievement of long term summary ecological-economical effect should become the principal criteria for traditional economic criteria. The achievement of sustainable forestry is not possible both on the regional and global scales without such a principal and methodological change.

The achievement of sustainable forestry goals is much more complicated process in transitional countries in comparison with development and market oriented countries. This happens because the developed countries are facing one set of changes-the transition from the market to ecologically oriented market. Transitional countries have two sets of changes to accomplish-first one is the transition from centralised socialist economy to the market economy and second one the transition to the ecological market. This process requires more time. and if we want achieve global sustainable forestry the transitional countries would need assistance in speeding up this process. One should not forget that large proportions of the planet's forests are located within the territories of former USSR countries. These forests have significant global ecological functions, as do tropical forests.

In the paper on Economic Problems of Forest Management Development presented by Yuriy Tunytsya in 1986 at XVIII IUFRO WORLD CONGRESS we presented the methodological concept of transition to sustainable forestry in socialism. Since 1986 the former socialist countries have undergone radical changes in their political and economic systems. in the paper we propose for the XXI IUFRO WORLD CONGRESS these changes will be analysed by using the results of new research in the forest sector of Ukraine Russia and Belarussia. in particular, we will analyse the results of a joint project, sponsored by INTAS, on the strategy for achieving sustainable forestry in Ukraine, Russia and Belarussia. This project was implemented under the leadership of Prof.Max Krott and the young Ukrainian researcher Taras Tunytsya was one of its participants.

Ecological-economic conception of sustainable forestry includes a number of problems. These problems could be solved under the following conditions: The system of ecological-economical education in post-socialist countries needs to be improved. The transition from centralised economy to sustainable forestry in the conditions of a market-oriented economy is not possible without trained specialists. We consider it important for IUFRO, as an influential international organisation, to undertake the forestry education as an important part of its activity. Then, IUFRO can be renamed as International Union of Forestry Research and Education Organisations (IUFREO). We think that then the role of IUFREO can become even more influential in the society.

-Eastern European countries need more joint research projects with western partners.

IUFRO should be involving more young people in their activity on forming sustainable forestry.

7.01.02 Mechanisms of tree resistance to phytophageous insects

Host tree - bark beetle interactions: effects of restoration of secondary Norway spruce (*Picea abies* [L.] Karst.) forests on food quality for *Ips typographus* L. (*Scolytidae*).

Peter Baier, Erwin Führer, Jutta Mattanovich, Christa Schafellner
University of Agriculture, Institute of Forest Entomology, Forest Pathology and Forest Protection
A - 1180 Vienna, Austria
Email: Jutta Mattanovich [jutta@ento.boku.ac.at]

The effects of thinning of pure spruce stands and converting pure spruce stands into mixed species stands (spruce, beech, fir) on the nutritional quality of the bark were studied. Chemical compounds in the phloem (*e.g.* nitrogen, carbohydrates, phenolic compounds) are undoubtedly relevant for nutrition and for breeding success of the phloem feeder and defence mechanisms of the tree. Changes of site and growth conditions resulting from restoration are expected to modify the chemistry of the host tree. Mass outbreaks of bark beetles like the eight spined spruce bark beetle, *Ips typographus*, frequently occur in secondary spruce stands (usually at altitudes below 1000m) after storm damages or snow breaks followed by warm and dry periods. The sites selected for this investigation repeatedly suffered from severe bark beetle epidemics. It is assumed that restoration of secondary spruce forests will reduce the risk of bark beetle attack.

We regard the following parameters as essential tree parameters determining the food quality for phloem feeders: the amount of nitrogen, protein, protein-bound and free amino acids, starch, soluble carbohydrates, organic acids, crude fat and fatty acids, mineral nutrients, polyphenolic compounds and tannins.

The results of our investigations on three different stands on seasonal changes in spruce bark chemistry during the breeding period are discussed with respect to breeding success of *Ips typographus*.

Characteristics of Douglas-fir trees resistant to damage from the western spruce budworm: Patterns from three populations

Karen M. Clancy
USDA Forest Service Research, Rocky Mountain Research Station, Southwest Forest Science Complex
2500 S. Pine Knoll Drive, AZ 86001-6381 Flagstaff, USA
FAX: 520-556-2131, Email: kclancy/rmrs_flagstaff@fs.fed.us

Differences in biochemical or phenological characteristics between Douglas-fir trees that have experienced light versus heavy defoliation by the western spruce budworm may provide clues regarding mechanisms of resistance to budworm attack. I previously compared levels of foliar nutrients (nitrogen, sugars, minerals) and allelochemicals (mono- and sesquiterpenes) between "resistant" and "susceptible" Douglas-fir trees from two populations sampled in 1989 and 1990. I found a third population of Douglas-fir with individual trees that are phenotypically resistant to budworm defoliation in 1994. Here, I present data on budbreak phenology and radial growth rates for 16 pairs of resistant versus susceptible trees at this site for 1995, and data on foliar nutrients and terpenes for 1995 and 1996. I also compare and contrast the patterns seen across all three populations sampled regarding characteristics of individual trees associated with resistance to damage from the budworm.

Influence of mineral and water nutrition of Scots pine on resistance to the bark-beetle *Ips acuminatus* Gill and their associated blue-stain-fungus *Ophiostoma brunneo-ciliatum* L.

N. Guerard, E. Dreyer and F. Lieutier
INRA d'Orleans, Zoologie Forestiee, Avenue de la Pomme de Pin B.P. 20619, 45166 Ardon, France
FAX: (33) 2 38 41 78 79, Email: lieutier@orleans.inra.fr

Relations between modifications in C/N ratio in tree, tree resistance parameters and pest and disease performances are investigated. Because the C/N ratio can be influenced by modifications of C assimilation and N availability, 3 levels of nutrient conditions were applied, combined with 2 levels of water availability on young potted Scots pine. The impacts of these treatments on trees were followed with physiological parameters (photosynthesis and water status), chemical parameters (nitrogen, carbon, minerals and chlorophyll foliar contents, monoterpenes and phenols), and dendrological parameters (height and radial growth, budburst, phenology and biomass). Tree resistance and pest performances were studied after artificial introduction of *Ips acuminatus* and high-density inoculation (above the threshold of inoculation density) with *Ophiostoma brunneo-ciliatum* (an *Ips acuminatus* associated blue-stain-fungus). Effects of this artificial attacks and inoculations were appreciated through observations of pathogen performances (length of egg galleries, percentage of attacks succes) and tree resistance (resin soaked sapwood, reaction zone length monoterpene and phenol concentrations in the wounded and unwounded phloem, stem water conductivity). The results are presented and discussed with regards to the effects of water and nutrients on tree physiology in association with tree resistance to bark-beetles and with consequences for pest.

Defoliated Scots pines display high resistance to subsequent attack by *Tomicus piniperda*.

Bo Langström, Annila, E., Varama, M.& Niemelä, P.
Swedish University of Agricultural Sciences, Dept. Entomology, Post Box # 7044, S-750 07 Uppsala, Sweden
Email: Bo.Langstrom@entom.slu.se

In 1990-1991, *Diprion pini* caused extensive defoliation in Lauhanvuori national park and surrounding areas in south-westen Finland. Most trees lost all their foliage in 1990. in 1991, the outbreak area was sprayed with diflubenzuron (Dimilin), except in the national the park where the sawfly larvae consumed, most of the remaining needles. No further defoliation occurred in 1992.

In spring 1992, pine trees with 0, 10, 30 and 100 % foliage left (10 small and 10 large trees in each category) were baited with pine bolts in order to induce stem attacks by pine shoot beetles. All baited trees were attacked by *Tomicus piniperda* and some also by *T. minor*, but the attacks failed in all trees except in the totally defoliated ones (and some of the small trees with little foliage left). Most unbaited trees escaped attack entirely, but a few totally defoliated were successfully colonized. Attack densities of *T. piniperda* were optimal on the lower stem (ca 100 egg galleries x m-2), but the corresponding brood production was modest (ca 500 exit holes x m-2). None of the measures (resin flow, cambial electrical resistance, size of induced defense reaction phloem starch and sugars) used to describe tree vigour gave better information than the estimated remaining foliage. Thus, the risk for beetle-induced mortality following defoliation is a function of remaining needle biomass and beetle pressure.

Tree mortality, foliage recovery and stem- and shoot-attacks by *Tomicus piniperda* were further recorded in spring 1993, 1994, 1995 and 1997 on sample plots along 3 survey lines (10 plots per line) situated in a totally (line 1) and severely defoliated (line 2) part of the national part, and in the Dimilin-treated area outside the park.

Two years of total defoliation resulted in ca 75 and 50 % mortality in small and large trees, respectively, whereas only occasional Dimilin-sprayed trees (suffering one year of defoliation) died. Most mortality occurred in 1992 and 1993, and in spring 1997, the sprayed trees had recovered full foliage, whereas trees on line 1 and 2 held ca 50 and 60% of full foliage, respectively.

Altogether, more than half of the dead trees were colonized by *T. piniperda*, and the rate of attacked trees peaked in 1993. in all year, successfully attacked trees carried less than 10 % foliage, while attacks failed on trees having more than 20 % foliage. Unattacked trees had ca 50 % foliage. As the mean needle biomass for all groups of surviving trees was above 25% in 1992, we conclude that depletion of suitable hosts terminated the beetle outbreak in the area. The high resistance of severely defoliated trees, indicates that carbon availability may be less important for resistance than expected so far. (Although growth losses are no treated in this context, we also conclude that preventing a second year of defoliation was highly justified from a silvicultural point of view.)

This abstract is a based on the following two papers:

Annila, E., Langström, B., Varama, M., Huikka, R. & Niemelä, P. 1999. Susceptibility of defoliated Scots pine to spontaneous and induced attack by *Tomicus piniperda* and *T. minor*. (ms accepted for publication in Silva Fennica).

Langström, B., Annila, E., Varama, M. & Niemelä, P. 1999. Tree mortality, needle biomass recovery and growth losses in Scots pine following defoliation by *Diprion pini* and subsequent attack by *Tomicus piniperda*. (Ms intended for submission to Scand. J. For. Res.).

Pinus spp. Chemical Composition and Host Selection by the Winter Pine Processionary Moth

Maria Rosa Paiva, E. Mateus, C. Pimentel, M.H. Farrall
Universidade Nova de Lisboa, FCT / DCEA, Q. da Torre, P - 2825-114 Monte de Caparica, Portugal
Tel: 00 351 21 2948300, FAX: 00 351 21 2948554, Email: mrp@mail.fct.unl.pt

Pine stands cover 1.3 million hectares in Portugal and are grown over extensive areas in the Mediterranean region. *Thaumetopoea pityocampa* (Den. and Schiff.) (*Lepidoptera, Thaumetopoeidae*), the winter pine processionary moth is a major defoliator causing economic damage, particularly to young plantations. Several authors have ranked *Pinus* species according to their relative susceptibility to *T. pityocampa* attack, but differences occur among geographical regions and altitudes. in the present study chemical analysis were made for 8 *Pinus* spp., some of which are native to Portugal and some introduced. Variations were detected among species, mainly in the terpene composition, which were related to the different levels of processionary moth attack recorded. Significant relationships were found between the relative percentages of b-pinene and limonene, present in the bouquets of the needles, and the percentage of pines having larval nests. in a separate experiment, the chemical composition of the needles of individual trees from a stand of *P. pinaster* originated by natural regeneration, were analysed. The variations detected, particularly in the relative amounts of some monoterpenes emitted by individual trees, were statistically related to the number of larval nests of *T. pityocampa* counted. in parallel, biotests were performed in an olfactometer, using extracts of needles of different pine species, to test host selection preferences by the adults. Results indicated a preference of the females for pine species which, under field conditions consistently suffer higher levels of attack in Portugal. Host selection and colonization by *T. pityocampa* thus appear to be influenced by monoterpene emissions of the pine trees.

7.02.07 Impacts od diseases on the sustainability of tropical forests

VA mycorrhizal *fungi* and their role in plant disease control

Joseph D. Bagyaraj
University of Agricultural Sciences, Department of Agricultural Microbiology, GKVK campus, 560 065 Bangalore, India
FAX: 091 - 080 - 3330422, Email: cksuresh@uasblr.kar.nic.in

Mycorrhizal association constitutes the most striking example of symbiosis in the plant kingdom. There are different types of *mycorrhizae*. The most common are ectomycorrhizae and vesicular *arbuscula*r *mycorrhizae* (VAM). Increased plant growth because of VAM colonization is well documented (Bagyaraj and Varma, 1995). The increased plant growth is attributed to enhanced uptake of diffusion limited nutrients, hormone production biological nitrogen fixation, drought resistance and suppression of root pathogens. Most reports in the literature indicate that VAM fungi decrease severity of diseases caused by root - pathogens. VAM fungi associated with different crop plants suppressing the fungal root pathogens like *Thielaviopsis basicola, Phytopthora parasitica Fusarium oxysporum, Gaeumannomyces graminis var. tritici, Sclerotium rolfsii, Pyrenochaeta terrestris* and *Pythium spp*. have been reported. Similarly, VAM fungi also alleviate the severity of diseases caused by plant pathogenic bacteria like *Pseudomonas syringae* and *P. solanacearum*. Reports on several hosts indicate that VAM fungi decrease the severity of pathogenic nematodes like *Meloidogyne avenaria, M. incognita, M. hapla, M. javanica, Tylenchulus semipenetrans, Pratylenchus brachyurus* and *Radophilus similis* (Sampangi and Bagyaraj, 1989). Mechanisms of suppression of root pathogens by VAM fungi: Studies conducted so far suggest that the mechanism of suppression may be due to morphological, physiological or biological alterations in the host. i. Morphological alterations: Thickening of the cell walls through lignification and production of other polysaccharides in mycorrhizal plants preventing the penetration and growth of pathogens have been demonstrated. A stronger vascular system observed in VAM plants increase the flow of nutrients, impart greater mechanical strength and diminish the effect of vascular pathogens. Smaller syncytia with fewer cells have been reported to impart resistance in the host against root - knot nematodes.

ii. Physiological and biochemical changes: Higher phosphorus concentration found in mycorrhizal plants can offset the severity of a disease caused by pathogens. Decreased root exudation in mycorrhizal plants possibly help in reducing the infection of roots by pathogens. High chitinase activity of the mycorrhizal tissue also may confine the growth of the pathogen in the host. Higher levels of certain chemicals like arginine, phenyl alanine, serine, orthodihydroxy phenols and sulphur containing amino acids reported in mycorrhizal roots were found to be inhibitory to root pathogens.

iii. Biological alterations: Mycorrhizal plants harbour higher population of microorganisms in the rhizosphere thus making it difficult for the pathogen to compete and gain access to the host root. It was also reported that roots colonised by VAM fungi harbour more actinomycetes antagonistic to root pathogens. Recently microorganisms producing siderophores, which are low molecular weight chelating agents that have high affinity for ferric iron and thus fungistatic to many pathogens, were observed in higher numbers in the rhizosphere of mycorrhizal plants. The biocontrol potential of VAM fungi can be exploited in field by further understanding the defence mechanisms and conditions favouring the experience of their protective ability. There is a need to strike an appropriate balance of pesticide - mycorrhiza - other biocontrol agent use in designing integrated plant disease management. The recent advances made in the biological control of rot pathogens of tree species will be discussed.

Nursery Diseases of Tropical Forest Plantations

M. Balasundaran
Kerala Forest Research Institute Peechi, Division of Pathology, Thrissur-680653 Kerala, India
FAX: 91 487 782249, Email: libkfri@md2.vsnl.net.in

Serious damage to forest nursery caused by seedling diseases often upsets planting programmes. Though seedlings of both exotics and indigenous tree species are affected by disease outbreak, exotics are more vulnerable to pathogen attack, especially after one or two rotations of growth in the host country. in the tropics, as more and more native species cross national boundaries and become accepted-exotics abroad, unknown pathogens also spring up suddenly in host countries causing disease outbreak in epidemic proportions. The warm humid climate prevailing in the tropics is most conducive for pathogen multiplication and host invasion.

Eucalypts, one of the most widely grown exotic species in the tropical countries are severely affected by leaf blight and stem infection caused by *Cylindrocladium spp*. in India, Vietnam, South Africa and South American countries. Wilt disease caused by *Burkholderia solanacearum* is the most damaging bacterial infection on *Eucalypts* seedlings in China and Australia, Brazil and quite recently in India. Among rust fungi, *Puccinia psidii* is the serious problem in Brazil, Taiwan and South Africa. *Cryptosporiopsis eucalyptii*, a recently described fungal pathogen causes leaf spot disease on several species of *Eucalypts* in Australia, Brazil, India, Japan, Thailand, Vietnam and Hawaii causing blight symptoms. *Kirramyces epicoccoides* affects growth and vigour of seedlings by causing leaf spot and subsequent defoliation in Africa, Australia, Brazil, India, Japan, Thailand and Vietnam.

In *Acacia*, though leaf spot diseases are reported from India, serious seedling diseases are rare except phyllode rust caused by *Atelocauda digitata* in Indonesia and powdery mildew in India and Vietnam. Pine needle blight caused by *Cercospora pinidensiflorae* is reported from Vietnam. Diseases like damping off caused by *Pythium* and *Verticillium* spp., collar rot caused by *Rhizoctonia solani* and seedling blight caused by *Sclerotium rolfsii* are the common seedling diseases occurring on indigenous as well as exotic tree species in several tropical countries. in teak, bacterial wilt caused by *Burkholderia solanacearum* and leaf spot caused by the fungus *Phomopsis* and *Colletotrichum* spp. are economically important diseases.

International movement of pathogens occur especially through exchange of infected seeds, and chaff and debris carried along with the seeds. Hence, effective disiffection and strict quarantine laws only can prevent international spread of diseases. Suitable silvicultural methods are adopted to prevent the occurrence of nursery diseases in all the countries. Judicious use of fungicides and bactericides are often recommended to control the economically serious diseases.

Ectomycorrhizas as a deterrent to seedling diseases of trees in the nursery

K. Natarajan
University of Madras, Cas in Botany Guindy Campus, 600 025 Chennai, India
Tel: 91-44-235 0401, FAX: 91-44-235 2494, Email: botany@md3.vsnl.net.in

Numerous investigators in the last several years have shown that ectomycorrhizas are essential to the establishment and growth of many tree species. Their beneficial effects are physiological in nature such as increased root absorption surface, selective in absorption and accumulation, ability to render unavailable substances in soil available to the plant host etc. A possible beneficial role of ectomycorrhizae in the tree growth and development is that the mycorrhizal fungus protects unsuberized roots from attack by parasitic fungi. It has been postulated that mycorrhizal fungi may conceivably afford protection to the root by i) utilizing root carbohydrates and other chemicals which would be attractive to pathogens, ii) providing a physical barrier to pathogens in the form of fungus mantle, iii) secreting antibiotics which inhibit or kill the pathogens and iv) supporting a protective rhizosphere population of the other micro-organisms. in common with many soil fungi, some mycorrhizal symbionts are capable of antibiotic action. The antibacterial and antifungal compounds produced by mycorrhizal fungi against root rot and damping off of nursery seedlings of tree species have been studied by several workers. They suggest that antibiotic production by the mycorrhizal fungi may be the factor in the survival of seedlings in nature by warding off attack by root pathogens. The production of antibacterial compounds by mycorrhizal fungi in pure culture has also been investigated.

Keywords: Mycorrhiza, Biocontrol, Root pathogens, Diseases of nursery seedlings.

Rust diseases of Indian Conifers

A. N. Shukla
Forest Research Institute, Forest Pathology Division, 248006 Dehra Dun, India
FAX: 91 0135 756865, Email: icfre-mis@x400.nicgw.nic.in

Indian conifers include pines, deodar, fir and spruce. Pines constitute one of the most divergent and economically important group of species found in the Himalayas. The pine species occurring in India number four and are *Pinus roxburghii*, *P. wallichiana*, *P. girardiana* and *P. kesiya*. of these *P. roxburghii* and *P. wallichiana* are distributed widely extending over a long strip of 3200 km from the west to east occupying an area of 6728 sq. km. and 2270 sq.km. respectively. The occurrence of *P. gerardiana* and *P. kesiya* is restricted, the former distributed in the dry zone of inner western Himalaya and the later to eastern Himalayas and Khasi hills occupying an area over 400 sq.km. and 2000 sq.km respectively. The conifers help in restoring the fragile ecosystem of Himalayas. Apart from this they provide valuable natural resources like resin which contributes significantly to the local employment and national economy. Deodar (*Cedrus deodara*) fir (*Abies pindrow*) and spruce (*Picea smithiana*) occur at different altitudes in Himalayaa and provide timber for buildings and packing boxes. in *P. roxburghii* or Chir pine, stem rust caused by *Cronartium himalayense* is a major problem in the younger plantations, causing mortality to the tune of 5-40% in different localities. The rust completes its life history on a local weed Swertia spp. of all the eight districts surveyed the incidence was found in six districts in Garhwal and Kumaun regions. The pathogen produces pycnia and aecia on Chir pine, causes girdling and kills the affected portions. *P. wallichiana* or Kail is reported to be attacked by *Cronartium ribicola* a macrocyclic and heterocious rust. The incidence is observed in Bushahr and Kullu in Himachal Pradesh and Hazara, Kashmir and Kangan in Jammu and Kashmir. From Uttar Pradesh it is reported from Chakrata. The rust attacks young plants on stem and branches which become swollen, blistered and girdled. It develops pycnia and aecia on blue pine and urredenia and telia on *Ribes rubrum* and *R. orientale*. *Cronartium quarcuum* attacks *P. kesiya* in mature trees around Shillong (Meghalaya). The branches become swollen and aecia develop profusely. The damage is not very significant. The needles of Chir and Kail pines are attacked by *Coleosporium campanulae* and *C. barclayense* respectively. Small orange to yellow sacs of aecia are produced on the needles numbering 2-15. It gives an ugly appearance to the plantations. Mostly the younger plants are affected. No apparent damage is caused as the affected needles are shed at about the same time as healthy needles. in *Cedrus deodara* (deodar) needle rust is caused by *Peridermium cedri*. It is an autoceous rust and attacks the young needles of current year's shoot. The infected needles bearing pycnia and aecia remain shorter and curve backwords. Infected needles are shed earlier and therefore, the folaige becomes sparse. Witches broom is produced on the affected branches and in extreme cases it may cause mortality to the branch and young trees.

Other needle rusts reported are *Ploioderma cedri* on deodar, *Caeoma himalayensis* on fir and *Peridermium*

thomsoni on spruce. But all of them are endemic to small areas in Jammu & Kashmir, Himachal Pradesh and hills of Uttar Pradesh.

Epidemic Diseases - potenial threat to plantation forestry in India

Choran Mohanan
Kerala Forest Research Institute, Peechi, 680 653
Kerala, India
FAX: 0487 782249, Email: libkfri@md2.vsnl.net.in

In India, plantation forestry commenced with the small-scale planting of teak, *Tectona grandis* in Nilambur valley, Kerala, the southernmost state in 1840s. Since then, teak has been growing on a large-scale in plantations as monoculture or mixed with broad-leaved softwood species through out the countries. Casuarinas were also introduced in the coastal belt of Peninsular India during the British colonial period for meeting the requirement of fuel wood for steam engines. At present casuarinas, especially *Casuarina Equisetifolia* have been growing on a large-scale under different afforestation programmes including agro-forestry in inland as well as coastal areas in Peninsular states of India. During 1960s large-scale planting of *Eucalypts* initiated in Kerala State by clear-felling the degraded semi-evergreen and moist deciduous forests in low and medium altitude areas and in grass lands in high altitude areas to meet the requirement of pulpwood industries. During the past 150 years of plantation history different timber and multipurpose tree species have been growing in different parts of the country. Though, the plantation forestry has experienced set-backs due to biotic factors like human interference and cattle grazing and abiotic factors like fire and erratic rainfall, epidemic outbreak of diseases posed threat recently. During 1970s epidemic outbreak of diseases occurred in *Eucalyptus tereticornis* plantations raised in humid areas in Kerala and Karnataka State devastating the crops entirely. Pink disease caused by *Corticium salmonicolor* affected the plants of >6 year-old and foliage blight caused by different species of *Cylindrocladium* affected the plants of <3 year-old severely. A second outbreak of pink disease in *E. tereticornis* plantations occurred in 1980s devastating the plantations in low and medium elevated areas through out the state. Recently, *E. grandis* raised in high altitude areas (950-1000 m above msl) which showed remarkable resistance to pink disease earlier, also become succumbed to severe attack by the disease. Pink disease and *Cylindrocladium* blight epidemics occurred in 1995 and 1996 and wiped out hectares of plantations to an extent alternative species like *Acacia auriculiformis* was sought for in *Eucalypts* failed areas. Teak, the hardy species with more than 150 years in plantation forestry in India, has also become severely damaged by the pink disease, recently, mainly due to the altered high input silvicultural practices. *Casuarina equisetifolia* plantations raised in inland and coastal areas in Peninsular states are found severely affected by stem wilt disease, caused by *Trichosporum vesiculosum*. Though the disease was noticed in 1905 in coastal plantations in Orissa State, epidemic outbreak of disease occurred recently, especially in Tamil Nadu, Karnataka and andhra Pradesh. The pathogen is indigenous and cause disease only in casuarinas. Whereas, Corticium salmonicolor has a wide host range of more than 420 tree species belonging to 104 genera both indigenous and exotic. Though biology of the fungus and etiology are well understood, disease management strategy heavily depends mostly on cultural measures due to economic constraints. At present, plantation forestry in the country is at the cross road and set backs from the epidemic outbreak of diseases have adversely affected the pulp, paper and rayon industries as well as the farmers. The paper highlights the possible influencing factors for the disease outbreak, and short-term as well as long-term disease management strategies to be adopted.

Status of forest Diseases in India and Future Research Needs

Jyoti K. Sharma
Kerala Forest Research Institute, Peechi 680 653 Kerala, India
Tel: +91-487-782062, FAX: +91-487-782249, Email: libkfri@md2.vsnl.net.in

With the increasing demand for wood in India, forestry has gained importance in recent years. To meet this challenge the productivity of forest plantations is being increased by intensive management. However, as the management intensifies with high inputs more and more disease problems are surfacing. Since, India's climate ranges from temperate in the northern region to tropical in the southern peninsula, types of diseases and incidence and severity show considerable variation chiefly due to the prevailing climatic conditions, edaphic factors and host species. This makes the management of forest diseases quite complex. The most widely planted species in India are *Acacia auriculiformis, Albizia falcataria, (Paraserianthes falcata), Azadiracta indica, Bambusa arundinacea, Bombax cieba, Cosuarina equisetifolia, Dalbergia, sissoo, Eucalyptus tereticornis, E. camaldulensis, Gmelina, arborea, Pinus, spp., Populus sp., Grevellia robusta, Tectona grandis, etc.*

Seedlings for raising plantations are grown either in conventional way in bareroot nurseries or more recently in root trainers with little management to high in-put management. This variation in nursery practices is reflected in the type and severity of diseases encountered. Generally, damping-off which occurs throughout India, is the most serious disease of young seedlings in forest nurseries. in temperate and drier regions, *Pythium, Fusarium* and *Macrophomina* are the dominant pathogens, whereas in tropical humid regions ubiquitous facultative parasites, *Rhizoctonia*, *Sclerotium* and *Cylindrocladium* are the major pathogens causing a wide variety of serious diseases. With the advent of root trainer nurseries problem of nematodes, otherwise unnoticed in conventional nurseries, has caused serious loss of teak seedlings in root trainers.

In plantations, various diseases affect the outplanted seedlings right from the beginning, till the time the crop is ready for harvest, the rotation period being from seven years in *Eucalyptus* to 60 years in teak. Since, some of the tree species are planted throughout the country under different agro climatic conditions in contrast to others limited to a particular climatic zone, two categories of diseases are identifiable: diseases of wide occurrence and diseases of restricted occurrence.

Among the serious diseases of wider occurrence, the prominent once are *Cylindrocladium* leaf blight (CLB) of *Eucalypts*, blister blight (BB) of *Casuarina (Trichosporium vesiculosum)* and phanerogamic parasite (mistletoe) of teak *(Dendroephthoe falcata)* which have been given some attention during the past two decades. However, bilster blight and teak mistletoe need more attention to work out strategies to control them. Since, CLB and BB are of international importance concerted efforts and networking of organizations in tackling them are warranted.

On the other hand there are certain diseases of restricted occurrence in a particular geographical area causing serious loss. Among them the important diseases are spike disease of *Santalum album* caused by phytoplasma, shoot blight of bamboos, heart rot of *Dalbergia sissoo*, *Cryphonectria* canker of *Eucalypts*, Hendersonula die-back of *Acacia mangium, Phomopsis* and *Macrophomina* die-back and *Melampsora* rust of *Populus*, and rust of native pines in Himalayas. Some of these diseases of restricted occurrence for example Hendersonula die-back are possibly manifested due to stress conditions under which the host is grown. Another category of diseases of rather recent origin is that appearing in high in-put plantations. The best example is that of pink disease of teak (*Corticium salmonicolor*) which came in prominence by causing more than 50 per cent incidence in high in-put plantations being grown by private companies as compared to 1-2 per cent in plantations raised by the State Forest Department. in the light of the above the paper evaluates the current status of some of the significant forest diseases in India and identifies priority areas of research for bridging the gaps in information for better management of diseases and increasing the much needed forest productivity.

Strategies linked to reduce the impact of *Cryphonectria* canker in South Africa

Schalk W. van Heerden, Michael J. Wingfield
University of Pretoria, Faculty of Biological and Agricultural Sciences, Forestry and Agricultural Biotechnology Institute (FABI, 0002 Pretoria, South Africa
FAX: +27124203938, Email: schalk.vanheerden@fabi.up.ac.za

Keywords: *Cryphonectria* canker; Population diversity; Double-stranded RNA

Cryphonectria canker caused by *Cryphonectria cubensis* is responsible for considerable damage to *Eucalyptus* plantations in tropical and sub-tropical areas of the world. It is, therefore, essential to have effective management strategies to limit the impact of this pathogen. Planting of disease tolerant clones is one approach, but the potential to reduce the virulence of the pathogen through double stranded (ds) RNA mediated-hypovirulence is also an attractive option. It is, however, necessary to possess knowledge regarding the population diversity of the fungus before biological control can be applied. in this study, a survey of diseased trees was undertaken to evaluate the occurrence of sexual reproductive structures, and thus to consider whether sexual reproduction is occurring in C. *cubensis* in South Africa. An experimental approach was undertaken to confirm these findings. The diversity of the South African C. *cubensis* population was assessed based on vegetative compatibility tests, and various measures of diversity were used to assess the data. A field inoculation was conducted to consider whether there was any correlation between VC groups and their virulence. Further the South African C. *cubensis* population was screened for the presence of dsRNA. Slow growing isolates were identified using growth studies and these were screened for dsRNA using column chromatography. Two dsRNA-containing isolates were obtained from a sample of 100 isolates. A greenhouse inoculation trial was conducted to determine whether the isolates containing dsRNA display hypovirulence. Results of this study showed

that only asexual reproduction occurs in C. *cubensis* in South Africa. Twenty-three VC groups were detected from a sample of 100 isolates each collected from single diseased trees in plantations in KwaZulu-Natal. Analysis showed that this represents a low degree of genetic diversity. Inoculation studies revealed that isolates belonging to different VC groups differ significantly in their ability to cause disease. Results of the inoculation to test for hypovirulence indicated that only one of the two isolates had a reduced capacity to cause disease. Studies are now being undertaken that will further promote the use of dsRNA for biological control of C. *cubensis* in the future.

7.02.10 Global spreading of pine wilt

Pine Wilt Disease: A Potential Threat to Coniferous Forests Around the World

Dale R. Bergdahl, S. Halik
University of Vermont, Department of Forestry, School of Natural Resources
Forest Pathology Laboratory, 05405 Burlington, USA
Email: dbergdah@nature.snr.uvm.edu

Throughout time, the distribution of the world's biota has not been static but has been gradually changing. This rate of change is much more rapid today because of biological invasions resulting from increased human activity, including international trade and travel and the disturbance of ecosystems. These invasions by exotic species include many unwanted forest pests, such as the pinewood nematode (PWN), *Bursaphelenchus xylophilus*, which has recently created havoc and concern around the world. This nematode is native to North America and is the causal agent of pine wilt disease (PWD) of *Pinus* spp., but other conifers may also serve as hosts. The PWN is vectored by *cerambycid* beetles (*Monochamus* spp.) which are normal inhabitants of coniferous forests worldwide. Different abiotic and biotic stress factors are reported to predispose trees to infection, however, variation in host specificity and pathogenicity has been noted for different PWN isolates. This nematode can also persist in living trees without inciting PWD.

As an exotic pest, the PWN is responsible for causing significant PWD in both native and exotic pines in Japan, South Korea, Taiwan, and The People's Republic of China. However, in North America, the PWN is not considered an important pathogen of native pines although it has caused PWD in some areas where exotic pines have been planted. The PWN is believed to have been introduced to Japan in logs from North America about 100 years ago, and today it is considered the most serious pest of pines by the Japanese. It is now also considered a very serious pathogen of pines in The People's Republic of China. The impact of this nematode and its vectors has resulted in enormous ecological, cultural, aesthetic, and economic impacts that will continue to create problems for generations to come. The PWN has a history of being transported in raw wood and wood products, and infested wood is believed responsible for spreading this nematode and its vectors both within and between Asian countries. Because of the perceived threat of PWD, some countries have established restrictions on importation or movement of coniferous wood from countries or regions of countries known to have the PWN. in Europe, a recent pest risk assessment concluded the PWN posed a potential threat to the continent's forests, so the nematode is now an A1 quarantine pest as described by the European Plant Protection Organization. As an exotic pest, the PWN should be considered a high-risk, disease-inciting agent for pine-growing regions worldwide. The threat of the PWN to coniferous forests is real and the only known way to reduce this threat is to be most restrictive in the importation and movement of potentially PWN-infested wood of all kinds.

Keywords: *Bursaphelenchus xylophilus*, pinewood nematode, *Pinus*, exotic pest, threat.

Unsuccessful experience in controlling the Pine Wilt in Japan

Kazuyoshi Futai
University of Kyoto, Japan
Email: futai@kais.kyoto-u.ac.jp

After the discovery of the pinewood nematode, *Bursaphelechus xylophilus* as a causal agent of the dreadful wilting disease of pine trees in 1970, enormous efforts have been made to control this forest epidemic disease.

Aerial application of insecticide has been carried out to obstruct maturation feeding of vector beetles on the healthy pine trees, thereby to prevent the transmission of nematodes into pine tissues. This measure seemed to be effective to reduce the pine wilt death, but has to been performed with many limitations because of environmental concerns. The procedure of felling down dead pine trees, and de-barking and then burning them should be effective, if carried out thoroughly, but this control measure has become impossible because of the shortage of forest workers. Trunk-injection of nematicides was developed to protect such precious pine trees as planted in gardens, golf courses, parks, shrines and temples. But this effective method has been able to apply neither to pine forests nor to mountain pine stands due to its high cost.

Without any limitations such as financial cost, labor shortage, environmental problems, could we be successful to control pine wilt disease? Perhaps, not. Because humankind itself has made an important role in long-distance transportation of pine wilt. The transportation of the pine logs infested with pine wood nematodes and/or with vector beetles has been legally regulated, but such dead pine trees have been transported from place to place, and thus pine wilt has spread over wide area. Further factors such as air pollutants, acid precipitation, difference in host resistance between local varieties of pines, difference in nematode virulence between isolates, and so on had to be taken into consideration to facilitate the control measures.

Another important point is that there may remain some potential carriers of pathogenic nematodes even after thorough sanitation of pine stands. When the carrier trees become stressed due to high temperature and/or drought, the host resistance could be impaired and nematodes build up their population to kill host trees. Thus, a few years after thorough control procedures, however, pine wilt epidemic could revive in the same pine stands.

Possible adaptation and pathogenicity of pinewood nematode, *Bursaphelenchus mucronatus*, in central European Russia

Oleg A. Kulinich, Vasyutin, A.S, Tjurin A.A.
All-Russian Research Institute of Plant Quarantine, Pogranichnaj 32, 140150 Moscow region, Russia
FAX: +7 096 46 22628, Email: kulinich@garnet.ru

The pinewood nematode, *Bursaphelecnhus xylophilus*, causes a serious wilt disease of native pines in Japan and China and is a quarantine pest for Russia. Based on a pest risk analysis for *B.xylophilus* it was concluded that this nematode poses a threat to conifer forests in several areas and territories of Russia (Kulinich, & Kolossova 1995). A closely related nematode, *Bursaphelenchus mucronatus* is widespread in Asia and Europe and may mate with *B.xylophilus*. Various experiments have shown that *B. mucronatus* is weakly pathogenic or non-pathogenic to pines. A field experiment to determine the pathogenicity of the different isolates of *Bursaphelenchus mucronatus* was conducted in the Moscow region (Russia) in 1996-1997. Two-year old, Scots pine, *Pinus sylvestris*, seedlings were inoculated in July, 1996, with each of three *B.mucronatus* isolates: BmCh (from China), BmKOMY (from Komy Republic, Russia) and BmRFE (from the Russian Far East, Primorski Krai). Control seedlings were inoculated with a solution of the fungi *Botrytis cinerea* and *Fusarium gramminearum* in distilled water. Initial inoculation was 1500 nematodes per seedling. The nematodes were extracted 2 months after seedling inoculation and again 1 year post-inoculation in September, 1997. Seedling stems, roots and soil were assayed for presence of *B. mucronatus* nematodes. No nematodes were found in seedling roots or soil. No seedlings had died 14 months after inoculation and only BmRFE isolate nematodes were extracted from seedling stem samples (1 inividual./g of stem tissue). All other nematode isolates failed to survival in seedlings. According to the recent studies of Eroshenko and Kruglik (1996), *B.mucronatus* isolates from Russian Far East were strongly pathogenic to different pine species under field conditions in Primorski Krai. Kulinich, O.A. and Kolossova, N.V. (1995) The potential of the pinewood nematode *Bursaphelenchus xylophilus* to become established in countries of the former USSR. Russian Journal of Nematology 3, 35-48.

Eroshenko, A.S. and Kruglik, I.A. (1996) [Korean pine pathogenic nematodes in the Russia Far East South.]. in "The cedar and deciduous forest of the Far East", Khabarovsk, 196-197 (In Russian).

Strategy of protection of European forests from pinewood nematodes

Christer Magnussen
The Norwegian Crop Research Institute, Plant Protection Centre, Department of Entomology and Nematology, Fellesbygget NO- 1432 Aas, Norway.
christer.magnusson@planteforsk.no

The widespread damage caused by the pinewood nematode (PWN) *Bursaphelenchus xylophilus* in Japan was well recognised by European scientists. There has been much controversy regarding the transmission biology of PWN, the danger of pine wilt disease and the risk management strategies. A pest risk assessment for the European Union (EU) has confirmed the quarantine status of PWN, justifying the phytosanitary measures taken to exclude this nematode from Europe. Furthermore, recent results from inoculation experiments indicate that PWN could pose a threat to pine forests of continental Europe. The total forested area of EU and Norway amounts to 146 million ha. The Nordic forests occupy almost 63 million ha, corresponding to 43% of this area. in the Nordic countries pine forests alone cover about 30 million ha. The annual softwood felling is in the order of 40 million m^3, which could represent a monetary value of about 3 000 million US$. The Nordic forests are of fundamental importance not only to the Nordic economies, but also as a major source of wood products for the entire EU. European coniferous forest ecosystems, regardless of locality, offer good opportunities for the establishment and spread of the PWN. The introduction of PWN into Europe could reduce forest productivity and enforce the erection of internal regulations of trade. There is also a risk of transfer of patogenicity from PWN to resident *B.mucronatus* by interbreeding. The most efficient strategy of protection is to prevent the introduction of the PWN. Preventive measures like forest selection and quality checks in processing would fail to detect latent PWN infections in asymptomatic trees. Thus, harvesting healthy-appearing trees for processing may not be adequate to prevent nematode infestation of wood products imported from areas infested by PWN. Heat treatments still remain the safest means of eradicating the PWN in wood. Methods should be developed to eradicate PWN also from forest products not suitable for kiln drying and pasteurisation. Treatments to eradicate PWN need also to apply for packaging and dunnage. in Europe efforts should be made to survey domestic wood products, and the forest areas for the presence of PWN and *B. mucronatus*, and to develop protocols suitable for monitoring nematode patogenicity on European conifers.

Nematode: characteristics and hazards of its global impact

John M. Webster
Simon Fraser University, Department of Biological Sciences, V5A 1S6 Burnaby, Vancouver, Canada
FAX: 604 291 3496, Email: jwebster@sfu.ca

Pine forests, one of the great natural resources of our planet, are threatened worldwide by the pine wilt disease caused by the pinewood nematode, *Bursaphelenchus xylophilus*, and its *Monochamus spp.* vector. The direct negative impact of the biological interaction between the *B. xylophilus* and susceptible pine trees has been exacerbated indirectly by wood product trading practices and by some misunderstanding of the biological relationship. Consequently, the potential seriousness of pine wilt disease to the world's pine forests is not always fully recognized, and appropriate action is not taken in the geographic areas where it is necessary in order to prevent and/or slow spread of the disease.

Bursaphelenchus xylophilus belongs to the family Aphelenchoididae, which includes many other nematode species that feed on fungi for some or all of their life cycle and which are closely associated with insects. Many bark beetles pests of forest trees carry aphelenchids in their intestine and vector them from one fungal-feeding site to the next in the cryptic galleries of the forest trees. There are about fifty *Bursaphelenchus* species many of which are associated with forest trees and insects but none of these are lethal like *B. xylophilus*. *Bursaphelenchus xylophilus* is most commonly vectored by *Monochamus alternatus* in east and southeast Asia, but many other *Monochamus* species worldwide, some with overlapping distributions, vector this nematode. *Aphelenchiodes ritzemabosi* interacts with *Rhodococcus fasciens* to cause cauliflower disease of strawberries, but no other aphelenchid species except *B. cocophilus*, the cause of red ring disease of coconut, causes host death. Both *B. xylophilus* and *B. cocophilus* cause death of the host tree within a few months of infection and both these nematodes require a mobile, plant-feeding coleopteran as the vector.

Many other tree species are parasitized by nematodes but none of them die so fast and the disease does not spread so rapidly. Orchard trees, are significantly affected by plant parasitic nematodes such as the citrus nematode, *Tylenchulus semipenetran*s (causing spreading decline of citrus) and the lesion nematode, *Pratylenchus spp*. (several species of which attack a range of fruit and nut tree species). However, the pathological impact of these nematodes tends to be modest and relatively gradual through wilting during drought and through nutrient depletion. These nematodes often do not significantly affect the host tree except during periods of severe plant stress. By contrast, *B. xylophilus* infected pine trees characteristically die within a few months of infection, though the physiological processes leading to tree death also can be exacerbated by stress factors such as fire and mistletoe. A few nematode species, *e.g. Aphelenchus avenae* and *Aphelenchoides composticola* debilitate forest trees by feeding on the mycorrhiza but this limits tree growth rather than causing death.

It is not only the susceptible pine species of our indigenous forests that are vulnerable to pine wilt disease but also the extensive monoculture plantings of susceptible, exotic, pine species especially in the southern hemisphere. These large areas of pine plantations are vulnerable if the temperature is high enough (about 25?C) for long enough (continuously for 8 weeks) and providing that an insect vector is present. Concurrently, there is extensive international trade of pine wood chips and bark-covered pine logs that potentially carry *Monochamus spp.* and *B.*

xylophilus from countries that have natural populations of *B. xylophilus* and its vector to countries that have susceptible pine species and appropriate climates for the disease. The high temperatures not only increase the rate of nematode reproduction but increase also the number of generations per year of the insect vector thereby quickly raising their population threshold for the disease to epidemic proportions. As well, the higher temperature stresses the trees physiologically in that within a few hours of nematode infection they lose water faster from the leaves and the tracheids became blocked.

Control of this nematode disease is difficult because it affects very large area of trees, often in less accessible areas, and the nematode population maintains itself on fungus infected dead trees as well as on living trees. As well, the vector is a vigorous flyer and survives on dead or dying trees. The development and propagation of genetically resistant trees is a viable though very long term option. Modification of trading practices could provide faster results.

Distribution of pine wilt disease and its spreading manner in China

Baojun Yang
The Chinese Academy of Forestry, Post Box # 12, 100091 Beijing, China
FAX: 0086-010-62884972, Email: nema@prot.forestry>ac.cn

Since the first discovery of PWN in Nanjing city, Jiangsu province in 1982,the nematode has distributed in 6 provinces Jiangsu, Anhui, Zhejiang, Shandong, Guangdong and Taiwan, as well as Hong Kong. There are 14 counties in Jiangsu, 16 counties in Anhui, 10 counties in Zhejiang, 3 counties in Guangdong, 1 county in Shandong. The total diseased area is about 70000 ha. The diseased pine species are *Pinus thunbergii* and *P. massoniana* mainly, as well as *P.densiflora*, *P.luchensis*, *P.elliottii* and *P. pinaster*. The vector of PWN is *Monochamus alternatus*. The phenomenon of the disease occurrence showes that the invasion of PWN into virgin areas is mainly caused by artificial transport of diseased lumber and packing box. The new diseased points are usually around new hotels,television transmission stations, factories, military units,public places and so on. Besides, it is supposed that wind, especially hurticane and typhoon, can bring the beetles (*Monochamus alternatus*), carrying PWN to virgin area far form the diseased area. Because the pines in small island can be attacked by PWN, the small island is above 7 miles from the diseased area and no body can go aboard the small island.

7.02.10 Epidemic factors of pine wilt

Ectomycorrhiza in pine forests infested with pine wilt disease

Kenji Fukuda, Shin Ugawa, Yu Ichihara, Kazuo Suzuki
The University of Tokyo, Department of Environmental Studies, 113-8657 Tokyo, Japan
FAX: +81-3-5802-2958, Email: fukuda@fr.a.u-tokyo.ac.jp

In order to clarify the relationships between the pine wilt incidence and ectomycorrhizas which may affect or be affected by vigor of host pine trees, fruit body occurrence and species composition of mycorrhizal fungi were surveyed in Japanese red pine stands exhibiting varying degrees of disease incidence around Mt. Tsukuba, Ibaraki Prefecture, Eastern Japan. in healthy stands many species of mycorrhizal fungi occurred, in contrast to the infested stands where mycorrhizal fungi were rare. From two healthy and one infested stands, soil cores were taken around living pine trees and mycorrhizal root tips were classified into morphological "types". Composition of mycorrhizal types among the stands were different from each other. However, in every stand mycorrhizas were formed on more than 95% of the observed root tips. From this fact, decline in fruit body number in infested stands was not caused by decrease of mycorrhiza on pine roots, but the decline of fruiting activity of the mycorrhizal fungi. Mycorrhizal growth in 5-year-old pine seedlings inoculated with pinewood nematodes were markedly inhibited in both killed and survived seedlings. This indicates that infection of nematode reduce the allocation of carbohydrates to the mycorrhiza. From these results, fruiting activity of ectomycorrhizal fungi seemed to be greatly influenced by the pine wilt damage not only by the death of the host tree, but also by the latent infection.

Wilt diseases- induced xylem embolism in trees

Takefumi Ikeda
Kansai Research Center, Forestry and Forest Products Research Institute, 621-0855 Kyoto, Fushimi, Japan
FAX: +81-75-611-1207, Email: takefumi@fsm.affrc.go.jp

Recently in the research field of tree water relations, the mechanisms and ecological meanings of the cavitation and the embolism in the tree xylem occurred during water stress and by freeze-thaw event have fairly been made clear. Three major wilt diseases are the Dutch elm diseases, oak wilt and pine wilt disease. Although it has been known that wilt disease induced water stress in their host by reducing the hydraulic conductivity of the cylem, embolism as a cause for this has received very little attention. in the case of Dutch Elm disease, embolism precedes any occlusion of vessel by other means. The exact causes of cavitation and embolism remain unclear. Pine wilt disease is characterized by rapid wilting during a short period of summer. The occurrence of cavitation and embolism during the disease development has been confirmed. This paper shows the general mechanism of cavitation and embolism occurred in trees suffered from three major wilt diseases.

Insect vector-nematode relationship and virulence of nematode against host plants.

Infestation level of parasite and disease-causing organisms is associated closely with a relationship between their virulence and transmission ability. Rapid change in virulence sometimes occurs by the introduction of the parasite into new ecosystems. How much does the enhanced virulence change transmission ability and its components? Pine wilt caused by the pinewood nematode gives an interesting case to study the virulence-transmission relationship. The pinewood nematodes (*Bursaphelenchus xylophilus* and *B. mucronatus*) are transmitted to healthy trees by pine sawyer beetles (the genus Monochamus) and the beetles oviposit on trees killed recently by virulent nematodes. Interestingly, the nematodes are also transmitted to dying trees via the oviposition wounds made by the beetles. So, different nematode virulence against host trees must affect the vector-nematode relationship. I used 3 systems for analysis; the Japanese *B. xylophilus-M. alternatus* system including virulent nematode against host trees, the Japanese *B. mucronatus-M. saltuarius* system including avirulent nematode, and the American *B. xylophilus-M. carolinensis* system including avirulent nematode.

Field study shows that avirulent nematode has much higher transmission rate per tree per year (0.13-0.17) than virulent nematode (0.0050-0.0064) in Japan. Thus, a negative relation is found between virulence and transmission ability. A wide variation is observed in the initial nematode load on insect vector. Extremely heavy nematode load makes beetle longevity shorter. As the nematode load increases, such effect is much larger for virulent nematode than for avirulent nematode. This seems to have influence on the frequency distribution of initial nematode load. Actually, its peak is biased toward lower load for virulent nematode while toward higher load for avirulent nematodes. Longevity-shortening effect of nematode load causes beetle's reproductive capacity to decrease. Such deleterious effect on beetle's reproductive capacity is estimated to be highest for the American *B. xylophilus-M. carolinensis* system and lowest for the Japanese *B. mucronatus-M. saltuarius* system. Short life of beetles is also related with the probability of nematode's surviving till successful invasion of pine trees. The deleterious effect on survival rate of nematodes is estimated to be much larger for virulent nematode.

The study of the pinewood nematode showed that a negative relation between virulence and transmission rate. Some components of nematode transmission ability is considered to be associated closely with nematode virulence and other with a short length of time during which species interactions have been continuing in Japan. I will compare the virulence-transmission relation among biological systems including nematode, insect vector and host plants.

Recent advances in studies on chemical ecology and behavior of the Japanese pine sawyer adult

Akiomi Yamane, Ryutaru Iwata
Nihon University Kameino, College of Bioresource Sciences, 252-8510 Fujisawa, Kanagawa, Japan
Tel: 81-466-84-3663/3664, FAX: 0466 80 11 35, Email: akyamane@brs.nihon-u.ac.jp

Keywords: pine sawyer, chemical ecology, attractant, oviposition, feeding

Factors affecting oviposition, feeding, etc. of *Monochamus alternatus* (JPS) were reviewed. Mature adults of both sexes are attracted to the suitable oviposition site, freshly felled pine bold, diseased pine tree caused by *Bursaphelenchus xylophilus* (PWN), etc. Female shows a series of actions; oviposition behavior sensu lato and sensu stricto. The orientation to the site is mediated by odor, of which the major components are monoterpenes and ethanol. Besides the attractant, some new substances were found to stimulate or mask attractiveness of oviposition site. Differences in attraction behavior between sexes were also reported.

For control and monitor the pine bark and wood-boring beetles which had been considered to be causal agents being responsible to deteriorate and kill pines "Hodoron", an attractant formulation for those beetles including JPS, of which the main components are eugenol (9.0%), benzoic acid (23.0%), iso-propanol and other organic solvents, had been developed. Since the findings of PWN and JPS, another attractant "Madara-call" had been developed for JPS attraction, of which main components are pinene and ethanol.

Both volatile and contact sex pheromones concerning mating were reported, but most of their nature remains unknown. Presence of jelly-like oviposition marker on oviposition acar and inhibition of another additional oviposition nearby the laid egg were reported.

For oviposition adequate moisture on the host surface was essential. Some sugars, sterols, etc. stimulated feeding and/or biting. Some new chemicals stimulating oviposition were reported recently.

So many behaviors of JPS are known to be closely associated with certain chemicals. Some of their stimulus-response relation have been described and elucidated, but most of them remains unknown yet. Toward the integrated pest management of pine wilt disease, especially that of JPS, behavior-controlling method could contribute greatly to the system, and we anticipate development of researches in the science and technology along this line in the near future.

7.03.00 Review of recent developments in the management of major tropical forest insect pests. Theory and practice

Management of the Sal Heartwood Borer, *Hoplocerambyx spinicornis* in India

R. K. Dey
State Forest Research Institute, Polipathar, Jabalpur, (482 008) Madhya Pradesh, India
Tel: 91-761-25540(off), FAX: 0097-761-411304, Email: kptiwari@hotmail.com

Keywords: *Hoplocerambyx*, sal, borer outbreak, *Shorea robusta*, trap-tree operation)

The sal heartwood borer, *Hoplocerambyx spinicornis* Newman (*Coleoptera*, *Cerambycidae*) is considered the most destructive forest pest in India and is well known for its periodic outbreaks in high risk sites. An epidemic which began in 1994 in Madhya Pradesh provided an opportunity to study the behaviour of the pest and the response of the host, on the face of the existing outbreak management system, which relies on (1) removal of infested trees and (2) trapping beetles using trap trees and killing them. Observations over a two-year period from March 1998 to February 2000, revealed several interesting features of the rise and fall of infestations, which are reported here. There was a definite preference of the pest for trees of higher girth class, throughout the epidemic. Some of the infested trees recovered in course of time. Removal of sparsely infested trees may also mean removal of potential new infestation sites, thereby increasing the risk of infestation of un-infested trees. Tests showed that beetles were attracted to light traps. Incidence of the elaterid predator, Alaus sp. was recorded.

The findings of this study suggest rethinking and refinement of the existing recommendation for sal borer outbreak management, particularly, limiting the removal of trees to the more severely infested categories. Future research should focus on (1) isolation of the chemical attractant present in the tree sap and developing suitable mechanical trapping devices using the attractant chemical(s) to replace the traditional tree-trap, (2) standardizing the use of light trap for trapping beetles, and (3) exploring the scope of using the elaterid predator for biological control. International cooperation will be useful for isolation and synthesis of the attractant sap chemical(s).

Teak Beehole Borer, *Xyleutes ceramica*: Ecology and Management

Chaweewan Hutacharern
Forest Research Office, Royal Forest Department, 61 Paholyotin Road, 10900 Bangkok, Thailand
Tel: +66-2-5798775, FAX: +66 2 5789775, Email: Chahut@forest.go.th

Keywords: Teak beehole borer, *Xyleutes ceramica*, control

The teak beehole borer, *Xyleutes ceramica* Walker (*Lepidoptera*, *Cossidae*) is the most important pest of teak in Thailand, in terms of its effect on reducing wood quality. It is also a serious pest in Myanmar, Thailand and Malaysia. This moth caterpillar bores in the wood of standing teak trees, making a big tunnel in the sapwood and heartwood, thereby causing serious depreciation of wood quality. Infestation takes place throughout the life of the tree and a 40-year old tree may have up to 165 tunnels. Infestation is localized; in some plantations, particularly in northern Thailand, up to 100 per cent of the trees may be infested.

Current control practices include removal of young larvae by scraping the infested bark using a knife, injection of insecticide into larval holes and trapping of newly eclosed moths. There is also indication of presence of beehole borer resistant provenances.

In Thailand, research has concentrated on life history and study of the sex pheromone. in collaboration with Japan International Cooperation Agency, the sex pheromone has been identified, purified and bioassayed and its use for monitoring and management of the beehole borer is being standardised.

Management of the Teak Defoliator, *Hyblaea Puera* - Current Status

K. S. S. Nair
Kerala Forest Research Institute, T.C. 9/1171 (3), Mangalam Lane, Sasthamangalam, 695 010 Trivandrum, Kerala, India
Tel: 91-471-310 470, FAX: 91-471-325 674 (attn: KSS Nair), Email: kssnair@md4.vsnl.net.in

Keywords: teak defoliator, *Hyblaea puera*, baculovirus, population dynamics)

Currently, there is an unprecedented expansion of teak plantations across the tropics. They are managed intensively to get maximum yield in a short rotation period. in this context, this paper examines the current status and prospects for management of the major teak pest, *Hyblaea puera* Cramer (Lepidoptera, Hyblaeidae). Commonly known as the teak defoliator, *H. puera* has been recognized as a serious pest of teak plantations for over a century. Originally distributed in the natural teak belt of the Asian tropics, it has now spread, along with teak plantations, to other tropical countries, particularly in the Asia pacific and some central American and African regions. Severe outbreak has recently been reported from Costa Rica. in most teak growing countries in the Asia Pacific, extensive and repeated outbreak of this defoliator is a spectacular, annual feature during the early part of the growth season. It was estimated to cause an annual loss of up to 3 cm^3 of potential volume increment per hectare of plantation.

Past recommendations for management, which relied on augmentation of native insect parasitoids through promotion of the alternative hosts of the parasitoids by manipulation of the vegetation cover, proved inadequate because of the unique population dynamics of the pest. Aerial application of chemical insecticides, although tried in the past, cannot be practiced widely because of environmental considerations. Search for genetic resistance to the pest did not yield useful results. The present situation on teak defoliator management is as follows. (1) in the extensive teak plantations maintained by Government Forest Departments or Government sponsored agencies in India, Myanmar, Thailand and Indonesia, generally no control measures are practiced and the plantations continue to suffer loss of increment. (2) in high-value plantations over small areas in Thailand, as well as on an experimental scale in India, the microbial insecticide, Bacillus thuringiensis is applied aerially. (3) in plantations raised by individuals and private commercial companies in several countries, including India, Thailand, Malaysia, and Costa Rica, chemical insecticides are applied aerially, in some situations. This practice is now on the increase due to the rapid expansion of commercial teak cultivation across the tropics and poses a threat to environmental quality.

Current research on teak defoliator management, particularly in India, focuses on the one hand, on the potential of total population management by preventing large-scale outbreaks by controlling the population build-up in the early outbreak epicentres and, on the other hand, use of a baculovirus isolated from H. puera. Scientific understanding of the causation of the sudden outbreak of this pest that follows the early monsoon rains and spreads subsequently over extensive areas, is essential for developing appropriate management strategies. Recent research in India has suggested two hypotheses for outbreak initiation- (1) wind-aided concentration of dispersed local populations, (2) Long-distance displacement of pre-existing high-density populations between countries.

Status and Management of Small Coleopterous Borers in Living Timbers in Tropical Africa

Hans G. Schabel, Seif Madoffe
University of Wisconsin, College of Natural Resources, WI 54481 Stevens Point, USA
FAX: (715) 346-3624, Email: hschabel@uwsp.edu

Keywords: Africa, Natural forests, Plantations, Bostrychidae, Platypodidae, Scolytidae

As natural forests in the tropics continue to shrink and plantation area increases, there is growing concern for the health of both. Managed forests and plantations in Africa often face difficult physical environments in combination with serious interference from pests, including insects. Among these, several borers are notorious for diminishing the quality of precious woods, either while a tree is still living or after its harvest. This paper synthesizes existing knowledge concerning three families of small, coleopterous borers (Bostrychidae, Platypodidae, Scolytidae), which are or may become, pests in living timbers in tropical Africa.

With a few exceptions, small coleopterous borers in Africa are polyphagous. They rarely attack healthy trees or seedlings, and direct mortality of hosts, other than heavily attacked seedlings, is exceptional. Their activity seems largely restricted to nurseries and plantations and their impact is mostly felt in conjunction with dry seasons, fire or other injuries.

Given global warming trends, increasing international commerce and future expansion of plantation culture, this group of insects could become a more serious factor in timber production and trade. Potential methods of dealing with them are discussed. It is suggested that in addition to cooperative quarantine efforts and innovative pest control methods, wherever feasible, the emphasis should be cultural i.e., a shift from plantations to more natural forest management, emphasizing more complex stand composition and structure.

7.03.03 Insect Pest Problems in Replanted Forests

Screening spruce for genetic resistance to white pine weevil in British Columbia, Canada

Rene Alfaro, John N. King, Cheng Ying, George Brown, Kornelia G. Lewis
Natural Resources Canada, Canadian Forest Service, Pacific Forestry Centre, 506 West Burnside Road, V8Z 1M5 Victoria B.C., Canada
Tel: 1-250-363-0660, FAX: 1-250-363-0775, Email: ralfaro@pfc.forestry.ca

The white pine weevil, *Pissodes strobi* Peck (Coleoptera: Curculionidae) is the most serious native pest of spruce regeneration in British Columbia, attacking primarily Sitka (*Picea sitchensis* (Bong.) Carr), white (*P. glauca* (Moench) Voss), and Engelmann spruce (*P. engelmanni* Parry). The weevil has one generation a year. The eggs are laid from late April to June in punctures made by the female in the bark below the buds of the terminal (year-old) shoot. The larvae burrow downward in the bark, feeding on the phloem, which eventually kills the terminal. Destruction of the apical shoot reduces growth and causes deformities.

With respect to white spruce, a large family trial near Clearwater, British Columbia, has been surveyed annually for weevil resistance between 1993 and 1998. The latest results confirm a preliminary resistance raking of each family developed in 1994 using an index which measured intensity of attack (number of attacks per tree), severity of each attack (how many internodes were destroyed) and tree tolerance to attack (i.e., if tree develops good form after an attack). The study demonstrated significant genetic variation in the attack resistance. Variation in resistance was related to ecoclimatic conditions of the parental tree source. Analysis showed that those parents from locations with high weevil hazard yielded higher proportion of resistant trees. These sites are primarily low elevation, low latitude sites, especially on Moist-Warm habitats of the Sub-Boreal-Spruce (SBS) biogeoclimatic zone.

On Vancouver Island Sitka spruce, screening has been conducted in seven test sites. Recent results obtained from measurements of weevil attack in new trials established by the BC Ministry of Forests, confirm the Big Qualicum area of Vancouver Island as a good source of resistant genotypes. To accelerate the screening process, and create a uniform weevil pressure, insect populations have been augmented at several trials. Spruce families with resistance have been able to withstand very high weevil populations. At Port Renfrew, BC, weevil attack was increased from less than 1%/year to 51% in one year, yielding new selections.

We hope that these new selections, along with earlier results, will form the basis for successful establishment of Sitka spruce plantations in B.C. These trials are also yielding important information on the population dynamics of the white pine weevil, the importance of its parasitoids in population control, the role of fungi in the weevil/host system as well as information on possible resistance mechanisms. We expect to integrate resistance as a component of an Integrated Pest Management System. An important consideration when utilizing resistant genotypes in reforestation programs is its deployment in mixtures with susceptible stock. Deployment of these genotypes should, at all times, take into consideration the need for avoiding the risk of insect selection

Insect pest problems in plantations in the high forests of Africa

Joe R. Cobbinah
Forestry Research Institute of Kumasi, Kumasi Ghana
Tel: +233 51 60122, FAX: +233 51 60121, Email: forig@africaonline.com.gh

Plantation forestry is a relatively recent phenomenon in the humid Tropical Africa probably because of the rich natural forests. However the high rate of deforestation (1.2%) coupled with the ever increasing population have necessitated the establishment of forest plantations to meet growing demand and variety of needs. Whilst pest problems are largely unknown in the natural forests serious problems have been reported in the replanted forests. Pests such as *Phytolyma lata Hypsipyla robusta*, *Lamprosima lateritialis*, *Apate monachus*, *Angophe venuta*, *Godasa sidae* and many others have hampered the establishment of native species plantations. The Cypress aphid *Cinara cupress* and *Leucenia psyllid. Heteropsylla cubana* have also had devastating effect on introduced plantation species.

The ecological implications to the broader issues of why pests are more devastating in planted forests and not natural forests and why exotic species are more prone to attack than native tree species are discussed.

The effect of biocontrol agents on populations of the large pine weevil (*Hylobius abietis*) in Ireland.

Keith Day, Cliff Henry
Environmental Research, University of Ulster, BT52 1RW Coleraine, United Kingdom
FAX: +44 1265 32 49 11, Email: kr.day@ulst.ac.uk

The large pine weevil (*Hylobius abietis*) continues to be a significant economic pest in Irish plantation forests where it inhibits re-establishment of transplanted conifers on clear-felled sites. Two broad approaches are considered when attempting to reduce the level of the damage caused by weevils. The first is to prevent or at least reduce the access of adult weevils to transplants while they are still small enough to sustain lethal damage. This is currently achieved using topical pesticides applied prior to transplantation, but in future this practice may be replaced by reliance on a combination of greater plant resistance and other silvicultural measures. The second approach is to reduce the productivity of weevils on the mosaic of clear-felled patches within forests where the problem is most acute.

Weevils breed in stumps of conifers left in the ground after felling. Stumps can be made less productive for larval development, or the adults, pupae and larvae could become more likely to suffer disease, predation or parasitism. A well-orchestrated and forest-wide strategy to suppress the weevil challenge to transplants, could add significantly to the first approach and lead to sustainable pest management (Leather et al. 1999). Ideally this would involve zero pesticide use, be at minimal cost and not affect forest biodiversity.

The parasitoid *Bracon hylobii* Ratz. selectively attacks the larvae of *Hylobius abietis* while they are below bark in the subterranean parts of tree stumps. The parasitoid is widespread on forest sites in the UK and in Ireland. On plantation clearfell sites studied over several years, it was found that a mean of 47% of larvae were killed by parasitism and a maximum rate of parasitism of 67% was observed. Only a small proportion of weevil larvae seem to occupy habitats inaccessible to parasitoids, and the hosts are available for parasitism for a long period during development. Research is being carried out to ascertain which forest conditions most clearly favour high levels of parasitism, and what relationship parasitism has to other biological controls such as the use of entomopathogenic nematodes.

Reference: Leather, S.R., Day, K.R. and Salisbury, A.N. (1999) The biology and ecology of the large pine weevil, *Hylobius abietis* L.: a problem of dispersal? Bulletin of Entomological Research, 89: 3-16.

Approach for an efficient control of defoliating insect damage: case of *Godasa sidae* (Lep. Noctuidae) attacks on *Mansonia altissima*

Bernard Foahom
IRAD/Tropenbos Cameroon Programme, Post Box # 219, Kribi, Cameroon
FAX: (237) 46 14 19, Email: 105405.1222@compuserve.com

It is a well-known fact, the impact of insect defoliation of forest tree species. *Godasa sidae* is a major pest of *Mansonia altissima*, one of the most important timber tree species in West and Central Africa regions. It has a high reproductive potential and a short life cycle, leading to many overlapping generations per year. However 2 outbreaks occur in the course of the year leading to a complete defoliation (100%) of the trees in plantations. Fourth and fifth instar larvae are those involved in the high intensity defoliation of the trees (more than 50% of defoliation is observed at these stages).

It was observed that the outbreaks are closely linked to the tree phenology for they occur when the leaves are suitable for eggs lying and young larvae feeding/survival.

The present paper addresses the what and how of the application of any control measure, with special attention to potential biological control.

Possible ways for an effective control of pest damage are discussed here. It is concluded that any efforts to undertake the control damage on trees as a result of defoliation must take place before the outbreak occurs, that is at an early stage of the pest life cycle.

Impact studies for a non-lethal pest (aphids, *Elatobium abietinum*) on spruce seedlings and mature plantations

Nigel A. Straw, NJ Fielding and G Green
Forest Research, Alice Holt Lodge, Wrecclesham, Farnham, GU10 4LH Surrey, United Kingdom
Tel: 01420 22255, FAX: 01420 23 653, Email: straw@forestry.gov.uk

Sitka spruce is the most important commercial tree species in the west and north of Britain. Over 530 000 ha of Sitka spruce have been planted since the 1920s and about 5000-6000 ha of new plantings and restocking of Sitka spruce currently takes place annually. However, spruce plantations throughout the UK are susceptible to attack by green spruce aphid, *Elatobium abietinum* (Walker) (Aphidadae), which can cause severe defoliation of older needles. Young spruce trees in plantations are also often infested with root aphids (*Pachypappa* and *Pachypappella* spp., *Pemphigidae*), especially up to and during the thicket stage. The impact of these aphids on the growth of young Sitka spruce has been investigated by means of a long-term, manipulative field experiment in Hafren Forest, Wales, involving insecticide exclusion of aphids and artificial infestation of trees, and a series of nursery trials on pot-grown plants carried out at Forestry Commission research stations. Results from these studies indicate that whereas root aphids at typical field densities have no detectable effect on the increment of established plants, *E. abietinum* has an immediate and lasting effect on tree height growth and a delayed effect on stem diameter and volume.

Height increment is typically reduced by 20-30% by the end of the season following moderate-severe infestation in the spring, and is further reduced in the following two years, although by a smaller amount. Stem diameter and volume increments are not reduced in the year of infestation, but show typical reductions of 10-15% and 20-25% respectively, in the second year. Diameter and volume increments generally return to normal in the third year. The almost exponential growth of young spruce trees after establishment and rapid replacement of lost foliage means that effects on increment from single defoliation events are short-lived, but the corresponding losses in total height and total stem volume persist and are still evident up to 5 years later.

7.03.07 Biological Invasion of Forest Insect Pests - Agents of global change

Butternut Canker: An Exotic Threat to Juglans cinerea

Dale R. Bergdahl, S. Halik
University of Vermont, Department of Forestry, School of Natural Resources, Forest Pathology Laboratory, 05405 Burlington, USA
Email: dbergdah@nature.snr.uvm.edu

Butternut (*Juglans cinerea* L.) is considered a minor component of the hardwood forests of eastern North America, yet it is highly valued as a commercial wood with a diversity of uses. This species also provides mast for wildlife and adds significantly to the biodiversity of our forests. However, the butternut canker fungus (*Sirococcus clavigignenti*-juglandacearum Nair Kostichka, and Kuntz) has decimated butternut throughout its range in eastern North America during the past 30 years. This fungus kills trees of all ages and also has been found to infest nuts. The fungus kills trees by causing multiple branch and stem cankers that will eventually girdle the tree, but multiple infections may also predispose the tree to attack by other opportunistic organisms which tend to hasten tree mortality. However, small branches and young trees are usually killed by a single canker.

Recent forest inventory data indicate that butternut canker has had a major impact on butternut survival during the last several decades. For example, in North Carolina and Virginia, 77% of the butternut trees were lost between 1966 and 1986, and Michigan has reported an 84% reduction in the species during the same period of time. A 1993 survey in Wisconsin found that 91% of live butternut trees were diseased and 27% of the total population surveyed were dead. in 1995-96, butternut canker was found on 94% of trees in the Lake Champlain Basin of Vermont and approximately 25% of the trees surveyed at that time were dead. Due to crown dieback, nut production appears limited and regeneration in the Vermont surveyed stands is lacking. Because of concern for butternut, several states have placed a moratorium on cutting healthy trees growing on state lands, and the USDA Forest Service has introduced butternut harvesting guidelines for National Forest lands. Also, the Forest Service, in cooperation with several state and academic institutions, has initiated a tree selection program based on phenotypic disease resistance. Some selections have been made and they are now being propagated by grafting.

The origin of *S. clavigignenti-juglandacearum* remains unknown, but it is believed to be a recently introduced exotic pathogen because of the rapid way the fungus has spread throughout the range of butternut, the aggressive nature of the fungus, the scarcity of disease resistance in the host, and the apparent lack of genetic diversity in the fungus population. Because of the serious impact of this canker disease, butternut is currently listed as a category 2 species and it soon may be placed on the federal government's threatened and endangered species list. Butternut already has been eliminated from the standpoint of sustainable wood production, and the future of butternut as a viable species now remains in serious question throughout the hardwood forest of eastern North America.

Occurrence of *Bursaphelenchus* species (Nematoda, Aphelenchoididae) worldwide and their international spread by coniferous timber trade

Helen Braasch
Federal Biological Research Centre for Agriculture and Forestry, Department for National and International Plant Health, D-14532 Kleinmachnow, Germany
Email: H.Braasch@BBA.DE

Keywords: *Bursaphelenchus* spp., distribution, conifers, wood, timber trade, spread

About 50 *Bursaphelenchus* species are known to occure worldwide. Due to new descriptions during recent years, their known number is increasing. These nematodes are, preferably, inhabitants of wood. Approximately two thirds of them live in conifer trees. They are distributed throughout the forests of the northern hemisphere and spread by insect vectors. Most of them are associated with Scolytidae, several species with Cerambycidae, Curculionidae or even Nitidulidae. Human activity is known to be the pricipal route for dispersal of *Bursaphelenchus* species over greater distances. *Bursaphelenchus* species have been intercepted on a number of occasions during international trade in wood and wood products. They easily survive adverse conditions. The likelihood of *Bursaphelenchus* species to be transferred to susceptible trees in new regions increases with the simultaneous presence of vector insects in the commodities.

South Africa is the only place in the southern hemisphere, where a determined *Bursaphelenchus* species (*B. leoni*) is known to occur. It has most probably been imported from the Mediterranean region. The most important species of the genera is B. *xylophilus*, the pinewood nematode, which has been imported with wood from North America to Japan. This nematode has been spreading by way of timber trade in East Asia and causes huge damage to pine forests in Japan, China and Korea. in 1999, the pinewood nematode was introduced into Europe and is now established in a restricted area in Portugal. Its introduction pathway is unknown. Some other *Bursaphelenchus* species, chiefly B. *mucronatus* and B. sexdentati have been found to exhibit a phytopathogenic potential in inoculation experiments. B. *mucronatus* is the most abundant species in timber imports from Russia.

The distribution of *Bursaphelenchus* species depends on geographic regions as well as on the availability of breeding places and vectors. *Bursaphelenchus* fauna differs from region to region and is basically divided into American and Eurasian species. Within Europe, preferences of species can be seen for southern and northern Europe. Some species and their vectors occur in Europe, Siberia and East Asia, others seem to be restricted to Asian far eastern regions. Several new records are presented. Temperature is important for the incidence of damage caused by relevant species on suitable hosts. Increasing international timber trade offers the possibility of their world-wide spread. Risks and limits of this process are discussed.

Studies on insect invasions in California's urban forests

D.L. Dahlsten, N. Brownfield, K. Stidt, D.L. Rowney, W.A. Cooper
University of California, 201 Wellman Hall,ESPM, Center for Biological Control, 94720-3112 Berkeley, California, USA
Tel: 510-643-5325, FAX: 510-642-7428, Email: donaldd@nature.berkeley.edu

California has a long history of invasions of exotic insects dating back to cottony cushion scale on oranges in the late 1800's. Since then there have been a number of successful invaders facilitated by major ports of entry and international airports. Urban forest invaders such as the elm leaf beetle have become major pests not only in California but in the United States. There are two major tactics that are used in dealing with these pests - eradication and biological control. Eradication programs have been very controversial due to their reliance on chemical pesticides. More recently biological control programs have come under scrutiny due to potential threats to native species and biodiversity. We have chosen to pursue what we believe to be the least disruptive approach - biological control.

We have studied three invading urban forest species in our laboratory - the elm leaf beetle, Xanthogaleruca luteola, the blue gum psyllid, *Ctenarytaina eucalypti*, and the eugenia psyllid, *Trioza eugeniae*. Our studies have resulted in an IPM program for one insect, complete biological control for another, and a partially successful biological control program for the other.

More recently an extensively planted exotic tree, *Eucalyptus camaldulensis*, river red gum, has been colonized by the red gum lerp psyllid, *Glycaspis brimblecombei*. Populations of this leaf sucking, honeydew producing insect have reached such high densities that trees have been defoliated in many parts of California. To date the insect has been found in 30 counties. It was found initially in Los Angeles in June of 1998 and spread rapidly throughout the state shortly after. in addition, the red gum lerp psyllid has been collected from 20 other *Eucalyptus* species planted throughout the state. We have confined our studies initially to river red gum, as this is the tree that is most seriously affected by the feeding of the psyllid.

With each of the invading species that we have studied we have used a similar approach. To begin with we sampled to determine the distribution and abundance of the life stages of the invading insect. We followed this with the development of a monitoring program. With the elm leaf beetle we use a presence-absence technique with the egg stage in the lower crown of the elms. With the psyllids we use yellow sticky traps for adults. Interestingly, the parasitoids of both the blue gum psyllid and the eugenia psyllid are attracted to the yellow traps which facilitates our evaluation of the efficacy of the natural enemy. Once the monitoring technique is in place we initiate foreign exploration and the importation of the natural enemies. We follow the parasitoids in quarantine to be sure that they are primary on the insect being studied and once we feel that they are specific to the host and relatively safe we release and evaluate the natural enemy's role in the dynamics of the pest population.

Without more rigid regulations, insects will continue to be introduced into California's urban forests, and some will become pests. We feel that our approach is the best long term solution to dealing with invasions of exotic forest insects.

Evaluating the risk of invasion by potential forest pests

Hugh Evans, Richard Baker
Forest Research, Alice Holt Lodge, Wrecclesham, Farnham, GU10 4LH Surrey, United Kingdom
FAX: +44 1420 23653, Email: h.evans@forestry,gov.uk

The rapid increase in volume, frequency and variety of global trade, together with the high speed at which it is conducted has resulted in many examples of pest establishment in exotic locations. This is certainly the case for forest pests where wood as a product in its own right and, especially, as packaging material for other products, is being moved around the world in very large volumes.

The risks associated with wood as a pathway for pests are recognised by national plant health services and Regional Plant Protection Organisations (RPPOs) and there is an increasing need for relevant and robust risk assessment methods that can be used consistently worldwide. in this paper we show how a pest risk assessment (PRA) scheme developed by the European and Mediterranean Plant Protection Organisation (EPPO) has been employed in the UK to carry out assessments of a number of potentially serious forest pests. We highlight the strengths and weaknesses of the scheme. The determination of environmental suitability in PRA is of key importance and we show how assessments can be improved by the use of predictive models, such as CLIMEX. Thus, based on pest status in their country of origin, some pests, such as the southern pine beetle (*Dendroctonus frontalis*) in the USA, appear to pose a high potential hazard but we show that local environmental conditions in the UK are unlikely to support successful pest development, even if initial establishment is possible. By contrast, the establishment of an Asian longhorn beetle, *Anoplophora glabripennis*, in the USA illustrates how a pest that is relatively unimportant in its country of origin can cause greater problems in a new location. A PRA on *A. glabripennis* indicates that the major pathway in international trade is wood used for packaging and showed, using CLIMEX, that this pest could establish in large areas of Europe. Such an example serves to emphasise that organisms with relatively low pest status in their country of origin may pose a high potential hazard in new locations, but the risks these pests represent is much more difficult to assess. in addition, there may also be unexpected establishment of pests, even though a priori evaluation indicates that risks are low. We illustrate this by describing the discovery of an infestation of the subterranean termite, Reticulitermes lucifugus, in the south-west of the UK. This appears to be just one of an increasing number of examples of pests expanding their ranges beyond the climatic limits previously thought to limit their successful development.

Incursion management drawing on recent New Zealand examples

E. Ruth Frampton
Ministry of Agriculture and Forestry, PO Box 2526, Wellington, New Zealand
Tel: +64 4 4989639, FAX: +64 4 4989888, Email: Framptonr@maf.govt.nz

Like other trading countries New Zealand has been continually subject to incursions of exotic arthropods and diseases. For the purposes of this paper, the term 'incursion' means an occurrence of an organism not previously known to be established in New Zealand, and does not include interceptions. While it is not always possible to predict the impacts of such incursions, there is no doubt that the number of these is increasing and different approaches are required to their management.

More often than not incursions of forest-inhabiting species are detected in urban situations. Clearly, conservationists, local authority arborists and production foresters favour the implementation of eradication programmes for those organisms that are potentially pests of forest tree species. However, eradication programmes are becoming more difficult to initiate in urban areas particularly with residents' concerns about pesticide use. Moreover, conflicts of interest arise between urban dwellers and programme beneficiaries - obvious programme beneficiaries being the rural forestry and horticultural sectors. Recent New Zealand examples of incursions of particular relevance to the forestry sector include: two lymantriid species, *Orgyia thyellina* (white spotted tussock moth) and Teia anartoides (painted apple moth); Stegommata sulfuratella; gum leaf skeletoniser (*Uraba lugens*); and *Ophiostoma novo-ulmi*, the causal organism of Dutch elm disease. The varying responses to the incursion of these organisms are outlined and compared with recommendations for future programmes.

Invasive Bark and Wood-boring Beetles in Western Canada

Leland M. Humble
Pacific Forest Research Centre, 506 West Burnside Road, V8Z 1M5 Victoria, British Columbia, Canada
Tel: 250-363-0644, FAX: 250-363-0775, Email: lhumble@pfc.forestry.ca

The introduction and establishment of non-indigenous insects in forest ecosystems is a continuing consequence human activity. Ongoing studies of the introduction and establishment of invasive bark and wood-boring insects around the major Canadian port of Vancouver, British Columbia, have shown that six previously unrecognized exotic species of *Scolytidae* and *Cerambycidae* have established in the urban forests. They include species originating from north temperate Europe and Asia, the subtropics, and from eastern North America. Four of these five Scolytidae have also been introduced into eastern North America and/or Europe through commerce.

Within urban forest sites, this recently discovered fauna, along with other previously introduced species, now comprise the major component of survey trap captures. As well, the introduced fauna now dominates the total complement of *Scolytidae* (both individuals and species) attacking some host tree species. One species exhibits a highly restricted distribution within the urban landscape, and two more species have not yet been found outside of urban forests. However, two of the recent introductions have successfully invaded adjacent managed forest lands. Indeed, one of the latter species, that within its native range is only known to attack deciduous hosts, has also been recovered from two species of conifers. Studies are currently underway to determine the extent to which these species have invaded both managed and natural forest ecosystems.

Although the full impact of these recent and other historical introductions is not yet understood, existing information does indicate the potential for some increased economic costs. Limited economic losses resulting from degrade of softwood lumber shipments as a consequence of attack by non-indigenous ambrosia beetles have occurred and attack has been observed in decked timber in managed forests. Preliminary evidence from survey and research trap captures indicates that the existing pheromone-based management systems used to control the levels of damage native ambrosia beetles at mill sites may not be as effective in attracting these exotic species. Thus new management systems may be required.

The biological and ecological impacts resulting from the establishment of these ambrosia beetles, and their associated ambrosial fungi, remains to be determined. These introduced species are now a major component of the scolytid diversity in some forest systems and may impact the diversity of native plant and animal species. The potential for the competitive exclusion of at least one rare native ambrosia beetle exists in British Columbia.

Control methods and management strategy of pine wood nematode in Japan: History and future scope

Naoto Kamata
Kanazawa University, Faculty of Science, Laboratory of Ecology, 930-1192 Kakuma, Kanazawa, Istukawa, Japan
FAX: +81-76-264-5708, Email: kamatan@kennroku.kanazawa-u.ac.jp

In pine wood nematode (PWN), *Bursaphelenchus xylophilus* (*Nematode: Aphelenchoididae*), which causes pine wilt disease (PWD), is believed to be native North America and is thought to have been introduced to Japan in the early 1900's. The main methods of controlling PWD in Japan has been cut & treat (*e.g.* cut & burn, and cut & use sprayor smoke insecticide). Because Japanese pine sawyer (JPS), *Monochamus alternatus* (*Coleoptera: Cerambycidae*), is the most important insect vector of PWN, the purpose of these cut & treat methods are to prevent PWN expansions by preventing the spread of adult JPS. Although it was in the early 1970s that PWN carried by JPS was confirmed to cause PWD, one of the reasons that PWD spread more slowly before the early 1960s was that the cut & burn method had been quite successful because infested dead pine trees were efficiently removed from forests and used for fuel. The spread of PWD accelerated after the 1970s, and PWD has now invaded all of Japan except for Hokkaido and Aomori, the northernmost prefecture of Honshu. Now with our understanding of PWD ecology, PWD would theoretically have been extinguished if all the dead trees were treated properly before the time of JPS adult emergence. According to a simulation by Shigesada et al. (1999), <10% of untreated dead trees may allow PWD to expand its range. Therefore, it is natural to think that there remained <10% of untreated dead trees every year and that this percentage increased after the 1970s. Possible reasons include:

1. Rapid industrialization of Japan made it difficult to treat dead pine trees completely, because the number of forest workers decreased and wood as fuel was rapidly replaced by gas and oil.

2. Many dead pine trees were treated after JPS adults had already emerged, which partially depended on a lack of knowledge of the life cycle of JPS and partially on the budget system; as the fiscal year starts in April making it difficult to perform complete eradication before the start of JPS emergence (May-June).

Because low temperatures cause a delay in host symptom development and a slower rate of both PWN and JPS population increase, the spread of the PWN and the number of infested pine trees have tended to slow down in northern Japan. This fact means that the control efforts and the intrinsic rate of increase of PWD are balanced in the regions it is speculated that the PWN will expand only slowly in northern Japan by the repeating processes of 'spread and establishment into uninfested areas in hot dry summers' and 'keeping the status quo in cool summers'. To stop the new invasion in the hot dry summers is the key to control strategy in the northern extremes of the PWN range. The result of a barrier zone defense project in the expanding front of northern Japan will be presented.

Biological invasion of forest insect pests - a threat to the stability of the world's forest ecosystems

Andrew Liebhold
USDA Forest Service, Northeastern Research Station, 180 Canfield St, WV 26505 Morgantown, USA
FAX: +01-304-285-1505, Email: sandy@gypsy.fsl.wvu.edu

For millions of years the world's biota has been separated by geographical barriers such as oceans and mountain ranges but humans are ever increasing their rate of world movement and this has caused an acceleration of rates of accidental introductions of species into new areas. Biological invasions represent a particularly major problem to Forestry because invading species often disrupt efforts to manage for natural ecosystem functions and/or for sustainable yield of wood products.

The ecological and economic effects of biological invasions in forestry probably already exceed those caused by either air pollution or climate change and the problem is likely to increase in magnitude in the future. The enormity of the problem appears to be incompletely understood by scientists and inadequately appreciated by policy-makers.

I present here a generalized theory of the ecology of invasions consisting of three related processes: arrival, establishment, and spread. Specific population processes dominate each phase of the invasion process and are affected by life history characteristics such that it is possible to use these characteristics to predict the risk of invasion posed by different organisms. This information can be used to develop optimal strategies for management of all phases of the invasion process. I present a simple model that can be applied to identify optimal management strategies during invasions.

Hemlock Woolly Adelgid in the United States: Status of Ongoing Biological Control Efforts

Scott Salom, Mark McClure
Virginia Tech, Dept. Entomology, VA 24061-0319 Blacksburg, USA
Tel: 540-231-2794, FAX: 540-231-9131, Email: salom@vt.edu

Hemlock woolly adelgid (HWA), *Adelges Tsugae* Annand (Homoptera: Adelgidae) was first discovered on hemlock (*Tsuga*e spp.) trees in western North America in the 1920's. It wasn't until the early 1950's that HWA was first reported in eastern North America, near Richmond, Virginia. HWA is considered native of *Tsuga spp*. in Asia, principally, China and Japan. Asian and western North American *Tsuga spp*. are resistant to HWA feeding and are able to sustain colonization and feeding with little damage resulting to the tree. The eastern *Tsuga spp*., (*Tsuga canandensis* (L.) Carr.and *T. caroliniana* Engelm.) are both susceptible to HWA and are often killed when infestation density is high. It was not until the 1980's that populations of HWA began to increase dramatically. Concurrent with that was the expansion of the insect's geographic range. It has spread as far north as Massachusetts and south to North Carolina. Prevailing westerly winds have probably played a role in slowing expansion west of the Appalachian range.

The insect has two generations per year on hemlock and can be found attached to the base of the needles. The insects insert their stylet into storage parenchyna cells below the abcission layer of the needles. New shoot development is impacted, affecting growth of new needles. Trees can be killed in as soon as four years, yet often live longer. Trees that are able to survive may either be more vigorous or less disposed to HWA genetically. Neither explanation has been rigorously tested. The insect secretes white woolly material that cover the insect and serve as ovisacs. The only mobile stage for movement from among hemlocks is the crawler stage immediately following eclosion of the eggs. Crawlers have no wings. Therefore, dispersal is passive. HWA poses a serious threat to eastern forests of North America. Both *Tsuga* spp. play important ecological roles in the forest, especially in riparian areas. The prospects of losing these species are real and efforts to address this problem have been undertaken. The most promising research underway for helping to reduce the impact of HWA is the importation of natural enemies from its native habitat. Searches in Japan and China have yielded numerous predators, most previously undescribed. Two coccinellid beetles show the greatest promise. From Japan, *Pseodoscymnus Tsuga*e Sasaji & McClure, has been studied extensively in the laboratory, and is being mass reared for limited field releases that are currently taking place throughout eastern North America where HWA occurs. This insect has survived in the field for up to two years and has reduced the density of HWA on trees in which it was released. Another coccinellid beetle *Scymnus sinuanodulus* Yu & Yao, has been studied in the lab. It has shown good promise as a predator and is considered ready for limited releases. in western North America, a predator commonly found associated with HWA *Laricobius nigrinus* Fender (*Coleoptera: Derodontidae*), has been imported to Virginia and is currently being studied at a quarantine laboratory located at Virginia Tech. This insect has been able to complete several generations on HWA only. This presentation will report on the latest research being carried out on these predators. Their potential role and effectiveness in regulating HWA populations will be discussed.

Modelling the Spread of pine Wilt Disease in Japan

Nanako Shigesada, Yamamota, N., Kawasaki, K., Takasu, F., Togashi, K., Nunotani, H.
Nara Women's University, Kita-Uoya Nishimachi, 630-8506 Nara, Japan
FAX: +81-742-20-3438, Email: sigesada@ics.nara-wu.ac.jp

An epidemic of pine wilt disease has been spreading in wide areas of Japan for nearly a century. The disease is caused by the pinewood nematode *Bursaphelenchus xylophilus*, with the pine sawyer, *Monochamus alternatus* as vector. We present a mathematical model to describe the host-parasite interaction between pines and pine sawyers carrying nematodes on the basis of detailed data taken from the incidence of pine wilt disease at a study site located on the northwest coast of Japan. With this model we simulate the temporal change in the incidence of the disease and predict how the epidemic could be controlled by eradication of the pine sawyer. Furthermore, the model is extended to study the spatial spread of disease on a large scale, by incorporating short-range dispersal of the pine sawyer together with long-range dispersal through air convection or transportation of logs infested with nematodes. The leap distance distribution of sawyers is estimated from experimental data.

The main results are:
1) There is a minimum threshold of the initial pine density for successful invasion of the disease. However, even if the pine density exceeds the

minimum threshold, the disease fails in invasion due to the Allee effect of the pine sawyer when its density is very low.
2) The minimum threshold density increases disproportionately with increase in the eradication rate.
3) Once the disease is established, its range expands at a constant speed depending on the pine density.
4) in areas where rapid spreads of the disease are observed, more than 10 percent of sawyers are estimated to undergo long-distance dispersal naturally or artificially.

Recent Invasions of Forest Insects Pests in Central Europe

Marek Turcani
Forest Research Institute Zvolen, Research Station Banska Stiavnica, Lesnicka 11, 96923 Banska Stiavnica, Slovakia
Tel: +421 859 6911144, FAX: +421 859 6911044, Email: turcani@spark.sk

The eastern part of central Europe (Hungary, the Czech Republic, the Slovak Republic and Poland) is an important transit corridor between Russia and Westem Europe and this causes a high risk for introduction of non native species. This region is heavily affected by anthropogenic factors (*e.g.* air pollution, changing climate) and these changes promote the expansion of species ranges to new areas as well. We describe 3 noteworthy invaders, the bark beetle *Ips duplicatus* C. R. Sahlberg 1836 and leaf miners *Parectopa robiniella* Clemens 1863 and *Cameraria ohridella* Deschka & Dinic 1986.

In 1993, an outbreak of a previously unknown bark beetle species (*Ips duplicatus*) was discovered in the northeastem part of the Czech Republic in stands of Norway spruce (*Picea abies* L.). The native range of this species includes northern Europe to west Siberia, but occasional records exist from Austria, the Czech Republic and south Poland. The outbreak has continued for 5 years and over 0.6 mil. m^3 of trees were killed. Beginning in 1997, pheromone traps have been used to delimit the extent of this insect in central Europe. Data indicate, that this species now occupies the northwestern part of Slovakia, the southern part of Poland and almost all area of the Czech Republic. Out of primary outbreak area the first groups of trees infected by this species have recently been found in the northwestern Slovak Republic and it appears, that the range of this species is expanding through central Europe.

In 1993, a leaf miner, *Cameraria ohridela*, was discovered for the first time in the southwestern of Hungary. The species probably origins from area near Ohrid Lake (Makedonia). This pest attacks the horse chestnut (*Aesculus hippocastanum* L.), frequently planted in parks, cemeteries and in special hunting areas. The pest has 3-5 flight periods during the year and causes heavy defoliation of tree at the beginning of summer often leading to their death after 1- 3 years defoliation depending on their health and weather conditions. in 1996,this species reached the Slovak and Czech republics and during 2 subsequent years infested almost all teitItory of both for the first time in the southwestem Hungary (1978 - 1979). in 1986, the species reached the Slova countries. Also during this period, black locust (*Robinia pseudoAcacia* L.) stands in the region were attacked by the leaf miner *Parectopa robiniella* (this species originales from North America). The pest was discovered k republic and in 1989, the Czech republic.

These examples illustrate the enorrnity of problems with invasive species to central Europe even though extensive quarantine efforts exist. These problems illustrate the importance of preparing the Global Forest Invasive Species Information System as a part of Global Forest Information Service at this time.

Global Spread of Insect-Associated Fungi On Exotic Plantation Pines

Michael J. Wingfield, Bernard Slippers, Zhou Xu Dong, Wilhelm de Beer and Brenda D. Wingfield
University of Pretoria, Department of Genetics and Department of Microbiology and Plant Pathology, 0001 Pretoria, South Africa
Tel: +27 12 4293938, FAX: +27-12 420 3960, Email: mike.wingfield@fabi.up.ac.za

During the course of the 20th Century, plantation forestry in the tropics and Southern Hemisphere has grown dramatically. This growth is associated with increased demand for wood and paper products and also with restrictions on the felling of native forests. Thus, huge industries have been established based on extensive areas planted to highly productive exotic pine species. An important reason for the success of exotic pine plantation forestry is that the trees have been separated from the insect pests and diseases that feed on them in their areas of origin. Pine-infesting insects have gradually begun to appear on trees previously separated from these pests. These accidental introductions have, in many cases, occurred despite outstanding quarantine. An aspect of the introduction (accidental or intended) of pine-infesting insects that is not commonly appreciated, is the fact that many of these insects live in association with fungi that are also detrimental to forestry. These associations range from relatively casual (*e.g. Fusarium circinatum* with cone and shoot-feeding insects) to highly specific (*e.g. Amylostereum* *areolatum* with the wood wasp *Sirex noctilio*). The identity of these fungal associates and the structure of their populations, provide outstanding clues to the origin of the insects. Such knowledge also has important implications for pest and disease avoidance in the future.

7.04.00 Air Pollution Impacts on Forest Ecosystems

Long-term impacts of photochemical smog on forests: Evaluation of effects at stand and landscape levels

Andrzej Bytnerowicz, Michael Arbaugh
USDA Forest Service, Pacific Southwest Research Station, 4955 Canyon Crest Drive, CA 92507 Riverside, USA
Tel: 909-680-1562, Email: andrzej@deltanet.com

Photochemical (oxidant) smog episodes have been occurring in North America, Europe and Asia for several decades. Negative effects on vegetation have been mostly attributed to ozone, although other smog components such as peroxyacetyl nitrate (PAN) and nitric acid (HN) vapor may also contribute to the observed phytotoxic effects. Long-term photochemical smog-related changes in mixed conifer forests of the San Bernardino Mountains in southern California are well known. The oxidant-related changes in vegetation have also been described in forests near Mexico City, the Sierra Nevada Mountains, the Appalachian Mountains, southern, central and western Europe, Taiwan, and Japan.

Development of injury symptoms (Ozone Injury Index, OII) on foliage of ponderosa pine trees is proportional to a dose of the ozone exposure measured as "SUM O". Passive ozone samplers can be used for measuring average ozone concentrations and calculations of "SUM O" indices for remote forest locations. This allows for development of a monitoring network at a landscape level. in the 1999 summer season concentrations of ozone were monitored at 85 sites located in the mixed conifer zone of the Sierra Nevada Mountains. Based on these monitoring efforts, models of spatial and temporal distribution of ozone concentrations will be developed for the Sierra Nevada range. Ozone concentrations will be correlated with foliar crown injury at selected locations (about 10% of the ozone monitoring sites). Results of these comparisons will be extrapolated to the entire mixed conifer zone of the Sierra Nevada. These results will also be used for prediction of ecological risks related to ozone and other pollutants in the mixed conifer forests of the entire Sierra Nevada mountain range. Similar monitoring and modeling efforts are also in progress in the Carpathian Mountains in Central Europe.

Although information on ozone exposure can be used for predictions of foliar injury, relationships between the pollutant exposure dose to physiological and growth changes in trees are difficult to establish. Influence of other factors, such as inputs of atmospheric nitrogen, water availability, temperature, relative humidity, mycorrhizae inoculation, presence of insects, and complexity of changes at a physiological level, affect tree growth response to ozone exposure. A much better understanding of mechanisms of pollutant effects in complex forest environment is needed before reliable models predicting growth changes and physiological responses of trees to ozone alone and photochemical smog in general may be developed. Rapidly increasing number of motor vehicles in the developing Asian countries will lead to elevated emissions of photochemical smog precursors (nitrogen oxides and hydrocarbons). in conditions of high solar radiation, high temperatures and thermal inversions the areas of potentially phytotoxic levels of ozone and other pollutants will expand. National and international air pollution and forest health monitoring programs should be aided by models that are able to extrapolate results from networks of point measurements to landscape and regional levels. Such models are essential for evaluation of risks and proper environmental planning.

The link between forest critical loads for acidity & nitrogen and the sustainability of forest ecosystems.

Peter Freer-Smith, Fiona Kennedy
Forest Research, Alice Holt Lodge, Wrecclesham, Farnham, GU10 4LH Surrey, United Kingdom
FAX: 01420 23653, Email: p.freer-smith@forestry.gov.uk

Enhanced sulphur and nitrogen depositions can lead to soil acidification thus detrimentally effecting both trees and forest ground flora by reducing nutrient availability and by increasing Al in soil solution to toxic values. Suitable targets for emission reductions are therefore vital for the sustainability of our forest ecosystems.

The calculation and mapping of critical loads (threshold values of pollutant deposition above which damage occurs to forest ecosystems) for sulphur, total acidity and nitrogen has been a major exercise co-ordinated by the UNECE under The Convention on Long-Range Transboundary Air Pollution. Outputs have informed the decision making behind the most recent protocol for decreasing sulphur emissions and are likely to determine future nitrogen emission controls. The use of the critical loads approach is also extending to developing countries.

For forests different methods have been used for setting critical loads ranging from the empirical, Simple Mass Balance through to dynamic modelling. The choice of model, data collection and model parameterisation requires careful consideration. in the UK a combination of published information and newly collected data are used. These data are also of very major value in predicting the sustainability of forest ecosystems (Freer-Smith, 1998).

This paper will present the approach, which has been adopted in the UK and will discuss the reasoning and implications of the decisions made. Some of the key data sets which are being used in the calculation of critical loads and judgement of sustainability will be presented (nutrient removal in harvesting, calculation of average volume increment, and wood nutrient content, base cation and pollutant depositions, critical chemical criteria in soils i.e. Al:Ca or Al:base cations and mineral weathering rates in forest soils). The experimental and survey work, which provides these data, will be described. Forest soil critical loads maps will be presented for the UK and their implications discussed.

Freer-Smith P H 1998 Do pollutant-related forest declines threaten the sustainability of forests. Ambio XXVII No 2 123-131

Wildland fires as a source of air pollution: recent experience in Southeast Asia

Bryan Lee, Michael Brady, Adi Sasitiwarih and Harby Sandhu
Canadian Forest Service, Natural Resources Canada, 5320-122 Street, P.O. Box 3910, T6H 3S5 Edmonton, Canada
Tel: 780-435-7210, FAX: 780-435-7356, Email: mbrady@nrcan.gc.ca

Keywords: air pollution, forests, fire danger, El Nino, Southeast Asia

Extreme weather conditions like droughts and floods usually result in environmental disasters in different parts of the world costing billions of dollars each year. Though El Nino-related droughts occur every two to seven years in Southeast Asia with varying intensity, the 1997 and 1998 El Nino events produced a prolonged drought in many parts of this region. This phenomenon also caused the monsoon to be delayed, greatly increasing the impact of the drought. Both of these El Nino events were classified as "type one", or the most severe on record. in Indonesia, the impact of 1997 El Nino was most severe in central Sumatra and West Kalimantan, while East Kalimantan received the most severe impacts during the 1998 event. Information on these events was obtained by monitoring hotspots, smoke distribution, fire danger, drought conditions and air quality.

The droughts of 1997 and 1998 resulted in producing heavy air pollution from wildland fires in large areas of Indonesia, Singapore, Malaysia, Brunei, Thailand and the Philippines. These fires burnt an estimated five million hectares during 1997 in Indonesia alone. The sources of these fires were agricultural and land conversion burning. These fires generated large emissions of carbon dioxide, carbon monoxide, nitrogen oxides, ozone, hydrocarbons, particulate matter (smoke) and other pollutants. These emissions contributed to the local and transboundary air pollution issues of visibility, climate change, acidic deposition and smog. Magnitude of the Haze Index (HI) and the Air Pollution Index (API) indicated that the worst air po1lution occurred in Sumatra and Kalimantan regions of Indonesia. Also, air quality readings in Singapore and Malaysia were at record highs. The wildland fires of 2000 also resulted in considerable smoke and haze problems in Indonesia. Since natural phenomenon can not be readily controlled by people, prevention and early detection of fires is the best way to minimize air pollution at the source and the resulting impacts.

In 1999, Canada signed a memorandum of understanding with Indonesia to develop a fire early warning system. The Fire Danger Rating System (FDRS) Project for South East Asia is a Joint Initiative of the Canadian Forest Service (CFS) and Indonesia's Agency for the Evaluation and Application of Technology (BPPT). The project is regional in nature and the participation and support of other countries and organizations in the region has been incorporated. The project will establish appropriate fire danger monitoring approaches at regional, national and provincial/state levels. Smoke estimation, atmospheric dispersion and management techniques are included in the scope of the project. Since the use of danger rating systems have been successful in Canada and other parts of the world, it is anticipated that FDRS project will help to alleviate the fire and haze situation in Southeast Asia.

2000 State of science on air pollution impacts on forests: Applicability to Asian Region

Keywords: air pollution, forests, forest health, global change

Global change poses one of the major threats to international forest health and sustainability in the 21st Century. Maintenance of forest health is essential for forest resilience to climate change and extreme weather events. Concentrations of tropospheric O_3 (smog) are increasing rapidly in developing regions and more gradually in developed ones. Acid deposition via rain, cloud and in dry form remain of concern despite recent international success at regulation of transboundary transport and in emissions abatement. Nitrogen saturation of forested watersheds is occurring in many regions. Cause-effect linkages may not always be made due to design of existing monitoring networks. Levels of O_3 may largely offset modelled gains in forest productivity from increasing global atmospheric CO_2 concentrations. Future predicted patterns of air pollution coupled with ongoing climate change (global change) may interact to significantly alter forest health and increase susceptibility to other biotic and abiotic agents of disease. in this paper we shall provide a brief summary of state of science on air pollution impacts on forest ecosystems emanating from the 19th IUFRO Research Group 7.04.00 meeting in Houghton, Michigan, May 2000 and other sources. Applicability of science from developed programmes to developing needs in the Asian region will be discussed.

Air pollution in China: Deposition and Effects on Forests

Youbin Zheng, Hideyuki Shimizu
CGER, National Institute for Environmental Studies, Tsukuba, Ibaraki, Japan
Email: zheng.youbin@nies.go.jp

Over the last two decades, China, a country with a population of 1.22 billion people - one fifth of the world's population, has undergone a period of rapid economic development.This fast economic and population growth, inevitably has been causing a rapid increase in energy consumption. As most of the other Asian developing countries, China has a higher rate of increase in energy consumption (mainly coal), but short of efficient air pollution control facilities, this has been causing a higher increase rate in air pollutant (SO_2, NO_x, particulate and CO_2) emission than that in developed countries. The increasing air pollutant emission already caused an alarming air quality deterioration in many big cities and industrial areas. Air pollution problem is so sever that it is responsible for more than 1 million deaths of people per year in China, or about one in every eight deaths nation wide. China has 134 million hectares of forest, about 14 percent of the total land area. in this talk, we present the up-to-date air pollution (SO_2, NO_x, O_3, particulate and acid precipitation) situation in China and a review of the effects of air pollutant deposition on forests (field evidences and research results) in this country.

Interference potential of *Casuarina Equisetifolia* L. in natural forests of North-Western India

Daizy R. Batish, Harminder Pal Singh, R.K. Kohli
Panjab University, Department of Botany, 160 014 Chandigarh, India
Tel: +91-172-546666, 547777, FAX: +91-172-541409, Email: kohli%botany@puniv.chd.nic.in

Keywords: *Casuarina*; Allelopathy; Understorey vegetation; Litter; Biodiversity; Seed germination.

Casuarina Equisetifolia L. (Family *Casuarinaceae*) commonly known as Horsetail tree is a fast growing, drought hardy, nitrogen fixing exotic tree with wide adaptability to different environmental conditions. A native of Australia, it has been introduced in various parts of India primarily for fuel, land reclamation and ornamental value. The monoculture plantations of *C. equisetifolia* can be seen various parts of the country including the Northern ones. Apparently, very little vegetation is seen under the canopy of these plantations as compared to the adjoining open area. This little vegetation is also probably due to grouping of the sensitive species with strong interactive ability. The ground, however, is seen covered with litter composed exclusively of cladodes or needle like branchlets, whorled, reduced and scaly leaves or cone like female flowers and echinate fruits. The presence of litter on the ground surface may affect nutrient availability and their accumulation in soil and may contribute alleloc hemicals in the soil leading to depletion in vegetation. Competition alone can not explain the reduction in phyto-diversity under *C. equisetifolia*. Allelopathy which is known to occur in many natural and managed ecosystems can be one of the stress factor. It is known to play an important role in regulating plant diversity, non random distribution of vegetation, zonation and organisation of plant communities. Keeping in view the was, therefore, planned to determine the ecological status of understorey vegetation and reasons of its depletion. The results indicate that the ecological status of the species under the monoculture plantations of *C. equisetifolia* and open area was strikingly different leading to clear cur differentiation. The Importance Value Index of the species, the indices of richness, diversity and evenness also varied. in order to find out the reason the leachates from the needles of the tree which were either fallen on the ground as well as fresh, females cones adversely affected the germination, growth and development of the few sensitive species. Allelopathy was, therefore, demonstrated as one of the causative factor.

Forecast of Forest Ecosystem Dynamics Under Different Scenarios of Forest Management (Mathematical Modelling On GIS-technology basis)

Sergei I Chumachenko, Marya M. Palyonova, Dmitrii A. Starostenko and Vladimir N. Korotkov
Moscow State Forest University, Institutskaya, 141005 Mytischi, Russia
Email: chumachn@mgul.ac.ru

Keywords: Forest management; Ecosystem dynamics; Modelling; GIS; Forest planning

The problem of forest ecosystem dynamics' forecast was solved within the framework of a program complex DBMS-GIS-MODEL, in which DBMS and GIS accumulate and process the attribute and spatial information for the forest object and MODEL ensures the forest dynamics forecasting. The most important feature of this model is the account of strata position and their mutual influence.

As initial information for the forecast module of the model, we have used the per-stratum data bank and cartographic bank of the forest planning and inventory works, which for particular forest management units, exists in the form of information systems (DBMS or GIS). As a result of the model works as similar information is obtained. To take into account bioecological processes in real forest communities, a large umber of reference databases is used within the simulation. The presented information technology helps to forecast and explain the causes of biodiversity changes in forest ecosystems under impact of forestry activity.

Geographic Specificity of Forest Cover within Side-Enisey Middle Taiga Area

S. M. Gorozhankina, Konstantinov V.D.
Academy of Sciences, Siberian Branch, V.N.Sukachev Institute of Forest, Krasnoyarsk, Russia
FAX: (3912) 433686, Email: dndr@ifor.krasnoyarsk.su

Keywords: Ecotone; Taiga; Landscape structure; Forest types; Russia.

Side-Enisey Siberia is an unique natural ecotone, placed at the boarder part of the greatest land structures - the young West Siberia platform and ancient Middle Siberia plate. It resulted in complicated landscape structure, which combined both west-siberian and middle-siberian features. Side-Enisey ecotone middle taiga section has been investigated within Central Siberia Biosphere Reserve territory with terrestrial co-ordinates at 62-64° latitude North and 88-92° longitude East. Several landscapes are determined here. I - recent valley of Enisey river, which includes flood-plain (absolute height is 30-60m) and loamy fluvial terraces (60-120m). II - loamy left-bank divides of low hypsometric level. III - piedmont mound-ridge plain. On account of great disparity in height the landscape is divided in two relief steps: IIIa - of low hypsometric level (150-200m) and IIIb - of high hypsometric level (250-300m). IV is the higher hypsometric step - 350-400, 660m. Stook-form mountains and table-form divides (with rock deposits - kurums, placed along the tops and slopes) alternate here with fragments of ancient glacier outflow hollows. Landscapes IIIb and IV are distinguished by severe climate, which results in wide spreading of frost ground forms and vertical differentiation in plant cover.

According to landscape structure forest complexes are defined here:
- scrub tall-herbage spruce forests within flood-plains of low and middle ecologic level;
- herb parvifoliate-spruce forests, combined with frost-mound forest-bog microcomplexes within flood-plains of high ecologic level;
- valley moss-herb parvifoliate-spruce forests, placed along solar high-angle and convex slopes;
- valley herb-moss parvifoliate-dark coniferous forests, placed along shadow gentle slopes and flat interfluves;
- dwarf shrub-moss parvifoliate-cedar forests within divides of low hypsometric level;
- lichen-moss parvifoliate-dark coniferous forests, combined with yernik open forests (along ancient outflow hollows) within divides of high hypsometric level.

The whole of tree species have the ecologic optimum within flood-plains and decrease edificator capacity following land surface absolute height increasing. Cedar (*Pinus sibirica*) and spruce (*Picea obovata*) are the dominating primary tree species. Cedar strengthens its edificator position, following the land surface absolute height increasing. Spruce ecologic optimum comes to nothing more than river valleys. Fir (*Abies sibirica*) as the forest-forming tree-species never exceeds the boundaries of flood-plains with rich and drained ecotopes. Pine (*Pinus silvestris*) timber stands develop within peaty lands mainly. Larch (*Larix sibirica*) spreads all over the territory as admixed tree species mainly and is the most competitive in rocky and perennially frozen sites. Parvifoliate species - birch (*Betula pendula*) and aspen (*Populus tremula*) are the secondary forest-forming edificators throughout the territory. Forest complexes within river valleys are floristically richest. They are specific with high phytocoenotic significance of grass living forms and great numerosity of species, which require rich nutrition and heat provided ecotopes. Forest complexes of divides floristically are comparatively arm at the expense of herbs lack. Cold-resistant dwarf-shrubs and mosses, which stand poor and nun-drained soils, have the heightened phytocoenotic significance instead.

Valley forests are characterised with moss-grass and grass ground cover. Within flood-plains the gramen (*Calamagrostis obtusata, C.langsdorffii*) are very much abundant, while at the terrace flat interfluves - *Equisetum sylvaticum, E. pratense* are. Within divide areas of low hypsometric level forest ground cover is usually formed with dwarf shrubs (*Vaccinium myrtillus, V.vitis-idaea Ledum palustre, Chamaedaphne calyculata*) and two groups of mosses - green (*Hylocomium splendens, Pleurozium schreberi, Polytrichum commune*) and sphagnum ones (*Sphagnum angustifolium, S.nemoreum*) dependently on site drainage. Within divides of high hypsometric level forest ground cover finds north expression thanks to heightened abundance of frost-resistant species - arctic scrubs (*Betula humilis, B.nana*), dwarf shrubs (*Vaccinium uliginosum, Ledum palustre, Empetrum nigrum*), Cladonia and Peltigera lichens, some Hepatica species.

Forest Ecosystem Management and Sustainable Development of Forestry in Northeast

Dai Limin, Hao Zhanqing, Wang Qingli, Deng Hongbing
Chinese Academy of Sciences, Institute of Applied Ecology, Post Box # 417, 110015 Shenyang, China
FAX: +86-24-23843313, Email: lmdai@iae.syb.ac.cn

Keywords: Forest ecosystem management; Sustainability; Biodiversity; Productivity; China.

In this paper, the conceptions and developments of ecosystem and ecosystem ecology were reviewed and summarized. Then, the conception, connotation, objective, and development of ecosystem management were expounded. Based on these discussions, forest ecosystem management was discussed. The viewpoint in this paper was that the former unreasonable forest resources management should be changed, and forest ecosystem management was a suitable way to sustainable development of forestry. The chief research contents were pointed out in this paper, and taking forestry in Northeastern China as focal, strategies on sustainable development of forestry were also advanced Northeastern forest, which has an important effect on national and regional economy development, is the most extensive forest in China and its area accounts 1/3 of the total forest area. But natural forest resources in Northeastern China have been decreasing rapidly and even will be exhausted because of unreasonable development and usage for a long time. in the eastern hilly area of this region, statistics data showed that the area of forest was 36 million hectare in 1935 and most of the forests were broad-leaved Korean pine forest and *Abies-Picea* forest. However, the virgin broad-leaved Korean pine forest and *Abies-Picea* forest have been almost vanished and replaced with secondary forest and artificial forest. Moreover, artificial larch forest has been constructed energetically since 1949. Now, 70-80% artificial forest is pure larch forest. The large area of artificial pure forests caused soil fertility and productivity decreasing and unstable ecosystem. It is another chief problem hindering sustainable development of northeastern forest. So, it is the most important task to conserve and reconstruct reasonable ecosystems, manage the ecosystems scientifically, and reach the objective of sustainable forest ecosystem development and resources utilization. Another important task of northeast forest is to construct the optimized model of sustainable artificial larch forest. Ecosystem management is a serious managing activity aimed at a sustainable development and its application should be guarded by policy, contracts, and factual measurements. On the basis of best awareness to necessary ecological actions and ecological processes that maintain components, structure and functions, ecosystem management focus on studying and monitoring, ensuring the suitability of management. Forest ecosystem management is, with a basis of ecosystem management, some management aiming at forest resources and all the forest ecosystem and it includes all the management and technological measure by which resources can be used sustainably. Forest ecosystem is a complex system, and forest ecosystem management must take maintaining dynamic equilibrium and protecting biodiversity as basis.

A conceptual framework for forest management plans

Jelle B. Maas Bijker, Hans C. Vellema
The Tropenbos Foundation, Post Box # 232, 6700 AE Wageningen, Netherlands
Tel: +31-317-426262, FAX: +31-317-423024, Email: j.b.maas@iac.agro.nl

Keywords: Forest management plans; Sustainable forest management; Land-use planning; Land evaluation.

Forest Management Plans (FMP) have gained in importance as both experts and donors place more and more emphasis on FMP as a tool for (sustainable) forest management. The Tropenbos Foundation experienced that there seems to be a lot of confusion about the concept of FMP.

In it most simple form an FMP is a plan which describes the management of a forested area in order to reach some (predefined) objectives. But the concepts of what an FMP comprises differs among people. Some plans are more forest management systems in order to sustain a certain logging operation while other complicated plans try to manage forests at a national level. But an FMP is not just a set of management activities. An FMP:

- Justifies the establishment of a management plan;
- Describes the management area, including its resource base (the entire ecosystem, including woody vegetation, fauna, soil etc.), actors and their objectives or needs;
- Provides an evaluation of forest use options;
- Elaborates on the choices made (objectives and activities);
- Describes practices and activities that best meet the objectives;
- Includes a mechanism to respond to changing circumstances and insights.

As such an FMP is not just about resource management practices, but comprises also the process of decision making

A definition of FMP is:

'A Forest Management Plan is the description of decisions and activities to produce anticipated objectives with regard to use and conservation of forest in an area'.

Conceptual framework

The development of an FMP takes place in different stages or levels of planning, *e.g.* strategic, tactical and operational planning. In the strategic plan the decisions concerning the objectives of the management, the allocation of forest land and forest functions, are taken. Societal needs, economic and political forces, current land use, land qualities and locations of the land first determine whether the land is allocated as forest land (kind of land use). An inventory of the resources base and the needs form the actors in the management area are made (land use objectives). Finally, the decisions on the management objectives are matched, resulting in a future desired forest

The tactical plan describes the management activities, which are needed to reach the stated objectives, derived from the strategic plan. The operational plan comprises the actual implementation of the management activities and practices.

Although not explicitly mentioned in figure 1 (not shown), monitoring and evaluation of an FMP and its execution is essential for the management. Management is continuous process. Circumstances and insights may change in the course of the management or assumptions may prove false and need to be adapted.

The conceptual framework will be enriched by operational experience gained by Tropenbos. and the role of research within FMP development will also be indicated.

Optimization of Parametrics of Ecological Monitoring

Jakov V. Malkov, Valentin S. Shalaev
Moscow State Forest University, Oblast Mytishchy-5, 141005 Moscow, Russia
Tel: +7-095-5869156, FAX: +7-095-5869134, Email: shalaev@mgul.ac.ru

Keywords: Ecological monitoring; Minimization of parameters; Technical diagnosis; Influence on ecosystem

Making ecologically significant decisions is possible if one has reliable information about the environment and its ecological conditions. Measurements of parameters of influence on the ecosystem as well as ecosystem itself must be correlated according to accuracy. Systematic approach is preferable when one can observe and control the most important correlation between parameters of influence on the ecosystem and ecosystem itself. Otherwise it can so happen that there are a lot of monitoring data but little information about actual state of the ecosystem.

Means of land and space monitoring meant for global transnational and regional levels of ecosystems control must be connected by universal methodology based on similar integral and local parameters of ecosystems and their counterparts. Hence the use of principles of technical diagnosis: genesis, diagnosis and prognosis of behavior of technical objects seems useful.

Universal algorithm of minimization of parameters of ecological monitoring:
1 - Setting tasks: inventory of all sources of parameters of influence on the ecosystems and qualitative evaluation of the expected content and amount of toxic substances.
- Single out objects of ecosystem their parameters according to which the reaction of the ecosystem to the influence will be monitored.
2 - Making research: monitoring all informative parameters of influence on the ecosystem.
- Estimation of the coefficient of pair correlation of all informative parameters of influence on the ecosystem.
- Creation of a set of basic diagnostic parameters of influence on the ecosystem.
- Measurement of all informative parameters of influence of the ecosystem.
Calculation of coefficients of pair correlation of all informative parameters of influence on the ecosystem.
- Specification of the set of basic diagnostic parameters of the system.
- Building up of "dose-effect" patterns.
- Evaluation of "dose-effect" correlation, their minimization (most sensitive and less correlated).
3 - At the stage routine ecological monitoring:
- Control of minimized set of "dose-effect" patterns only.
- Criterial evaluation of ecosystem condition.

An Assessment of Multi-data Fusion in Forest Resource Management for the Northern Part Selangor, Malaysia

Muhamed K. Musa, Yousif Ali Hussin, Michael Weir
The Internationa Institute for Aerospace Survey and Earth Sciences (ITC), 99 Hengelostraat, 7500 AA Enschede, Netherlands
FAX: (31) 53-4874-444, Email: hussin@itc.nl

Keywords: Forest resource management; Sustainability; Satellite remote sensing; Resource inventory; Monitoring; TM image; Malaysia.

The aim of this research was to evaluate the potential use of fused multi-sensor images to supply information to strengthening the Malaysian forest resources management programme. The work explores the combination of the optical and SAR data using two image fusion techniques namely, Brovey and Intensity, Hue and Saturation (IHS), and assesses their efficiency and effectiveness for forest resource management.

Natural resources, and forest in particular, are becoming increasingly scarce and exhausted. As it was addressed in Agenda 21 of the Rio Convention, June 1992, the concept of sustainable forest management has become critical issue that must be addressed if the impact on the environment and the quality of life is not to be further threatened. To achieve sustainability, forest managers require information, not only about the current status of the forest availability and utilisation, but also about the future trends. The need for information requires continuous inventorying of the resources, in order to plan, manage and conserve the forest resources on a sustainable basis. Satellite remote sensing is recognised as a powerful tool for forest resources inventory monitoring and management.

In Malaysia, the limitations of cloud cover and the sensitivity of optical sensors to atmospheric disturbances hamper the use of remotely sensed data, such as Landsat TM, that use the optical range of the electromagnetic spectrum. in addition, forestry sector faces with difficulties such as broken terrain, multi-storied forest canopies, and few maps and other baseline data. The fusion of optical remotely sensed data with images acquired from radar seems to be a powerful method to optimise and enhance information extraction. Until now, Malaysian experience in the fusion of data sets from different sensor or platform for forest resources monitoring is still in research stage. in recent years, however, more effort has made to take advantage of the availability of both optical and SAR systems.

This research concentrates on the integrated use of Landsat Thematic Mapper (TM) imagery fused with either JERS-1, ERS-1 or Radarsat Synthetic Aperture Radar (SAR) imagery in a test area in Northern Parts of Selangor State, Malaysia. Two images fusion techniques, Brovey and Intensity, Hue and Saturation (IHS) transformation, were used to classify 11 types of forest ecosystem and five types of non-forest classes. The classification of fused images shows that the best overall accuracy (91.4%) was obtained from Landsat TM Principle Component bands 123 fused with JERS-1 through the Brovey transformation. The results indicate that the possibility of extracting more and accurate information from fused images is high and that it proves to be of great benefit to forest management. It helps to reduce the effect of cloud cover and supply more information about multi-stories forest canopy and can therefore directly contribute to sustainable forest management.

Forest Fuel Inventory in Plantation Forest

Ahmad Ainuddin Nuruddin, Dalinsip Pangalin and Khamurudin Mohd. Noor
Universiti Putra Malaysia, Faculty of Forestry, 43400 UPM Serdang Selangor, Malaysia
FAX: 603-943-2514, Email: ainuddin@forr.upm.edu.my

Keywords: Fuelwood; Fuel component; Fuel loading; Forest Fire risk; Malaysia.

Forest fuel inventory is a way to describe fuel components, fuel quantity and estimates its volume. This information can be used to detect high risk and hazardous areas. However, the study of this nature has not been conducted in Malaysia. This study was conducted to determine the fuel components on forest floor of two different age stands and to estimate the fuel loading of the various fuel components. This study was carried out at Bukit Tarek Forest Reserve, Hulu Selangor, Selangor Darul Ehsan, at two stand age of *Acacia mangium* of 5 and 9 year-old. Fuel components of downed woody material and duff were sampled along transect lines. Shrubs, litter, herbaceous and small trees (< 3 m height) were sampled from quadratic plots. The results showed that the components of forest fuel and their vegetation on both stands were similar but not in term of their fuel loading and density. The 5 year-old stand showed 23.31 tonne/ha of fuel components (downed woody material, litter and herbaceous), 1.73 cm of duff depth, 37,030 stem/ha of shrubs density and 2,175 tree/ha of small trees. The 9 year-old stand showed 17.42 tonne/ha of fuel components 3.03 cm of duff depth, 39,151 stem/ha shrubs density and 3,515 tree/ha of small trees. Downed woody material made up of 89% and 74% of the total fuel weight for 5 year and 9 year old stands, respectively. Comparison between two different age stands, showed that 5 year old stand has higher quantity of downed woody materials than 9 year-old stand. with 20.66 tonne/ha and 12.82 tonne/ha, respectively. Based on diameter class interval, the weight of downed woody material, diameter class of 0-7.6 cm were higher compared to diameter class of > 7.6 cm. The fuel weight for 0-7.6 cm diameter class were 12.48 tonne/ha and 9.94 tonne/ha for 5 and 9 year-old stands, respectively. Statistical analysis showed that the loading of downed woody material on 5 year-old stand was significantly greater than the 9 year-old stand. However, litter loading was greater on the 9 year-old stand than the 5 year-old stand (P=0.05). The study concludes that in terms of fuel loading, 5 year old stand has higher fire risk than 9 year old stand. This is due to the silviculture activities in the 5 year old stand.

Analysis of allelopathic substances from roots and leaves of *Robinia pseudoacacia*

Young-Goo Park, K.S., Kwon
Kyungpook National University, Department of Forestry, Lab. of Forest Genetics, Department of Forestry
702-701 Taegu, Korea R.
FAX: 82-53-950-6798, Email: ygpark@kyungpook.ac.kr

Keywords: Allelopathic substance; Leaching; Seed germination; Black locust.

Robinia pseudoAcacia (black locust), whose origin is in America, was introduced to the Korean Peninsula from China in about 1897. This species was planted extensively for fuel in rural areas during the 1970's, and plantations currently cover about 320,000 ha. Black locust now has many additional uses in Korea such as building materials, soil conservation, shade trees, forage and honey production. This tree exhibits rapid growth and is ecologically aggressive with allelopathic effects on other species. We analyzed the allelopathic substances in leachates from roots and leaves of black locust using HPLC, and determined leachate effects on seed germination.

Leachates from black locust roots inhibited seed germination of *Alnus firma* and *Pinus taeda* by more than 50% compared with distilled water. Germination frequency of Lespedeza bicolor was less than 54% of the control in treatments with leachates from fallen leaves of black locust. Seed germination of Arundinella anomala was also highly inhibited by 68% with leachates from live black locust leaves obtained in October.

Germination rate of lettuce was reduced to 10% with a 30% dilution of leachate from leaves (200 g/L distilled water, 24 h extraction). Complete suppression of germination was obtained with a 50% dilution and undiluted leaf leachate solutions. Leachates from root bark (200 g/L distilled water, 24 h extraction) suppressed lettuce germination by 70%. A mixture of leachates from leaves and root bark reduced seed germination of lettuce to 10%.

Phenolic compounds in leachates were analyzed by HPLC using a Microbondapak C18 column (300 x 3.9 mm) with 0.5% acetic acid in distilled water and 0.5% acetic acid in acetonitrile supplied at a flow rate of 1.5 mL/min. Detection was made at 260, 280 and 320 nm. *Robinia* leaves contain about seven times more phenolic acids than *Robinia* roots per unit dry weight. Although paracommaric acid is in lesser quantities in roots (18843 ng) than leaves (42142 ng), this acid accounts for the majority of phenolic acids in roots. in leaves, gentisic acids are the major phenolic component followed by parahydroxybenzoic acid.

Migration Technical Pollutions in Mountain Landscapes of Ukrainian Carpathians

Y. S. Shparyk
Ukrainian mountain forestry research institute (UkrMFRI)
Grushevskogo street, 31, 284000 Ivano - Frankivsk, Ukraine
Tel: 380-03422-25216, Email: victor@galytska.if.ua

Keywords: Ecological monitoring; Natural landscape; Toxic elements; Pollution; Ukraine

In region of Ukrainian Carpathians of work on ecological monitoring of forests are conducted UkrMFRI since 1990 under the european program "ICP-Forest". On the first level monitoring (the network of 16 x 16 kms) is incorporated 80 plots of constant supervision behind a condition of forests in Lvov, Ivano-Frankovsk, Zakarpatye and Chernovtsy areas. in 1996 the institute has begun development of the second level monitoring, which purpose is the profound study of biogeochemical laws of functioning of natural landscapes. On all of plots are selected the tests of basic structural elements forestry ecosystems:

soil, litter, herbaceous covering, mosses, lichen, bark and also atmospheric downfalls (snow). in 1997 year are begun researches on biogeochemical indication: estimated absolute contents 39 chemical elements in tests, analyse their deflation coefficients and migration on system "atmosphere - soil - plant".

For contents estimation technical pollutions in tests pressed into the service of method nuclear issue in inductively connected plasma (ICP). Set a presence in all of analysed structural elements of mountain forests of such toxic microelements: B, Be, Bi, Cd, Ce, Cu, La, Pb, Sn, V, Zn. Now detailed biogeochemical estimation develops of vertical migration technical pollutions into mountain landscapes.

Done such previous deductions:

- on regions territory takes place accumulation in forestry ecosystems cadmium and molybdenum, and in atmospheric downfalls - barium, cobalt, to chrome, copper, iron, to manganese, to molybdenum, to nickel and to lead. On all of counted elements set anomalies on their concentrations in environment.

- in territorial attitude all pollutions both in soil and in snow waters characterize by maximum concentrations in more industrial parts of region. This bears witness to dominating role of local sources pollutions in forming of environments contamination.

- checked off exceeding of admissible levels for contents in soils to lead and to chrome, and in snow waters - copper, molybdenum, vanadium and zinc. Analysis of correlation matrices gives a possibility to affirm, that exists a definite elements group, which determines contamination of regions environment, and by them source there are local aerotechnical pollutions.

- calculated a geochemical background for region of Ukrainian Carpathians on contents in soils of analysed microelements. Will check essential off difference on his senses for forest and industrial regions.

- amount of definite microelements most in atmospheric downfalls, and diminishes in row: soil, litter, herbages, mosses, lichen, bark. This shows, that basic by dint of contamination of mountain forests is atmospheric falls.

Important, on our thought there is also fact intercommunication a forests state indexes with environment contamination levels of Ukrainian Carpathians. Consequently, forests defoliation arrives at maximum senses in such regions: alpine parts north - east megaslope, regions of great entranse technical pollutions with atmospheric falls and on territory of south part country between river Dnister and Prut. The minimum parametres of defoliation are marked into north - to western part of Carpathians region. Dechromation of trees indicates on appearance damage (technical pollutions) and reaches to maximum in industrial regions too.

Secondary Forests in Slash-and-Burn Agriculture in Latin America: Opportunities for Rural Livelihoods and Environmental Improvement?

Joyotee Smith, Cesar Sabogal, Bryan Finegan, Socorro Ferreira, Gilberto Dominguez, Alejandro Mejia and Dean Current.
Center for International Forestry Research (CIFOR), Post Box # 6596 JKPWB, 10065 Jakarta, Indonesia
FAX: +62 251 622 100, Email: e.smith@cgiar.org

Keywords: Slash-and-burn agriculture; Secondary forest; Regeneration; Productivity; Ecosystem management

The regeneration of secondary forests (SF) on previously cleared land in the forest margins of Latin America is a promising development within the generally pessimistic scenarios of tropical deforestation. This has stimulated efforts to augment the value of SF to their owners, to induce them to increase the area in SF and delay their re-conversion to other uses. This is expected to improve the livelihoods of the rural poor, while simultaneously contributing to environmental improvement.

This paper synthesizes results from the emerging literature on SF to take the first steps towards the development of a strategy for increasing the value of SF. We present future scenarios of SF by analyzing how SF change as colonist frontier areas develop over time. We identify major problems resulting from these scenarios and the problems which research could significantly ameliorate.

We then make preliminary assessments of possible strategies for ameliorating these problems.

The paper uses a dynamic conceptual framework for analyzing how secondary forests evolve with the development of colonist frontier areas over time. Results draw on interdisciplinary field studies carried out by the authors in areas settled by slash-and-burn migrants in the forest margins of Brazil, Peru and Nicaragua. These include farm surveys and floristic inventories in each of the three countries, with sites selected to provide an international continuum in the frontier development process.

Results available so far show that the area in SF increases over time in areas of low population density. in areas settled about 100 years ago, SF is the only forest cover and covers about 25% of farm area. This implies that deforestation in slash-and-burn farming may be less than previously believed. SF is regenerated primarily to recuperate the soil. Multivariate analysis shows that farmers increase fallow periods over time, because site productivity decreases with repeated cycles of crop production. This gives rise to SF. in older areas, farmers change their strategy and compensate for declining productivity by increasing the area under cultivation, which is achieved by reducing fallow periods. Thus unsustainable agriculture eventually leads to a decline in SF and the elimination of forest cover on farms. If an increase in SF value, could induce longer fallow periods, this could increase farmer incomes, contribute to the sustainability of agriculture and maintain forest cover on farms.

The current potential of SF for timber production is generally limited, as the succession is only occasionally allowed to pass beyond the stage of dominance by pioneers. *Guazuma crinita*, a pioneer tree with an established market in Peru, is one of the few exceptions. Older stands generally have greater timber production potential, made up mainly of species of the long-lived pioneer ecological group. Families also use SF plant species for multiple purposes, with medicinal use and firewood being particularly important.

Well-documented factors such as productivity declines over time may limit the forest management potential of SF. Frequent uncontrolled fires are shown to represent a major barrier to the development of productive stands. These results indicate that innovative ways to increase the value of SF will have to be identified, such as the possibility of using carbon-offsets (under the Kyoto Protocol) to stimulate an increase in fallow periods. Marketing and processing improvements could also contribute, as well as policy changes, such as the removal of incentives for extensive cattle production.

What is needed is not a single "magic solution", but an "ecosystem management approach" which looks for synergies among the multiple products and environmental services that SF are capable of providing, identifies the need for policy changes and harnesses new opportunities at the global level.

A study on the Ecological and Environmental Quality in the Main Managerial Areas of Plantations in China

Xianfeng Su, Wang Bing
Chinese Academy of Forestry, 100091 Beijing, China
Tel: 86-10-62889073, FAX: 62884972, Email: wangbing@fee.forestry.ac.cn

Keywords: Plantations, ecological and environmental quality, insect pests and diseases, soil fertility, water loss and soil erosion.

A comprehensive analysis was made on the forest ecological and environmental state and quality by the five years successive monitoring from 46 located monitoring sites of newly established plantations for 7 main species in the managerial areas in China. The results showed that the decisive factors affecting the ecological and environmental quality were water loss and soil erosion soil fertility states and occurrence of insect pests and diseases.

Basing on the statistics and analysis of soil erosion monitoring, the results indicated that the soil erosion mainly occurred in the first and the second year after the plantations established. and about 81% of monitoring sites showed extremely slight or slight soil erosion, 16% of sites showed heavy soil erosion. High intensive site preparation and young plantations tending were the main causes of soil erosion, especially the over all ploughing. The soil nutrient loss was simultaneous with soil erosion. The amount of organic matter loss was the largest, while the amount of available NPK was the least among the total amount of lost nutrients.

According to the observations conducted to the pests and diseases, the occurrence rate caused by both insect pests and diseases in the plantations of masson pine, loblolly pine and poplar were high, while, the disease occurred frequently in *Eucalyptus* plantations either. and only 2.5% of monitoring sites were damaged heavily by insect pests, 5.1% by disease, most of the monitoring sites were attacked slightly. The damage of insect pests and diseases was slight to the main managerial areas of plantations in China.

The study on the monitoring findings of soil fertility showed that the soil available nutrients changed significantly, especially the available P. Fertilization affected the available nutrient of soil, particularly, the available P would increased significantly by the application of P fertilizer. A multiple regression analysis was done on the forest ecological and environmental quality by soil erosion, soil fertility and insect pests and disease, and a model Y=f(x1,x2,x3) between the ecological and environmental quality (Y) and soil erosion (x1), soil fertility (x2), pests and diseases(x3) was made.

Al stress on the photosynthesis of *Quercus glauca* Thumb

Chisato Takenaka, Masayuki Akaya
Nagoya University, Bioagricultural Sciences, Chikisa-ku, 464-8601 Nagoya, Japan
Tel: 81-52-789-4052, FAX: 81-52-789-4055, Email: chisato@agr.nagoya-u.ac.jp

Keywords: Al stress; photosynthesis; *Quercus glauca* Thumb; Ca/Al;

Soil acidification is one of the serious forest environmental problems caused by human activity. The effect of Aluminum on trees is the most critical among the various impacts by soil acidification. Not only the Al concentration but also the Ca/Al ratio in soil solution have been considered as important factors for the assessment of Al stress. Although many studies about Al stress on photosynthesis have been reported, the specific response and mechanisms by each tree species are ambiguous. The purpose of this study is to clarify the mechanism of Al effects on the photosynthesis of *Quercus glauca* Thumb, which is the typical tree species in the Japanese temperate forests.

To investigate the effects of Al concentration and Ca/Al ratio in root environment on the photosynthesis of *Quercus glauca* Thumb, three-year-old seedlings planted in glass beads instead of soil were exposed to various nutrient solutions containing Al at two concentration levels (5 and 10 mM) with three levels of Ca/Al ratios (5.0, 1.0, and 0.16). The pH of the solutions were adjusted to 3.3-3.4 to avoid the precipitation of Al. The treatments were continued for 14 weeks. Before, during and after the Al treatments, photosynthesis activities and chlorophyll fluorescence were measured. After the treatments, the morphology and the water absorption ability of roots were observed The contents of various elements and chlorophyll in the leaves were also determined.

The exposure to the nutrient solutions, in which the Al concentration was 10 mM (Ca/Al=0.16), limited the photosynthesis and caused a decrease in the stomatal conductance. The treatments with 5 mM Al did not affect the photosynthesis even when the Ca/Al ratios were 0.16. The results of the chlorophyll fluorescence and chlorophyll content, which showed no significant differences among the treatments, indicated no effect of the Al treatments on the photochemical processes. This means that the photosynthesis limitation should be due to the stomatal closure and the decrease in the carbon dioxide fixation process. All seedlings treated with Al had increased Al contents in the leaves, decreased P contents in the leaves and decreased water absorption ability in the roots. These results indicate that the Al treatments affected the nutrient availability and function of the roots. However, since the effect on photosynthesis was observed only with the 10mM treatment, it is suggested that the Al effects on the root functions were not correlated with the decrease in photosynthesis.

In addition to these results, the changes in the enzymatic activities due to Al stress will be shown and the mechanism of stress transmission from the root to the photosynthesis function in leaves will be discussed.

Decision making on cutting cycles in neotropical forests in Costa Rica and Bolivia

Juvenal Valerio, William Cordero
Instituto Tecnol¢gico de Costa Rica, School of Forestry, Post Box # 159, 159-7050 Cartago, Costa Rica
FAX: 506 591 4182, Email: jvalerio@itcr.ac.cr

Keywords: Logging; Sustainable forest management; Cutting cycle; Neotropical forest.

One of the points of departure for the sustainable forest management is that the logged volume must be equivalent to the growth of the forest in a determinated period of time. in the case of the polyciclic forest management of mixed, irregular forests, this period is the cutting cycle and is determined by the structure of the residual forest and its growth rate. That is the importance of growth studies.

Twelve one-hectare Permanent Sample Plots (PSP) have been established before logging in a rainforest at the Osa Peninsula, Costa Rica. Eighty, one-thousand square meters, PSP were established in a dry forest at Las Trancas, Lomerios Region in Santa Cruz Department, Bolivia (eight hectares sample). in both cases increment models have been fitted by regression.

The models of increment show that in bolivian forest the diametric increment, three years after harvest is 29 per cent lower than that of two years after logging. in the case of costa rican forest the increments, five years after logging are 35 percent lower than the observed in the period of three years after harvest.

The models have been used to predict the growth of residual forests and to determine the time required to growth a volume equivalent to harvest. A spread sheet program has been used in order to simulate growth. Changes in increment rates causes differences in estimated cutting cycle

In conclusion:

It has been observed, and measured, that growth rates of logged forests shows changes in different periods after logging. Then it is necessary to adjust the time period of the cutting cycle, in order to avoid a harvest greater than growth. PSP have showed to be an excellent tool for the monitoring of the main factors that assure sustainability in wood production. It is necessary to make a revision of the Forest Management Plan each five years. Forester must use information from the PSP established in the forest or from other similar forests.

Goals and Goal Conflicts in Forestry

Stig Wandén
Swedish Environmental Protection Agency, s-10648 Stockholm, Sweden
FAX: +46-8-69815585, Email: stig.wanden@environ.se

Keywords**:** integration, environmental goals, goal conflicts, evaluation.

In the European Union, as well as in Sweden, there is now a general consensus to accept the principle of integration, meaning that environmental protection should be integrated into the definition and implementation of other societal policies and activities. In other words, every sector of society - such as transport, energy, agriculture, forestry, and defence - is required to integrate environmental goals with its "ordinary" activities. In Sweden, this principle is closely connected to the introduction of explicit environmental goals. Thus, the national environmental goals are to be broken down into goals for each sector, which is then in principle responsible for their implementation. The process of defining goals on different levels is presently under way.

The Swedish Parliament has decided that the production goal of forestry (producing enough timber and pulp for forest industry) should be combined with environmental goals such as preserving old forests and biological diversity, avoiding acidification and eutrophication, and saving cultural values. The Forestry Board in October 1999 proposed more concrete goals concerning biotopes, ecological processes and functions, cultural values, diversified use of forests, and recycling. These goals are partly quantified, such as the area to be assigned to National Parks and the area of older forests to be preserved.

However, the problem of goal conflicts then arises, including not only conflicts between environmental and other goals (external conflicts), but also conflicts between different environmental goals (internal conflicts). The paper outlines an on-going evaluation of the principle of integration and goal conflicts. The evaluation uses methods from the social sciences, including questionnaires and interviews. The results of these are presently being analysed. One observation is that government agencies, as well as private sector actors, widely differ between each other - a fact which may have farreaching consequences for environmental policies. A number of suggestions to improve sector integration are also being considered, e.g. establishing principles for solving goal conflicts before they occur, more rational goal formulations including alternative goals, a more rational distribution of responsibilities, and better and open information about goal conflicts.

Net primary production and nitrogen mineralization of 12 forest ecosystems in Shikoku District, Japan

Yoshiyuki Inagaki, Satoru Miura
Shikoku Research Center, Forestry and Forest Product Research Institute, 915-2 Asakura Nishi machi, 780-8077 Kochi city, Japan
Tel: +888-44-1121, FAX: +888-44-1130, Email: yinagaki@ffpri-skk.affrc.go.jp

Keywords: Nitrogen mineralisatiion; Net primary production; Conifer forest; Deciduous forests; Japan

Nitrogen (N) is one of the limiting nutrients for productivity in temperate forest ecosystems. Thus, one could expect that nitrogen availability index such as net mineralization rate is positively correlated with forest productivity. Although many studies have revealed that the productivity of some plantations in Japan is significantly related with soil conditions such as water status and C/N ratio, little is known about the effect of net N mineralization rate. in the present study, we investigated the relationship between nitrogen availability determined by the laboratory incubation technique and forest productivity of 12 forest ecosystems in Shikoku District, Japan. They are composed of four different types of forests; Sugi (*Cryptomeria japonica*) plantations, Hinoki (*Chamaecyparis obtusa*) plantations, pine (*Pinus densiflora*) forests, and secondary temperate deciduous forests.

In addition, we estimated annual N input rates via litterfall for 2 years using litter traps. The study site has the warm climate and high annual precipitation (2800mm), which favours plant growth. Net N mineralization rates during 28-day laboratory incubation ranged from 7 to 207 ugN g^{-1}, which was higher in the deciduous broadleaf forests and lower in the Hinoki plantations and the pine forests. Annual litterfall N input rates ranged from 2.1 to 7.0 gN m-2 yr^{-1}, which was significantly correlated with net mineralization rates ($r=0.79$, $p<0.01$). This indicates the supply of N via litterfall is a crucial factor to affect the net N mineralization rate in soil. Indices of primary production, mean annual diameter growth of canopy trees and mean annual increment of stem biomass, were higher in the coniferous forests and lower in the deciduous broadleaf forests. We found no significant relationship between net primary productivity and net N mineralization in these forests. It is noted that high net N mineralization was observed in the deciduous forests with low productivity. On the contrary, litterfall N input to soil was negatively correlated with net primary production. This suggests the species, which has the high potential biomass production, can reduce N loss by litterfall. Nitrogen loss by litterfall implies the N loss form the ecosystem by leaching due to heavy rainfall in the region. in the deciduous forests, the net N mineralization rate during the 28-day incubation was as much as the annual litterfall N rate. This suggests that net N mineralization is very high and exceeds the plant demand in this ecosystem. In summary, we concluded that net N mineralization rate of soil is largely determined by the litterfall N input, and the effect of species is a primary factor in these forest soils. The differences of the net primary production were largely due to the inherent natures of the species rather than net N mineralization rates.

Relationship between Human Activities and Condition of Floodplain Forest Ecosystems in Central Europe

Emil Klimo
University of Agriculture and Forestry, Institute of Forest Ecology, Brno, Czech Republic
Email: tesarjar@mendelu.cz

Keywords: Flood-plain forests; Anthopogenic effects; Regional comparison; Central Europe

In Central Europe, floodplain forests represent a residual biome that persisted after profound changes in landscape use taking place in the past. The first human settlements were established in the territory of floodplain forests so that their area and nature gradually changed due to the anthropological effects. Floodplain forests in the alluvia of Morava, Dyje and Danube rivers represent today unique biomes which show a high level of production, excellent biodiversity of both plant and animal species, and valuable aesthetic and recreational functions in the landscape. in this territory, there is a national park, several protected landscape and many natural preserves. At present, the responsible organs try to take measures, which would enable their reconstruction, extension and re-vitalisation. Using the ecosystem of Central-European floodplain forests as an example we shall try to describe the extent, present condition and way of use of these forests by man. We have selected floodplain forests in the Litovelské Pomoraví alluvium (Czech Republic) as well as those along the confluence of the Morava and Dyje rivers (Czech Republic and Austria), in the National Park Danube (Austria), floodplain forests along the Morava river in Western Slovakia, floodplain forests near the Gabekovo dam in South Slovakia, and a unique example of floodplain forests situated within an urban region of Leipzig (Germany).

Simulating landscape scale forest management of disturbance-prone forest ecosystems

Volker C. Radeloff, David J. Mladenoff, Eric J. Gustafson, Donald R. Field, and Paul Voss
University of Wisconsin, Department of Forest Ecology and Management, 1630 Linden Drive, WI 53706-1598 Madison, USA

Keywords: Forest modeling; Landscape scale; Forest management; Disurbance; Land-use US

Landscape patterns of many unmanaged forest ecosystems are shaped by fire disturbance. These patterns tend to change once forests are managed; for example, forests become denser and large openings no longer occur. Such changes are often detrimental to wildlife species adapted to openings previously created by fire. It has been suggested that the spatial patterns of forest management should be altered so that they resemble natural disturbance patterns more closely. However, very little experience exists with such management, and experiments are difficult to conduct at the landscape scale. Our objective was to simulate landscape scale forest management of the Pine Barrens in northwest Wisconsin, U.S.A, to test how closely different management scenarios mimic natural disturbance patterns. The Pine Barrens region was shaped by fire until European settlement began around 1860. Detailed vegetation assessments of the pre-settlement vegetation are available. Also available is a satellite classification of the current vegetation cover, which is significantly different from the historic landscape due to logging, farming, fire suppression, and forest management. We used LANDIS, a landscape model that incorporates fire, windthrow, succession, seed dispersal and forest management to simulate possible future conditions of the Pine Barrens. We conducted a factorial experiment and changed the variables 'clear-cut size', 'rotation length', 'tree species for forest regeneration', and 'spatial allocation of clear-cuts' within LANDIS. The model was run under each management scenario for 500 years. We summarized the results as the abundance of openings for wildlife, and the volume of timber being harvested. The comparison of different management scenarios allows resource managers to choose the optimal management strategy according to their management goals. Our analysis reveals that forest management options exist that improve landscape patterns for wildlife without decreasing timber production significantly. However, different landowners in the Pine Barrens will manage their lands for different goals. We specified several management areas according to land-ownership and housing density, and conducted further LANDIS runs with spatially variable forest management scenarios. For instance, areas with high housing density and small private landowners are unlikely to be harvested in large clear-cuts. Land owned by industrial forest corporations may be harvested in large blocks, but economic considerations are likely to determine management decisions. Public forestland may be managed to maintain both large openings and commodity production. By allowing for different management practices for different landowners we were able to simulate future states of the Pine Barrens realistically. Landscape scale forest modeling can provide realistic predictions about the future of landscapes. These predictions are important for forest managers when they attempt to achieve multiple goals, such as wildlife habitat and commodity production over extended periods of time, and across entire landscapes. Our results highlight the potential and the limitations of forest management to restore landscape patterns previously created by natural disturbances. We suggest that similar modeling approaches may be suitable for many other forested ecosystems previously shaped by fire.

Long-term chronosequences of Norway spruce primary succession

Johan Svensson
Swedish University of Agricultural Sciences, Department of Forest Ecology, S-90183 Umea, Sweden
Tel: +46 90 7865895, FAX: +46 90 7867750, Email: Johan.Svensson@sek.slu.se

Keywords: *Picea abies*; Primary succession; Postglacial rebound; Chronosequence; Old-growth

The Fennoscandian crust is experiencing postglacial land uplift following the weight down by the Weichselian ice mass. A consequence is a perpetual exposure of new ground along the shores of the Gulf of Bothnia, ground on which primary succession is occurring as plants colonize and community forms. The ongoing land uplift provides a topographic sequence equivalent to a chronosequence - the lower the elevation the younger the land with younger, pio-neer communities, the higher the elevation the older the land and the more develo-ped the communities. The uplift amounts to maximum 0,092 m/year in the northern part of the Gulf of Bothnia. On a specific shore, the vegetational gradient reflects the actual course of succession. As long as no major disturbance interferes the primary succession continues progressively towards the regional climax for each ecosite type. The exposure of a specific shore is a key-factor that influences the vegetational gradient, i.e. species composition, initial establishment levels, rate of succession, etc. Thus, islands and peninsulas continue to rise seawards, and con-sequently the ex-posure of a specific shore may change (decrease) over time because of changed (increased) relative shelter. Moreover, as the community matures the importance of allochthonous plant colonization decreases, while the importance of autochthonous resurgence increases. It can furthermore be assumed that early successional processes primarily are under abiotic control while biotic factors take on greater importance later in the sequence. As the condition changes, this may modify the successional sequence by trigging a switch, or maintain a continuous change, in the pathway. Hence, multiple successional pathways should be taken into consideration, as well as disruptions in the presumed chronosequence.

8.02.00 Site: soil carbon

Soil properties under different types of tropical seasonal forests, in western Thailand

Keizo Hirai, Masamichi Takahashi and Pitayakon Limtong
Forestry and Forest Priducts Research Institute, Soil Chem. Lab., Forest Site Envir. Sec., Forest Envir. Div., 1 Matsunosato, Kukizaki, Matsunosato, Inashiki, 305-8687 Ibaraki, Japan
Tel: +81-298-73-3211(Ext.362), FAX: +81-298-73-1542, Email: hirai@ffpri.affrc.go.jp

In tropical seasonal forest area, soil moisture gradients are one of the major factors for regulating forest types, so that soil chemical and physical properties would be different among forest types. The aim of this research is to clarify the characteristics of soil properties under different types of tropical seasonal forests in western Thailand. It is necessary to evaluate soil productivity for sustainable management of qualitative and quantitative maintenance of tropical seasonal forest. Sites and methods The study site is located at the Mae Klong Watershed Research Station, Kanchanaburi western Thailand (Suksawang, 1995). Soil type around study site was classified to Ultisol or Inceptisol (USDA 1997). Natural vegetation types around the watershed are mainly mixed deciduous forest (MDF), dry dipterocarp forest (DDF) and dry evergreen forest (DEF). Teak (*Tectona grandis*) plantations (TPF) and grassland that was used for shifting cultivation (GRL) in the watershed were also surveyed. in 1995, seventeen soil profiles under different forest types and topographic positions were described, and soil samples are collected for soil chemical and physical analysis. Nitrogen availability of top and sub surface soil samples were also determined. Results and discussion

Amounts of carbon storage in soil were higher 205t/ha/100cm depth in DEF and lowest 71 t/ha/100cm depth in DDF. The carbon storage on MDF, TPF, and GRL did not vary among pedons. Organic carbon and total nitrogen content in GRL were higher than another soils but these contents among another soil were not so different. in most case, carbon contents decreased gradually from top to lower horizon but the soils under DDF showed drastically decrease in carbon contents from the surface horizons. The same trends were observed for nitrogen distribution patterns in the soil profiles. Available nitrogen contents in soils of MDF and DDF types were 0.45-1.1mg-N/kg dry soil. GRL also had high available nitrogen in soils (1.3-1.6mg-N/kg dry soil) while TPF had low available nitrogen (0.5 mg-N/kg dry soil). in each forest type Soils in lower slopes showed higher nitrogen availability than in ridge and upper slopes. Nitrate nitrogen was major part of available nitrogen. Nitrification rate (nitrate nitrogen to available nitrogen) were more than 80% in almost of surface soil samples. Calcium is a major exchangeable base and following to magnesium and potassium. The content of Ca and Mg were also high in GRL, DEF and lower slope of TPF but were on the lower than those in the soils of limestone plateau near the watershed reported by Janmahasatien et al. (1997).

Conclusion: The results of soil chemical properties indicate that soils in this watershed are relatively fertile, especially for soils under DEF. The GRL also showed high soil fertility although they used to be utilized for shifting cultivation. The soils in TPF contained lower nutrients even though they located on lower slope. The reason is not sure but this may be caused by high nutriment requirement of tree growth or surface soil erosion of teak plantation. We are great thanks to National Research Council of Thailand Science and Technology Agency Japan and Japan International Research Center for Agricultural Sciences for their financial support in this research.

Nutrient Dynamics in the Throughfall, Stemflow and Litterfall of Korean Pine, Japanese Larch and Hardwood Stands at Kyunggi-Do, Korea

Don Koo Lee, Dong Yeob Kim and Young Dae Park
Seoul National University, Dept. Forest Resources, 103 Seodun-Dong, Kwonsun-Gu, 441-744 Suwon, Korea R. Tel: +82-331-290-2337, FAX: +82-331-293-1797, Email: leedk@plaza.snu.ac.kr

Keywords: Nutrient dynamics; *Pinus koraiensis*; *Larix leptolepis*; Hardwood

The objective of this study was to examine the amount of nutrient input and dynamics by throughfall, stemflow and litterfall among *Pinus koraiensis*, *Larix leptolepis* and hardwood stands including oak forests at Kyunggi-Do, Korea. The nutrient distribution and cycling in a forest ecosystem was strongly influenced by tree species and human impacts including forest practices. The amount of Ca in the aboveground vegetation was the highest, followed by N, K, Mg, P and Na in descending order. Nutrient content in the hardwood stand was relatively high, although its tree biomass was low. The amount of K in the hardwood stand was exceptionally high whereas that of *L. leptolepis* stand was the lowest in nutrient contents. The amount of litter nutrient in the *P. koraiensis* stand was relatively lower than other stands, which seems to be due to the forest practices. The amount of N in the litterfall was the highest, followed by Ca, Mg, P, K and Na in descending order.

Monthly amount of nutrient input by throughfall and stemflow was significantly affected by the characteristics of rainfall and stand structure. The amount of throughfall in the hardwood and *L. leptolepis* stands showed greater than *P. koraiensis* stand while that of stemflow in the hardwood stand did greater than other stands. The differences in the amount of throughfall and stemflow for each of the stands seemed to be caused by its leaf-retaining period and physiological characteristics.

The ion concentrations of throughfall and stemflow showed in the following order: NH_4^+-N>K^+> Ca^{2+}> Na^+> Mg^{2+} for cations and SO_4^{2-}> NO_3^-N> Cl^- for anions. After the precipitation passed through the canopy, K^+ increased most in the hardwood stand, whereas NH_4+-N did most in the *P. koraiensis* and *L. leptolepis* stands.

Ectomycorrhizal fungal flora in the miombo woodlands of Africa: diversity and sensitivity to land-use

Esron Munyanziza
Sokoine University of Agriculture, Department of Forest Economics, Post Box # 3011, Morogoro, Tanzania
Tel: +255 56 4865, FAX: 255 56 4648/3718, Email: dofe@suanet.ac.tz

Keywords: Miombo woodlands; Ectomycorrhizal fungi; Mushroom; Thinning; Tap root; Africa

The miombo woodlands occur in the eastern, central and southern African countries. They are found in areas having limited rainfall, experiencing regular wildfires and subject to continuous human disturbance. They are the most extensive vegetation and the most used type of woody ecosystem in Africa. Millions of humans and animals depend upon the miombo woodlands for food, water and shelter. Wild mushrooms are among the most frequent resources and yet the most vulnerable and the most endangered. in order to cope with uncertainties and capture short-lived opportunities, the miombo trees focus on the development of the root compartment. (1) They develop a very extensive and robust tap root system where they store carbon and water. (2) They are associated with ectomycorrhizal fungi, which help extract water and minerals in a hostile physical environment.

The working hypothesis was that sugar reserve in the taproot is a necessary store to enhance and sustain mushroom occurrence during the period when the top is thinned in the cropping season. This kind of thinning is common in the miomo zone. in order to test this hypothesis selective cutting of all ectomycorrhizal trees of the genera Julbernardia globiflora or Brachystegia species was implemented in the middle of the miombo woodlands in Morogoro, Tanzania. Cutting was made just prior to the short rains, which usually start towards the end of October. Subsequent shoots, which sprouted from the stumps, were regularly thinned to zero. Stumps were kept alive. The control plots were demarcated in the surrounding of cut plots. These were left intact. Farms established in the neighbourhood by total clearing of the miombo woodlands were identified. During the short rains and the long rains, which fall sometimes between end of February to the end of May, daily visits were made to the plots and mushroom occurrence assessed in the cleared and the non cleared plots. Similar assessments were made in agricultural lands where miombo trees were earlier cut with regular thinning of sprouts or uprooted and replaced by exotic agroforestry trees. Selective cutting of ectomycorrhizal trees followed by removal of sprouts from the stumps inhibited the occurrence of ectomycorrhizal mushrooms in the site and in the farms. in the cleared plots only saprophytic fungi produced sporophores while a wide range of ectomycorrhizal fungi produced mushrooms in the control. The study revealed the very intimate relationship between the trees and the mushrooms. It showed the sensitive part of the host: the leaves. The study suggests that the energy stored in the root system or in the stem is either unfit for ectomycorrhizal fungal use or is set aside for particular function of the tree prbably to reinitiate sprouting after the long dry season or after top removal. This study carries the message for the sustainable management of the miombo woodlands for multiple uses.

Planting trials of indigenous species at sandy soil area in southern Thailand

Keywords: Reforestation; Sandy soil; Indigenous species; *Dipterocarps*; Southern Thailand

We have been carried out reforestation trials since 1994 in southern part of Thailand, where infertile sandy soil area is expanded as a result of a failure of agricultural development. We have been trying to plant valuable trees focusing on indigenous species including *Dipterocarps*. Twenty-three tree species have been tried; *Anisoptera sp., Dipterocarpus alatus, D. chartaceus, D. obtusifolius, Hopea odorata, Shorea glauca, Shorea hypochra, Shorea leprosula, Shorea roxburghii, Parashorea sp., Vatica pauciflora, Acacia mangium, Acacia auriculiformis, Anacardium occidentale, Alstonia macrophylla, Alstonia spatulata, Casuarina equisetifolia, Euodia roxburghiana, Fagraea fragrans, Syzygium grande, Syzygium kunstleri, Syzygium oblatum* and *Syzygium spicatum.* The area undergoes a severe drought in dry season and is waterlogged in rainy season. in dry season, the surface soil temperature exceeds 40 oC. The seedlings planted in such area are faced to harsh environmental stresses, resulting in low survival ratio and little growth. Our trials revealed that planting *Acacia mangium* proceeding to the purposed-tree planting improves the seedlings' survival and growth. in *Acacia mangium* forest, light intensity was diminished and soil surface temperature was dramatically lowered than those in open area, which may weaken the photodamage under infertile condition or high temperature stress. *Acacia mangium* itself also suffers from the harsh environment, resulting in low survival ratio in case of no treatment. Plowing brought remarkable improvement of the *Acacia mangium* survival, which confirms its beneficial ability to nurse the subsequently-planted indigenous species. Pot size effects on seedlings' survival and growth were examined on some dipterocarp species. Larger pots brought better seedlings survival without any help of *Acacia mangium*. Ecophysiological studies have also been carried out for better understanding of the planted seedlings' growth performance. Among the dipterocarp species examined for planting at open site, *D. obtusifolius* showed obviously better survival than others. We compared photosynthetic performance of *D. obtusifolius*, D. chartaceus and H. odorata, which revealed remarkably higher light-saturated photosynthetic rates in *D. obtusifolius* than in other two species. Additionally, the light-saturated photosynthetic rates of *D. obtusifolius* were even higher than those of *Acacia mangium*.

Properties of organic matter and the soil adsorption complex in forest ecosystems of Croatia

Nikola Pernar, Darko Baksic
University of Zagreb, Faculty of Forestry,
Svetosimunska 25, Zagreb, Croatia
Tel: 385 1 235 24 29, Email: nikola.pernar@zg.tel.hr

Keywords: Organic matter; Humus; Soil adsorption complex; Forest ecosystems

Transformation and movement of matter and energy is a characteristic feature of every ecosystem. A specific correspondence among individual elements of an ecosystem is manifested in a particular manner in the soil. in forest associations, which are in natural harmony with the climate and parent substrate, the properties of physical-chemical soil sorption and the condition of organic matter in the surface part of the soil are very interesting. This is significant pedogenetically in terms of transformation and migration of matter, and physiographically in terms of the nutritive soil status analysis and the related ecosystem diversity.

Research was done on the humus content and the adsorption complex saturation in humus-accumulative soil horizons in characteristic climatozonal associations in the vegetation belts located in flat, hilly, and mountainous regions in Croatia. The results of research have shown that some forest ecosystems have characteristic humus properties, characteristics of the adsorption complex display considerable variability, the correspondence between the properties of humus and the adsorption complex can be explained with internal and external factors, the adsorption complex and humus correspond well to floristic diversity of forest stands, in clayey and sandy substrates (or substrates that release either clayey or sandy material via transformation) an influence can be detected not only on the state of adsorption complex, but also on the state of humus.

Brazilian ecological classification for tree planting

Maria das Gracas F. Reis, Ivone P.S. Moreira, Leonaldo A. Andrade; Victor H. Acosta
Federal University of Vicosa, Department of Forestry, 36571-000 Vicosa, Brazil
Tel: 55-031-8991209, FAX: 55-031-8992478, Email: mgfreis@mail.ufv.br

Keywords: Ecological classification; Brazilian territory; Tree planting

An ecological classification of the Brazilian territory has been developed in order to subdivide the country into ecological regions and sub-regions with the aim to subsidize tree species selection for planting. The classification system was subdivided into two levels: at the first one, the country has been subdivided into ecological regions using the altitude and several climatic variables related to air temperature, precipitation, humidity and some of the Thornthwaite? indices; at the second one, native vegetation types, soil classes, geological groups, relief classes and drainage density have been used to subdivide the country into ecological sub-regions.

In order to obtain the delimitation of the territory into ecological regions, the steps are described as follow. All published data available from meteorological stations have been used. Considering the reduced number of meteorological stations in Brazil, precipitation data have been obtained from pluviometric stations. Estimated temperatures have been obtained for all pluviometric stations lacking this information. At first, these data were submitted to interpolation, using cells of about 15 x 15 km, in order to have an even distribution of the data. This analysis has been developed in blocks of 4o by 4o of latitude and longitude. in the next step, the data were submitted to factorial analysis. Factorial loads with correlation higher than 70% were extracted from each factor to constitute the linear indices, which replaced the original variables. These indices originated the input data for grouping and discriminant analysis, generating the subdivision of the territory into ecological regions. Each region was described based on the average value of the cells contained on it, for each variable analyzed.

In order to obtain the delimitation of the territory into ecological sub-regions, the steps are described as follow. The maps containing native vegetation types, soil classes, geological groups, relief classes and drainage, when available, were digitalized. A net corresponding to 8 x 8 km in the field was designed over the map in order to obtain the proportion of cover of each variable per cell. These data were submitted directly to both non-hierarchical grouping and discriminatory analysis, making possible the delimitation and characterization of each ecological sub-region.

At the ecological region level, the results have shown that three to four factors can be responsible for 80 to 88% of the cumulative explanation of the original data. The first factor usually explains from 40 to 59% of the variance in the original data and is mainly constituted by altitude and temperature variables. The recent inclusion of Thornthwaite? indices improved substantially the delimitation of the ecological region, once most indices were included in the first or second factors, in special for the northeastern region, where water availability is quite variable within very short distances. in the southern region of Brazil precipitation is quite high and uniformly distributed. For this region, humidity was more important than precipitation with all humidity variables used being included in the second factor.

At the ecological sub-region level, the method was already applied to one block of 4o by 4o. The discriminant analysis proved that 94% of the cells were correctly allocated to the ecological sub-regions, using a subdivision into 12 sub-regions. The variables used were complimentary, i.e., when two or three regions were similar in terms of one variable they differed from each other based on other group of variables.

Carbon and Nutrient Cycling in a Mixed Deciduous Forest of western Thailand

Masamichi Takahashi, P. Limtong, S. Suksawang, U. Kutintara, P. Tummakate, S. Anunspongsak, K. Hirai, and K. Ishizuka
Forestry and Forest Products Research Institute, Tsukuba Norin Kenkyu Danchi-nai, P.O.Box 16, 305-8687 Ibaraki, Japan
Tel: +81-298-733211, FAX: +81-298-731542, Email: masamiti@ffpri.affrc.go.jp.

Keywords: Nutrient cycling; Seasonally dry tropical forest; Soil conditions; Mineralization

Nutrient cycling is an essential knowledge for sustainable forest management. Especially in tropical countries, biomass is largely accumulated in aboveground on relatively nutrient poor soils, which indicates that deterioration of forest would directly result in loss of nutrient from the ecosystems. Many studies on the distribution of carbon and nutrient pools in the forest ecosystems were conducted in the tropical rain forests but a few studies are available in seasonally dry tropical forests. Mixed deciduous forest (MDF), a vegetation type of seasonally dry tropical forest, is widely distributed in eastern Asia, from India to Thailand. It is concerned that intensive uses and frequent fire may reduce forest resources and nutrient pools in the ecosystem. The objective of this study is to determine the pool sizes and fluxes of carbon and nutrients in MDF of western Thailand for understanding nutrient dynamics in undisturbed condition. The study was conducted at an undisturbed mixed deciduous forest in the Mae Klong watershed research station, Kanchanaburi, western Thailand. Annual rainfall is about 1,600 mm and it falls mostly from April to November. Mean annual air-temperature is about 27 C. Dominant tree species are Shorea siamensis, Dillenia parviflora var. kerrii, Xylia xylocarpa var. kerrii, and Vitex peduncularis. Most of the forest understory was prevailing with bamboo species. Ultisols are dominant soil types, which are derived from sedimentary rocks and gneiss. in this watershed, limestone is also found. Soils show slightly acidic and lightly clay textures.

In the total ecosystem, carbon was sequestrated 308 MgC/ha. Above and below ground biomass were accounted for 130 and 43 MgC/ha, respectively. Bamboo understory showed 16.4 MgC/ha for aboveground, and 3.1 MgC/ha for belowground. Mineral soil (0-1m in depth) stored 125 MgC/ha. For dead organic matter, a carbon pool in standing dead of trees and bamboos (6.8 MgC/ha) were larger than that in litter layer (2.8 MgC/ha). Annual carbon input was 4.5 MgC/ha by litterfall and carbon release by soil respiration was estimated 19.3 MgC/ha annually.

The amounts of nitrogen in the above and below vegetation were 1,470 and 593 kg/ha. Soil is a largest pool for nitrogen and the pool size was 9,170 kg/ha. Phosphorus was distributed 166 kg/ha for aboveground vegetation and 57 kg/ha for belowground. For cation distributions, vegetation is a main nutrient pool. Around 56 - 60 % of cations were stored in the aboveground biomass. Nutrient pools in the soil were small for available P and exchangeable cations: 13 - 15 % of total pool.

Annual litter production was 9.0 Mg/ha and 66% of the total litterfall was leaf litter. The fluxes of nitrogen and phosphorous by litterfall were 66 kgN/ha and 5.5 kgP/ha, respectively. For cations, 39 kg/ha of K, 129 kg/ha of Ca, and 27 kg/ha of Mg were return to the soil by litter annually. in these nutrient returns, more than 90% of each element was transferred via leaf litter.

MDF contained relatively larger amount of nutrients in aboveground biomass than tropical rain forests reported. Low ratios of biomass: elements in fresh litter also indicate that there was no nutrient deficiency in this ecosystem.

Effects of carbon properties on characteristics of nitrogen mineralization in forest soil

Keywords: Carbon mineralization; C/N ratio; Kinetics model; Nitrogen mineralization; Nitrogen immobilization

Nitrogen (N) is usually the most limiting nutrient in forest ecosystem vegetation. The amount of N mineralization by microorganisms is an important indicator of N availability in forest soils. in general, the net N mineralization of organic matter is small when the carbon/nitrogen (C/N) ratio of soil is high because inorganic N is immobilized by soil microbes. Nitrogen availability in soil is frequently limited by not only the amount of carbon (C) or the C/N ratio, but also by the amount of available C. in this report, the characteristics parameters of N and C mineralization in forest soils were investigated by analyzing the kinetics model. It was based on the results of the following in vitro incubation. The soil samples were taken from Japanese cedar (*Cryptomeria japonica*) stands (3 plots), Japanese cypress (*Chamaecyparis obtusa*) stands (3 plots), deciduous broad-leaved stands (1 plot) and evergreen broad-leaved stands (2 plots) in Kanto region, Japan. Soil samples were taken at depths of 0-10cm and 10-20cm in each plot. The organic layer (O-layer) samples of forest soil were taken from 5 plots. The fresh soil samples were sifted through a 4mm sieve, and the fresh O-layer samples were cut into about 10mm pieces, and incubated at 20, 25, and 30? for 100 to 200 days. The samples were extracted at 3-30 day intervals, and the amount of inorganic N and the rate of C dioxide (CO_2) evolution were measured. Using Arrhenius' law, experimental results obtained under each temperature conditions can be transformed into a mineralization rate at a standard temperature (25°). Parameters of N mineralization potential (N0), the N mineralization rate constant (k) at 25° and apparent activation energy (Ea) are normally estimated by mathematical analysis using a simple type of kinetics model in forest soil. The N mineralization process in the O-layer of forest soil was fitted to a kinetics model of N mineralization combined with an immobilization. in the case of the O-layer, the potential of gross N mineralization (Nm0), immobilization (Ni0) and net N mineralization (netN0 = Nm0 - Ni0) were examined. The amount of C mineralization was calculated by integration of the CO_2 evolution rate. The integration of C mineralization was fitted to a simple type of the kinetics model, and the C mineralization potential (C0) was examined. The relationship between the C/N ratio and N mineralization parameters was not significant in any of the soil samples. However, in soil samples where the C/N ratio was >20, the C/N ratio and N0 had a negative correlation and the C/N ratio and Ea had a positive correlation. These suggest that N mineralization was limited by the C/N ratio of soil because active N was immobilized in soil where the C/N ratio was >20. in soil samples where the C/N ratio was <20, N mineralization was not limited by the C/N ratio because N immobilization activity in the soil was depressed. There was a positive correlation between C0 and N0; the regression line was C0/N0=20. The potential C/N ratio of available organic matter utilized by microbes was about 20 in the forest soil. k was the greatest and Ea was the smallest when C0 was 7-8% of total C (C0/C). This suggests that there is little C0 available for N mineralization when C0/C<7-8%, and that there is sufficient C0 for N immobilization when C0/C>7-8%. Thus, C properties are important as indicators of movements of the amount of available N in forest soil.

8.03.00 Forest Hydrology and Water Quality

Applying the caesium-137 technique for studying sediment redistribution at basin scale

Vito Ferro, C. Di Stefano, G. Callegari, F. Iovino, P. Porto, A. Veltri, S. Rizzo

Keywords: caesium, sediment yield, tracers

Identifying areas of the landscape that are most sensitive or susceptible to erosion stimulated the study of within-basin variability of the sediment delivery processes and the use of spatially distributed models coupled with Geographical Information Systems.

The progress of distributed models is hindered by the lack of measurements able to establish the link between the eroded soil leaving an area and the patterns of erosion and deposition occurring along the hydraulic path from the considered area to the nearest stream reach. Tracer techniques afford an alternative to the use of plots and a means of overcoming the problems of measurement representativeness and spatial variability.

The tracer most widely used in soil erosion and sediment yield studies is caesium-137, an artificial radionuclide which was released into the environment as a result of above-ground thermonuclear weapons testing. Fallout deposition on the land surface occurred mainly with precipitation. When fallout caesium-137 comes in contact with soil, it is readily fixed or adsorbed on the organic and clay particles and subsequent movement by natural chemical and processes is limited.

In this paper caesium-137 measurements available for two basins with different crop covers, located in Sicily and in Calabria, are used for validating the Sediment Delivery Distributed (SEDD) approach based on the Revised Universal Soil Loss Equation and the sediment delivery ratio of each morphological unit into which the basin is divided. For the Sicilian basin, which is used for wheat cropping, the predictive ability of the SEDD model is positively tested comparing the calculated sediment yield values with the measured ones obtained by the caesiographic map and the proportional method of Martz and de Jong. For the Calabrian basin, which is covered by *Eucalyptus occidentalis* Engl., the testing of the SEDD approach is carried out by comparing the calculated sediment yield and the caesium loss at the morphological unit and basin scale.

Assessment of Selected Water Channels as Affected by Waste Disposal in Nangalisan, Tuba, Benguet, Philippines

Filmorie G. Ganzon
Ecosystems Research and Development Service,
Department of Environment and Natural Resources
Cordillera Administrative Region, Loakan Road, 2600
Baguio City, Philippines
FAX: 0063-442-4531, Email: erds-car@mozcom.com
Key words: water quality, biochemical oxygen demand

In the Philippines, water quality assessment started at Irisan, Baguio City (dumpsite) and Calot Sablan, Benguet (piggery farm). The other sampling points chosen for consideration were closely monitored and evaluated as to which tributaries may contribute water pollution to stream and rivers.

The BOD (Biochemical Oxygen Demand) for all water samples collected during the rainy season is within or below the limits of 5 mg/l (yearly average values). The results of analyses during the dry months are also below this limit. The findings revealed that the stream can presently accommodate the approximate quantity of oxygen that will be required to biologically degrade/stabilize the organic matter present but in a specified time and temperature.

On the other hand, the DO (Dissolved Oxygen) in all water samples collected from the sampling points established at various locations during the rainy season is above the limit of 5.0 mg/l. Surprisingly, when it was compared to the results taken during the dry season, it is still above this limit. From laboratory tests, it appears that dissolved oxygen is sufficient to support and maintain all forms of aquatic life. Although it is being contaminated by various combinations of liquid and solid wastes from residences and industrial establishments, aerobic decomposition is still taking place in the presence of oxygen.

Meanwhile, the total coliform organisms detected in colonies per 10 ml of water samples at 24 hours included Escherichia coli, Citrobacter freundii, E. agglomerans and Enterobacter aerogenes. Water samples tested on site have pHs ranging from 6.5 to 8.5 indicating that microbial growth can be accommodated but if the pH falls below 5, microbial activity will cease. No health-based guidelines have been proposed for pH.

Sustainable Management of a Forested Catchment following Conversion from *Eucalypt* Forest to Radiata Pine Plantation

Peter Hopmans, L.J. Bren, and D.W. Flinn
Centre for Forest Tree Technology, Post Box # 137, 3084 Heidelberg, Australia
Tel: +61 3 9450 8693, FAX: +61 3 9450 8644, Email: p.hopmans@nre.vic.gov.au
Key words: water quality, water yield, radiata pine

Australia has a large trade deficit in forest products and extensive plantations of radiata pine have been established as part of a strategy to expand the nations wood resources. Initially, softwood plantations replaced native eucalypt forest, but since the mid 1980s plantations have been established mainly on cleared agricultural land. Associated with this conversion of catchments to intensively managed, fast-growing plantations are changes in hydrology and potential impacts affecting water yield and water quality.

Australia has adopted the Montreal Process of socio-economic and environmental criteria and indicators for the sustainable management of forests. The maintenance of water quality within the range of historic variation is one of the environmental indicators included in this Process.

In the mid 1970s the Cropper Creek Hydrology project was established to study the hydrology of three small catchments of mixed species eucalypt forest. in 1980 one catchment was cleared except for a 30-m wide riparian zone for the establishment of a plantation of *radiata* pine. in the short term this change in land use increased annual water yield by 3.5 ML/ha, but yield gradually decreased to pre-treatment values with time from clearing (Bren and Papworth 1991). Only minor changes in water quality were observed, but export of suspended solids and nutrients in streamwater increased because of higher water yield in response to clearing (Hopmans et al. 1987).

In 1997, the Cropper Creek study was resumed to evaluate the long-term changes in hydrology and water quality of the 17 year-old radiata pine plantation compared with historic data for the forested catchment prior to conversion. This showed little change in water yield and water quality. Present median values for turbidity (3.6 NTU), total suspended solids (4.2 mg/L), electrical conductivity (2.9 mS/m), and concentrations of sodium (2.4 mg/L), potassium (0.6 mg/L), calcium (0.8 mg/L), and magnesium (1.5 mg/L) are in close agreement with historic values. Furthermore, results also showed that the variation (median absolute deviation) for each of these parameters at the mid-rotation stage of the plantation closely matches the historic variation of the catchment under native eucalypt forest. These results indicate that the change in land use to more intensively managed softwood plantations has maintained the high quality of the water from this forested catchment.

Modelling the Water Balance on Small Mountaineous Catchments

Pavel Kovar
Czech University of Agriculture, Forestry Faculty, Kamycka 129, 165 21 Prague 6 Prague, Czech Republic
Tel: + 420-2-24382148, FAX: + 420-2-20922252, Email: kovar@lf.czu.cz
Key words: Water balance, torrent control, deforestation

Land use and management in a catchment can significantly influence rainfall-runoff processes. This effect is even greater on small mountainous catchments with highly fluctuating water discharges and with substantial sediment transport. To reduce the detrimental impacts associated with storm rainfalls, foresters may apply a broad variety of torrent control measures on a catchment.

Expensive hydraulic structures and heavy embankments in river beds are usually less effective than those implemented sustainably over the whole catchment. However, this does not mean that torrent control associated specifically with rivers should be minimized, and land use or forest protection applied exclusively as a safeguarding measure. Foresters are usually well aware that a combination of both technical and biological aspects applied over the whole catchment is necessary for effective torrent control. Such a qualitative assessment is well known. However it is necessary to quantify rainfall-runoff processes and to understand them better before deciding on a final form of torrent control.

To better analyse natural processes in a catchment, the implementation of hydrological models is recommended. With this view in mind the WBCM-5 model (Water Balance Conceptual Model, version 5, Kovar et al., 1996) has been developed. This model can provide a good simulation of the catchment water balance when rainfall-runoff data are available. in the case of ungauged catchments the model parameters can be estimated from hydrological and geomorphological analyses. Furthermore, the WBCM can be used to predict the impact of changes in land use, and forest pattern especially species displacement and age structure. The model is physically based on probability distributed values of parameters over a catchment in respect to their area variability. It has 13 parameters only three of which need to be optimized according to runoff observation or "adjusted" to resemble similar soil-hydraulic conditions. The other parameters can be determined from maps and from commonly available data. The WBCM model considers all substantial interactions between individual horizontal zones as vegetation, land surface, active (root) zone, unsaturated and groundwater zones. It simulates the following processes:

- Potential evapotranspiration and interception
- Surface runoff and active zone dynamics
- Unsaturated zone moisture and actual evapotranspiration
- Saturated zone dynamics, basic runoff, total runoff

In this study, the water balance of a small experimental catchment, CERNA NISA in northern Bohemia in the Czech Republic (area: 1.87 k m^2, length of stream 2.10 km with the slope of 2.3%, average altitude 800 m a.s.l., average annual rainfall 1070 mm, average annual runoff 666 mm) was analyzed. The outlet of CERNA NISA is gauged (profile UHLIRSKA) and the daily flow was first used for the model parameter assessment. Data for the growing seasons from 1980 to 1996 were used to simulate the water balance. The next step was to implement the model further in a simulation of hypothetical scenarios representing changes in land use and deforestation in particular. It has been shown to what extent deforestation can influence individual components of the water balance. It usually decreases interception and actual evapotranspiration, and increases surface runoff. These changes have been quantified by the WBCM model in other places in the Czech Republic (Kovar, 1998). The model can also be used to predict flood levels when the active zone is close to saturation.

The mountainous stream water chemistry from Japan to northern Thailand

Yasunori Nakagawa, Goro Iwatsubo
Kyoto University, Laboratory of Forest Ecology, Graduate School of Agriculture, Oiwake-cho, Kitashirakawa, Sakyo-Ku, 606-8502, Kyoto, Japan
FAX: +81 75-753-6080, Email: yasunori@kais.kyoto-u.ac.jp

Key words: stream water chemistry

The chemistry of mountainous stream waters from 12 forested watersheds in six regions was evaluated. Three watersheds were selected from Shibecha (43°17’ N, 147°37’ E), Hokkaido Prefecture, two from Takayama (36°11’ N, 137°19’ E), Gifu Prefecture, two from the Mt. Hiei (35°06’ N, 135°51’ E) in Otsu, Shiga Prefecture, three from Kagawa Prefecture (34°12’ N, 134°12’ E), one from Jiulianshan (24°31’ N, 114°28’ E), southern China, and Chiang Mai (18°47’ N, 98°37’ E), northern Thailand. pH was determined by glass electrode; EC (electrical conductivity) by a conductivity meter; Na^+, NH_4^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, NO_3^-, and SO_4^{2-} by ion chromatography; Si (only for stream water) by inductively coupled plasma (ICP) spectrometry. The concentrations of HCO_3^- (meq/L) were calculated from the difference between total measured cation and anion concentrations.

EC and strong acid anion concentrations in stream water increased with low Humidity Index (HI) values, suggesting that dry conditions increased concentrations due to high rates of evapotranspiration. Anion concentrations were also affected by other factors. The Cl^- concentrations in stream waters were higher in those watersheds which had closed canopies and were nearer to the ocean. The NO_3^- concentrations were higher in those watersheds having well developed soils and high moisture conditions, but were lower in tropical and subtropical watersheds which had high rates of nitrogen uptake and for watersheds with large areas of saturated soils. The SO_4^{2-} concentrations were affected by SO_4^{2-} adsorption properties of the soils: at Shibecha, Jiulianshan and Chiang Mai with high adsorption capacities. SO_4^{2-} concentrations in streams were low. High SO_4^{2-} concentrations were found at Mt. Hiei and Kagawa due to the weathering of sulfur minerals and high levels of atmospheric sulfur deposition. Within the regions, SO_4^{2-} concentrations were inversely related to NO_3^- concentrations. However, HCO_3^- concentration did not exhibit a clear relationship with HI. This may be caused by the fact that (a) HCO_3^- concentration is affected by CO_2 partial pressure, pH and geological conditions, and (b) HCO_3^- concentrations may include some organic anions in this study. A comparison among all watersheds exhibited significant positive correlation between HCO_3^- concentration and pH, suggesting that H^+ consumption in deeper soil increased pH and HCO_3^- concentrations. The correlation between pH and EC was clearer than that between pH and HCO_3^- concentrations in stream water. The relationship between pH and EC was determined mainly by that between pH and HCO_3^- concentrations, and partially by the neutralization of strong acid anions in soil.

Water yield from *Pinus radiata* plantations: A review

Lindsay Rowe, B D Fahey, R J Jackson
Landcare Research, PB # 69, 8152 Lincoln, New Zealand
Tel: +64 3 325 6701, FAX: +64 325 2418, Email: rowel@landcare.cri.nz

Key words: water yield, *Pinus radiata*, plantations, afforestation

Globally, there are fears that the establishment of plantations of exotic forest species for wood fibre production may have a detrimental effect on the environment, especially those aspects relating to water yield, water quality, erosion and sedimentation, soil degradation, and biodiversity, These fears are often raised where *Pinus* and *Eucalyptus* forests are established in the headwaters of catchments in areas where there could be diminished water yields. Arguments can then arise between foresters who 'use' rain water to meet the biological needs of trees for growth, and downstream-users who require water for municipal, stock-water and irrigation supplies, and to sustain minimum levels in rivers for recreation and maintaining-stream habitats, especially at times of seasonally low river flows. This paper reviews data on water yields from catchments with established *Pinus radiata* plantations. The information, mainly from studies in New Zealand, Australia and South Africa, has been obtained from a search of the literature in world-wide databases. A number of these studies report on the differences in water yield between pine-covered catchments and those with other vegetation covers, e.g., indigenous forests, grasslands, and pasture.

Layang Reservoir sorbed-phosphorous loadings estimation

Supiah Shamsudin, Mohd Azraii Kassim
University Putra Malaysia (UPM), Serdang 43400 Selangor, Malaysia

Key words: phosphorous loadings, sediment yield

Phosphorous (P) and sediment inflow from reservoir drainage areas can accelerate the process of eutrophication or lake aging. The phosphorous and sediment inflows may originate from forests or agricultural activities and plantations around the drainage area. Recent investigations seem to favour phosphorous as the limiting factor for reservoir productivity (Henderson 1979). The purpose of this study was to estimate the rate of phosphorous loadings from the drainage area into Sungai Layang Reservoir situated in Johor, Malaysia. The phosphorous loadings rate at the Sungai Layang Reservoir was determined by using an event-based stochastic model developed by Duckstein and Bogardi (1978).

The area surrounding Sungai Layang Reservoir is covered with palm oil and rubber trees with some portions under primary forest. The remaining land is used for agriculture, cultivation of fresh water fish, etc. Fertilizer was used to increase the agricultural yield. There are some chicken and pig breeding areas which affected the water quality of the reservoir. There are five rivers flowing into the reservoir. However, all of the rivers except the river flowing through Ladang Ban Foo are dry most of the time, but the main channel has water flowing throughout the year. All other rivers have water flowing only during heavy rainfall.

The model described by Duckstein and Bogardi took into account the two types of phosphorous: dissolved-phosphorous and sorbed-phosphorous. Sorbed-phosphorous is also known as sediment-phosphorous. In the precipitation event-based stochastic model the stochastic nature of the nutrient input is recognized. The model also encoded uncertainties in the form of a relative frequency distribution and probability density function (pdf). Daily inflows for the stochasticity estimation are acquired by means of the Mike 11 NAM model. The probabilistic description of phosphorous loadings in terms of relative frequency, mean and variance is sought.

Water samples were taken randomly from both the river and reservoir at the water surface, and the middle, and bottom layers. The water samples were tested with reagent phos Ver 3 phosphate using DR 3000 to indicate the phosphorous content in mg/l. Preliminary studies indicated that dissolved phosphorous concentrations ranged from 0.01 mg/l to 1.07 mg/l from various locations in the river and reservoir. The total average concentration obtained from the study was 0.0410 mg/l @ 41.0 ug/l. Other aspects of water quality were also recorded: average pH was 6.95, while the average DO was 7.19 mg/l. The mean dissolved-phosphorous loadings per storm computed from the event-based stochastic model was 0.095 t/event while the variance was 0.021 t/event. The mean annual total dissolved P-loadings was 4.175 t/yr and the variance was 3.81 t/yr.

Sediment yield was estimated using the Modified Soil Loss Equation (MUSLE) developed by Williams (1975a). The average annual sediment yield was estimated at approximately 400 tons/ha/yr. This value was compared to information given by the Department of Agriculture. The sediment yield value was used to compute the total sediment-phosphorous loadings.

In order to retain overall lake water quality, activities within the watershed should be properly and systematically managed. The various control methods proposed to decrease the content of phosphorous in the lake include soil erosion control, better techniques for fertilizer utilization, the timing, amount and method of application, chemical treatment by alum or copper sulphate, and bubbling oxygen through anaerobic layers of stratified lakes. Wetland construction could be considered as an alternative technique for phosphorous removal besides improving the nature of the landscapes upstream of the reservoir.

Interactions of Woody Debris and Sediment in Headwater Channels of Coastal Alaska

Roy C. Sidle, T. Gomi
University of British Columbia, Department of Forest Resources Management/Geography
2424 Main Mall - 2nd floor, V6T 1Z4 Vancouver, Canada
Tel: +1-604-822-3169, FAX: +1-604-822-9106, Email: sidle@interchange.ubc.ca
Key words: large woody debris, timber harvesting

Numerous studies in larger low gradient forest streams have noted the importance of large woody debris (LWD) in relation to fish habitat, sediment storage, and channel morphology. Very few studies have been conducted in headwater channels even though these systems are more directly impacted by timber harvesting. Headwater streams are dynamic environments because of their steep gradients (usually > 10%), susceptibility to landslides and debris flows, and direct effects of land use activities, especially when channels are deeply incised. To address the hydrologic and geomorphic linkages between the hillslope and channel in steep terrain as well as the dynamics of sediment and water movement related to riparian vegetation and woody debris in streams, a series of headwater channels on Prince of Wales Island, Alaska was investigated.

All streams were in steep glaciated valleys; some of the sites were clearcut in the late 1950s, others were clearcut in 1995, and still others were in old-growth Sitka spruce-western hemlock forests. Six of the 15 channels studied were impacted by debris flows: 3 of the channels were scoured by debris flows in the early 1960s several years after clearcutting; the remaining 3 channels were scoured by more recent debris flows in 1993. of the other 9 streams, 3 were in old-growth forests, 3 in recent clearcuts, and 3 in older clearcut areas that were not significantly impacted by debris flows. Riparian zones of channels scoured by earlier debris flows have recolonized with alder. The steep upper portion of these headwater channels, as well as the channels impacted by more recent debris flows, contain less woody debris than other channels. LWD was transported to the lower reaches of these systems where large volumes of sediment collected behind these dams. The recent clearcut sites contain large accumulations of logging slash. While this slash is storing some sediment in these headwater systems, it is doubtful that stability of such small dams will withstand large stormflow events. It appears that the smaller diameter woody material associated with the debris flow and recent clearcut channels is rather effective in storing sediment from more chronic erosion processes, e.g., minor bank erosion, bedload transport, surface erosion from old landslide scars. in contrast, the old-growth sites have less but larger diameter LWD in their channels. These jams trap a lesser amount of sediment, presumably because of the undisturbed nature of the drainage, but the deposited sediment appears more stable. For more episodic events (e.g., large storms, small debris flows), LWD dams may fail sequentially based on structural integrity and position. Additionally, we are investigating the effect of LWD type, volume, and location in these headwater systems on the channel roughness as it affects the routing of water and suspended sediment to larger fish-bearing streams. Such information is useful to help evaluate the effects of timber harvesting in steep terrain on sediment dynamics and hydrology of headwater systems as well as to estimate downstream impacts.

Stream Chemistry and The Sources of Solutes in Rainforest Catchments Underlain By Metamorphic Sandstone

Zulkiflli Yusop, Abdul Rahim Nik and Baharuddin Kasran
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia

Keywords: stream water chemistry

Streamwater quality of two forested catchments namely, C1 and C2 was monitored over 3 years at Bukit Tarek Experimental Watershed (BTEW) in the State of Selangor, Peninsular Malaysia. The forest was logged more than thirty years ago and now has fully regenerated. The area is underlain by metamorphic sandstone. Streamwaters were grab sampled during baseflow conditions and sampled by automatic water samplers during storms.

The water is slightly acidic with mean pHs of 5.57 and 5.30 for C1 and C2, respectively. The acidity was significantly higher during high flow conditions and seemed to be governed by NO_3 concentrations. Levels of electrical conductivity (EC) were low with a mean of 8.3 μS/cm. The EC levels increased during storms and were accompanied by increases in the concentrations of major ions (K^+, Ca^{2+}, Mg^{2+}). This indicates that the upper soil horizon could be equally important in providing nutrients/solutes to the ecosystem especially for sites that have low weathering rates. The sources of nutrients in the upper horizon are mainly leached from canopies and forest litter. The concentrations of K^+, Ca^{2+}, Mg^{2+} and Na^+ at BTEW were generally lower than those reported for catchments of different lithologies.

Total ionic contents were higher in the stormflow samples than in the baseflow: 181.4 vs. 162.3 μeq/l in C1 and 189.9 vs. 150.4 μeq/ in C2. This showed that stormflow components were more dominant than baseflow for delivering ions into the streams. The sum of cations exceeded the anions during both baseflow and stormflow conditions. The anionic deficits vary from 10.3 to 37.4% and most probably are due to unanalyzed organic compounds. in both catchments, the baseflow was dominated by Mg^{2+} with slight differences in the cationic sequence as follows:

C1: $Mg^{2+} > Ca^{2+} > K^+ > Na^+ > NH_4{}^+ > H^+$; C2: $Mg^{2+} > K^+ > Ca^{2+} > Na^+ > NH_4{}^+ > H^+$

With Mg^{2+}, Ca^{2+} and K^+ dominating the cations, the weathering sources could be attributed to micas and plagioclase which are common minerals in metamorphic rocks. The sequence shifted slightly during storms with K^+ becoming more dominant than Ca^{2+}, and H^+ took over from NH^+. K is a major element in plant tissues and could be easily leached from the organic horizon. The two catchments shared similar anionic sequences with HCO_3^- dominating the baseflow and NO_3^- the stormflow as follows:

Baseflow: $HCO_3^- > NO_3^- > Cl^- > SO_4^{2-} > PO_4^{3-}$; Stormflow: $NO_3 > HCO_3^- > Cl^- > SO_4^{2-} > PO_4^{3-}$

HCO_3^- is the by-product of silicate weathering from the deeper soil layer whereas NO_3^- was entrained from the upper soil during storms.

It is evident that stream chemistry is influenced by the paths by which water travels to the stream channel. The slower path at the deeper soil profile carries ions from the weathering front whereas the more rapid flow is dominated by ions derived from organic matter in the upper soil horizon.

Hydrologic Effects of Forest Harvest in Northwestern California, USA

Robert Ziemer
USDA Forest Service, 1700 Bayview Drive, CA 95521
Arcata, USA
Tel: +01-707-825-2936, FAX: +01-707-825-2901, Email: rrz7001@axe.humboldt.edu

Key words: forest harvesting effects, peakflows, lowflows

Streamflow, suspended sediment, and bedload have been monitored since 1962 in the 473-ha North Fork and the 424-ha South Fork of Caspar Creek. These watersheds are about 7 km from the Pacific Ocean, on the Jackson Demonstration State Forest, 10 km south of Fort Bragg, California, USA. About 35% of the slopes are less than 17° and 7% are steeper than 35°. Elevation ranges from 37 to 320 m. The soils of the basins are well-drained clay-loams, 1 to 2 m in depth, and are derived from Franciscan graywacke sandstone and weathered, coarse-grained shale of Cretaceous Age. About 90% of the average annual precipitation of 1200 mm falls from October through April. Snow is rare and rainfall intensities are low.

Prior to treatment, the watersheds supported a 90-year-old second-growth forest composed of coast redwood (*Sequoia sempervirens* (D.Don) Endl.), Douglas-fir (*PseudoTsuga menziesii* (Mirb.) Franco), western hemlock (*Tsuga heterophylla* (Raf.) Sarg.), and grand fir (*Abies grandis* (Dougl. ex D.Don) Lindl.). From 1963 to 1967, both forested watersheds were measured in an "untreated" condition. in 1967, logging roads were built in the South Fork. From 1971 through 1973, about 65% of the stand volume was selectively cut from the South Fork watershed, while the North Fork remained as an untreated control. Logging began in the North Fork in 1985 and ended in 1991. The timber volume removed from the North Fork watershed approximated that cut from the South Fork in the early 1970s, but clearcutting rather than selective harvest was used. The size of clearcut blocks in the North Fork ranged from 9 to 60 ha and occupied 35% to 100% of individual tributaries.

Logging-induced changes in the South Fork's peak streamflow were greatest for the first storms following lengthy dry periods. There was no significant change in the largest peakflows (>10-year return interval) after selectively logging the South Fork. Peak streamflows following clearcut logging in the North Fork behaved similarly. There was a mean increase of 17% for the class of peakflows with return intervals >0.45-year (>0.004 m^3 s-1 ha^{-1}). Annual runoff in the South Fork increased between 9% and 30% for the first 5 years after selective logging. This is equivalent to an average increase in water yield of 900 m^3 ha^{-1}. The increased annual water yield slowly returned to prelogging levels over the following 15 years. After clearcut logging in the North Fork, the annual increase in water yield varied from 9% to 58% in the first 7 years, with an average increase of 945 m^3 ha^{-1}. This result is similar to that observed following the removal of about the same volume of trees from the South Fork. However, 7 years after clearcutting, there is still no trend of return to prelogging levels.

Selection logging of the South Fork increased summer lowflow by about 0.3 l-s-1-km-2 for each of the first 3 years after logging, an increase of about 80% from that predicted by the pre-logging regression. This increased summer flow declined with regrowth of the vegetation so that within 7 to 8 years after logging, summer lowflow had returned to pre-logging levels. Clearcut logging about 50% of the North Fork produced minimum summer flows averaging 0.4 l-s-1-km-2 (146%) larger than predicted. The increased flow was greatest (250%) during the first 2 years after clearcutting, but 7 years after cutting, summer flow was still 112% above prelogging levels.

8.04.00 Natural disasters

Krottenthaler Graben Landslide - Disaster Documentation - An Approach To A Solution

Günther Bunza, Göttle, Albert
Bayerisches Landesamt für Wasserwirtschaft, Lazarettstrasse 67 (Postfach 19 02 41), 80602 München, Germany
Tel: (089) 92 14-01, FAX: (089) 92 14-14 35, Email: guenther.bunza@lfw.bayern.de

Keywords: Landslide case history; Ground water; Preventive measures

The "Krottenthaler Graben landslide" near Geitau, municipality of Bayrischzell, county Miesbach happened on 21 November 1996 at the north - exposed slope of the "Miesing massif" (1,861 m above sea level) orographically situated on the right of the so-called "Krottenthaler Graben". The main fracture area of the landslide lies at an altitude of 1,370 m above sea level, its lowest level at 965 m. The loose masses of a cone-shaped debris slope partly stocked with forest and dwarf mountain-pines were affected by these movements. in all, some two million cubic metres of material covering an area of approx. 50 acres started to move. Whereas between 1,030 m and 1,100 m above sea level the highly piled up masses blocked the Krottenthaler Graben for a short term, eastern parts of the masses were moving downwards the slope in a debris flow manner (see also sketch referring to local and geological situation).

Triggering factors for the slope movement were:
- the saturated debris masses resulting from heavy summer rainfall
- the movement of previously occurring wet snow-falls
- the inflow of karst water and the damming up of water by aquiclude strata underneath.

In November and December 1996 the landslide was still very active, meanwhile it became stabilised. The water of the Krottenthaler Graben discharges without problems below the debris masses. A reactivation of the slope movement seems only possible when the prevalent coarse-grained material is highly soaked. Extreme conditions can, however, lead to the damming up of the Krottenthaler Graben, which may end in a breakthrough of debris flow extending to the valley floor, thus endangering the settlement at the foot of the debris cone and the trunk road B 307.

As a preventive measure the office for regional water management in Rosenheim arranged for the clearing of the retention basins downstream of existing torrent defence works and gravel traps in order to dispose of some 40,000 cubic metres of receiving volume. The costs of these measures amounted to about one million DM.

As further preventive measures the Bavarian State Office for Water Management (LfW) and the State Office for Geology (GLA) prepared an investigation and observation concept. The relevant investigations will be based on previously performed laser-scan air photography in 1998.

Urban growth and geodynamic processes in the high jungle of Peru

Raol C. Carreno, Susana Kalafatovich
Swiss Federal Institute of Technology - Lausanne (EPFL), DGC-Ecublens, CH-1015 Lausanne, Switzerland
FAX: + 41 - 21 - 693 4153, Email: raul.carreno@epfl.ch

Keywords: Subandean cities development; Agricultural exploitations; Floods and debris flows; Geological setting

The transition area between the andean mountain range and the amazonian plain of Peru is known as forest brow or high forest (*Ceja de selva o Selva alta*). This region is characterized by its relatively narrow valleys and their high slope. The soils plows not very stable and easily prone to erosion.

The climatic conditions and the abundance of humus favour the abundant vegetation and the high biological diversity.

Historically this region has not a significant human occupation, especially due to the existence of illnesses against those the andean inhabitants didn't have defenses. The Inkas didn't end up conquering this region, where small cultures or tribes only existed. The colonization of the high forest begins strongly in the XIX century, after the peak of the rubber, the vanilla and the chestnut. Some valleys were previously only busy for the cultivation of coca and fruits. Due to the social problems of the coastal and of the mountainous regions, as well as for the arrival of European and Japanese immigrants, the colonization of this region acquires great importance and they have been formed the first cities approximately for one century.

The main characteristic of these cities is that they settle in alluvial terraces or in the few places where the rivers form wide plains. These cities have strong dependence of the agricultural and forest activities.

In the last times, several subandean cities shows a great urban growth that induced them to occupy hillsides and unstable terranes. This process goes accompanied by the qualification of new agricultural exploitations in and lives sheer lands it lives. The destruction of the natural forests is quick.

The most tangible effects in this process of urban and agricultural growth are given in the field of the geodynamic disasters. in the last decades the flood episodes, debris flow and big mass removals have increasing, forming natural dams and overflowings. The soils erosion is alarming, the same as the reactivacition of large landslides.

The geological setting favor these processes, because the predominance of the paleozoic materials (mainly Schists), and the Quaternary deposits are not well consolidated. Besides it, the seismic activity is important, due to the existence of active regional faults, like they are those related with the of Abancay and Huancabamba deflexions.

Cities like Oxapampa, VillaRica, Quillabamba, Huanuco, Satipo, etc. are affected almost annually by floods and debris flow. The access highways to these areas are continually off for collapses and landslides. The economic effects are devastating, mainly during the rainy season: the supply of services and the supply of products are disrupted. The lost of crops and the prices increasing accompanies to these phenomena.

Another aggravating factor is the lack of urban planning that disables an orderly growth of the cities. of another side, the ignorance of the soils characteristics and of the geodynamic processes prevents to begin or to organize prevention and mitigation activities. in this way, many cities of the Peruvian high forest go a state of permanent disaster, thanks to the irreversible environmental deterioration that suffer the surrounding ecosystems.

Determination and designation of flood plains in Bavaria

Albert Göttle, Karl Deindl
Bavarian State Ministry for Regional Planning and Environmental Affairs, Postfach 810140, 81901 Munich, Germany
Tel: +49 89 92 14 ext 43 78, FAX: +49 89 92 14 ext 22 66, Email: albert.goettle@stmlu.bayern.de

Keywords: Flood control storage; High water discharge; Aerial photographs

The most effective way to avoid risks for the population as well as flood damages is the prevention of danger potentials in areas, which are susceptible to flooding. Sustainable regional planning can be achieved by preventive flood protection measures, especially by providing special-use corridors which are designed for flooding or must be kept free from settlements or other similar uses. To secure these special-use corridors for flood control storage and high water discharge the designation of flood plains is provided for in the German water laws. in order to fulfill this legal obligation within the scope of a nation-wide initiative, Bavaria started in June 1996 the project "Determination and designation of flood plains in Bavaria" Approximately one third of the required designations have been put in practice. Priority of this project is, however, to determine flood plains along waters of a total length of about 6,000 km and make them ready for designation. It is planned to achieve most of this task until the end of the year 2005. To obtain the necessary actual data and working basis for this project, aerial photographs of flood plains have been taken since the year 1997.

Gold exploitation and erosion processes in the rain forest of southeastern Peru

Susana Kalafatovich, Raul Carreno
PROEPTI, Apartado postal 638, Cusco, Peru
Email: proepti@mail.cosapidata.com.pe

Keywords: Peruvian high jungle; Alluvial gold ore exploitation; Forest ecosystems; Soil erosion and contamination; Socio-economic problems

The well-known region as high jungle (*Selva alta*) corresponds to the subtropical humid forest (and*ean piedmont*) and it constitutes the transition area between the andean mountain range and the amazonian plain. The soils of this region are extremely fragile, for their little tickness and their high organic content. The erosion processes is developed quickly by effect of forestal activity, agricultural or mining exploitations. This is favoured by the intense rains concentrated on few months a year.

In this subandean region located at the southeast of Peru, there are very important Quaternary geological formations that possess big alluvial gold ore deposits. Most of these locations are exploited of handmade way. The depredation of the forest ecosystems become highly disturbing. Due to the low tenor of the ore deposits, a very high removal of masses is required. in the last years begun is had to it introduces heavy machinery but without any planning neither control. of another side, in spite of the great thickness of the Quaternary formations, the exploitation is only bounded to the superior strata, while the deepest deposits cannot be exploited by technical and economic questions.

The erosion is heady directly to the rivers (especially the fine silts) while the thick materials form piles where the vegetation difficultly can be regenerated. At the moment there are among 120'000 to 150'000 people working in the gold exploitation in Madsre de Dios department, at southeast of the Cusco. The great majority of these workers comes from the andean region and they develop a parallel agricultural activity to the mining, the same one that is also depredatory since it applies inappropriate technical agricultural for the forest. Equally they hunt species in risk and they destroy unique ecosystems of the subtropical rainy forests. Among the problems caused by this irrational exploitation we have:
- Beginning of a wide desertificaction process, for destruction of the vegetable covering and for the laundry of the fine particles of the floor. The recovery of the forests seems impossible. Neither the agricultural use is viable.
- Appearance of fronts of regressive erosion that affect to the forest and they advance toward areas of more slope.
- Permanent water turbidity that affects to the flora and the fluvial fauna and it produces the elevation of beds, with what the flood dangers increase.
- Strong contamination of the soils, waters and plants for irrational use of the mercury.
- Climatic alteration.
- Contamination of soils for petroleum and oils.
- Biotopes and endemic species destruction, with alteration of the biological general regime of the area.

Besides these effects on the environment, big socio-economic problems announce many great scale conflicts in the future. Another secondary effect is the permanent installation of human groups in the forest, above its soportability limits. After the exhaustion of the auriferous locations or the technical impossibility of continuing their exploitation, the workers opt for the agriculture.

The soils of the forest are not very favorable for the intensive agriculture, for what a process of migrant agriculture begins, where after three or four years of exploitation, people are obligated to leave these locations, to enable new lands, leaving desertified spaces.

Network constructions for wood debris control in torrents

Anton Loipersberger, Albert Göttle
Bavarian Water Management Agency, Lazarettstrasse 67, D - 80 636 München, Germany
Tel: +49-89-92141042, FAX: +49-89-92141041, Email: anton.loipersberger@lfw.bayern.de

Keywords: Torrent control; Wood debris control; Construction works

Not only in Bavaria, but all over the europian alps mountain forests are widely not in a good status, moreover the situation tends to deteriorate even more. Consequently wood debris has become an increasing problem in the recent years. Due to blockage of bridges or in the torrent bed itself additional damages are caused, which otherwise would not have occurred.

During the last few years different constructions for wood debris control have been developed, consisting of various types of grid or slit construction. Sometimes they are built in combination with check dams. As experiences in Switzerland (Sachseln 1997) show, this combination may fail in special situations and the retention of the wood debris does not work.

In Bavaria we have been using network constructions for about 10 years successfully in the field of avalanche control. So the idea arised, to transfer the experience to torrent control works for the retention of wood debris. in fact the idea of network or rope constructions for torrential works is not completely new. in East-Tyrol (Austria) this type has been used for about 10 to 15 years. The main purpose here is the retention of bedload.

For the first works carried out we developed a design method based on theoretical considerations. The development of the network construction in practice was accompanied by a physical model at the Water

Research Institut of the Technical University Munich. of course we are aware of the fact, that the simulation of a complex natural process is very difficult. Nevertheless we expected a better understanding of the process and also some information about the influence and sensitivity of different design criteria. Now as the simulations are completed some valuable results and tendencies became obvious. At the moment we are considering another test in a 1: 1 scale in nature. This should serve detailed information about the external static and dynamic load on the construction which couldn't be investigated sufficiently in the model.

Mechanical Estimation of Biotechnical Slope Stability Effect by Tree Root Systems

Masanori Suyama
Shizuoka University, Fac.of Agriculture, Ohya 836, 422-8529 Shizuoka, Japan
Tel: +8154 238 4889, FAX: 81-54-238-4889, Email: aemsuya@agr.shizuoka.ac.jp

Keywords: Suburban Forest, Tree Root Morphology, Tensile Strength, Shear Strength, Slope Stability

In the metropolitan area and the Kansai district of Japan, there are many urban and suburban forests. These forests serve frequently as disasterprevention forests. Recently in Japan, improvement of techniques for the creation and maintenance of disaster prevention forests and urban and suburban forests has been urgent. Accordingly, the existing protection forests of urban and suburban areas were firstly described. in order to find out mechanism of biotechnical slope stability maintained by tree rootsystems, the variety of tensile strength of tree roots between several species was discussed by comparing hillside revegetation works in urban and suburban forests. and the latest topics about the efffect of environmental conservation function of forest from the above mentioned point of view will be comparatively discussed. On the other hand, the shear strength decreases due to distance from a solitary tree and the distribution of shear strength changes at the middle of sample tree were also discussed for the urban forests in Kyoto.

The forests in Japan, in response to the various requirements of the national economy, have an important role in providing steady supplies of timber and other forest products. The forests, on the other hand, possess a function of public benefits as conservation of national land and water resources, filtration of air and water, and promotion of health and recreation for the people. Thus, the forests in Japan have close interaction with the people's life. Especially, as a result of significant economic development of Japan in recent years, the foot of mountains near cities were developed into housing land and leisure facilities in many areas after felling forest trees so that the danger of the occurrence of natural disasters tended to increase. After all, urban and suburban forests around residential areas are more important than remote mountain forests when natural disasters such as landslides, falling rocks, and debris flow are likely to occur. Consequently, it is necessary to improve techniques for the creation and maintenance of urban and suburban forests in order to prevent disasters. With respect to the effects of forests in urban and suburban areas on the surrounding microclimate, the degree and range of the effects of forests on temperature and humidity has been studied based on the balance of solar energy among forests with different tree species and stand density. On the other hand, the estimation of the environmental conservation effect of urban and suburban forests has not studied completely yet. In the present research, the slope stability of forests were generally determined from the incidents of slope failures by investigating the forest conditions in mountainous regions where the failures occurred frequently after heavy rains according to the classification such as planted forest,natural forest, conifer tree, broad leaf tree, tree age and forest density and it confirms that trees are used to control erosion on slopes, to stabilize landslide scars, and to absorb debris flow impacts. Roots due to their tensile strength and frictional or adhesive properties, reinforce the soil, increase soil shear strength. Particularly, the tree roots may anchor into firm strata providing support with the upslope soil mantle through buttressing and arching. In this paper, the latest topics about the effect of environmental conservation function of forests from the above mentioned point of view was comparatively discussed. Then we reported on the results of our survey of the actual situation of urban and suburban forests and we discussed the mechanical evaluation method for the beneficial factors in terms of slope stability due to the presence of urban and suburban forests.

The role of forests in slope stability and preventing landsliding processes

Ahmad bin Mat Isa Zainal, Haron bin Hj. Abu Hassan
Institut Rimbawan Malaysia, Forestry Deapartment, 50660 Salahuddin, Malaysia
Tel: 03 2988244, FAX: 603 2925657, Email: azainal@forestry.gov.my

Keywords: Landslides; Storm precipitation; Ground water in forests; Slope stability; Pore pressure increase

Malaysia's commitment to achieve sustainable forest management in the overall context of sustainable development will continue to emphasize pollution control and prevention, the integration of environmental factors into project planning and implementation as well as incorporation of environmental inputs into resource and regional development. Concerted efforts and development towards sustainable management are diverse and manifold whereby Forestry Departments of Peninsular Malaysia, Sabah and Sarawak and other related agencies will enhance their policies, strategies and programmes towards the attainment of the goals of sustainable development and integrated environmental considerations in decision making process.

The paper describes the present situation elaborating on the role of rainfall and groundwater in landsliding processes and slope stability concern in forestry with special reference to Peninsular Malaysia. Landslides and washouts are becoming a common cause of accidents on the steep terrain areas. Landslides occur naturally in undisturbed areas or are influenced by effects of management and development activities especially with regards to roads. Roads have the capability of altering natural water pathways of subsurface moisture flow and road drainage design as well as maintenance should be a major management concern. It is noted that climate strongly influences landslide occurrences. in addition, landslides rates are strongly influenced by intense precipitation events and saturated antecedent conditions. As such, it is also observed that landslides invariably occur during periods of storm precipitation. Among other occurrences in Malaysia, as reported by the STAR on the 3 July 1995 (Monday), the tragedy of two landslides occurred at the Genting Highlands slip road that took the lives of at least 20 people and injured another 23. The second landslide caused most of the damage of bringing down large volume of gushing water and uprooting a 150 m stretch of trees.

The paper also articulates the need to enhance the understanding of relevant factors such as topography, bedrock geology, the hydraulic properties of forest soil and the hydrologic properties of water that have major effects on subsurface flow processes during large rainfall events.

The paper highlights the important mechanism for causing slope failures which emphasizes the height of saturation above a potential failure plane (and the accompanying increase in pore pressure) decreases the shear strength of forest soils. Lack of information in areas of steep terrain where landslides occur is an issue to be looked into. The matter of concern is our ability to model or predict stream flow responses from rainfall events and our ability to simulate subsurface water levels in landslide-prone terrain.

8.05.00 Forest Fire

A study of fire history and the vegetation change of a lowland, peat swamp forest in the Lake Sentarum Wildlife Reserve, West Kalimantan, Indonesia

Gusti Z. Anshari
Monash University, Dept. Geography & Environmental Science, Wellington Rd, Victoria 3168 Clayton, Australia
Email: Gusti.Anshari@arts.monash.edu.au

Keywords: Tropical lowland peat land; Biomass burning; Vegetation history; Pollen study

This research provides a long-term perspective on impacts of fires on tropical lowland peatland forest, and record vegetation change in the Lake Sentarum Wildlife Reserve. This study used pollen and microscopic charcoal analyses of sediment cores collected from the peat swamp forest within the reserve. The correlation of pollen spectra with the present vegetation types in the Lake Sentarum Wildlife Reserve was analysed, using correspondence analysis, while impacts of prehistoric fires on past vegetation was valued, using Monte Carlo permutation tests.

Peat land forests in the Lake Sentarum Wildlife Reserve has existed since at least 30000 yr BP. The initiation of peat in Late Pleistocene in this reserve suggests that this area is predominantly ever wet. This study also indicates that prehistoric forest fires frequently occurred in this region. These fire disturbances have minor effects on past vegetation communities, but recent forest fires, probably since 3000 yr BP, seem to have persistently shifted the forest types, from closed peatland forests to secondary forest types. Human activities and recent El Nino phenomenon may have significant roles in this current change.

Fire in Temperate and Boreal Forests-Global Change, Fire Management, and Sustainability

Susan G. Conard, Brian J. Stocks
USDA Forest Service, Vegetation Management and Protection Research, Sidney R. Yates Federal Building (1CEN), PO Box 96090, 20090-6090 Washington, D.C., USA
FAX: 1-202-205-2497, Email: sconard/wo@fs.fed.us

Keywords: Global carbon budget; Boreal/temperate fire emissions; Management strategies

While the importance of temperate and boreal forests as potential carbon sinks is widely recognized, the role of wildland fire in the dynamics of these sinks is not. in some instances, accurate accounting of fire emissions may completely alter estimates of source/sink relationships. in most of these forest types, surface fires or stand-replacement crown fires have been part of the landscape for thousands of years. These fire patterns are altered by human activities (such as fire suppression, grazing, forestry practices, urbanization, or intentional or unplanned ignitions), by interactions with other disturbances such as insect outbreaks, or by short and long-term changes in climate. Changes in frequency, intensity or size of fires, in fuel structure, or in forest health and composition can have important effects on net carbon storage, on forest health and sustainability, and on susceptibility to future fires. Fires in boreal and temperate forests contribute perhaps 20-30 percent of the global carbon emissions from biomass burning. Fires are also sources of key greenhouse gases, which add to the potential impact of changing fire regimes on global climate. Estimates based on global climate change models suggest that fire hazard in boreal zone forests could increase substantially in the future. Management of global carbon requires a full understanding of the factors affecting carbon release from fires, and of the potentials and pitfalls for managing fire regimes to enhance sequestration. For example, attempts to increase carbon storage through elimination of fire on a landscape scale can lead to increased risk of insect and disease attack, increases in flammable fuels, and greater danger of severe fires in the future. While intensive silvicultural treatments, such as thinning, can reduce these risks, they are not practical on the scale that would be necessary for fire protection across the vast landscapes of temperate and boreal forests. and the ecological impacts of substituting mechanical treatments for fire on a broad scale are poorly understood. Despite the global importance of understanding the role, management, and impacts of fire on forest health and sustainability, we do not have adequate monitoring systems to accurately quantify burned areas, fire severity, or the effects of boreal and temperate forest fires on carbon storage (or trace gas emissions). Forest management, and estimates of global carbon balance, must consider the changing role and impacts of fire and impacts of alternate fire management strategies and changing climate in these temperate and boreal systems.

Forests fire: monitoring and management using satellite remote sensing data

Mohd. Hasmadi Ismail, Kamaruzaman Jusoff

Keywords: Satellite remote sensing; Forest fire; ASEAN Region; Malaysia

Forest fire has an important influence on the vegetation cover, dependent animal, soil, stream flow, air quality, microclimate and perhaps life and even the world climate. The loss of timber, destruction of wildlife, property and recreation value are also readily perceived. Unfortunately, the damage to the protective values of the forest are not equally discernable. It is quite clear that an innovative approach on forest fire hazard monitoring and management requires the use of new technique to obtain, process and display spatial information in a timely and cost effective ways. The large size, remoteness, and temporal variability in occurrence of wildfires in tropical forest regions make remote sensing/GIS techniques well suited for monitoring and studying wildfire.

In other situation, the information gathered are useful in helping to make decision on the wildfire area. This paper focussed and emphasized on Malaysia and South East Asia due to the frequent occurrence of many forest fires during the past few years. The main objective of this paper is to promote the usefulness and capability of satellite remote sensing as an alternative tool for monitoring, mapping and managing forest fire in the ASEAN region.

Forest Fire Monitoring and Damage Assessment Using Remotely Sensed Data and GIS: A Case Study from East Kalimantan, Indonesia.

Keywords: Forest fire hazard; Damage assessment; Remote sensing; GIS

Forests are inestimable and renewable natural resource of a nation. They are gaining prominence increasingly day by day on account of their protective, productive, recreational and ecological values. So is the case with the wildlife, of which forests are the abode. Furthermore, soil and water are to be given salience of the highest order as these two support the plant kingdom directly and ultimately affect mankind in its varied dimensions. Thus, soil, water and forests form the trinity which is indispensable for the existence and survival of mankind. But unfortunately these forests of utmost importance are subject to various kinds of injuries, out of which forest fire is the most consequential incite, doing incalculable harm to the forests.

Forest fire has an portentous influence on most of the vegetation and, through it, on dependent fauna, soil, stream flow, air quality, microclimate, and perhaps even general climate. Many of the direct, immediate effects of fire are common knowledge; they are also the reasons why fire is a matter of concern for foresters. The cumulative impacts of the environmental perturbations unleashed by the forest fire, poses insurmountable threat on the supply of natural resources. in an area of wildlife the risk is even more pronounced as they can be devoured by the fire or asphyxiated by the scorching debilitated air.

Indonesia, as a part of Malaysian botanical region, is the richest tropical rain forest in the world. Those forests are second only to Brazil's forest in size, and represent 10 percent of the world remaining tropical rain forest. of its total land area of 193 million hectares, about 144 million hectares or nearly 75 percent are classified as "forest land". More than 95 percent of those forest land are outside Java island (80 percent in Sumatra, Kalimantan, and Irian Jaya). Indonesia suffered from huge forest fires in 1983, 1986 and last year (1998).

Forest fire in Indonesia is a yearly potential caused for forest degradation. Insufficient information available about the main factors that promote the forest fire and information about the forest condition after the forest fire. This is one of the reason why forest area neglected after they are burned. Remote sensing and GIS are helpful tools to provide a quick and accurate data acquisition and that can describe the forest condition after the forest fire.

The objectives of this research were to asses the ability of satellite remotely sensing data to detect, identify and classify forest damage caused by fire and to develop a forest fire hazard spatial model.

Sustainable Management of Natural resources: Forest and Fire (Ghana)

Paul Kankam
Forestry Research Institute of Ghana, BOX 632, Kumasi, Ghana
FAX: 233-51-60121, Email: forig@africaonline.com.gh

Keywords: Ghana forest/savanna fires; Fire damage; Control and prevention

This paper describes how the tropical country in the world began to record most of its important forest fire events from the early 1970s which normally spread occasionally from nearby savannah along the northern margin of forest zone. in 1983, fire in the forest zone of West Africa were so severe and extensive that everyone become aware of their importance. The year was notable for prolonged and extensive drought in West Africa and in many of the worlds tropical forest areas.

During that time, the environmental damage from the combined effects of fire and drought was unprecedented with great losses of crop yield and the destruction of an estimated 4 million cubic meters of timber in savannah dry semi-deciduous forests, a middle zone vegetation. Since than fires have recurred in years with unexceptional dry season, carving a progressive degradation of the forest especially on the northern margin vegetation bothering the forest zone in the south and savannah zone in the north which are the two main vegetational types in Ghana.

The major causes of the bush fire have been harsh climate condition and anthropogenic or human activities. Due to this activities forest fire in the countries have had adverse and widespread influence on especially the semi-deciduous forest. Following the drought of 1982-1983, fire has significantly altered the structure and composition of about 30 percent of these forests. The stem densities have been reduced and proportion of pioneer trees in the community increased. The effect of the fire is the considerable reduction of the economic value of forest in terms of stands timber. The measures which have been taken for forest protection through prevention and control include fire risk assessment and publicity, fire breaks, early burning, operational forest fire management and policy and legislation. Therefore a more intensive collaborative approach is being adopted to ensure a better protection of the country forest. There are also plants to intensify the development of more feasible forest fire management action plan and policy which will fully integrated not only. Monitory, research, institutional framework and capacity development but also socio-economic considerations land resources management ad utilization, training and education. It is importance to identify the need to prevent and suppress wildfire and to rehabilitate degraded forest reserves.

Fire-related Regeneration Dynamics in the Moist Deciduous Forests of Western Ghats: A case study

A. R. R. Menon, K.J. Martin Lowel
Kerala Forest Research Institute, PeechiThrissur, 680 653. Kerala, India
FAX: 0487 - 782247, Email: libkfri@md2.vsnl.net in

Keywords: West Ghats; Tropical forest fire impacts; Regeneration; Fire behavior

One of the major causes of degradation in tropical forests and particularly the moist deciduous forests, is the recurrent incidence of fire. It is well known that fire causes extensive damage in the forest ecosystem by affecting regeneration and stocking and ultimately leading to poor status. Impact of fire on regeneration largely depend on the intensity and periodicity of fire and the level of the regeneration. The present paper deals with impact of fire on the regeneration of moist deciduous forest at a location in the Western ghats in Thrissur forest division, Kerala State, India, at varying fire frequencies.

Twelve 0.25ha (50m x 50m) plots were established for different burning treatments, viz. early-burn, late-burn, one year and two-year fire frequencies and control, with three replications. Regenerating elements of tree species (1-10cm dbh) were tagged and enumerated in all the plots. Shrubs with height above 50cm and dbh below 1cm were identified, height measured and recorded from randomly selected 4m x 5m quadrats in each of the plots. Herbs (height below 50cm) were also identified and counted from randomly selected 1m x 1m quadrats. All the observations were taken before and after prescribed burning and compared with the control (no burn) plots.

The intrime results indicate that impact of fire is more in lower diameter classes (1-2.5cm dbh and 2.6-5cm dbh), whereas regeneration above 5cm dbh are less effected. Prescribed burning carried out in the early summer season was found to cause the minimum damage to regeneration, as compared to burning carried out in the late summer season. Shrubs and herbs showed an apparent increase either in total number or species diversity after fire. Fire favoured the growth of secondary tree species, herbs and grasses. This trend was more obvious in late burn plots. Among the different moist deciduous tree species, thick bark species such as Gmelina arborea and Pterocarpus marsupium were found to be more resistant to fire. Air temperature and air humidity play a very critical role in predicting fire behaviour. It is observed that once the fuel quantity and fuel moisture content cross a certain limit which is sufficient for occurrence of fire, further change in fire behaviour is controlled by fuel porosity and fuel continuity. Other factors which control the rate of fire spread are size and thickness of leaves, rate of decomposition, soil moisture regime, wind and presence of grasses. The paper elucidate the different aspects of this experiment and concludes on the possible impact of fire on the status of moist deciduous forests in this part of India.

Haze, Forest Fires and Landuse Practices: An Assessment

Samsudin Musa, Shamsudin Ibrahim, Ismail Harun Raja Barizan, Azman Hassan, Wan Mohd Shukri & Ismail Parlan
Forest Research Institute Malaysia (FRIM), Natural Forest Division, Kepong, 52109 Kuala Lumpur, Malaysia

Keywords: Indonesian fires; Transboundary smoke/haze impacts; Cross-sectoral approach

Malaysia and some of her neighbouring countries namely, Indonesia, Singapore and the Philippines have of late experienced one of the worst occurrences of haze. The Problems is mainly caused by poor landuse practices of burning secondary forests and agricultural lands during preparation for agriculture. This phenomenon is not new and has been occurring almost every mainly in Indonesia. However, its severity and impacts have increased to such an extent that environmentalists have called the 1997 haze and forest fires in these region ecological disasters. The fires had resulted in a significant loss to property, loss of income, reduced the quality of the environment and also caused health problems to nearby communities. However, several issues pertaining to the occurrence of the fires has not been properly addressed and the extent of these negative impacts not adequately assessed. It is evident the problems are transboundary in nature and that a collective effort is required to address them. At the same time, the problems are also cross-sector in nature involving a variety of different agencies and ministries and thus an integrated effort would be necessary. This paper gives an assessment of the extent of the fires, its causes and impacts, and efforts that could or that are being made to overcome the problem.

History of Forest Fires in the Province of Pinar del Rio, Cuba

Marcos Pedro Ramos Rodriguez, Ronaldo Viana Soares
University of Pinar del Rio, Pinar del Rio, Cuba
FAX: +55-41-253-2332, Email: rvsoares@cce.ufpr.br

Keywords: Cuban fire dynamics; Fire causes; Impacts; Fire control efforts

The knowledge of the fire occurrence history in a region is of great usefulness for the efficient planning of fire control activities, because it permits to establish the: i) locals of greater occurrences; ii) length of the fire season; iii) main causes of the fires; iv) types of vegetation affected by the fires; v) extension of burned areas by periods of time; and vi) evaluation of the efficiency in fire control. in this paper the history of fire occurrence in the province of Pinar del Rio during a 22 year period (1975 to 1996) is analyzed in order to contribute to the increase of the efficiency on fire control in the region. Pinar del Rio, region of natural occurrence of *Pinus caribaea var*. *caribaea*, the most important forest species in Cuba, is located between the latitudes 21° 45' and 23° 01' North and the longitudes 82° 51' and 84° 57' West, covering an area of 10,901 k m^2. During the observation period the total annual precipitation varied from 1,089 to 2,229 mm; the monthly average temperature ranged from 21.59 C in January to 26.85 C in August; the mean wind speed ranged from 7.0 km.-1 in August to 12.0 km-1 in March; and the mean relative humidity varied from 76% in April to 84% in September. Pinar del Rio is the most important forest province in Cuba and also the number one in fire occurrence, with 21.48% of the total forest fires recorded in the country. The majority of the fires (93.28%) and the area burned (94.44%) were observed in native or planted forests of *Pinus* spp (76.72% of the recorded fires), *Eucalyptus* spp (11.56%), and *Casuarina* spp (5.00%). Statistical analysis showed that fires were significantly more frequent in forestry plantations than in natural forests. The main cause of the fires was lightning (47.46%) but most of the burned area (39.42%) was due to fires caused by negligence, the second main cause, with 27.38% of the recorded fires. About 83.70% of the fires and 92.40% of the burned area were recorded from March to August, and 69.43% of the fires occurred between 1:00 to 4:00 PM. During the studied period the annual average number of fires was 55.45 and the mean burned area 460.46 ha. Using indicators cited in the literature, the efficiency of forest fire control in the province of Pinar del Rio, when compared to other countries, can be considered very good.

Managing Smoke in Forestry and Crop Estate Sector in Indonesia

Eulis Retnowati
Forest and Nature Conservation Research and Development Center, FORDA, Jl. Gunung Batu, PO BOX 165, Bogor, Indonesia
Tel: +62-251-325111, FAX: +62-251-325111, Email: slitbang@bogor.indo.net.id

Keywords: Smoke impacts; Fire research; Shifting cultivation; El Nino

The increase of destruction in Indonesian forest fires in 1997 and 1998 totaled around 10 million ha, with damage estimates of US$ 10 billion. Other negative impacts included heavy smoke effecting flora and fauna, humans, and relations between other countries. Law enforcement was weak, proving that the management of forest fire prevention, suppression, mitigation and rehabilitation was neither satisfactory nor effective. Even with highly advanced equipment used to fight, millions of US$ spent, and many international groups and thousand of peoples involved, the fire did not stop, ending with heavy rains at the end of May 1998. It was found that Indonesian forest fire management lacked useful data rooted in forest fire research, making effective action against forest fires very weak. There was also a weakness in the interest of the people who working in the forest plantations and agricultural activities such as rubber and oil palm plantations that use fire in land preparation without any clear guidelines. There is no alternative solution for shifting cultivators who have been using fire for land clearing for thousand of years. There is also a loss of control from the government side which cause rules and laws become absurd. This situation has remained for a long time, even there were a large forest fires in 1982/1983 which destroyed 3.6 million ha. Unfortunately forest fires have occurred every year from small to large scales as happened in 1994, destroying 5.4 million ha of forest and land. Shifting cultivation and El-Nino would be blamed for those fires, without any clear solution on how to solve the problem. To solve this problem, the management of Indonesian forest fires must be based on information sources from research; and not just those directly translated from other countries experiences without any adjustments. The local people who live near the forest must also be approached, giving them the best alternative solutions, so that their life style will be highly appreciated. Full attention must also be

focused on the peoples working in the forest and with agriculture activities using fire. They must be given clear guidelines and law enforcement must be defined and established correctly. The government side should give full support for this mechanism, including their official staff not only in the forestry and environmental sectors but also from the justice side along with other sectors.

Fire Research and Society Interest as Limiting Factors in Minimizing Large Forest Fires in Indonesia

The Interest of Students on Forest Fire Studies (Bogor, Indonesia)

Lailan Syaufina
Universiti Putra Malaysia, Faculty of Forestry, 43400 UPM Serdang, Malaysia
Tel: 603-9486101-10 Ext.2405, FAX: 603-9432514, Email: Lailans@hotmail.com

Keywords: Forest fires; Insects; Disease; Regeneration; Fire danger rating; Forestry students

There are about 32 undergraduate thesis of the students of the Faculty of Forestry, Bogor Agricultural University, Indonesia on forest fire in the period of 1984 to 1998. Though the figure seems to be fluctuating during the period, however it indicates a positive tendency of the interest of the students on forest fire studies. The studies were conducted in forest plantation as well as in natural forest in Java, Sumatra and Kalimantan which consist of varies areas of forest fire such as: forest fire impacts (12 titles or 37.5 %), fire danger rating (9 titles or 28.1 %), fire season (3 titles or 9.4 %), fire causing factors (3 titles or 9.4 %), fire behaviour (2 titles or 6.3 %) and control (3 titles or 9.4 %). of which 2 titles (6.3 %) were laboratory studies while the other 30 titles (93.7 %) were field works. The studies on forest fire impacts were primarily emphasised on soil and vegetation damages, appearance of pest and diseases, forest regeneration, besides on socio economic condition of forest dependent people. Forest regeneration and inventory of dead trees and injured trees, which are classified by species and diameter classes, were common studies in the last few years. Besides, the studies on the appearance of pest and diseases in fire affected areas were also get interest by the students. While, the impacts of fire on soil were still on early stage of which emphasised on soil properties and erosion. Economical loss of forest resources, wood and non-wood forest products, gets more attention in recent years. Fire danger rating was the second most interesting study of the students. The following are some examples of the studies: the application of fire danger meter types such as 8-100-0 and Rocky

Mountain, Drought Index calculation, determination of relationship between Vegetation Stress Index and Normalised Difference Vegetation Index, and determination of relationship between Drought Index and Normalised Difference Vegetation Index. Close to the study is fire season, which had also been an interesting study of the students. Since almost all forest fires in Indonesia are caused by human factor, the study on fire causing factors seemed to have little attention. The study in Java stressed on clarifying the socio economic background of forest dependent people as the most common fire-causing factor. On the other hand, the study in the other outer islands more focused on classification of activities using fire in land clearing for plantation, timber estates and traditional agriculture. Besides, there was a study on the role of cigar on forest fuel burning in laboratory scale. Though fire management is an important area in the study of forest fire, it seemed that the students had paid lees attention on the area. The studies were still in the preliminary study, which is focused on fire prevention, such as: vegetative fire breaks, fire prevention system and fire application techniques in land clearing. Similarly, the study on fire behaviour got also less intention. So far, only two titles concern with the area, namely: the influence of wind velocity and aspect on fire spread and the influence of forest fuel characteristics on fire spread.

Based on the above information, it can be highlighted that there is still lack of studies in the area of: fire behaviour and fire characteristics, fire management including forest fire prevention and suppression, and also fire ecology. Therefore, it is required to imply some efforts in encouraging the students in conducting their studies in those important areas.

8.06.00 Wildlife

Planning for conservation of biological diversity: lessons learned from Sri Lanka

Vinod B. Mathur
Wildlife Institute of India, Post Box # 18, 248 00248 001 Chandrabani, Dehradun, India
Tel: +91-135-640112 to 115, FAX: +91-135-640117, Email: vbm@wii.gov.in

Keywords: Biological Diversity; Conservation; Protected Areas; Conflict Resolution

Sri Lanka, though one of the smallest nations in Asia harbours biological diversity of global significance. Its varied topography, diverse physical environment, unique biogeographic location and tropical conditions have given rise to extremely high levels of biological diversity, higher than in most other tropical Asian countries, when measured per unit area. Much of this diversity is endemic, presumably a reflection of the island's separation from the Indian subcontinent since the late Mesozoic. More than 3650 species of flowering plants, 300 species of *pteridophytes*, about 400 birds, almost 100mammals and more than 160 reptiles are known to occur and new species, of even higher plants and animals, are still being discovered. Sri Lanka is also one of the Asia's most densely populated countries and much of its natural forest has been cleared for settlement, cultivation, development and timber production. The forest area per capita has declined from 1.3 ha in 1900 to less than 0.1 ha in the 1999. Sri Lanka fortunately has a strong tradition in conservation and its system of conservation areas is one of the most extensive in Asia and covers about 14% of the total land area. These relatively impressive area figures notwithstanding, a number of deficiencies beset the conservation of its biological diversity and management of wildlife and protected areas (PAs). These arise mainly from the Department of Wildlife Conservation (DWLC), the agency responsible for the management of PAs, not being able to keep pace with the drastic demographic, land use, socio-economic and political changes that have come about since its inception in the mid 50s. Management of PAs is largely ineffective and suffers from inadequate scientific inputs and weak institutional structures. The situation is further compounded by a majority of PAs being small (30% of PAs are less than 100 ha and 54% are less than 1000 ha) and isolated, reflecting the fragmented nature of the remaining natural habitats.

No systematic PA management plans exist which could meet the scientific requirements of wildlife and biodiversity conservation, as well as relate to the ground realities of the pressures and problems of the local communities. It is widely recognized that a good management plan is a pre-requisite for good management as the plan provides strategies for resolving conflicts between conservation objectives and prescribes actions for achieving the management objectives. Realizing the importance of the management plans for scientific and efficient management of PAs, the Global Environment Facility (GEF) project of the DWLC initiated the process of management plan preparation for its PAs in 1996.

The paper discusses the lessons learned in the preparation of scientific management plans for PAs in the dry zone of Sri Lanka. New strategies for maintaining the integrity of PA boundaries, organizational strengthening, conflict resolution, mitigation of man-elephant conflict, ecodevelopment, ecotourism, research and monitoring have been adopted in the planning process. It is felt that the speedy implementation of these strategies would go a long way in conserving the rich and varied biological diversity of this island nation.

Wildlife conservation amidst development: challenges in Indian scenario

Asha Rajvanshi
Wildlife Institute of India, Post Box # 18, Chandrabani, 248 001 Dehradun, India
Tel: +91-135-640112 to 115, FAX: +91-135-640117, Email: ar@wii.gov.in

Keywords: Hydropower projects; Wildlife conservation; Biodiversity impacts; Socio-economic impacts; Mitigation planning

India with varied attributes of geology, terrain, hydrology and climatic regimes, harbours approximately 7% of the world's flora and 6.4% of the world's fauna on approximately 2.2% of the global land that actually represents 0.5% of the total world's forested area. India also enjoys the dubious distinction of being the world's second most populous country supporting 16% of the world's population (846.3 million) and 14% of the world's livestock population (415.8 million). Given the constraints imposed by the adverse ratios of people to land and wildlife species to wildlife habitats, setting aside of 4.5% of the country's geographical area and subsequent proposal for an increase to 5.6% for the conservation of wildlife in protected areas has been a formidable undertaking.

Incongruities and aberrations in landuse continue to remain and are increasing. These, coupled with unsound development strategies have led to increasing challenges in wildlife conservation which so far have been partially achieved against several odds. The existing inadequacy in the coverage of wildlife areas under Protected Areas, and the loss of forest due to diversion of land for agriculture (2.6 m ha.), river valley projects (0.5 m ha.), transportation and infrastructure projects (0.8 m ha.), industries (0.13 m ha.) and other miscellaneous uses (1.0 m ha.) in last one decade, have severely jeopardized the wildlife conservation efforts in highly man modified environments of the wilderness areas of the country.

This paper illustrates through some select examples, the inherent inconsistencies between development and conservation that are linked to generation of hydroelectric power projects. The creation of valley bottom water reservoirs is now an integral part of the planned development in India. Developments of this form undoubtedly place the greatest demands on some of the country's finest forests and wilderness tracts. Experiences of impact assessment studies of most of the water resource projects in the country suggests that the diversion of forest land and the non forest wilderness areas for river valley projects and their associated losses of wildlife and genetic resources may lead to some irreversible ecological trends. These trends if not halted or arrested, can lead to the genetic impoverishment of some of the wildlife areas of the country.

The growing economic instability of the forest dependent society, generally induced due to the marginalistion of the land and the shrinking resource base that supports the sustenance driven demands of the local people is another undesirable dimension of water resource development projects.

Given the present scenario of disparities in development and conservation interest, pressures will continue to mount to both use and conserve our resources, as a result of which it may not be possible to fully prevent the impacts of development. The paper suggests the need for evolving and implementing more pragmatic approaches for mitigating biodiversity losses that involve the enhancement of productivity of croplands and the increased protection in the residual wilderness areas.

Importance of Bird Species in Forest Reproduction

Mohamed Zakaria, Mohd Nordin
Universiti Putra Malaysia, Department of Forest Management, Faculty of Foresty, 43400 UPM Serdang, Malaysia
FAX: 603-9432514, Email: mzakaria@forr.upm.edu.my

Keywords: Primary forest; Logged forest; Frugivorous bird; Seed-trap; Disperse

Selective logging has created great impact to flora and fauna in Malaysia (Nordin and Zakaria 1996, Zakaria 1994). Although only the timber species were harvested, non-timber species were also destroyed during logging. Most of these non-timber species were fruit trees important for birds (Howe and Smallwood 1982). As a result most of the fruit-eating birds (frugivores) were less often observed feeding on fruit trees in logged forest compared to primary forest (Zakaria and Nordin 1998). Chapman and Chapman (1995) asserts that when frugivore community was no longer intact, recruitment of fruiting trees might be reduced and thus, the long-term persistence of tree species is questionable. However, there was no evidence to show that fewer seeds were dispersed in logged forest compared to primary forest.

Thus, in this paper, results of an 18-month detail study on the amount of seeds dispersed by frugivorous bird species in primary and logged forest were presented. The study was conducted at the Ulu Segama Forest Concession, in the state of Sabah, East Malaysia. Two study sites were chosen - a primary forest which was located within the Danum Valley Conservation Area (DVCA), and a two-year-old logged forest which was located adjacent to the DVCA. Seed traps were used to estimate the number of seeds being dispersed in both study sites. Each trap was made-up of four PVC pipes (75cm long) and a net (100% polyester cloth) of about 1 m^2 in area. The net was raised at each corner by the four PVC pipes to about 30cm above the ground, depending on the ground level. Fifty traps were placed at random in each study site.

This study clearly shows that more of the smaller size seeds (less than 5mm in length) were being dispersed in logged than in primary forest. This is consistent with earlier study that found that in logged forest there were abundant of small size birds particularly bulbul species (Nordin and Zakaria 1996). Bulbuls are colonising species and prefer to feed on small size fruits especially of secondary or pioneer species such as Macaranga. in primary forest, bulbuls were uncommon and mostly dominated by larger size frugivores such as barbets, myna, bluebirds and hornbills (Zakaria and Nordin 1998). This suggested that they prefer to eat larger size fruits and thus, dispersed larger size seeds (more than 5mm in length). Larger size fruits are normally produced by primary plants species (pers. observations). This is probably the reason why higher number of large size seeds was obtained in primary forest.

The implication of this study is that more seeds of the secondary species were being dispersed in logged forest. Vice versa, more seeds of the primary species were being dispersed in primary forest. Logged forest would then be dominated by secondary species of plants. This would eventually change the species composition as compared to the primary forest. Therefore, the survival of frugivorous birds is vital to the survival of fruiting trees and in maintaining the biodiversity of our tropical forests.

As a result re-establishment of original stands particularly of primary fruit tree species important to birds would take longer period of time in logged forest. If they fail to establish and become mature within 30 years, many of the fruit tree species might become extinct since the next cycle of logging would happen in 30 years. These species might not have an opportunity to produce and disperse their seeds because it has been shown that many species require more than 80 years to mature and reproduce (Liew 1978). Thus, it is concluded that logged forest might be able to regenerate, but it might not be able to fully recover as the original species composition.

Keywords: Forest biodiversity; Conservation and development; Multi-taxa; Forest assessment and monitoring

The Smithsonian Institution/Monitoring and Assessment of Biodiversity Program (SI/MAB) and Shell Prospecting and Development B.V. Per (SPDP), in cooperation with national and international organizations, joined efforts for the environmentally sensitive development of world class reservoirs of natural gas and condensates. The area is located in the heart of Amazon rain forest hot spot for biodiversity. For sensitive development and forest conservation, two main goals were established: 1) through the forest biological assessment of six taxonomic groups (vegetation, aquatic systems, invertebrates, amphibians and reptiles, birds, and mammals), to obtain baseline information on the distribution and abundance of species for long-term monitoring in order to determine possible changes due to the industrial operation; and 2) to provide SPDP with the information necessary to make decisions concerning their operation. The assessment started in August 1996 and ended in November 1998, when SPDP and the Peruvian government failed to reach an agreement concerning the full development of the area. We found high diversity in all groups studied, and published reports have being distributed widely. Through adaptive management, we influenced SPDP in three important decisions: 1) the location for the development of a gas plant; 2) the continued use of an "off-shore" policy by using helicopters rather than building roads; and 3) the depth in which the proposed pipeline had to be burried for immediate revegetation with native species. A forest biodiversity conservation and development model was developed.

The BEAR-project: Indicators for monitoring and evaluation of forest biodiversity in Europe

Tor-Bjorn Larsson
Swedish Environmental Protection Agency, S 106 48 Stockholm, Sweden
Email: tbl@environ.se

Keywords: Biodiversity indicators; European forests; Biodiversity evaluation tools; Assessment and monitoring methodology

The need for Indicators and Biodiversity Evaluation Tools

European countries have agreed upon a common goal to conserve the biodiversity of forests. This is essential for the sustainable use of the forests as well as for preserving forest ecosystem functions. European forestry is diverse, ranging from industrially managed forest areas supplying wood to export industries to private forests treated to meet the owners, specific needs.

Furthermore, forests may primarily be managed with respect to multiple socioeconomic goals, like recreation, beauty, biodiversity, historical value, water protection etc. Grazed areas are currently being transformed into forested land. Sustainability with respect to timber harvesting is since long an accepted prerequisite for European forestry. The sustainable management of forests is further developed in a panEuropean cooperation signed by the Forest Ministers ("The Ministerial Process for Protection of Forest in Europe"). The environmental awareness of the customers of forest products has resulted in certification procedures. Forest management and silvicultural methods are thus currently being further developed in order to satisfy the increasing environmental awareness, including the conservation of biodiversity. Landscape approaches are introduced, in which the arrangement in time and space of forest types and ages are considered when the planning of forestry operations. Biodiversity Evaluation Tools (BETs) are required to make these new planning and silvicultural methods effective. The BEAR-project will formulate an integrated system of indicators of forest biodiversity that are applicable over a wide range of European biogeographic regions, and at regional, landscape and stand levels.

The work procedure will recognise potential indicators of forest biodiversity by: (1) Identification of key parameters with respect to biodiversity according to forest structure and dynamics in a wide range of European forest types, (2) Identifying potential indicators of forest biodiversity for these forest types, (3) Agreeing on the preferred methodology for assessing these indicators. (4) Performing a dialogue on feasability with endusers (5) Packaging the results as Biodiversity Evaluation Tools (BETs).

In the conference, the followings will be presented;
1) What are indicators and BETs?
2) How will we work?
3) The BEAR-workplan

Species Diversity and Stand Structure of Secondary Forests after Different Disturbance Events

Junji Sano
Tottori University, Department of Forest Science, 4-101 Koyama-minami, 680-8553 Tottori, Japan
Tel: +81-857-31-5376, FAX: +81-857-31-5347, Email: jsano@muses.tottori-u.ac.jp

Keywords: Deciduous broad-leaved secondary forest; Disturbance events; Fire-oak hypothesis; Prescribed fire; *Quercus serrata*; Selective cutting; Species diversity; Sprouting capacity; Tree species composition

The patterns of species diversity are due to the effects of different disturbance regimes on life history strategies (Denslow, 1980). The forest structure is also dependent on the pattern of forest development following major disturbances (Oliver, 1981). in this study, the species diversity and stand structure were examined in deciduous broad-leaved secondary forests dominated by *Quercus serrata* and the other species in western Japan, with an emphasis on the effects of different disturbance events on the species diversity of trees in the secondary forests. Although the substrate and topography are fairly homogeneous in both forests, they have different disturbance histories. The secondary forests established after different disturbance events (fire and selective cutting) showed different patterns in species composition and stand structure. Lower diversity with even-aged structure dominated by *Q. serrata* was shown in the site after fire whereas higher diversity with many sprouts was shown in the site after selective cutting.

Fire and selective cutting are a large-scale and a small-scale disturbance, respectively. Large-scale disturbances are likely to contain relatively few species adapted to patches with the size and environmental conditions created by fire (Denslow, 1985). The domination of *Q. serrata* and even-aged structure after fire must be an evidence of the fire-oak hypothesis (Abrams, 1992). As establishment patterns and species composition affect stand development patterns (Cobb et al., 1992), the *Quercus* domination will have a profound influence on the growth and development of other species.

The stand seems to be in the understory reinitiation stage of the forest stand development (Oliver, 1981) from the point of stand structure with two strata. The lack of *Quercus* in the understory suggests its shade-intolerant and early successional traits (Goebel and Hix, 1996). *Quercus*, however, may be able to regenerate in the old-growth stage after several decades or more (Sano 1997).

Impact of selective logging on avian community with respect to environmental and habitat condition in Wanariset Sangai, Central Kalimantan

Titiek Setyawati, Timothy J. Boyle, Agus Salim
CIFOR, Center for International Forestry Research, Post Box # 6596 JKPWB, 10065 Jakarta, Indonesia
Tel: 62-251-622622, FAX: 62-251-622100, Email: t.setyawati@cgiar.org

Keywords: Selective logging; Dipterocarp forest; Avian community; Species at risk; Impacts of forestry practices; Species Diversity

In Indonesia there are approximately 25-30,000 species of flowering plants, 750 mammals species and 1250 birds species. Logging and clearance for agriculture had threatened the island of Kalimantan or Borneo which known as the most extensive remaining *Dipterocarps* forest remaining within the region. Selective logging is likely to deplete the density of bird species that may cause to the extinction of some sensitive species. Still, no one know precisely on what extent that several birds species can sometime survive suffering such a heavy disturbance or some would easily gone even after experiencing the light one. This study is aimed to further examine the effect of selective logging on avian community and find out its relationship between vegetation structure. Field study was carried out within a logging concession in the Lowland *Dipterocarps* forest of Central Kalimantan. We looked over three location of one unlogged and two logged over forest for comparison (3 and 8 years) within 3000 ha concession areas. Environmental model was used to predict the availability of physical resources necessary for plant growth. The use of this method has advantages over field observation in that it can calculate attributes that are not readily observable in the field. It was shown from research result that logging become the most important factor in determining the vegetation structure. The aspect of vegetation structure affected may be grouped as follows: canopy/understorey structure (height and furcation index of trees, frequency of poles and sapling), abundance of lianas, volume and state of dead wood and leaf size classes. These vegetation structure variables were correlated with various indices of bird species diversity. Under further analysis, number of species is not significantly differs among the three sites but species composition within guild are changing with respect to logging. It was recorded that 7 species from unlogged forest disappeared including 2 endemic species, 19 new species were added within 3 years over logged site (1 of migrants) and 5 new species appeared in logged over 8 years site. The vegetation structure caused by different intensity of logging may create diversity of microclimate preferably to certain bird species and cause to the distinction in species composition and high variability in number of individual per species among the sites. Other factors for example differences in landscape formation prevailed on any single site may contribute to such and influence as well. Some common species to the primary forest that found within logged over forest indicating that the environment is not much differ from the pristine site or it may due to the less intensive logging prevailed. It is clear that every single species may response differently based on their capability to adapt with the environmental changes and these will be further discussed in the full paper. Hence, to find out the underlying causes of animal dynamic in some extent need to justify the sample sizes, which that for birds will certainly require much larger study areas. It is recommended to conduct further study on specific bird species within particular guild sensitive to disturbance.

Plant Species Diversity of Larch Ecosystems of Siberian Cryolithic Zone and its Post-fire Transformation

O. A. Zyryanova, T.N. Bugaenko, N.N. Bugaenko
V.N.Sukachev Institute of Forest SB RAS, Akademgorodok, 660036 Krasnoyarsk, Russia
Tel: +7(3912) 49-44-65, FAX: +7(3912) 43-36-86, Email: frost@ifor.krasnoyarsk.su

Keywords: Species diversity; Siberian forest ecosystems; Fire disturbance; Larch forests

Larch ecosystems of Siberian cryolithic zone are characterized by the lowest plant species diversity among the forest ecosystems of the Northern Eurasia. It has resulted from the small heatrovision and geological youth of the subpolar landscapes. The phytodiversity of the northern forests has been forming at the permafrost conditions. The ground wildfires are the main disturbing factors of the region. They destroy the millions of the forested area annually.

Plant species diversity (diversity according to R.H.Whittaker (1977)) of Siberian larch ecosystems has a number of the peculiarities. There are many evolutionary primitive plants in their composition. The share of the wooden plants is usually more than a half (56%) of the total species number. The mosses and lichens occupy almost all forest habitats. Their amount can vary from 27 till 45% per each larch association. Subarctic and boreal species (their ratio is equal to 53.7:58.2%) combine in the floristic composition as well.

Northern larch associations have very complex structure. There are 4- species groups in them which differ in dominance degree. As a result, the dominance-diversity curves have the multistep shape. Such species composition has resulted from the cryogenic microrelief as well as from mixed hydrothermal and edaphic conditions.

The ground fires considerably change plant species composition of larch associations. in 3 years after the fire the number of the vascular plants is 1, 2, 3 times more as compared to that of beforefire association. Both the appearance of the new plant species and their families as well as the restitution of beforefire plants are responsible for such increase of species diversity. The initial plant species diversity has usually regenerated in 3 postfire years. Green moss and lichen species composition is completely changed after the fire. It regenerates extremely slowly. The pioneer moss species of the permafrost burned areas is Marchantia polymorpha.

Temporal and spatial structure of larch associations begins to change only in 2 years after fire. The dominance-diversity curve analysis witnesses this fact. The following years the microrelief destroyed, the permafrost depth decreased, the hydrothermal and edaphic conditions of the habitats changed as well. Structureless plant associations are characteristic of such postfire progressive stages. They include annually change single dominant species and a large number of the separate plants of small abundance. The first structural elements of the new secondary communities appear in four years after the wildfire. Plant species diversity of 90year old larch associations is the result of the interspecific competition. The experimental distributions for such associations are more similar to the geometric series distribution.

8.08.00 Forest and Climate

Interconnection between environmental change and forest on the mountainous territory of the South Central Asia.

Hukmatullo M. Ahmadov
Tajik Forest Institute, 724055 Dushanbe, Tadjikistan
FAX: (3772) 213332, Email: farhod@kokul.td.silk.org

Keywords: Environmental change; Mountain forests; Desertification; Reforestation; Drought

One of the biggest parts of the mountainous territory of the South Central Asia is the Pamirs-Alai mountain system. The most investigated area of this system is situated on whole territory of Tajikistan 93 % of territory of our republic compose of mountain ranges which altitudes come up to 7500 m above sea level. The insignificant violation of fragile mountainous ecosystem always can lead to many catastrophic consequences. At the beginning of century the area of forests of Tajikistan was in several times bigger than it is at the moment. The modern position of wood and bush vegetation is damaged by human activities and it is necessary to start the intensive restoring processes. Otherwise the climatic drought and desertification (erosion processes) can be really strengthened and their consequences would be very tragic. The main role in the mountainous ecosystem play wood and bush vegetation. This is because the mountainous forests are the main components in the mountain landscape formation. The insignificant negative anthropogen influence of human on mountainous landscape can lead to many negative consequences. The connection between changes in environment and forests takes place by such scheme: first of all the destruction or cutting of wood and bush vegetation <=> desertification (degradation of soils) and dynamic processes <=> the changes of water balances <=> changing of climate <=> biodiversity etc. All elements of environment are tightly connected between themselves and forests are taking the main place in this structure. in the different parts of South Central Asia the connection between wood and bush vegetation with another components and their changes was investigated. It is determinated that the main role in this process plays human. in different climatic zones it happens differently and depend on complex of some natural, anthropogenal and economical factors. The huge tracts of forests are in good conditions only in the zones there the big coalfields are found. The local population is sparing the mountainous forests. The lack of fuel is lead to destruction of unique mountainous forest- massifs and valley tugays. By the time the peoples don't think about future consequences and about life of next generation. They don't execute the reconstruction of these forests. The

Tajikistan in some conditions has the really big possibilities for reconstruction and widening of forest- and rarely forest- areas. The interconnections between mountainous forests and mountainous river- balance, dynamic processes and degradation of soils, intensive cattle grazing and etc. parameters were determinated.

The recommendation of plantation of new wide leafed and small leafed antierosion forests was compiling. in the low mountain and middle mountain zones the big attention spared to pistachio and nut plantations and in middle and high mountain zones to juniper plantations.

For the first time in Tajikistan the map of environment change degree which found under the influence of anthropogen factors (cutting and destruction of forests, degradation of soils in forest zones, intensity of watershed agriculture) was compiled.

The common scheme of interconnection between forest formation with another natural anthropogen components and of their degree of influencing on environment were compiled.

Environmental changes recording in Russian protected areas

Vladimir A. Borissoff
All-Russian Research and Information Centre For Forest Resources, 69, Novochermushkinskaya Str., 117418 Moscow, Russia
Tel: +7-095-332-5360, FAX: +7-095-331-0533, Email: aricfr@aha.ru

Keywords: Nature reserve; Environmental monitoring; Global change; Natural disaster; Biodiversity

By end-1998 Russia had 99 strict nature reserves (zapovedniks) and 34 national parks taking up respectively 32.6 and nearly 7 million hectares (other kinds of protected nature areas corresponding to the IUCN categories III, VI number several thousands and occupy tens million hectares). State zapovedniks and national parks are territories of Federal importance. The purposes of these two categories are determined in the Law no as to protect and to study unique and typical natural complexes and features, remarkable natural formations, features and gene pool of plant and animal life, processes in the Biosphere and to monitor changes in its state. Since the beginning, the main task of Russian State Nature Zapovedniks research consisted in carrying out stationary year-round interdisciplinary studies in situ of unimpeded course of natural processes and phenomena.

Recording of every changes in the natural environment of the Nature Zapovedniks forms a special document called Chronicles of Nature. It is a yearly master data register of the state of the protected areas, of all biogeocoenological observations. Some of Zapovedniks have been keeping records of their Chronicles over 60 years. This work is to be performed in all Zapovedniks following an unified programme agreed by researchers throughout the country. The programme was prescribed to mark not only common, usual phenomena, but also extraordinary ones. The document should mark various deviations in the natural environment: droughts, severe winters, avalanches, high floods, downpours, forest fires, epizooties, etc. The data obtained in such a manner are united each year in the book called Charonicles of Nature, and once in 5 years a summary book is compiled. The highly developed network of biotic observation posts and stations given by the State Nature Zapovedniks has allowed to obtain reliable information on biodiversity changes in selected territories in all natural zones of Russia.

Research carried out in most State Nature Zapovedniks and in some National Parks differs from that in other forest areas, first of all, by almost complete exclusion of experiments in nature. in this respect, forest research in these two categories is in opposition, and at the same time, a complement forest experimental stations. Research in protected areas is a conditio sine qua non for environmental monitoring. Unspoiled plots are ideal points of reference for surveying natural and anthropogenic changes in the natural environment.

Even excluded from direct econimic use, the Zapovedniks of the central areas of Russia situated less than 50 km from large cities and major industrial centres are appreciably affected be human impacts, acid rains, alien wildlife species intrusion, increased concentration of game animals that leads to degradation of vegetation and soil cover. Research in remote Pas allows monitoring background changes in the natural environment.

Modifications in Microclimate and Litter Fall Production and Decomposition Caused by Forestry Use of Natural *Nothofagus pumilio* Forests in Magallanes, Chile

Juan Caldentey, Ibarra Manuel, Schmidt Harald, Promis Alvaro y Hernandez Jorge
Universidad de Chile, Departamento de Silvicultura, Casilla Postal 9206, Santiago, Chile
FAX: 56 - 2 -541 79 55, Email: jcaldent@abello.dic.uchile.cl

Keywords: Forest; *NothoFagus pumilio*; Intervention; Nutrient; Litter fall; Decomposition; Biomass

The use of a forest ecosystem under sustainable assumptions implies the need of evaluating the distribution and total amount of existing products feasible of being extracted from a forest with each forestry intervention. The productive capacity of a forest site may be determined through quantification of existing biomass (dry weight unit/surface unit). This information may be supplemented with the study of nutrient accumulation in trees to optimize forest resource use.

In order to estimate the effects of natural *NothoFagus pumilio* forest management on biomass and nutrient extraction, two stands - one pure, uneveraged of the species, and another one mixed, uneveraged with *NothoFagus betuloides* - were studied, both located in the Province of Magallanes, Chile.

In order to estimate existing biomass in each stand, allometric equations providing the dry weight of the different tree components were adjusted using BHD and their total height as predictive variables. Nutrient accumulation was estimated by weighing biomass amount with nutrient concentrations determined in tissue subsamples. Forestry intervention in each stand was simulated using extraction rates accepted under Chilean legislation, estimating biomass and nutrient amounts extracted, to remain standing, and to remain as waste on the forest floor, comparing two treatments: one with and the other without barking.

Total accumulated biomass in the pure stand was 421.8 t/ha (85.1% boles and 14.9% crowns). Total estimated aerial mineralomass reached 5,572 kg/ha (96% accumulated in woody tissues and 4% in leaves), with percentage distributions of 55.2, 29.2, 6.7, 4.4, 2.2, 1.6, 0.3, 0.4, 0.7, and 0.03 in Ca, N, K, Mg, P, Mn, Fe, Zn, B, and Cu, respectively.

The mixed stand exhibited a total accumulated biomass of 322.2 t/ha (81% boles and 18.6% crowns). Total estimated aerial mineralomass was 3,480.2 kg/ha distributed on a percentage basis in 52.9, 27.2, 9.7, 4.5, 3.6, and 1.1 of Ca, N, Mg, K, P, and Mn, respectively. The remaining 1% corresponds to Cu, Fe, Zn, and B.

When simulating application of a protective felling (shelterwood system) on the pure stand with a 49.6% reduction in the basal area and a protective canopy of 161 trees to remain standing, 129 t/ha of biomass would be extracted and 79 t/ha would remain as harvesting waste. An amount of 521 kg/ha of mineralomass (97.9% macro-nutrientes and 2.1% micro-nutrients) would be removed. A figure of 1,935 kg/ha of nutrientes in the waste would remain on the forest floor. If extracted boles were barked on site, extracted biomass would descend 7.2% and the removed mineralomass amount would be 422.5 kg/ha.

When simulating application of a protective felling on the mixed stand, with a 45.2% reduction in the basal area and a protective canopy of 176 trees to remain standing, 146.2 t/ha of biomass would be extracted and 30.4 t/ha would remain as harvesting waste. Development would remove 1,125 kg/ha of mineralomass (98.2% macro-nutrients and 1.8% micro-nutrients). A figure of 564 kg/ha of nutrients in the waste would remain on the forest floor. If barking is considered, extracted biomass diminishes 9.6% and exported mineralomass amounts to 462 kg/ha.

Estimation of soil erosion levels

David Lopez Cornelio
Shimane University, Faculty of Life and Environmental Science, Office #505, 690 Matsue, Japan
Email: a98950@matsu.shimane-u.ac.jp

Keywords: Soil erosion; Deforestation; Tropical forests; Land-use change; Satellite observation; Biodiversity

In Peru, nearly 1,800 acres of tropical and subtropical forests are cut daily, amounting to 670,000 deforested acres each year; this phenomena eliminates critical habitats for wildlife and plants species (Peru ranks number two in the world in bird diversity, number three in mammal diversity and number five in plant diversity, within its borders exists 83 of the worlds 114 natural community types). An accurate and up to date assessment of forest area and rates of depletion is fundamental to the development of improved national forest management strategies. Satellite observations provide an objective and quantitative approach to the measurement of land-cover change; a research is proposed in order to determine the land use change, the conversion from active agriculture to secondary forest (re growth), infer the patterns of land use by type in the long term considering the past and present trends, and propose an ideal map of sustainable land use according to the ecological and socioeconomic characteristics of the site, in a representative area of Peruvian tropical rainforests (Iquitos region, a 75km x75 km area located in the Amazon watershed at 3*43*46 South Latitude, 73*14*18 West Longitude) using JERS-1 images. The Japanese Earth Resources Satellite ?1 has been continuing to observe and collect data since 1992 with a mission data recorder by the high performance Synthetic Aperture Radar (SAR) and Optical Sensor (OPS); TNT mips will be used in order to process the images, a processing system for geo spatial analysis with fully integrated GIS, CAD, TIN, desktop cartography and geo spatial database management.

Monitoring of the Forest Damaged by the Salt-winds and the Gale of the Typhoon

Tadashi Nakashima
Kyoto University Forest in Hokkaido, Tawa, Shibecha-cho Kawakami-gun, 088-2339 Hokkaido, Japan
FAX: +81-1548-5-3667, Email: tnakashi@kais.kyoto-u.ac.jp

Keywords: Forest; Wind damage; Salt-wind; Typhoon

There was a great deal of damage throughout Japan caused by typhoon No.19 in 1991. As the peak gust records in many of the meteo-rological observatory were renewed, a great deal of damage was caused by gales. Damage to the forests in the northern part of Kyushu and the western part of Chugoku were very severe, and salt-wind damage was added in Chugoku.

The damaged forests near Tokuyama Experimental Forest (T.E.F.) were investigated. The southeast gales came over the ridges. The heavily damaged forests are situated on the ridges, on the slopes of the valley and in the depths of the valleys. The leaves of bamboo around T.E.F. were changed to yellow or white and those of needle-leaved trees in the edge of forest turned brown. Three years after, the leaves damaged by the salt-winds seemed to have recovered, but the leaves and trunks damaged by the gale had either not recovered or had some after effects of injuries.

The change of a damaged forest, which is situated in the depths of a valley has been observed. This forest is the 28 years old plantation of Hinoki (cypress) and has about 400 trees. According to annual numbers of dead trees and the stem analysis of those, remarkable affections by the typhoon is clear.

The Effect of Reforestation and Forest Plantation Programme On Carbon Sinks

Zuraina Samli
RCFM + FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603 - 6377233, Email: zuraina@psph.frim.gov.my

Keywords: Carbon sink; Tropical forests; Reforestation; Forest plantation

Although deforestation in the tropics has been identified as one of the main contributing factors, very few studies have actually been made on the effect of reforestation and forest plantation programme on carbon sinks. Since the early seventies the debate on the increase of carbon dioxide concentration in the atmosphere and its predicted impact on global climate has been the focus of many national, regional and international discussions. The large amount of carbon in its vegetation and in its soil has made forests to be one of important factor to be considered in regulating climate. It has been acknowledge that the release of carbon from this vegetation and soil due to human activities could have significant impact to the climate. This paper highlights the important contribution of forest ecosystem to the total carbon budget including absorption and release of carbon in Malaysia. Preliminary results from a study conducted in Malaysia show that tropical forests particularly the undisturbed forests, play an important role as a carbon sinks in the global carbon cycle. Based on the analysis using COPATH method in the project under Sustainable Forest Management, result shows that total carbon above ground portion for Superior Forest based on third National Forest Inventory in Peninsular Malaysia is about 205.8 million ton. Thus, any form of destruction (burning) or reduction in area of these forests will lead to a substantial increase of carbon dioxide concentration in the atmosphere. It is anticipated that carbon sinks will be increased through appropriate reforestation and forest plantation programs.

A Free Atmospheric Carbon Enrichment Experiment on Short Rotation. Intensive Poplar Plantation

Giuseppe Scarascia-Mugnozza, P. DeAngelis, M. Sabatti and G. Matteucci
University of Tuscia, DISAFRI, 01100 Viterbo, Italy
Tel: +39-0761-357395, FAX: +39-0761-357389,
Email: gscaras@unitus.it

Keywords: Plantation; Poplar; Global change; Agroforestry; Productivity; CO_2

The mechanistic and process-based responses of trees and tree communities to global change, particularly in response to the predicted increase of atmospheric [CO_2], will be crucial in determining the ability of woody plantations and natural forests to sequester carbon at the global scale. Despite the key role played by trees and forests within the terrestrial biosphere, we still have very limited information on the total responses of agro-forestry and forest systems to enhanced CO_2 because of the complex web of possible interactions. The few studies conducted at the whole-tree and community scale indicate that there will be a marked increase of primary production, but this increment will be mainly allocated into below-ground biomass. However, the proportionality of this response may well depend on nutrients and water availability in the soil and, also, on genotypic characteristics. A fundamental issue of the research on global change effects on terrestrial biosphere is the need to appropriately design the experiments to be conducted at the community and ecosystem level. The FACE technology has the great merit of not altering the general microclimate of the test area and allows to conduct the research on impacts of global change truly at the ecosystem level; however, FACE facilities should be combined with adequate forest tree systems in order to avoid such drawbacks as lack of replication, large genetic variability and delayed response of already adult trees. The aim of this research is to improve our understanding of the effects of elevated [CO_2] on forest ecosystem, using a short rotation intensive plantation of poplar trees as a model system. Poplar trees represent a unique opportunity to study processes and mechanisms determining biomass production at the ecosystem level, since they are extremely fast growing, have genetic reproducibility and a short life-cycle, especially when grown as short-rotation coppice. Therefore, the research we present is rather unique because we combined a fast growing, agro-forestry ecosystem, capable of elevated biomass production, with a large-scale FACE system. The performance of the FACE system together with the growth and physiological responses of three poplar clones grown under CO_2-enriched atmosphere will be discussed.

The forest fire transformation of soil cover condition

L. I. Sukhorukova, Belenets Y.E., Kobrin N.Y.
St.-Petersburg Forestry Research Institute, Institutsky pr., 21, 194021 Saint-Petersburg, Russia
FAX: (812) 552-80-42, Email: spb330@spb.sitek.net

Keywords: Forest fire; Ground vegetation; Boreal forests; Soil structure; Soil chemistry

To study changes in forest function of growth and qualities of forest soils, subjected to fires, two types of burned-out forest lines were defined. Each line was presented by five burned-out plots (from latest to 25 year-old ones) and a test virginal plot. The type of fire is low with elements of debris layer and humus. Variants with low and high fire intensity were observed. These experimental plots were located in Leningrad region in different forest growth conditions. The first line consists of *Pinetum hylocomosum* of the IV age class and III quality of locality class, which grow on semipodzol rough (coarse) sandy soils typical for these sites. On the plots subjected to the high degree of fire intensity the soil is damaged to great extent: the ground vegetation and debris layers burn out and the lower podzolic mineral horizon A2 uncovers. It leads to the considerable loss of soil productivity. On the plots with low fire intensity only partial damage of top soil cover is observed: ground vegetation and part of debris layer (the thickness of debris layer is 1-3cm on this plot and 3-4cm on the test virginal plot). The second line is presented by *Picetum myrtillosum* of the V age class and II quality of locality class, growing on the peaty podzol loamy sandy and loamy soils. in these moistening conditions thicker debris layer and A2 horizon are formed, which are the high-quality combustibles in the dry period of a year. When the organic horizon is destroyed by fire, spruce rots burn out and the tree falls down. in the burned-out forests of this line there are such spruce trees. in this case, on the plots subjected to fires of high intensity the vegetation layer and debris layer and peat horizon that is organic synusia and the organic burn out. The plots subjected to fires of low intensity can be referred to the category of slightly damaged debris layer and peat horizon is only partially destroyed. Thus influence of fires on soils is versatile. Intensive debris-humic fires cause the greatest damages, changing morphological qualities of soils. Soils under investigation have an acid reaction. Organic and A2 horizons are characterized by higher acidity (pH3,25-3,90). in the lower soil layers its level evidently decreases (pH 4,57-5,52). Soil-colloidal complex has a low degree of base richness (saturation)-less than50%. in the organic soil horizons the content of carbon is 32-37%. The great quantity of carbon is concentrated in the debris layer. The content of humus in the top soil layer varies from 0,72 to 2,45%. The supply of podzol soils by the elements of mineral nutrition wholly depends upon their level of humicilization (presence of humus). The quantity of nitrogen available in hydrolyzed organic compounds makes up 15-20 mg/100g in debris layers and 0,7-1,8 mg/100g in top mineral layers.

After the fire which partially or completely destroys organic part of soil a new pirogenic horizon appears. Thus, the top soil profile is characterized by neutral and alkaline reactions (pH 7,0-8,0), low exchange and hydrolytic acidity and high quantity of exchange bases. The content of carbon, nitrogen, phosphorus and potassium is lower than on the test virginal plot. Carbon losses make up 10-14 t/hectare. The level of trophogenic soil productivity decreases. Deterioration of soil conditions influences the general state of forest stand.

The researches carried out on the burned-out forest plots showed that as a result of forest fires, acidious indicators get to their norm in 8-10 years, whereas neutral and alkaline reactions transform into sub-acid reaction even in 2-3 years. Restoration of mineral nutrition and humus contents is a slower process. Five years after the fire the content of carbon makes up about 2,5-3,0 t/hectare (15-20%) of the initial quantity. It will take no less than 25-30 years for complete restoration of carbon. According to our data, restoration of flora and phytocoenosical structure of vegetation layer will take about 25 years. Only then differences in debris layer on the test virginal plot and experimental plots completely disappear.

Effects of global warming on the mountain vegetation in Japan

FAX: +81(Japan)-(0)298-73-3796, Email: ntanaka@ffpri.affrc.go.jp

Keywords: Mountain forests; Natural vegetation; Global warming; Litter decompostion; Spatial distribution; Snow cover

Studies on effects of climate change on mountain vegetation were conducted in mountains of central and northeastern Japan. Among the topics, thermal conditions and soil properties, alpine dwarf pine scrubs, snow patch vegetation and beech forests have been dealt with in detail.

1. Effects of temperature on soil properties on Mt. Akaishi

One of the studies evaluated the effects of thermal conditions on soil properties, measuring thermal and soil conditions along a slope from the montane (1120 m a.s.l.) to the alpine zones (2725 m a.s.l.) of the Akaishi Mountains, central Japan (Kobayashi et al. 1996). These results suggests that the global warming will accelerate litter decomposition rate at higher elevation in subalpine and the acidity of topsoil will be more neutral.

2. Alpine dwarf pine scrubs on Mt. Kinpu

Kajimoto et al. (1996) studied the effects of temperature increase caused by global warming on the population dynamics of the alpine dwarf pine (*Pinus pumila*) in relation to the predicted upward shift of subalpine conifer trees on Mt. Kinpu, central Japan. It is suggested that subalpine confers expand into alpine regions, but hardly succeed the vegetation zone where well-developed *P. pumila* scrubs had already occupied, even under the higher temperature conditions.

3. Snow patch vegetation on Mt. Zarumori

Two studies focus on the snow patch vegetation on Mt. Zarumori, Northeast. in snow patches formed by snowdrifts, the spatial distribution of the snow depth is mainly affected by the interaction between topography and the prevailing wind direction in winter. One study on microclimate and phenology of snow patch plants revealed that the phenological stages of Faulia crista-galli, that is one of the dominant species in the snow patch, are closely related to the effective accumulated temperature which is determined by locations on the slope and vary mainly with the distance from the snow patch (Ohtani et al. 1996). It appears that the F. crista-galli changes its phenological stages with an increase in the effective accumulated temperature. Another study reconstructed past climatic conditions by means of alpine-subalpine meadow soil stratigraphy, which records past snow disappearance time in nivation hollows (Daimaru and Ikeda 1996). The analysis of fossil peat soils suggests that "Medieval Warm Period" was prevailed in the meadows in Northeast Japan. When the warming will exceed 2 C (BC, snow patches and the alpine-subalpine meadows will shrink considerably and when it will be accompanied by decreasing snowfall and snow accumulation, the shrinkage will be accelerated and many meadows will disappear.

4. Beech forests in the Pacific Ocean and the Sea of Japan sides

Similar to the cases of snow patch vegetation, but in the larger scale, the distribution area of beech (Fagus crenata) is affected by snowcover as well as by temperature. There is a climatic gradient of snowfall between the Pacific Ocean side and the Sea of Japan side of the Honshu Island as well as a temperature gradient along latitude. in view on the time scale of more than 100 years, the present pattern of beech distribution may shift upward in response to the global warming if the precipitation conditions do not change. On the other hand, changes in winter precipitation may affect beech distribution, even if the thermal conditions do not change. in the Pacific Ocean side, an increase in snowfall may assist beech to expand its habitat along elevation and increase its dominance in forests. in the Sea of Japan side, a decrease in snowfall may reduce its elevational distribution and dominance in forests. in conclusion, these researches indicate the importance of snowcover and topography as controlling factors of vegetation distribution as well as temperature. Effects of global warming on vegetation will not only induce the shift of vegetation zones toward north and higher elevation in macro-scale, but also complex changes depending on the diverse controlling environmental factors in smaller scales.

Long-term carbon dioxide and water vapour fluxes of European forests and interactions with the climate system

Riccardo Valentini
University of Tuscia, Department of Forest Environment and Resources (DISAFRI), Via San Camillo de Lellis, I-01100 Viterbo, Italy
FAX: +39 0761 357389, Email: rik@unitus.it

Keywords: Carbon absorption; Gas fluxes; Eddy covariance; European forests

The EUROFLUX program, funded by the EU for three years (1996-98), investigated the relevant biosphere atmosphere exchanges of European forests.

The quantitative estimation of fluxes is needed to develop surface parameterizations and aggregation schemes in order to scale up from the patchwork of landscape evident in Europe to regional and, ultimately, global scale. Atmospheric exchange of European forest ecosystem deserve special attention due first to their potential mesoscale effects on rainfall distribution and soil water storage, and also because of their potential role in the long-term CO_2 uptake from the atmosphere and carbon storage.

The long-term continuous measurements of atmospheric fluxes by means of the eddy covariance technology are a powerful tool for investigating the overall ecosystem exchanges and hence to determine the annual budgets of carbon and water. Furthermore the possibility to analyze the response of the ecosystems to climatic and biotic perturbations, in a variety of conditions, including extremes events, represent a unique framework for biogeochemical models evaluation and improvement.

In synthesis the general objectives of the project can be summarized as follow:

1. Characterize long-term fluxes and energy exchange of representative European forests in order to provide useful parameters to modelers and to analyze the variables that determine energy partitioning by forests in different climatic conditions;

2. Determine the sink strength of European forests for carbon and analyze the variables that determine the gains are the losses of carbon from different forests;

3. Analyze the response of European forest water and carbon fluxes to climate factors in order to aid regional scale modeling designed to predict impacts of global environmental change on forests;

4. Provide objective data for the validation of forest models, related to growth, partitioning of primary production, water cycling and hydrology;

5. Recommend management strategies for the conservation of carbon stores in forests.

The project was carried out at 15 representative forest sites encompassing the entire range in European climate, species distribution, and site conditions. in addition 2 sites with external funding have joined the consortium. Common protocols and hardware requirements have been defined and implemented, as well as data quality checking and missing data interpolation policies. The variation of the ecological parameters and climatic factors is rather interesting and allow to explore the ecosystem responses along environmental gradients.

There has been also a modeling component within the Euroflux program. The aims of Euroflux in this respect were to develop tools be used for interpolate missing data, extend in spatial scale the flux measurements and establish a bridge between our project and other existing initiatives.

The presentation will describe the project with more details and results from 1996 to 1998 will be presented. Overall, the results indicated a greater carbon uptake of temperate forests versus the northern boreal forests, with a pronounced internal variability site by site.

8.09.00 Human impacts on tropical rain forests with long term view

Effects of selective logging on understorey butterflies and flower visiting beetles after 30 years

Keywords: Balloon trap system; Attractant trap; *Scarabaeidae*; *Dasyvalgus*; Canopy fauna

Lowland tropical forests should be preserved because of the importance of genetic resources for future human beings. On the other hand most of all tropical lowland forests have already been developed. Therefore, one of the best ways to preserve bio-diversity in tropical forests is to practice sustainable use of secondary forests based on thoughtful consideration for bio-diversity.

Though selective logging is the most typical forest treatment in tropical forests, there is little data on the effects of the treatment on bio-diversity in tropical rain forests, especially a long time after logging. Also, we do not know how many years it takes to recover the primary arthropod assembly of tropical rain forests after selective logging. Therefore, we attempted to estimate effects of selective logging on bio-diversity of forest arthropods. Comparative analysis of flower visiting beetles and butterflies were carried out between primary and secondary forest logged about 30 years ago, in Pasoh Forest Reserve, Peninsular Malaysia.

Ten plots to research on flower visiting beetles were set from edge to core along a path in Pasoh Forest Reserve. Two attractant traps to catch flower visiting beetles using flower flagrance, linalool and eugenool, were hung from emergent trees at the height of 20m and 10m in each plot. The number of *Dasyvalgus* spp., one of the main flower visiting groups, in the core area (primary forest) was significantly greater than that in buffer area (secondary forest), whilst *Mecinonota*, another dominant flower visitor, showed no difference. Species structures of *Dasyvalgus* were different from each other. We established research plots (100m X 100m) in secondary forests selectively logged 30 years ago (S1) and in a primary forest (P1). We set flower fragrance attractant traps on forest canopies in plot S1 and P1 for flower visiting beetles. Numbers of dominant species of *Dasyvalgus* in the primary plot (P1) were greater than those in secondary plot (S1).

We compared the assemblies of understorey butterflies, as representatives of understorey insect herbivores, between two primary (P1, P2) and two secondary (S1, S2) plots. We placed every 8 fruit-bait traps around the 1 ha square plots to attract and catch understorey butterflies. Twenty-two nymphalid species were captured, with 0.65 individuals per day per trap. The similarity in species composition was very high between the two secondary plots, though they were most distant from each other. On the other hand, it was low between the primary plots, thus the total number of species captured in the primary plots (19 species) was about 1.5 times that in the secondary plots (13 species). It is most likely that the assembly of understorey butterflies and flower visiting beetles has not completely recovered after selective logging about 30 years ago. Understorey butterflies can be quantitatively sampled with the traps and are rather easily identified by non-specialists, thus they should be counted as one of high priority indicator groups for the monitoring of protected or disturbed forests, in addition to birds and mammals.

Recovery assessment of logged-over forest areas in Negeri Sembilan, Malaysia

Mohd Zaki Hamzah

FAX: 03-9432514, Email: zakihamzah@yahoo.com

Keywords: Forest recovery; Logged-over forest; Malaysia

Over the years, large tracts of tropical forests in Peninsular Malaysia have been deforested mainly for the expansion of crop-tree plantations. The remaining forests are under constant pressure from commercial and illegal harvesting. These forest stands require some kind of assessment as to their natural recovery and succession. Forest recovery assessment based on phytosociological vegetation studies was made in the state of Negeri Sembilan, Malaysia to elucidate the state of natural recovery of the degraded, logged-over forest areas. This approach called for vegetation surveys to be conducted on logged-over areas (harvested in 1950s, 1960s, 1970s, 1980s and 1990s) as well as primary forests in the state. A total of 35 phytosociological releves were made in four forest reserves during the two-year study period (early 1997 to the end of 1998). The natural recovery is very slow for areas that were heavily logged and compacted, such as sites formerly used as logging roads and timber landings during forest harvesting. Only highly adapted, early-successional species, such as METLAstoma, Eupatorium and Paspalum, managed to inhabit the sites. Such sites with very poor environmental conditions will take a long time to recover their pristine original state, unless intensive rehabilitation is carried out. Similarly, sites that were harvested from 1963 to 1973 with conventional harvesting techniques (under the Malayan Uniform System) have shown a relatively slow recovery rate. The sites have small average coverage by emergent and dominant trees, and only a few *Dipterocarps* occupy this layer. However, the stands have recovered in terms of species abundance and dominance. in these stands a few more years are required for the dipterocarp species from the lower layers to reach dominant and emergent sizes. On the other hand, the sites harvested in 1984 under the Selective Management System recorded an average ST-layer coverage of 12% and fairly even coverage in the tree (dominant), tree understorey (co-dominant), shrub and herb layers. Due to lack of dipterocarp species in these forests, the forests require replanting of dipterocarp species to enrich them. The 1996 stand is in the beginning of its recovery following harvesting recently. As in the forest harvested in 1984, this 1996 stand requires replanting of some dipterocarp species. The only complete recovery was achieved by the stands harvested in 1950s. The stands have recovered both in terms of canopy structure and species abundance and dominance. The mean emergent height in these stands is 47m which is similar to the natural stands, and the average canopy coverage (of emergent and dominant) is insignificantly different from the primary forests. The study shows that it takes at least around 40 years for the logged-over stands to recover to the original state. It is proven through this study that the phytosociological vegetation study approach is very useful to assess the present status of natural recovery (succession) of the deforested area.

Monitoring of CO_2 flux above Pasoh Forest

Keywords: CO_2 flux; Eddy correlation method; NEE; Rain forest

The CO_2 flux over tropical rain forest was measured by an application of the eddy correlation method. The forest for our study was in Pasoh Forest Reserve, Forest Research Institute Malaysia, located in the center of Peninsular Malaysia (2ø58N 102ø18E). The elevation of the gently undulated terrain was approximately 120 m. The forest had a complex canopy, i.e. the general height was approximately 35 m, although emergent trees exceeded 45 m. A 52 m tall tower constructed in the forest was used for the platform of the meteorological observations. A three dimensional ultrasonic anemometer-thermometer (DAT-600, Kaijo) and an air inlet were installed on the tower at a height of 52.6 m. The fluctuation of CO_2 concentration in the air was measured by the closed-path CO_2 gas analyzer (Li-6262, Li-Cor). Data were recorded at the sampling frequency of 10 Hz. The CO_2 concentration at the different 6 heights above and within the forest was also measured to calculate the storage changes. The net ecosystem exchange (NEE) was a main interest of the observation. The NEE is defined as NEE = Fc + Qc, where Fc is the CO_2 flux at the reference height. and Qc is the storage term that the temporal change of the CO_2 storage below the reference height. The diurnal change of the CO_2 flux, storage and NEE were obtained for the representative days.

The maximum CO_2 flux was approximately 0.3 mgm-2s-1 and 0.8 mgm-2s-1 for the release in the night time and the absorption in the day time, respectively, on a fair day in March. The magnitude of the storage term was comparable to that of the flux. The CO_2 flux rapidly changed from release to absorption at 10 MST, and it showed the maximum absorption at around 13 MST. After 13 MST, the CO_2 flux (absorption) gradually decrease until 18 MST, and then it changed to release. However, the CO_2 storage rapidly changed from increase (release) to decrease (absorption) approximately 2 hours earlier than the flux, and it showed the maximum absorption at 10 MST. The storage term decreased rapidly after 10 MST, then it showed almost zero at 13 MST.

In the early morning, the large CO_2 absorption by the ecosystem was initiated when the decrease of the stored canopy CO_2 in the night time seemed to be the main contributor. This continued approximately for 2 hours, then the CO_2 concentration of the canopy air decreased. in the day time after 10 am, the flux played the main contributor for the ecosystem absorption. The daily NEE showed absorption ranged from 7.4 to 8.1 $gm^{-2}day^{-1}$ through the observation period.

Effect of Selective Logging on Canopy Structure and Tree species diversity in a Lowland Dipterocarp Forest in Peninsular Malaysia

NIES (National Insititute for Environmental Studies), Onogawa 16-2, 305-0053 Tsukuba, Japan
FAX: +81-298-50-2483, Email: okuda@nies.go.jp

Keywords: Canopy structure; Lowland Tropical Rainforest; Selective logging; Species Diversity

In order to study the impact of selective logging on the tropical rain forest, canopy structure and species diversity were compared between primary and regenerating forests in Pasoh Reserve, (2o58'N, 102o18'E) in the state of Negeri Sembilan, about 70 km southeast of Kuala Lumpur, Malaysia. For the primary forest, a data set taken in a 50-ha plot in 1995 was used. For the regenerating forest, a 6-ha plot was selected in 1997 in an area at the southern end of the reserve that was selectively logged under the Malaysian Uniform System (MUS) between 1955 and 1960. in both plots, all woody plants of 1 cm in diameter or larger within these plots were identified, measured, tagged and mapped to the nearest 10 cm. The canopy height was determined every 2.5 m intervals from aerial photographs taken at a scale of 1:6000 in February 1997, which covered the entire part of the 50-ha and 6 ha study plots, and canopy digital elevation model (CDEM) was made for both plots. Canopy surface area was acquired in every 10 x 10 m mesh based upon CDEM. Crown size of trees in canopy layer was determined by tracing the crown edges shown in the aerial photographs.

There was no distinct difference in the mean canopy height between the primary (27.4 m) and regenerating forests (24.8 m). However, the variance of the mean height was much larger in the primary than in the regenerating forest. This implies that there are many more emergent and canopy trees > 40 m in height and many more canopy gaps in the primary forest than in the regenerating forest.

The mean canopy surface area per hectare in the primary forest was 27844 m^2, 1.5 times as large as that in the regenerating forest (19288 m^2). The mean crown size of individual trees of the canopy layer in the primary forest was 95 m^2, which was twice as large as that in the regenerating forest (43 m^2). The number of trees whose crown size >300 m^2 was 3.3/ha in the primary forest and 0.5/ha in the regenerating forest. On the other hand, the number of trees with smaller size crown (<100 m^2) was 49.5/ha in the primary forest and 177.5/ha in the regenerating forest. However, the species area curves derived from the tree map data were not distinctively different between plots. The two plots did not differ in the ten families having the largest number of species. The stem density was not distinctly different between the two plots; 6418 individuals /ha in the primary forest and 6067 individuals/ha in the regenerating forest. The basal area in the primary forest was 42.2 m^2/ha and 43.3 m^2/ha in the regenerating forest.

These results suggest that selective logging under MUS regime did not significantly change tree species components and diversity, but resulted in monotonous canopy structure which was formed by small canopy trees growing in high density. These findings also imply that gap formation and structural development take a long time in a regenerating forest, owing to the time taken for self-thinning among the trees.

Species assembly and site preference of tree species in a primary Seraya-Ridge Forest in Peninsular Malaysia

Keywords: Cluster analysis; Ordination; Indicator species; Seraya-Ridge forest

The paper describes the use of common species as the criteria to classify forest sites using multivariate methods. The main objective is to clarify indicator species and its site preferences in a typical primary Seraya-Ridge Forest. The sample is based on a contiguous 150 subplots of 20 m x 20 m from a six hectares plot (200 m x 300 m). The group of sites was detected using hierarchical clustering analysis and site ranking by ordination method. The indicator species analysis determined the characteristic species of that particular site group. Eight site groups were identified. The ordination results showed a strong correlation with elevation gradient. Most of the characteristic species showed a strong association with elevation gradient and topographic positions, while generalist species showed a weak correlation. The indicator values of thirty-nine characteristic species at each step of hierarchical structure were computed and tested with the mean indicator value obtained from a Monte Carlo randomization procedure at P-value 0.01. The characteristic species which have broad niche breadth in the higher elevation were *Shorea curtisii Lithocarpus wallichianus, Eurycoma longifolia,* etc., while in the lower elevation the characteristics species were *Pimelodendron griffithianum, Antidesma cuspidatum, Artocarpus lanceifolius,* etc. These species were responsible for similarities between habitat and for the nested hierarchy structure in the site typology. Several species such as *Drypetes polyneura* and *Gironniera parvifolia* had been identified as requiring narrower site preferences. The diagram of hierarchical cluster and associated indicator species provides a simple and intuitive way to express species assembly, while the ordination helps in explaining their site preferences.

Excess nitrogen in a fragile montane forest ecosystem

Robert Jandl, Lee Heng, Jiri Simunek
Forest Research Center, Seckendorff Gudent Weg 8, 1131 Vienna, Austria
Tel: +43-1-87838-1302, FAX: +43-1-87838-1250,
Email: Robert.Jandl@fbva.bmlf.gv.at

Montane forests on calcareous limestone are fragile ecosystems of the Alps. We investigate, if there are already indications for nitrogen saturation and derive its consequences for the regional water quality. The soils are mostly shallow and often have a low water holding capacity. The growth of most of these forests has been limited by nitrogen until now. The nitrogen demand of the forest stand and the herbaceous vegetation was high enough to almost fully exploit the nitrogen supplied by the soil solution. The last few decades have modified the biogeochemistry forest ecosystems in Europe. Due to the increase in combustion processes and the increase in N emissions from agricultural sources the availability of nitrogen has generally increased. The recently shown increase of growth rates of European forests is understood as a consequence of a nitrogen eutrophication. Ecosystems, that used to be a sink for nitrogen, will no longer retain it fully. Consequently nitrogen is lost from the ecosystem, primarily dissolved as nitrate in seepage water, and secondarily in gaseous form as nitrous oxide. The surface waters draining montane forests have so far been of the highest chemical quality and have been suited as drinking water without further treatment. So settlements, as potential polluters, had access to water of highest purity and local pollution was diluted to water of still good quality. If nitrogen leaks out of montane forests indeed, this favorable situation may be history. Society will be able to rely to a lesser extent on the water purification by montane forests.

Our study site is located in the province of the Tyrol. It is a mature spruce forest with some true fir and beech. We monitor the quantity and chemical quality of precipitation above and below the stand canopy, soil temperature and moisture, and emissions of trace gases. The assessment of geochemical fluxes is especially difficult, because soils are gravelly and shallow. Karst phenomena inhibit the direct measurement of stream water because an unidentified quantity of groundwater leaches into subterranean caveats. We therefore use a combined soil chemical- physical simulation program, UNSATCHEM, to derive a nutrient budget. We intend to present both the results of our locally valid case study, but also extend our results to a bigger picture, that considers the regional water balance. Moreover we intend to present the remedies, that can be offered by silvicultural management practices, that help to improve the utilization of the available nitrogen.

Keywords: nitrogen deposition, eutrophication, montane forest

The adaptation potential of Central European mountain forests under scenarios of climatic change - an ecological risk assessment

Manfred Lexer, Karl Hönninger, Helfried Scheifinger; Matulla, Ch., Groll, N., Kromp-Kolb, H.

Keywords: risk assessment; climate change; climate change impact; mountain forests; patch model;

Central European forests comprise a wide range of ecological site conditions from high altitude coniferous mountain forests to low elevation forests dominated by broadleaved species. These forests in general have to serve a multitude of functions and in particular play an irresistible role in maintaining alpine landscapes. Discussions on a likely global climate change give rise to questions on possible impacts on forest ecosystems. So far model applications to assess the potential impacts of climate change on forests suffered from several shortcomings: (a) simulation studies for individual more or less synthetic site conditions conducted with forest succession models of the gap-model type miss the spatial dimension and coverage, (b) risk asesment studies with static vegetation-site equilibrium models miss the individualistic nature in the formation of vegetation composition, and (c) the non-consideration of todays forest composition and structure in climate change related simulation experiments. To circumvent these limitations in this contribution a risk assessment procedure for the identification of potential impacts of climatic change on mountain forest ecosystems in the Eastern Alps in Austria is presented.

In our approach a newly developed 3D-patch model is employed to simulate vegetation development at approximately 3.000 sample plots of the Austrian Forest Inventory (AFI) under current climate and under climate change scenarios. The model runs are initialized with ground true site (slope, aspect, water holding capacity, pH, C/N-ratio) and vegetation (species, diameter distributions regeneration) data provided by AFI. The sampling scheme of AFI with more than 10.000 of sample plots all over Austria allows to sample from the multi-variate space of vegetation/site-combinations of Austrian forests. Current climate data were interpolated from a network of more than 800 climate stations of the Austrian weather services. Simulated vegetation development under current climatic conditions is used as a control-run. For each involved sample plot several climate change scenarios were derived from global circulation model (GCM) output by statistical downscaling techniques. No management interventions are assumed to capture the potential natural transient behaviour of current forests. To synthesize the various model output variables as rational as possible the analytic hierarchy process (AHP) and multiple-attribute-utility-methodology (MAUT) were utilized. Indicators used in this approach represent both the transient as well as the longterm response of current forests, and comprise shifts in the potential natural vegetation composition (PNV), short- to midterm vegetation development (species, accumulated biomass) and detailed thermoenergetical indices of potential biotic stressors such as phloem feeding insects.

In a demonstration example for a subregion in the Eastern Alps substantial shifts of the potential natural vegetation under altered climate occured indicating changes of the ecological site potential. Under the climate as produced by the global circulation model ECHAM4 under the "business as usual run" of the IPCC just at a small portion (11.7 %) of 409 simulated sample plots included in the example abrupt changes in species composition or biomass occured, thus indicating forest dieback events due to the underlying climate change scenario.

From our experiences we conclude that the presented methodology is well suited to identify potential problem areas where the functioning of forests might not be granted under the assumed climatic changes. We found it especially important to evaluate the possible range of forest responses to a changing climate by using several different climate change scenarios, thus covering the uncertainties involved with predictions of future climates. To derive management scenarios to mitigate possible adverse impacts of a climate change and to secure the sustainable functioning of alpine forest ecosystems forest management has to be considered explicitely. However, it is important to note, that optimized silvicultural response strategies within the frame of a multiple purpose forestry have to be planned at spatial scales beyond the stand level.

Modeling Tropical Deforestation and Carbon Flux Scenarios

Matti Palo, Erkki Lehto
Finnish Forest Research Institute (METLA), Unioninkatu 40 A, FIN-00170 Helsinki, Finland
Tel: +358 9 857051, FAX: +358 9 85705 717, Email: Matti.Palo@metla.fi

Keywords: tropics, deforestation, carbon fluxes, modeling, scenarios

The purpose of our paper is to make quantitative scenario analyses on tropical deforestation and its consequences to carbon fluxes up to 2025 and 2050. The study comprises natural tropical forests, which means that plantation forests, trees outside forests and other wooded lands are excluded.

The empirical source of forest, land and ecological zone data is FAO's FORIS-database, which covers 117 tropical countries and about 600 subnational units. The original inventory year data from 1953 to 1998 from the FORIS database are used. The number of countries was reduced to 62 when more independent variables were included in the modeling.

Scenarios are based on trends and multiple regression models for tropical Africa, Asia and Latin America. The trend scenarios assume that deforestation continues as in the 1970's and in the 1980's. The linear trend with equal deforested area in the future is adopted as a base scenario (zero alternatives). Three other trends were computed including another kind of linear and two non-linear trends.

The regression models were estimated using ordinary least squares method (OLS) with standard statistical tests. Cases were weighted with forest areas because in the scenario making this would reflect in a more valid way the different roles of the small and large countries and their subnational areas in the deforestation process.

Regression scenarios until 2025 were computed by continents. The results indicate that forest area would decrease in Latin America by 29-39, in Africa by 37-41 and in Asia by 31-36 percent. Accordingly, tropical America has the largest potential for carbon conservation (40-55GT C) if deforestation is decelerating, followed by tropical Africa (21-23 GT C) and tropical Asia (15-17 GT C).

New modeling of deforestation scenarios was made for this conference. The model has not only income, population and reliability of forest data variables as changing independent variables but also agricultural productivity and the openness of trade as key independent variables. The other - time-invariant - independent variables consist of moist and dry ecological zones, total land area as well as two dummy variables for island and African identification.

The model is operational and statistically sound. It nearly doubles the previous degrees of determination (R2 = 0.79 in this latest model). The previous regression scenarios are respectively revisited. in the conference paper proper we shall report primarily the results from this new modeling.

The new provisional scenarios indicate somewhat lower scenarios on deforestation and carbon fluxes than the previous results. Increasing agricultural productivity is decreasing deforestation whereas the growth of openness in foreign trade tends to expand deforestation under tropical land tenure conditions where often open access to forests is existing. This effectively slows down the appearance of competitive stumpage markets which would automatically decelerate deforestation.

Our results indicate higher deforestation than FAO has modeled for 1990-1995 in the State of World Forests in 1997. We have the following explanation for this difference. in the two studies different models are applied - in our case regression modeling with log-log transformation of the variables and Chapman-Richards-model by FAO. Our model has some more relevant variables, such as an income variable, which are missing from the model by FAO. We believe that our modeling approach is more relevant for this purpose.

Wood-to-ethanol: process options and targets for commercialization

John N. Saddler, David J. Gregg
Faculty of Forestry, University of British Columbia, Forest Products Biotechnology, Department of Wood Science
2424 Main Mall, V6T 1Z4 Vancouver, BC, Canada
Tel: 1 604 822 9741, FAX: 1 604 822 8154, Email: saddler@interchg.ubc.ca

There is growing concern that the continual build-up of atmospheric CO_2 is contributing to global climate change. The combustion of gasoline in transportation vehicles represents a significant source of CO_2 produced anthropogenically. Several groups around the world are researching ways to convert forestry and agricultural residues to ethanol as a way of displacing gasoline for transportation vehicles.

When ethanol is produced from renewable sources such as biomass it can both decrease urban air pollution and reduce the accumulation of carbon dioxide. Thus replacement of gasoline with ethanol, derived from renewable biomass feedstocks that sequester carbon dioxide during growth, is expected to reduce carbon dioxide emissions by 90-100%. Researchers in the U.S. estimated that enough neat ethanol could be made from the available local cellulosic biomass residues to replace twice the amount of gasoline consumed within that country.

The bioconversion of lignocellulosics (including wood) to ethanol is a complicated and strongly interdependent series of process steps. Currently there are no true examples of commercial or totally integrated demonstration-sized plants which can convert lignocellulosic materials to ethanol. Although some of the current and past pilot plants have been able to demonstrate the successful operation of entire sets of process steps, these plants have not been able to operate over a prolonged period of time.

Through our association with the International Energy Agency (IEA) we have come in contact with a number of groups researching and commercializing various lignocellulosic-to-ethanol processes. We are aware, through this association with IEA, that there are currently a number of commercial interests building pilot and demonstration facilities to technically prove a number of the process steps. However, at this time, there does not seem to be a single group that possesses all of process steps required to provide a complete continuous process particularly when presented with a number of different lignocellulosic feedstocks (agricultural, hardwood and softwood residues). This presentation will review some of these attempts at demonstrating biomass-to-ethanol process elements and provide a likely scenario for the future.

Our group at the University of British Columbia (UBC) has been researching the potential of using softwood sawmill residues as a feedstock for producing fuel ethanol. Our recent techno-economic modelling work has shown us that it is crucial for economic viability to recover as much of the original cost of the feedstock in the form of marketable products. Most of the past research (agricultural residues and hardwoods) concentrated on processing only the cellulosic component to a marketable product (ethanol). The lignin component was assumed to be burned to produce energy and steam for the rest of the process and the hemicellulose component was discarded or only minimally utilized to produce a marketable product (ethanol). Our more recent research has focused on optimizing the recovery and utilization of all three main components as marketable products and developing new processing methods for softwoods (processes that were developed for hardwoods and agricultural residues are not effective for softwoods). This presentation will provide a summary of current worldwide research directions.

Greenhouse gas (GHG) emissions from the forestry sector in Malaysia

Azman Zainal Abidin, Jenny Wong Siew Chiong, and Ramdzani Abdullah Abdullah
Universiti Putra Malaysia, Department of Environmental Sciences, 43400 UPM Serdang, Selangor D.E., Malaysia
FAX: 603-9438109, Email: azmanza@fsas.upm.edu.my

The world community has many needs for reliable estimates of greenhouse gas (GHG) emissions as it discusses global climate change. Emission estimates can be used to compare the relative contribution of different emission sources and different GHGs to climate change, and to ascertain the portions of emissions attributable to individual countries and different regions of the world.

A preliminary GHG inventory for the country was first carried out in 1995, in which the emissions of carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) were estimated from the various sectors. However, in that inventory, the component on land use change and forestry (LUCF) was not included due to lack of appropriate data at that time.

The present study was therefore carried out to fill in that missing gap. The objectives of the study were to estimate the GHG emissions and sinks from the LUCF sector, and to determine if Malaysia was a net CO_2 emitter or sink in as far as the LUCF sector was concerned. in carrying out the study, the following procedures were adopted: 1) the collection of relevant secondary data, 2) the preparation of the inventory using the 1995 Intergovernmental Panel on Climate Change (IPCC) Guidelines, and 3) the comparison between the emissions and sinks for the years 1990 to 1996.

From the inventory exercise carried out, it was found that in the LUCF sector, Malaysia was a net CO_2 sink. Keywords: Greenhouse gases (GHGs), carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), land use change and forestry (LUCF), Intergovernmental Panel on Climate Change (IPCC).

Characterization of Agroforestry Experiences with Coffee in the Zona da Mata of Minas Gerais, Brazil

Fernando Silveira Franco, Laercio Couto, Irene Maria Cardoso, Cassio Murilo Moreira Trovatto, Marcos Iwao Ito, Juliana Sialino Müller
Universidade Federal de Vicosa, Departamento de Engenharia Florestal, 36570.000 Vicosa, Minas Gerais, Brazil
FAX: (031) 899-2478, Email: fsfranco@alunos.ufv.br

Agroforest systems are alternatives in natural resource management in which woody species (trees, bushes, palms) are utilized in deliberate association with agriculture and/or animal husbandry in the same area, either simultaneously or sequentially, with significant ecological and economic interactions between components. These alternative systems can use natural resources to augment or maintain land productivity without further degradation beyond that already seen in the elevated degree on occupied and cultivated lands that do not permit such augmentations to food, fiber, energy, or other products. Agroforest systems are viable practices that can be utilized to recuperate landscapes degraded and fragmented by farming and grazing, common situations in the Zona da Mata. The Zona da Mata is characterized by centuries of agricultural occupation, traditional agricultural practices, and a preponderance of smallholder production. The resulting landscapes are insufficiently productive for natural recuperation to their productive potential. For many local farmers, coffee cultivation still represents the principal source of income to meet family needs. Many agro-ecosystems of the Zona da Mata are characterized by declining productivity and low soil fertility derived from the adoption of technologies ill-suited to the region.

The central objectives of this work are to contribute to an ecologically and economically efficient agriculture, strengthen coffee cultivation, and create conditions in which the cultivator may diversify and sustain production through agroforest systems. To these ends, surveys were undertaken of agroforest systems and trees associated with coffee in the Zona da Mata to describe their predominant functions, the phyiological comportment of coffee under the shade of these trees, and the establishment of a system to record descriptive and quantitative information on the systems and species located.

To develop this work visits were undertaken to properties where the concept of agroforest systems were integrated in the method of production and coffee was the principal product. Twelve experiences of family production, one experimental area of the Federal University of Vicosa, and one experimental area of the Vicosa Family Agriculture Group were studied during the years 1997-98. The visits utilized Rapid Participatory Diagnosis through the technique of semi-structured interviews characterized by a few pre-established questions to provide a line of discussion and a basic structure connected to themes in which all subjects were permitted. in this way the interviewees were considerd the "experts" in their respective areas of activity and in the way in which they related their opinions, thoughts, and desires. The protocol used covered History (land use, degree of awareness of adoption, reasons for adopting the system, natural vegetation prior to implantation); Resources, including natural (solo, water, temperature, exposure, et cetera), agricultural (size, quality, and ownership of land; skill and availability of labor), capital (financial physical,), and productive; and Systems, including species (objectives for the components, interactions, spatial and temporal arrangements), management (species comportment, succession, silvicultural techniques), and evaluation.

The majority of experiences were initiated four years prior in areas of low carrying capacity. Vegetative species numbered 115, representing 49 plant families. By category of use, these species were implanted in different stages of soil recovery, succession, and agroforest production and furnished foods, medicinals, and other products such as fuelwood and sawtimber. Diverse types of systems were identified, from simple associations of coffee with two forest species to more complex systems involving 76 species with a variety of objectives (rapid production, green manures, nitrogen-fixation, shade production, advancing natural succession, et cetera). Conclusions include both ecological and economic benefits (reduced erosion, greater soil moisture and organic matter, reduced use of agro-chemicals, and reduced labor expense at later stages) described by the interviewees as well as limitations related to management and economics.

Global Distribution of Mountain Forests

Val Kapos, J. Rhind, I. Lysenko, C. Ravilious and M. Price
World Conservation Monitoring Centre, 219 Huntingdon Road, CB3 0DL Cambridge, United Kingdom
FAX: +44 (0)1223 277136, Email: val.kapos@wcmc.org.uk

Despite constituting only a small proportion of the world's forests, mountain forests are especially important in providing resources that benefit human populations and are particularly susceptible to damage and loss. The importance of sound management of mountain forests has recently been recognised increasingly in international policy fora; a thorough understanding of their global distribution is critical to identifying policy and management issues that need to be addressed at international scales. in this paper we present the results of an analysis combining global forest distribution and protection data with topographic data to generate the first mapped dataset on the distribution and protection of mountain forests world-wide.

The importance of mountain forests for mankind is multifaceted. They are vital as sources of water for irrigation and power generation. They intercept and store water from rainfall, mist and snow, and release it slowly, thereby reducing soil erosion and downstream flooding impacts. Mountain forests are very important as repositories of biodiversity. The proximity of many different ecosystem types in steep topography and an evolutionary history of climatic fluctuation and species migration, have led many mountain forests to develop diverse and complex faunas and floras. Because they are usually isolated from similar ecosystems by steep terrain and intervening lowlands they are frequently sites of high species endemism. That very isolation and the increasing pressures on the forest below make many mountain forest species very vulnerable, a fact reflected in the occurrence of many mountain forest species on the lists of the world's most critically endangered species.

Mountain forests are often highly threatened by the activities of growing human populations around them. Some of the most densely populated areas of the world are mountain zones, where demands for land to grow crops, for fuelwood for cooking and heating, and for construction materials combine to exert high pressure on remaining forests. FAO (1993) has estimated the annual loss of forest from upland regions in the tropics to be 1.1%, 30% higher than elsewhere in the tropics.

Despite the importance and vulnerability of mountain forests their distribution has been poorly understood. The first global digital map of forests was published by WCMC in 1996, but this did not identify mountain forests. While subsequent versions did identify some mountain forests based on classifications in the source data, coverage of these important ecosystems was not consistent.

Global forest data are constantly being updated both at WCMC and through remote sensing programmes (*e.g.* EROS Data Centre in collaboration with FAO and WCMC), but explicitly identifying mountain forests in a globally consistent manner has not previously been included in any of these efforts.

The analysis presented in this paper addresses a number of the difficulties inherent in considering mountain forests. While globally accepted definitions of "forest" exist, the problem is with identifying those that fill the important roles and characteristics of mountain forests. Though it is not in itself sufficient, elevation is one key component in defining mountain forests. A newly available global digital elevation model (DEM; GTOPO30) provides new possibilities for defining and identifying mountain areas; elevational difference as a proxy for slope and total local altitudinal range were employed to try to include those mountain forests that occur at relatively low elevations as a result of the "Massenerhebung effect" and related phenomena. By developing such methods of identifying mountain areas using the DEM and combining the result with digital forest cover data, it has been possible to produce a preliminary map of mountain forests in order to highlight regions of potential conservation concern.

Wild Edible Herbs and Maple Sap as an Income Source in Mountain Areas of Korea

Don Koo Lee, Gab T. Kim
Seoul National University, Dept. of Forest Resources, 103 Seodun-Dong, Kwonsun-Gu, 441-744 Suwon, Korea R.
Tel: +82-331-290-2337, FAX: +82-331-293-1797, Email: leedk@plaza.snu.ac.kr

Characterized by four distinct seasons and mountainous topography, extending southward from the northeastern part of the Asian continent, China and Russia, the Korean peninsula has a wide range of habitats and corresponding vegetation types - located at the latitudes 34° 40' to 43° 39' N and the longitudes 124° 0' to 132° 42' E. of these plants, wild edible herbs widely distributed in mountain forests are useful and valuable as sources of food or for their medicinal effects or commercial attraction.

However, only a small minority of wild edible herbs has been studied by biologists or for their role in the local economy. This paper presents a case study on wild edible herbs in mountain forests, conducted at Mt. Gariwang (about 5000 ha, Pyungchang-gun Kangwon-do, South Korea) with a focus on their distribution and contribution.

At Mt. Gariwang, there were 58 species of wild edible herbs and 80 species of wild medicinal herbs. These are important beneficial species - their high economic value makes them highly attractive to mountain villagers. However, increasing market demand for such resources has resulted in their rapid depletion in recent years.

Of the 58 species of wild edible herbs, *Pimpinella brachycarpa*, *Ligularia fisheri* and *Codonopsis lanceolata* provide the largest source of income. The distribution of herbs was diverse and distinctive: *P. brachycarpa* was distributed mostly in mixed broadleaved forests; *L. fisheri* in clear-cut areas, meadow and oak forests; and *C. lanceolata* randomly. *P. brachycarpa* and *L. fisheri* were found under wet soil-moisture conditions, and slope orientation was one of the major determinants of distribution. *C. lanceolata* was generally found on north-facing slopes. Most species of wild herbs were absent from conifer plantations.

Leaf production of wild edible herbs differed with forest type: *P. brachycarpa* yielded 37.9 kg. ha^{-1} in oak forests, 34.5 $kg.ha^{-1}$ in mixed broadleaved forests and 2.5 kg. ha^{-1} from clear-cut areas and meadow. Leaf production of *L. fisheri* was 30.3 $kg.ha^{-1}$, 24 kg.ha-1 and 34.6 kg.ha-1, respectively, while that of *C. lanceolata* was 2.5 kg.ha-1 in oak forests and 1.5 kg.ha-1 in mixed broadleaved forests. Annual leaf production of wild edible herbs was estimated as follows: *P. brachycarpa* yielded 48 t.year-1 fresh weight (10 t.year-1 dry weight). Annual leaf production of *L. fisheri* was 40 t.year-1 and 9 t.year-1, respectively, while that of *C. lanceolata* was 2 t.year-1 and 0.5 t.year-1, respectively.

Overall, 25% of households collected wild herbs, with an average of 1.2 collectors per household. The collection period was from mid-April to early June and the mean number of collecting days was 12.6 per year. The mean amount of wild edible herbs collected by mountain villagers was estimated to be 12 kg.day-1.person-1. of this, 58% was sold and 42% consumed by the household. (73% raw 27% cooked).

A survey of mountain villagers found that 71% considered wild edible herbs highly profitable. For 28%, the economic contribution of wild edible herbs to total income ranged from 10% to 20%. Half of the villagers questioned expressed great concern regarding the rapid reduction of plants due to over-collection, and increasing numbers of collectors from outside the area.

The geographical distribution, habitat, growth, field characters and chemical contents of wild edible herbs should be further studied. Based on well-established biological information on wild edible herbs, economic potential of the plants can be much enlarged. Considering its demand as the essential source of food and relative rarity in amount, marketability of wild edible herbs is brisk and steady. Therefore, development of appropriate cultivation methods in mountain areas is indispensable to meet the increasing demands and help maintain sustainable production of the plants concerned. in particular, utilization of marginal agricultural upland areas, which are expanded by 30,000 ha per year countrywide, can be advantageous to the economy and environment of the local communities.

Maple (*Acer mono*) saps were collected below 800m of Mt. Gariwang during 10 - 15 days in March. Mean amount of saps per day was 2,250 ml from maples with DBH of 12 to 25 cm and mean amount collected from single maple tree ranged from 22.5 to 33.7 litters. The collecting period at Mt. Gariwang was later than that at Mt. Baekwoon located in Southern areas of Korea and the collecting amount at Mt. Gariwang was greater by 20 litters than that at Mt. Baekwoon.

A total of 231 trees in Mt. Baekwoon and Mt. Chiri were monitored for daily sap flow from 1993 to 1995 to understand factors affecting spring sap flow of *Acer mono* Max. Major factors were tree size, tapping methods, weather and site conditions.

Annual mean sap flow per tree was 6.73 liters in 1993, 11.20 liters in 1994, and 11.30 liters in 1995 with mean DBH of 21.4cm. Sap flow increased with increasing crown diameter, DBH and tree age, with a correlation coefficient of 0.52, 0.49 and 0.56, respectively. Size of tap hole did not affect the sap flow, but number of tap holes per tree from one to two holes increased sap flow substantially. Maples in north-facing slope produced more sap than those in south-facing slope. A large temperature fluctuation between day and night raised sap flow. Night temperature below freezing point, clear sky of the daytime and slight breeze considered favorable weather conditions for sap flow. Day time for heaviest sap flow was observed during 2 to 4 p.m. As of July 1997, there were a total of 99,347 A. mono trees in 16,211 ha: 6.1 trees/ha. Mean frequency of A. mono was 20.7%. The 73.9% of maple trees were younger than 40 years with less than DBH of 20cm. Therefore, sap production is expected to increase naturally with tree age.

Further research on maple sap production is needed to develop strategies for sustainable management of Acer mono; to promote its natural regeneration and to grow them in artificial plantations.

Multifunctional management in the Alpine mountain forests

Claudio Pollini, Vittorio Tosi
Wood Technology Institute (ITL-CNR), 38010 San Michele a/A. (Trento) Via Biasi, 75, Trento, Italy
Tel: +39 0461 660111, FAX: +39 0461 650045, Email: isafa.biofor@tqs.it

Management of the mountain forests has changed gradually over the last few decades: sylvicultural objectives characterised by the primary aim of timber production have been replaced by the development of multi-functional cultivation models designed to satisfy a range of new and differing needs.

The interest of the community for other forest functions has been increasing and at the same time a naturalistic type of sylviculture (near-to-nature) has developed, attempting to harmonise differing and sometimes opposing interests which tends to:
- search for cultivation equilibrium characterised by a high degree of naturalness and stability;
- maximise the different functions exercised by the forest;
- reduce conflicts that may appear among the different functions;
- favour forest self-defence capability against both natural and human attack.

Cosequently forests are managed according to management plans prepared by the Province's or Community's forestry technical office. Adapting traditional forest management practices is deemed essential: one must develop techniques that are cost -effective, that respect the typical structure of the stand and that allow a continued maintenance of these forests, so that they can exert at best their protective, productive and recreational roles. Moreover, considering the different roles of mountain forests, one must approach the silviculture and the harvesting of these stand in an holistic, coherent and objective way, in order to implement the most effective strategy for each specific objective.

This is the approach of a particular experimental project, carried out in the Italian Alpine region by a multi-disciplinary team of silvicolturists, forest managers and harvesting experts.

One of the experimental sites was chosen in a secondary valley (Sadole) of Fiemme valley (Province of Trento), where, because the high slope, the forest cover has a primary role of protection for the people and the infrastructures, limiting the breakdown and the rocks rolling caused by the steepness of the slope. The forest cover is also a source of wood production. Besides it has an additional role in landscape and recreation.

The forest is represented by pure spruce stands or, in some cases, by stands of prevailing spruce with larch and Swiss stone pine.The structure partition of the stand is almost even-aged; mature over mature stand and adult trees prevail. The one stored structure of the stands depend on the natural tendency of the primary species present (*P.abies*). in this site the rules adopted for the forest planning are based on the sylvicultural needs of the various stands.

It was decided to begin a regeneration phase of the mature and over mature stands, starting from the groups that are in the best site conditions in regard to the stability of the stand. With these remarks, in the area the general rules of forest system are followed, using the clear cutting by hole inside the older stand to stimulate the regeneration of spruce and larch, and in the same time it is tried to satisfy the multi-functions of the area (protection, recreation, landscape and wood). A first felling was carried out during 1996 in two holes. The timber was yarded by using a sky-line crane.

The operation was a complete success because it was possible to apply the sylvicultural forest system as designed, in an attempt to reach a number of goals. The important hydrological function of this forest was left intact. Releasing a number of green screens along the cut was extremely effective in this respect. After two years no erosive problems interested the slope. No rockfalls have reached the valley bottom. Furthermore the cut did not detract from the scenic value of the landscape. Although rather large, the patches were managed in a way that they are screened if observed from the most popular observation points. The adequate space of each opening will certainly favour the regeneration of spruce and of other less common species, such ass Swiss stone pine and larch which could increase the local biodiversity and the ecosystem level.

In conclusion, this trial gives us a founded hope that the most part of Sadole forest could be successfully rejuvenated in the next years. That entails that if a large regeneration effort must be conducted in a short time span, it may be worth planning some improvements that will make the operation even more effective.

Enjeux écologiques et financiers de la revégétalisation des mines en Nouvelle-Calédonie

Jean Michel Sarrailh, A. Cornu, C. Le Roux
CIRAD-Forêt Programme Arbres et Plantations, BP 10001 Noum,a, New Caledonia, France
Tel: 687 - 246515, FAX: 687 - 246519, Email: jean-michel.sarrailh@cirad.fr

Un grand massif de péridotites s'étend sur un tiers de la superficie de la Nouvelle Calédonie faisant de ce Territoire le troisième producteur mondial de nickel. Jusqu'à récemment les entreprises déversaient systématiquement les stériles dans les pentes. A l'impact environnemental de première grandeur – stérilisation des terres, pollution des cours d'eau, dégradation du paysage, pollution du lagon – s'ajoute une perte progressive de la biodiversité, le milieu possédant une flore unique au monde avec 90% des espèces végétales endémiques.

Aujourd'hui les sociétés minières adoptent une attitude beaucoup plus respectueuse, mais faute de réglementation contraignante les travaux de revégétalisation n'ont réellement commencé que vers 1993. Chaque société intervient à sa guise, selon des priorités qui lui sont propres. Certaines affichent une volonté de maintenir avant tout la biodiversité et la conservation d'espèces emblématiques des lieux où elles exercent leur activité. D'autres, plus préoccupées de corriger la dégradation du paysage et de réduire l'érosion choisissent une revégétalisation considérée comme plus pragmatique, à plus grande échelle. Pour y parvenir, elles interviennent au moyen d'espèces, parfois même introduites, dont l'utilisation avec des techniques appropriées permet des résultats rapidement visibles et relativement fiables.

Cette dualité entre un contexte d'urgence et le maintien de la biodiversité est au cœur de la problématique posée par la revégétalisation sur le Territoire.

L'environnement industriel et financier évolue sensiblement avec une baisse structurelle des cours du nickel et l'arrivée de compagnies internationales. Il imposera une approche beaucoup plus économique de la revégétalisation.

Les recherches menées par le CIRAD – Forêt en Nouvelle Calédonie doivent permettre de définir des itinéraires techniques qui soient un compromis satisfaisant entre la biodiversité et le coût de réalisation. En effet la revégétalisation des talus est difficile en Nouvelle-Calédonie et nécessite pour l'essentiel l'utilisation d'espèces endémiques dont la mobilisation est onéreuse. Ces expérimentations devraient garantir à terme (dans les vingt à trente ans) une variabilité d'espèces suffisante, mais aussi l'installation d'une couverture végétale complète qui diminuera rapidement l'érosion et apportera rapidement une forte amélioration paysagère, avec des coûts d'installation convenables.

On a montré, par exemple, que deux espèces ligneuses locales, *Acacia spirorbis* et *Casuarina collina* avaient une croissance rapide sur ces milieux dès que l'on apportait de la matière organique et formaient aisément des peuplements denses et fermés. Ces deux espèces faciles à multiplier permettent actuellement le meilleur rapport résultats-coûts. Il est cependant possible d'ajouter quelques autres espèces à développement moins rapide et de définir des modes d'installation et de gestion qui vont garantir une diversification propice au développement naturel d'autres espèces et à la durabilité du système. Les travaux menées en microbiologie autorise à espérer des avancées rapides dans la maîtrise des associations bactéries ou mycorhizes avec les espèces plantées.

Rehabiliation of Degraded Forestlands by the Poor Families in the Hills of Nepal: the Community-based Action research

Bijay Kumar Singh
FAO Representative, GPO Box 25, Kathmandu, Nepal
FAX: 977-1-242640, Email: fao@hlffdp.wlink.com.np

The paper summaries the results of community-based action researches in the Leasehold Forestry and Forage Development for poor in which process has been developed for the rehabilitation of degraded forestlands remained barren for long period and degrading each year. All the researches have been conducted between 400-2000 metre altitude from average sea level (asl) mostly in sloppy hills and mountains of Nepal which are most fragile. These forestlands are now a good source of income for poor families with a new concept of forage farming in multiple product forestry. The technologies and processes are simple but effective that include: (a) zero (no) grazing in the degraded lease land; (b) forage farming (with proper inoculation) of perennial species preferably legumes with a minimum tillage, (d) establishment of legume hedgerows that also provide forage, (e) cut-and-carry system for animal rearing, (f) application of A-Frame to find out contours and planting of fast growing multipurpose tree and fodder species along contours, (g) multiple product forestry that render both short-term and long-term products and benefits to rural poor.

The institutional arrangement for the action research encompassed: (i) formation of small functional groups of families living below poverty line ranging 5-10 families, (ii) land tenurial ownership of degraded forestland to these groups up to forty years and renewable of another term, (iii) participatory action research facilitated by the Nepal Agriculture Research Council (NARC) involving leasehold groups members (poor families), (iv) minimum input supply including seeds and planting materials and training to the leasehold members, (v) research plots in the open degraded lands without fencing and protection responsibility of the leasehold members, (vi) assurance of ownership on products (forage and tree) to the leasehold groups but harvesting of crops at the presence and observation of researchers for data recording.

The action-research package contains Integrated Research, Development, Extension and Training (IRDET) which covers research with poor farmers at open forestlands (without barbed wire fencing). Field staffs and farmers are trained in this aspect and lessons learned are replicated in other areas as well.

The results of action researches are obvious that the project, on its initial three-year exploratory phase, initiated and tested the technologies and processes in four project districts. High level Mid-term Evaluation Mission (including representatives from the (FAO/IFAD/HMGN) evaluated the findings and very interesting lessons were learnt from the action-researches. Now the concept of leasehold forestry for poor and its technologies have been successfully replicated in ten hilly districts of Nepal. in total 4268 hectares degraded forestlands have been brought under productive area that accrue a good source of income to the poor families chiefly through improved animal rearing. of the ten species tested, Stylo (*Stylosanthes species*) and molasses (*Melinis minutiflora*) are found the promising species for eradicating forest killer (*Eupatorium odoratum*) and improving soil. Other species that stabilizes the degraded forestlands and also provides short-term benefits to poor families are: broomgrass(*Thysonaleana maxica*), bamboo (*Dendrocalamus*), Arunodnaria and suitable fruit trees in the locality. Shrub species like Flemengia, sunhemp (*Crotalaria juncea*) are found suitable leguminous hedgerow forage species in the restoration of degraded forestlands.

Research Establishment and Maintenance of Access Racks' Network in Relation to tending Operations of Young Sessile Oak Stands

Mihai-Liviu Daia, Ion I. Florescu and Norocel-Valeriu Nicolescu
National Forest Administration Romsilva, B-dul Magheru 31, 70164 Bucharest, Romania
Tel: 01- 659 20 20, Email: nicolescu@yahoo.com

Sessile Oak (*Quercus petraea* (Mattuschka) Mill.) is one of the most valuable forest species in Romania, covering about 720,000 ha (3 per cent of the forest area). Usually, it is naturally regenerated by using group shelterwood system and young stands are extremely dense (tens of thousands of seedlings per hectare), pure and impenetrable.

Taking into account some of its main characteristics (e.g., high stand density; relative intolerance of shade; danger of epicormic brancing; quite slow growth), the silvicultural models traditionally applied to the Romanian young sessile oak stands, before the first commercial thinning, includes low moderate intensity weedings and cleanings, reducing stand density down to about 80 per cent.

Based on research works carried out in different sessile oak-based stands from the Tirgoviste Branch of the Romanian Forest Administration since 1992, a new approach is proposed and includes:

- opening and maintenance of access racks, 0.8 - 1.0 m wide (seedling stage) up to 1.5-2.5 m wide (thicket stage), made at intervals also depending on development stage (between 6-12m in seedling stage in 25-40 m in thicket stage);

- weedings and cleanings of various intensities (e.g., moderate in highly dense stands, non-treated from the very beginning, with high slenderness indices (over 120-150), where stand density is reduced down to about 85 per cent or moderate-high in continuously treated stands, where stand density can be reduced down to 80 or even 75 per cent).

Costing Study of Implementing Selective Management System (SMS) for an Integrated Timber Complex in Peninsular Malaysia

Ahmad Fauzi Puasa, Abdul Rahim Nik, Mohd Azmi Mohamed Idris, Salleh Mat, Mohd Shahwaid Othman and Awang Nor Abdul Ghaani
Forest Research Institute Malaysia, Techno-Economics Division, Kepong, 52109 Kuala Lumpur, Malaysia

The current practice of forest management in Peninsular Malaysia is based on Selective Management System (SMS) with the objectives of optimising the management objectives of economic and efficient timber harvest, sustainability of forest and minimum forest development cost, under prevailing conditions. The practice requires the selection of management regimes based on inventory data, which will be equitable to both logger and the government, as well as ensure ecological balance and environment quality. This paper deliberates on the costs incurred in implementing the current SMS practices incorporating Malaysian Criteria & Indicator (MC&I) verses conventional SMS in an integrated timber complex in Peninsular Malaysia. The actual costs of forest management activities were collected using data from thirty-seven logging compartments for the period 1992 to 1997. The cost of forest management activities was computed for eight activities: pre-felling inventory; tree marking; boundary delineation; road and log yard construction; harvesting; closing report; post felling inventory; and silvicultural rehabilitation cost. The breakdown of the logging cost components was reported and cost equations of each of this forest management were estimated using linear regression model. The cost function was estimated using the ordinary least square technique. Results of the study show the cost of implementing the SMS varies by different forest management activities. Timber harvesting and administration costs accounted for about 62.37 percent of the total cost, either per hectare of area logged or per cubic meter of timber harvested. The average cost of timber harvesting and administration is estimated at RM2, 454.10 per hector (RM50.41 per cubic meter) and Rm1, 746.79 per hectare (RM37.30 per cubic meter), respectively. The higher proportion of cost incurred by these two activities is due intensive forest management activities during harvesting and planning stags. Regression analysis indicates that such factors as timber output, area of the distance of forest to the main road and altitude affect each cost component in a different manner. The depends on the nature of forest management activities carried out by the Concessionaire. If the logging concessionaires were to comply with the sustainable forest management guidelines using the MC&I, higher costs would be expected since many additional activities and specifications of forest management activities will have to be followed by the concessionaire. The implication is that the incremental cost would have significant effects on the economics of timber harvesting and forest management. Suggestions on appropriate policy to ensure long term benefits of sustainable forest management resulting from incremental cost of forest management activities is also highlighted in the paper.

Elementos tecnicos para la producción sostenible de recursos vegetales no maderables del bosque tropical

Daniel Marmillod, Roger Villalobos, Gabriel Robles
CATIE, 7170 Turrialba, Costa Rica
Tel: (506) 556 0301, FAX: (506) 556 8417, Email: rvillalo@catie.ac.cr

Desde 1989 el Centro Agronómico Tropical de Investigación y Enseñanza (CATIE) estudia la problemática del aprovechamiento sostenible de los bienes del bosque diferentes a la madera, como alternativas para el desarrollo. La experiencia de estos años de investigación se ha sistematizado en una metodología para incorporar especies vegetales en procesos de manejo forestal diversificado, entendido como un manejo técnico de las poblaciones naturales y no como algunas prácticas extractivas tradicionales, carentes de indicadores sobre la capacidad y limitaciones productivas del recurso. Esta metodología esta basada en estudios sobre plantas con diversos tipos de producto y hábitos de crecimiento.

El desarrollo de nuevos criterios de manejo en el bosque tropical debe ser paralelo al aprovechamiento, por lo cual la selección cuidadosa y sistemática de las especies a incluir en ese proceso constituye el primer paso del mismo, y se basa en su capacidad de adaptarse a los objetivos últimos del plan de manejo. Considerando la gran gama de combinaciones de las especies no maderables en cuanto a hábitos de crecimiento, órganos cosechados y tipos de mercado, la definición clara del producto a cosechar en cada caso y sus normas de calidad es el segundo paso, sin el cual es imposible definir las herramientas del trabajo posterior, solo debe salir del bosque la biomasa que será aprovechada.

El tercer paso es la definición del proceso productivo, esto incluye el conocimiento mínimo de la especie en cuanto a su hábito de crecimiento y requisitos ambientales generales. Posteriormente se desarrollan herramientas para caracterizar su estructura de población, es decir variables prácticas de medición que permitan diferenciar estados de madurez de los individuos, calificarlos como productivos o no productivos y estimar la cantidad de producto de cosecha por unidad de área. La información que se obtiene a partir del diámetro a la altura del pecho de los árboles maderables puede obtenerse de otro tipo de variables en el caso de especies no maderables, como número de cepas por macolla o dimensiones de una hoja. El desarrollo de un sistema silvícola y plan de aprovechamiento para cada especie en particular implica determinar la respuesta de la especie a diferentes condiciones ambientales y tratamientos de manejo, así como sus tasas de crecimiento y regeneración de la biomasa de cosecha.

El cuarto paso se refiere a la integración de varias especies dentro del proceso de aprovechamiento integral del bosque, es decir la concepción del sistema de manejo diversificado del bosque. Para ello se deben definir metodologías de inventario diversificado que reduzcan los costos y determinar la compatibilidad o antagonismo entre especies en función de su respuesta a los tratamientos silvícolas. La experiencia de CATIE demuestra que este proceso es práctico y factible de realizar, como una forma de contribuir a la valoración y conservación subsecuente de la biodiversidad en bosques tropicales.

Vers des Aménagements Forestiers Villageois de Concepcion Evolutive

Regine Peltier, S. Dan Baria, H. Djibo, S. Giraud, P. Montagne
CIRAD-Forêt et E.N.G.R.E.F., Montpellier, France
Email: Genevieve Reynaud [Reynaud@Engref.Fr]

En 1992, le projet Energie II a initié l'aménagement de plusieurs forêts du Sud-Niger au profit des populations riveraines. Des groupements villageois denommés "Marchés Ruraux" (M.R.) ont été créés pour commercialiser le bois de feu.

Six années plus tard, en 1998, une évaluation technique et socio-économique de ces aménagements et des organisations villageoises denommées "Structures Locales de Gestions" (S.L.G.) a été réalisée.

Il s'avère que certaines S.L.G. ont fait preuve de dynamisme tant dans le domaine des réalisations sociales au profit du village que dans celui de la gestion des forêts villageoises. D'autres au contraire se sont rapidement essoufflées dès que l'encadrement du projet s'est retiré.

Les notions de quota, de parcellaire, de rotation, d'espèces protégées, de diamètre minimum et de hauteur de coupe ainsi que les techniques simples de régénération (paillage) ont été assimilées et réappropriées par la majorité des bûcherons.

On constate que les aménagements ne peuvent être durables que s'ils sont conçus de façon évolutive afin de pouvoir s'adapter aux aléas climatiques (nécessité d'exploiter d'avantage à l'occasion des années d'alimentation déficitaire) et aux nouvelles connaissances acquises par l'encadrement ou par les bûcherons eux-mêmes. La composition de la S.L.G.

doit également être revue régulièrement. L'aménagement doit donc pouvoir être modifié légèrement en cas de nécessité et, plus profondément, à chaque rotation de coupe.

En général, lors de la création d'un M.R., les villageois sont méfiants par rapport à l'administration ou au projet et ne veulent s'imposer qu'un minimum de contraintes concernant la gestion des forêts. Ce n'est qu'au bout de quelques années de fonctionnement de la S.L.G. qu'une confiance mutuelle peut s'établir entre l'administration et cette structure. Cette dernière peut alors imposer aux bûcherons des règles plus contraignantes. On peut ainsi passer d'une gestion très simplifiée, à un aménagement préservant l'écosystème et garantissant une production soutenue. L'Etat peut alors accorder des baisses importantes de taxes, sur le bois provenant de ces forêts, pour encourager cette démarche patrimoniale. Il doit alors être vigilant sur le contrôle de son application réelle sur le terrain.

On comprend donc que les états qui se sont engagés dans ce type de stratégie de gestion décentralisée doivent tout faire pour que leurs fonctionnaires apportent un appui effectif aux structures locales de gestion.

Development of Criteria and Indicators for Sustainable Management of Forest in India: Bhopal-India Process

Ram Prasad, S. Raghavan, Bharati Joshi
Indian Institute of Forest Management, Nehru Nagar, PO Box 357, 462003 Bhopal, MP, India
Tel: +91-755-775716, FAX: +91-755-772878, Email: ramprasad@iimb.ren.nic.in

Over a hundred years ago India adopted the principle of sustained timber yield management from its forests. The other dimensions of sustainability, though considered during the development of management plans for forest divisions, were given lesser priority. However there were major changes and some reversal of priorities in the National Forest Policy (1988). The main focus of forest management from now on was to maintain environmental stability through preservation and restoration of ecological balance and the conservation and enhancement of biological diversity. Direction of forest management has to be focussed towards the increase in forest productivity and to meet the basic requirements of fuelwood, smallwood, fodder and non-timber forest produce of the rural and tribal people. Sustainability in the Indian context is the dynamic and complex interaction of the existing social, economic and ecological conditions. Well being of the forest dependant communities along with the well being of the forest health is the key to figuring out sustainability of India's forests. However, there was no mechanism to monitor the progress of achievement of sustainability as envisaged in the 1988 Forest Policy.

A hierarchical framework of "Criteria and Indicators" (C&I) is being used in eight different regional processes as part of the UNCED sustainable forest management (SFM) initiative. Due to the unique nature of the socio-economic and forest conditions in India it was found that none of the earlier regional processes would be appropriate to assess sustainability in Indian conditions. For Sustainable forest management (SFM) of India's forests, a separate set of C&I was designed to provide cost-effective information for helping in the sustainable management of forests in conditions of the South Asia subcontinent. A set of eight criteria and fifty-one indicators was developed under the Bhopal-India process. Assessment of the sustainable development of India's forest and simultaneously the achievement of the forest policy principles is to be done at the national level by using these C&Is. Though these indicators would not directly establish whether management is sustainable or not, the direction of change of indicators would provide insights into the directions of change towards sustainable forest management. This would help in developing or revising policies and legislation and refining national forestry programs.

The eight criteria identified in the Bhopal India process were based on the principles enunciated in the 1988 forest policy. These are the extent of forest and tree cover, forest ecosystem and vitality, biodiversity conservation and soil and water conservation. and also other criteria like forest resource productivity, forest resource utilisation, social cultural and spiritual needs and policy, legal and institutional framework.

This paper deals with the method of evolution and development of each criterion and its associated indicators and verifiers. The paper also discusses the research needs required for each criterion and the development of norms or standard for some verifiers and indicators. The applicability of these criteria and indicators at the regional or state level is discussed and the type of changes required to adapt these C&I at the forest management unit level is also discussed.

Sustainability of remaining forest fragments in the Atlantic forest region

Maria das Gracias F. Reis, Geraldo G. Reis; Jose S. Almeida-Junior, Agostinho L. Souza; Joao A. A. Meira Neto
Federal University of Vicosa, Department of Forestry, 36571-000 Vicosa, Brazil
Tel: 55-031-8991209, FAX: 55-031-8992478, Email: mgfreis@mail.ufv.br

The floristic, successional stage and landscape characteristics were studied in four secondary forest fragments within the Atlantic Forest domain in Minas Gerais State, southeastern region of Brazil. Fragments 1 and 2 are elongated with an area of 12 and 13 ha, respectively, and fragments 3 and 4 tended to round with an area of 23 and 18 ha. All fragments were mostly located on the upper part of the slope.

The point centered quarter method was used to obtain the data. Three approach levels were taken into account to proceed analyses: height: 3 m and DBH: 5cm; 5 cm DBH: 10 cm; DBH 10 cm.

It was sampled 57 species in the fragment 1 and 77 in the fragment 2, which are elongated, and 85 in fragments 3 and 4, which tended to round.

The initial secondary species group predominated in all fragments, however, these fragments present different successional stages. The fragments 1 (elongated) and 4 (round) exhibited the earliest and latest successional stage, respectively. Lianas were present in all fragments and represent a serious barrier for natural regeneration, and imposed high mortality of trees.

The biodiversity was deeply depreciated in all fragments due to their small size, strong edge effects, low surround permeability (roads, crops, pastures) and high antropic pressure, specially for the fragment 1. The fragment 1 presented 19.3 % of species with a population smaller than 50 individuals with height greater than 3 m. The values for fragments 2, 3 and 4 were 14.2, 0.0 and 10.5 %, respectively. These results indicate that fragment 1 presents the lowest sustainability, followed by fragment 2, both with elongated form and small size.

Ecosystem Management of Forests in Russia: Strategy of Forest Account Works

Valentin V. Strakhov, andrey N. Filipchuk
All- Russian Research and Information Centre for Forest Resources, Novocheremushkinskaya STr. 117418, Moscow 69 Moscow, Russia
Tel: 7-095-332-5338, FAX: 7-095-331-0533, Email: aricfr@aha.ru

Economic reforms in Russian are conducted to delimit mechanisms employed in State management and economic development. in all branches of economy they are directed, first of all, on a decentralisation of management and of decision-making procedures. However, as regards the forest management and system of forest accounting, first of all, with inventory and planning, the most persistent inertia survives in preserving centralisation of planning and financing regardless of real needs of regions. Enlargement of approaches, completeness and depth in realisation of the whole complex of forest accounts needed.

The sustainable forest management is connected, first of all, to the economic activity. Transition to anew quality of human interrelations with forests from "using" to "management", brings on the first plan the interconnection of ecological, social and economic process. The economic aspect, thus, moves from the first to the last place in the system "Nature - Society - Economics". The estimation only of timber resources concedes a place to a complex estimation of forests as ecosystems. Therefore, traditional use of existing base of knowledge on forests becomes insufficient for sustainable forest management.

Forest, these spatially distributed natural features, require a geographical approach (i.e. use of extract co-ordinates for the describing and updating data); that is especially important for ensuring sustainable development of land and forest uses. Besides, and influenced by economic activity and environmental changes, is necessary. It needs urgently to fix priorities concerning depth completeness and timeliness of the information on forest.

It is obvious that t the State level (federal and Regional) of forest management we should have the possibility to assess truly key parameters of the forests' dynamics. This issue could be carried out with a system of State Forest Inventory (SFI), budget-fed irrespective of the pattern of ownership of forest parcels.

SFI should provide for collecting, transmitting, processing and analysing information on forest and for selective driving it to bodies of forest management and of nature conservation, as well as to various users. The information is intended for duly revealing of changes in the forest state, their estimation, prevention and elimination of consequences of negative processes. It will be also an practical opportunity to integrate data of Russian forests into world information system of world-wide forest resources assessment.

Accuracy and the reliability of the SFI will guarantee bodies of forest management against making strategically faulty decisions, they will allow to reliably assess contribution of Russian forests into global processes of climatic changes and preservation of a biological diversity.

Genetic Impacts of Forest Fragmentation in Northwestern Costa Rica

Johnathan Cornelius, Timothy J. B. Boyle and Francis C. Yeh
Tropical Agricultural Center for Research and Higher Education, 7170 Turrialba, Costa Rica

Since the sixteenth century, grazing and agriculture have transformed the landscape of the Bagaces Valley, northwestern Costa Rica; where once was forest interrupted only by rivers, there remain only riparian and non-riparian forest patches embedded in pastureland, sugar-cane and rice-fields. As genetic diversity of forest trees is thought to influence their population viability the genetic characteristics of fragment populations have important implications for the conservation of biodiversity in such landscapes. We report on such characteristics, concentrating on two species. *Plumeria rubra* (*Apocynaceae*) is a wind-dispersed, hawkmoth-pollinated pioneer. Within the study zone, it is typically found on the exposed rock of the many river canyons, with outliers on similar, but non-riparian, habitats. *Anacardium excelsum* (*Anacardiaceae*) is bat- and gravity-dispersed and pollinated by small-to-medium-sized insects. It is found predominantly as the dominant species of the gallery forest, but also occurs as non-linear, discrete fragments. We report on allozyme diversity, effective sizes and mating systems within fragment populations of these contrasting species, and their relation to variables such as fragment size, shape and degree of isolation. in our conclusions, we address the implications of our results for biodiversity conservation.

Genetic Consequences of Intensive and Alternative Silvicultural Systems

Yousry A. El-Kassaby, Michael Stoehr
The University of British Columbia, Department of Forest Sciences, Faculty of Forestry, Vancouver, BC, Canada
Tel: (250) 381-1404 Local 230, FAX: (250) 381-0252, Email: YElKassaby@prtgroup.com

The effects of various intensive silviculture options such as tree improvement delivery systems and alternative silviculture methods such as partial cutting and commercial thinning on genetic diversity are assessed. Intensive management methods of parent tree selection before and after progeny testing, genetics of seed orchards and seedling production are evaluated. More importantly, seed orchard "after-effects" that are resulting from the common practice of moving seed orchard parents by several degrees of latitude from their origin to locations that are suitable for seed production are assessed and reviewed. Alternative silviculture systems such as seed tree, shelterwood and patch cuts were compared to clear cut and control old growth forest and the genetic quality of natural regeneration is determined. Finally, commercial thinning practices are evaluated and their impact on tree species' genetic diversity and the understorey plant species community dynamics are evaluated.

Impact of logging on tropical forest resources

K. Wickneswari, Ho, W.S.; Lee, C.T.
Universiti Kebangsaan Malaysia, School of Environmental and Natural Resource Sciences, Faculty of Science and Technology, 4360015KM Bangi, Selangor, Malaysia

Tropical forests are found in more than 80 countries and account for about one third of the world's forest cover. Although deforestation occurs in all types of tropical forests ranging from lush rainforests to arid thorn woodlands, logging is more predominant in the humid tropical forests. Annually more than 4.0 million hectares of tropical rainforests are logged for timber. The volume of timber extracted varies from region to region according to the stocking of commercially valuable stems. The damage to the stand is generally related to the number of stems harvested per hectare and the nature of the logging operations. Logging not only has an impact on the timber species being harvested but also on all other goods and services provided by the forest viz, fuel food, fodder, shade, shelter, environmental stabilization, and amenity, cultural and spiritual values. Hence, a continuous assessment of damages to the biotic and abiotic components due to logging is important for sustainable management of forests for its goods and services. This paper will address the impact of logging on forest genetic resources, mainly the plants which form the base for most life forms.

Reduction in basal area of trees from different size classes due to a single logging event can range from 13-56% in tropical rainforests with large tees of low abundant limber species being most affected. However, recruitment of seedlings and presence of saplings are generally high in immediately logged-over forests. A decrease in genetic diversity ranging from 5-23% has been detected in adult individuals of timber and non-timber species immediately after logging. An evaluation of young regenerants of three tree species immediately after logging revealed high genetic diversities. Pedigree analysis of regenerants in one species showed substantial contribution of genes from neighbouring stands in the logged stand. No significant change in genetic diversity has been observed for a number of plant species in regenerated forests after about 40-45 years of logging. Implications of these and other demographic and genetic diversity changes on harvesting practices and sustainable management of tropical forest genetic resources will be discussed in this paper.

Terrestrial Biosphere Models and Forest-Atmosphere Interactions

Michael Raupach and Damian Barrett
CSIRO Land and Water, Canberra, Australia
Tel: +61-2-6246 5848, Fax: +61-2-6246 5845, E-mail: michael.raupach@cbr.clw.csiro.au

The terrestrial biosphere, encompassing vegetation and the adjacent soil and atmosphere, is a biogeochemical crossroads. Here the fluxes of water, carbon, energy and nutrients all interact and influence one another, to an extent greater than practically anywhere else in the cycles of these entities. To understand the transfer of any one entity through the terrestrial biosphere, say water, it is necessary to recognise the relationships among these crucial fluxes. Why are they crucial? From the standpoint of a catchment or forest hydrologist, the cycles of water and nutrients through vegetation exert crucial influences on vegetation growth, catchment water yield, and water quality. From an atmospheric standpoint, the energy and water fluxes at the earth's surface largely control atmospheric motions and the global hydrological cycle. From the standpoint of the biogeochemistry of the earth system, key fluxes through the terrestrial biosphere include those of chemically or radiatively active gases such as CO_2, methane, N_2O, volatile organic carbon compounds (VOCs) and particulates.

Because of these diverse motivations, transport processes in terrestrial biosphere are important in meteorology and climatology, plant physiology, agricultural science, ecology, remote sensing science, and hydrology (including forest hydrology as an important sub-discipline). However, these disciplines have developed views of essentially a single set of processes which are surprisingly distinct. When encapsulated in model form, the resulting descriptions are often known as terrestrial biosphere models, or sometimes as SVATS (Soil-Vegetation-Atmosphere Transfer Schemes). Examples of extant terrestrial biosphere models include SiB, Century, Biomass, Biome-BGC, SCAM, WAVES, and others.

The task of this chapter is to review the current state and development of terrestrial biosphere models, especially from the standpoint of forest hydrology, and to highlight some directions for future development. A theme throughout is that there is a great deal of convergent evolution between terrestrial biosphere models arising from different parent disciplines. This is happening as a small part of a much larger movement towards a unified study of the earth system, in which the interactions between components (atmosphere, oceans, soils, terrestrial water, ecosystems and humans) are the primary focus of study rather than processes within any of these components.

The chapter begins with a description of a terrestrial biosphere model, followed by a description of the key processes operating in the system. We then consider the integration of these process descriptions to canopy scale, and introduce the new phenomena that need to be handled at this level of integration. These include nutrient distributions and light use efficiency, gross and net primary productivity, and plant growth and resource allocation. We describe new techniques for parameter estimation which move away from the traditional view of a model as an *a priori* predictor from specified data on the meteorological variables and process parameters. Finally, we demonstrate how the terrestrial biosphere (as a complex system described by a terrestrial biosphere model) exhibits simple or at least understandable behaviours at large (canopy and greater) scales. These behaviours emerge from the negative feedbacks exhibited by the system, and are manifested as quasi-equilibrium states.

Forest Management Induced Leaching of Nitrogen from Temperate Forests

Karsten R. Rasmussen, Per Gundersen
Danish Forest and Landscape Research Institute,
Department of Forest Ecology, Hoersholm Kongevej 11, DK-2970 Hoersholm, Denmark
Tel: +45 4576 3200, FAX: +45 4576 3233, Email: krr@fsl.dk

Nitrogen leaching may potentially cause eutrophication of surface water and contamination of ground water. Generally, water from forests is of good quality with a relative low concentration of dissolved nitrogen. Water resources from forests are already in use for drinking water purposes in several regions and this use may increase in the future since other land use (agriculture industry and urban use) expose a high risk for contamination of ground and surface waters. Afforestation on agricultural land takes place, *e.g.* in Northern Europe, to improve the water quality and to secure water resources in the future.

Temperate forests are generally considered nitrogen limited and they are characterised by a very tight nitrogen cycle. Losses of nitrogen are low with background levels less than 0.3-0.5 mg N l^{-1} in soil water. Often the losses mainly occur as organic nitrogen. However, low concentrations of nitrogen in seepage water from forests may not per se be expected. Several investigations show concentrations of nitrate in the soil solution and stream water well above the background levels.

In parts of Europe and North America, air pollution with nitrogen compounds is the main reason for increased nitrogen leaching. Inputs often above 10-20 kg N ha^{-1} yr^{-1} increase nitrogen concentrations in foliage and foliage litter, increase nitrogen mineralisation and thus accelerate the nitrogen cycle. Recent advances in the understanding of nitrogen cycling in forest and the effect of nitrogen deposition have identified the conditions where there is risk for nitrate leaching from mature forests at least for coniferous forests. As an example coniferous sites with nitrogen concentrations in needles above 1.7 mg g^{-1}, total nitrogen input to soil (throughfall + litterfall nitrogen input) above 80 kg N ha^{-1} yr^{-1} and/or forest floor C/N ratio lower than 25 were leaching nitrate if nitrogen deposition was elevated.

Other reasons for elevated nitrate leaching may be related to forest management. The classical experiment at Hubbard Brook in the 1960s with clear-cut and herbicide treatment of a whole catchment illustrated the potential vast impact on water quality (leaching of 140 kg N ha^{-1} yr^{-1}) at extreme forest disturbance.

Forest management induced leaching may result from one or a combination of the following impacts on the nitrogen cycle:

Increased input of nitrogen (fertilisation, planting of N_2 fixing trees)

Decreased biological uptake (clear-cut, thinning, weed control)

Increased net mineralisation (liming, soil preparation, ditching (lowering of groundwater)).

Following the Hubbard Brook experiments forest research in Europe and North America have substantially increased the knowledge on impacts of forest management. Especially the impacts of clear-cut are well established demonstrating that the risk for nitrogen losses is highest at nitrogen rich sites. High nitrogen losses have been demonstrated after liming and ditching, as well as after planting of coniferous species on former deciduous forest soils.

Afforestation on former agricultural land will be an important silvicultural activity at least in Europe during the next century. Modern agricultural soils are characterised by high pH, high amounts of nitrogen bound in organic matter with a C/N ratio often below 10 and nitrogen mineralisation dominated by nitrification. in the first years after afforestation nitrate leaching will occur until the plant cover has developed. The question is how the nitrogen cycling will develop in the long-term on these types of soils. Recent studies of forests developed on formerly cultivated soils have shown that the soil still have nitrogen cycling characteristics more comparable to cultivated soils than to soils with continuous forest cover even 100 years after afforestation.

In the paper, findings on the impact of silvicultural management on soil solution chemistry and freshwater quality from the temperate forest regions will be synthesized. The interaction between management and air pollution nitrogen input will be discussed as well as ways to reduce the impact of silviculture on water quality.

Effects of disturbance on nutrient export from forested catchments in the humid tropics

Paul Reddell, Michael J. Webb
CSIRO, Tropical Forest Research Centre, Atherton, Queensland, Australia

Site fertility affects the productivity, structure and functioning of tropical forests. Consequently, the maintenance of site fertility is an essential biophysical element in the sustainable utilization of forest resources in humid tropical landscapes. Disturbance events (both natural and man-induced) frequently cause the release or 'mobilisation' of nutrients within the ecosystem and this may result in an increased potential for nutrient loss or 'leakage' out of the system. A predictive understanding of the likely risks and levels of nutrient export from ecosystems and catchments associated with particular forest disturbances in the humid tropics is thus critical to the sustainable long-term management of both natural and plantation forests in these landscapes.

In this review we consider:

- the pathways of potential nutrient loss from tropical forest catchments;

- the features of disturbance events in natural and plantation forests that govern the extent of possible nutrient export, and;

- some of the methodological problems involved in measuring nutrient export from catchments.

The importance of integrating research in nutrient dynamics, hydrology and plant ecology to address issues of sustainable utilization of forest resources in the tropics is emphasised.

Transpiration of Trees and shrubs and hydrological balance in water limited environments under Xerothermo Mediterranean climate

Gabriel Schiller, Yehezkel Cohen and Shabtai Cohen
The Volcani Center, Department of Agronomy and Natural Resources, Post Box # 6, 50250 Bet-Dagan, Israel
Tel: +972-3-9683678, FAX: +972-3-9669642, Email: vcgabi@agri.gov.il

Studies were conducted in the late 60is and early 70is on the hydrological balance of areas of various vegetation types and cover, in Thermo-Mediterranean climatic conditions sensu Emberger et al. 1963. Interest in these studies resulted from concern about the hydrological balance of Israel's aquifers as influenced by large afforestation projects and reclamation of devastated natural oak scrub formations. The studies failed to produce accurate data due to calibration problems of the different methods used, and the extremely large spatial variabilityin site conditions, which prevented the determination of the water storage capacity of the bedrock-soil complex.

One of the ways to determine the water balance of forest areas is to use physiological parameters of the vegetation itself as an indicator of the bedrock-soil complex water availability. of the several parameters available, we selected the sap flow velocity, i.e., transpiration measured by the improved and calibrated heat pulse technique sensu Cohen et al. (1981, 1989) in the tree's trunk.

Sup flow, (i.e., transpiration) was measured continuously during several days on between 8 to 15 dates during a year in eight or 16 trees, whose diameter distribution represent the diameter distribution of all the trees growing in a plot situated either in *Pinus halepensis*, *Quercus calliprinos*, *Q. ithaburensis*, *Phillyrea latifolia* and *Tamarix aphylla* forests, (all native species); and in *Eucalyptus camaldulensis* plantations, a introduced species. Results of these measurements were used to scale up the single tree water use to stand water use at a given environment.

The relationshipe between water availability (rainfall), and the estimated amount of water used by the forest vegetation, should be regarded as a majore factor in forest management.

The hydrologic and growth response of eucalypt forests to soil salinity and waterlogging.

Richard P. Silberstein, Robert Vertessy
CSIRO Land and Water, CRC for Catchment Hydrology, Canberra, Australia
Tel: +61-2-6246 5848, FAX: +61-2-6246 5845, Email: Richard.Silberstein@clw.csiro.au

The response of trees to salt in the soil is a vexed problem for land managers in much of southern Australia. Clearing native woodland for agriculture has resulted in dramatic increases in waterlogging and secondary salinisation which are arguably our two greatest land management issues. Over the last 10-15 years there has been a concerted effort by government, and private groups and individuals, to put trees back on the land, and to do this in a way which complements rather than replaces existing agricultural systems. This "greening" of agricultural areas is intended to ameliorate the hydrologic imbalance which has arisen from the forest clearing, and simultaneously provide an alternative crop for farmers.

However, there is considerable debate over the likely success of replanting much of the degraded land. Many of the commercial tree species are sensitive to salinity and waterlogging in their root zone. These sensitivities are compounded by the degradation of soil structure which has arisen from cultivation and from the rise in, often saline, watertables. The structure of the clayey subsoils has also been degraded by changes in the soil water electrolyte mix which accompanied the rising watertables.

Most of the native forest and woodland cleared in Australia grew in regions with mean annual rainfall from 300 to 1100 mm. The trees adapted, and flourished, in conditions where small scale salinity levels were very high, but the depth and extension of their root systems appeared to allow them to capture water where it was available. This strategy resulted in forests and woodlands which could survive drought periods, as well as locally concentrated salt. This ability to exploit the soil depended on macropores from old root channels and pedological structures, features which may well be hampered by the changes in soil structure. This paper reviews knowledge of how the native, largely *Eucalyptus*, forests of southern Australia respond to soil salinity, soil water deficit, and waterlogging conditions, and implications these have for integration of plantations with agriculture.

Web-based information resources for forestry research on the Internet

Alois Kempf
Swiss Federal Research Institute WSL, Zürcherstrasse 111, CH-8903 Birmensdorf, Switzerland
Email: kempf@wsl.ch

Keywords: bibliography; reference information; document type; public access; knowledge exchange; resource discovery; electronic publishing

Internet applications have evolved in many ways during recent years. One extraordinary development is the multiple use of World Wide Web features. This is especially true in the scientific context, but developments in e-commerce, web-based messaging, cyber-administration, distance learning or in the entertainment industry are also shaping interpersonal communication and business processes. These changes can be observed in the forestry and wood sector as well as in the field of forest sciences, e.g., electronic publications, directory information on the Web, archives of mailing lists, downloading of software, e-shop facilities, document repositories, modelling programmes.

In fact, facing the mass of data available by an Internet address (URL) on the Web the user is looking for support in locating, filtering, selecting or sorting relevant information. The retrieval process has become - in a paradoxical manner - simpler and more complex at the same time. New search engines may link very fast to a specific document or data set by their weighting mechanisms.

However, in other cases only the visit of an authoritative source on the net will allow to search for the information needed in a database stored "locally" .

A few examples will illustrate the current situation with respect to both fee-based services and publicly accessible data. As far as forestry research is concerned one can expect quite a broad range of bibliographic collections available through web interfaces: library catalogues / web-OPAC, publisher's price lists, table of contents or cited references produced by research institutions and scholarly associations, personal homepages, etc. Additionally one can find other types of reference information, i.e., current research descriptions, meta-data services, media collections (images, audio files, ...) or even basic data on patent literature. Terminological aids, classification schemes, virtual libraries and other tools which facilitate a high quality profile of interaction within the scientific community are increasingly in use on the Web.

IUFRO is also supporting these activities by its web site and special projects, namely the Task Force GFIS (Global Forest Information Service), the terminology clearinghouse SilvaVoc, its bibliographies/catalogue, search engine, and documents in PDF. The Task Force on Internet Resources has contributing in the past to setting up a basic information infrastructure in favour of the IUFRO research network.

The Role of Libraries and Information Centres in the Global Forest Information Service

R. A. Mills
University of Oxford, Oxford Forestry Institute, South Parks Road, OX1 3RB OXFORD, United Kingdom
Tel: +44 1865 275080, FAX: +44 1865 275074, Email: roger.mills@plants.ox.ac.uk

As the information society develops, traditional libraries and information providers are changing: moving from physical 'places' to digital 'spaces'. Electronic resources supplement and in part replace local holdings, and formerly stand-alone services are increasingly integrated into institution-wide, country-wide or regional facilities. Despite this, there remain huge distributed collections of printed material, not available in electronic format but still of high relevance to forest research; and even though electronic publishing is growing fast, so is print: every year sees a further rise in the numbers of printed scientific journals published. The provision of access to non-electronic material is thus a key element of the Global Forest Information Service and this paper examines the role of libraries in meeting that challenge.

Libraries have traditionally had both a curatorial and an educational role, which applies as much to electronic as to conventional resources. Digital material poses difficulties in organisation, long-term retention and preservation, just as other media do, and librarians have long experience in devising innovative solutions to these problems. The profession is devoted both to the preservation and dissemination of knowledge, working with educators and researchers to facilitate its creation, sharing and use. The computer, and the internet in particular, provide powerful tools in aiding this process, but human input is required in all three of its facets; machine based systems speed up its operation, but also create increasing demands for reliable, well-evaluated resources and high-quality education in their use.

Libraries within the GFIS subject envelope can help meet these demands by:
- locating, describing and classifying relevant resources in all formats
- guiding local and remote users in their most efficient use
- providing rapid access to requested material by traditional and electronic means
- identifying non-electronic resources for digitisation
- organising the creation and maintenance of digital archives
- providing local access to electronic resources which cannot be globally networked
- developing inter-connected catalogues hyperlinked directly to electronic resources
- encouraging IT literacy and the development of electronic publishing
- advising on copyright and other intellectual property issues
- publicising GFIS in conjunction with local and regional networks of all sorts
- offering a 'human face' for electronic systems, in a familiar context and local language

This paper reviews how far these and related activities have already progressed, what more can be implemented with current technology and which areas need further investment.

IUFRO Task Force Global Forest Information Service (GFIS) for improving access to information on forests

Risto Päivinen, Reynolds, J., Landis, E. Martin, M. Mills, R., Petrokofsky, G., Richards, T., Saarikko, J. and Schuck, A.
European Forest Institute, Torikatu 34, FIN-80100 Joensuu, Finland
Tel: +358.13.252.020, FAX: +358.13.124393, Email: risto.paivinen@efi.fi

Improving access to forest information was formally recognised as a priority by the United Nations Conference on Environment and Development in 1992 when it stated in Agenda 21, Chapter 40: "Countries and organisations should exploit various initiatives for electronic links to support information sharing, to provide access to databases and other information sources, to facilitate communication for meeting broader objectives, such as the implementation of Agenda 21.The Intergovernmental Panel on Forests in 1997 "emphasised the need to review and improve information systems. Attention should be given to world-wide access to information systems that would encourage effective implementation of national forest programmes, increased private-sector investment efficient development and transfer of appropriate technologies, and improved co-operation".

The aim of the Task Force on Global Forest Information Service is to develop a strategy for, and to implement an Internet-based meta-data service that will allow co-ordinated world-wide access to forest information. The resulting service will provide multiple benefits to information users and providers including: faster access to key information sources; and improved dissemination and quality of forest-related data and information.

The service will provide access to both digital and non-digital information on forest resources, forest policy, criteria and indicators for sustainable forest management, research activities, and other timely and relevant issues.

Technical & Design Options for Implementation

Tim Richards, Reynolds, J.

Space Applications Institute, Joint Research Centre; TP 641, Via E Fermi,1, I-21020 Ispra, Italy
Tel: +39-0332-789102, FAX: +39-0332-789960, Email: tim.richards@jrc.it

The mission of the Task Force on Global Forest Information Service (GFIS) is to develop a strategy for, and to implement, an Internet-based catalogue service that will provide access to forest information world-wide. The resulting service will provide multiple benefits to information users and providers including faster access to information resources; and improved dissemination and quality of forest-related data and information. The service will provide access to both digital and non-digital information on forest resources, forest policy, criteria and indicators for sustainable forest management, research activities, and other timely and relevant topics.

This paper describes the technical options for implementation of GFIS. By definition, GFIS facilitates information dissemination between forest information providers and the user community using the Internet. Users should be able to find the information they require in a simple and logically consistent manner, and in such a way that ownership and attribution of the information is respected.

GFIS has predecessors in other disciplines than forestry, and there are many lessons to learn. Different design options are reviewed and one is proposed based on the model of a regional network of 'information servers' which, taken together, form a single distributed catalogue (known as a metadatabase). With such an arrangement, users may search for 'metainformation' held in diverse and disparate databases. Having located the information required, they can then access the information through appropriate hyperlinks. The information server concept enables peers to interact in a virtual community.

The language used by information specialists differs from that used in other disciplines, including forestry. This paper attempts to describe the implementation of GFIS in language that both communities can understand.

Mobilising and Disseminating Information on Forests to Promote Sustainable Management in Africa

Robert Szaro, Cobbinah, Joseph; Martin, P. Michael; David Langor
International Union of Forestry Research Organizations, Seckendorff-Gudent-Weg 8, A-1131 Vienna, Austria
Email: Szaro@forvie.ac.at

Keywords: Global Forest Information Service, Africa, Networking, Capacity building

Much of the groundwork for building capacity in African countries that are signatories to the Lomé Convention (ACP countries) has already been completed: contact has been made with the relevant international forest information providers, a prototype of the Global Forest Information Service (GFIS) has been launched on the Web, a Users' Needs Analysis has been carried out, and enthusiastic agreement in principle to the concept of the GFIS has been received from FAO, JRC, EFI, OFI, IUFRO, CIFOR and WFI. This Service will answer needs highlighted by the Convention on Biological Diversity, the Intergovernmental Panel on Forests, the Convention on Climate Change and the Forest Principles. Without access to good information on forests, policy-makers, forest managers, economic planners and researchers from many disciplines do not have a solid basis on which to operate. This is particularly important in tropical forest countries, where forest change is happening most rapidly. GFIS will serve the needs of a great variety of people, and ultimately lead to a better understanding of the world's forests and management impacts, both positive and negative.

With the approval of the 3 year project by the European Commission DG VIII "Mobilizing scientific information on forests to promote their sustainable management in ACP countries" the establishment of five nodes within Africa began. These nodes will facilitate access to and dissemination of scientific and technical information on forests and their utilization. The location of these nodes are Western Africa (Ghana and Senegal), Eastern Africa (Kenya), Southern Africa (Zimbabwe), and Island Africa (Madagascar).

GFIS and its regional nodes will be a valuable information resource for decision-makers in tropical forest countries, and others. in particular it will provide forest information and generating integrated information products. The use of the World Wide Web is rapidly increasing in the developing countries, and GFIS will give agencies in those countries an opportunity to use information that has up to now only been accessible through inter-library loans or after long searches through foreign institutional facilities.

Two project staff members will be located at FAO in Rome and will have responsibility for developing the interfaces for GFIS-AFRICA and for helping to set up equipment. Each node will be provided equipment, training, salary for an information specialist and operational costs for each of the five nodes. As the project is implemented many new partners will be included to help develop the network.

The objectives are: (1) to improve access to reliable scientifically based information on forests in ACP countries and their utilization, (2) to build capacity in selected regional research institutions to develop and manage internet-based systems to facilitate broad access to research information on forests in the ACP countries, (3) to share experience and good practice in information management between ACP countries, and (4) to enhance integration and comparability between national data on forests throughout the ACP countries.

How social values have affected forest policy

Jo Ellen Force, Greg Fizzell
University of Idaho, Forest Resources, ID 83844
Moscow, USA
Tel: 885-7311, Email: joellen@uidaho.edu

Social values are difficult to define and measure. Social scientists define social values as desired end-states that go beyond self to address the concerns of the larger society; they are not necessarily values held by the majority of society. Two primary indicators of social values are public opinion and people's behavior. The American people associate a wide range of social values with our forests. Forest policies attempt to respond to and reflect a range of social values. The challenge facing foresters is the disconnect between public opinion which supports increased environmental protection and reduced forest commodity production (i.e., "what I say") and people's behavior which demands an increased amount of forest products and services (i.e., "what I do"). We suggest that public judgment, which goes beyond public opinion and addresses taking responsibility for the consequences of one's behavior, merits consideration. Foresters have an important role to play in facilitating public judgments about our forest resources.

Keywords: Social values, public opinion, behavior, public judgment, forest policy

Qualitative Comparative Analysis: Opening New Paths for Social Science Research in Forestry

Eeva Hellström, Kati Rantala
Finnish Forest Association, Salomonkatu 17 B, FIN-00100 Helsinki, Finland
Tel: +358-9-685 088 12, FAX: +358-9-68508820, Email: eeva.hellstrom@smy.fi

The internationalisation of the forestry dialogue and subsequent internationalisation of forest policy brings about new challenges for social science research in forestry. One evident need is to increase our understanding of similarities and differences between cases through comparative studies at both regional and global scale.

On the one hand, comprehensive social or policy research in forestry typically addresses a large number of economic, resource, social, policy and cultural aspects, not all of which are quantifiable so that they could be analysed with quantitative methodology. On the other hand, despite significant advances in qualitative analysis software, most qualitative methods are rarely used to do more than "pattern" analysis, that is discovering structural patterns (*e.g.* groupings) in the data. Accordingly, many policy researchers face the problem of having to compare extensive data, consisting of both qualitative and quantitative elements, in a large numbers of cases in a systematic way.

Qualitative Comparative Analysis (QCA) is a comparative tool which has been developed by Charles Ragin to bridge some of the gap between qualitative and quantitative analysis. The method uses Boolean algebra for a systematic analysis of similarities and differences across cases. It is gaining popularity in sociology and political science, and it is also taking its first steps in comparative forest policy research. Therefore, it is reasonable to ask what this new tool is like. Which type of applications have most potential for social science research in forestry, and why?

QCA is mostly associated with causal terminology and applications, which makes it unattractive to many qualitative researchers. in our view, the greatest problems related to QCA are not based on the technique of the method but on the limited ways in which it has been applied. Although not commonly recognised, the method has no in-built premises validating only causal applications.

This paper aims to provide an understanding of QCA that would encourage experimentation with the method in social science in forestry, regarding different kinds of research, data and questions asked. This is done by presenting an example of two different types of non-causal approaches to QCA in research that compares environmental forestry conflicts during 1984-95 in seven cases (Finland, Sweden, Norway, France, Germany, Minnesota and the Pacific Northwest region of the USA). The data for the research consists of a total of 210 focused interviews conducted within these countries.

At first, the data is analysed with the "empirical typology" approach to QCA. in this approach, the value, policy, market and resource aspects of environmental forestry conflicts are analysed separately, with the aim to organise and condense the data in a systematic way. The empirical typology approach is already known in literature but it has been used in very few applications with real data. Secondly, the "hermeneutic" approach to QCA is used to explore the interface and to discover interactions between value, policy, market and resource aspects of environmental conflicts. This application to QCA has been developed within research conducted by the authors of this paper.

These non-causal applications increase flexibility in the use of QCA and, thus, greatly extend the applicability of the method in comparative social research in forestry. It will also be demonstrated that when applying QCA, different types of applications may be combined in order to produce an understanding of the whole.

Changer de mode de régulation de l'utilisation des ressources forestiere Madagascar

Bruno Ramamonjisoa
Ecologie Politique et Biodiversite, C/o ESSA Forêts BP 3044, 101 Antananarivo, Madagascar
FAX: 261 20 22 611 84, Email: epbfor@dts.mg

Madagascar s'est doté d'une nouvelle politique forestière depuis 1995 avec l'appui méthodologique des universitaires. Cette politique pour sa mise en œuvre préconise plusieurs types de moyens stratégiques dont celui de la gestion participative, le désengagement de l'Etat de la gestion opérationnelle et la réforme de l'administration forestière. Malgré que l'Etat et les bailleurs de fonds se sont engagés pour sa mise en œuvre, cette politique présente des difficultés d'ordre méthodologiques. En effet, la société malgache vit avec un ancrage culturel profond qui fait que les méthodologies découvertes ailleurs rencontrent des problèmes d'adaptation pour leur utilisation dans des projets forestiers Malgaches. Ainsi, la gestion participative qui constitue le moyen stratégique par excellence pour l'intégration des acteurs dans la préservation et l'exploitation de la ressource risque d'aboutir, dans le cas d'échec, à un résultat totalement contraire. C'est dans cette perspective que la recherche sur la formulation de méthodologie ayant rapport à l'élaboration de norme a été conduit depuis 1997 au niveau de la Division d'Enseignement et de Recherche en Economie et Politique forestières du Département Forêts de l'ESSA. Cette étude a pour but de mettre à disposition des forestiers de terrain une méthodologie pour la mise en œuvre d'une gestion participative d'une ressource forestière.

La recherche est conduite sur plusieurs sites malgache correspondant à une typologie écologique mais aussi culturelle notamment Mandraka et Ranomafana (forêt dense humide et une population d'agriculteur à niveau d'éducation élevé) sur la falaise orientale Malgache, Morondava (forêt dense sèche décidue et une population d'agriculteur-éleveur) sur la Côte Ouest et Tampolo (forêt dense humide littorale et population d'agriculteur itinérant).

L'approche utilisée a été celle systémique qui englobe à la fois l'analyse des pratiques forestière (produits ligneux et non ligneux, défrichement) et des systèmes de gestion de la ressource mais aussi l'analyse du système de production, celle du système de gestion publique et de la dynamique régionale ainsi que l'analyse du système de taxation forestière.

Au niveau des pratiques forestières les acteurs qui jouent les rôles les plus importants sont pour la plupart des citadins pour ce qui concerne les filières de produits ligneux. Ce sont ces dernières qui représentent la plus importante chiffre d'affaire en valeur monétaire. Pour les produits non ligneux les communautés riveraines des ressources maîtrisent la décision de coupe mais les filières ne représentent qu'un chiffre d'affaire monétaire minime. Au niveau de ces pratiques, et quels que soient les sites d'études, plus le chiffre d'affaire est important et plus le rôle des spéculateurs urbains devient prépondérant. Mais le système de gestion de la ressource bute aussi sur des problèmes de gestion technique proprement dit tant au niveau de l'exploitation (forte perte) qu'au niveau de la reconstitution de la ressource (manque de données).

Au niveau du système de gestion public les communautés sont assez différentes mais présentent des ressemblances notamment sur l'existence de deux types de pouvoir: celui légal qui est constamment contourné et celui coutumier qui est plus ou moins respectée. Les premières conclusions ont mis en évidence la nécessité de faire transiter par les droits coutumiers les règles de gestion.

Mais la durabilité de la gestion participative réside aussi dans la possibilité de répartir équitablement entre les acteurs la ressource monétaire mobilisable à partir des taxes forestières. En effet, les enjeux monétaires sont telles que les activités sources de revenus sont rapidement contrôlées par les acteurs dominants que sont les spéculateurs urbains. Le système actuel de taxation transitant par des circuits administratifs trop classiques ne peut que développer la pratique de la corruption et nécessite un besoin de réarrangement institutionnel qui devrait suivre le processus de la décentralisation du pouvoir à Madagascar.

Mots clés: Politique forestière, gestion communautaire, fiscalité forestière, dynamique régionale

Forestry in Transition

Tamas Szedlak
Ministry of Agriculture, Bureau of Forestry (Erdészeti Hivatal), Pf. 1, 1860 Budapest 55, Hungary
Tel: 36-1-301-4000, FAX: 36-1-301-46-78, Email: szedlak@netscape.net

Keywords: political changes, countries in transition, sustainable forestry, public awareness, climate change.

There are many changes and challenges for the mankind at the end of the 20th century. The world changed dramatically during the last hundred years while the population reached the 6 milliard peoples. There are substantial changes in natural, political and social environments and these components have a certain reaction one another. The political changes promote the natural awareness in the former socialist countries. These countries are the "countries in transition", because the centrally planned system is replaced by market economy conditions. Since 1990 also the Forestry is adapting to the market economy. Co-operative forests have been given back to their former private owners, and one part of the state forest have been privatised together with some technical services and wood processing plants. These changes are coinciding with the reorientation of the international environmental and forest policy. in accord with the increasing public awareness in environmental issues, the non-wood forest functions got higher priority, and the sustainable forest management are interpreted in a much wider context, where the conservation of biological diversity and sustainable development of the natural and human environment are equally important criteria. While the other part of the world the area of the forests decreases, in Europe increases. The multifunctional forestry appears important in this densely populated continent. The climatic and economic changes in the last decade arose the importance of forests, forest science and forest policy. The transition includes a large scale changes in ownership in course of privatisation in the eastern part of Europe. Some of these countries have a large agricultural potential, while they want to join into the European Union which has a great problem with his own agricultural policy. The changes in environment and society were the main elements which made the legislation to create new acts for forestry and environment protection in these transition countries. How can the forests serve the needs of the environment protection, rural development under the changing climate, economy and society? There will be the main questions for the forestry, forest policy and forest science in the beginning of the next century.

Foreign Direct Investments of Forest Industries in a Global Economy

Jussi Uusivuori and Susanna Laaksonen-Craig
Finnish Forest Research Institute, Unioninkatu 40 A, FIN 00170 Helsinki, Finland
Tel: +358-9-857051, FAX: +358 9 8570 5717, Email: jussi.uusivuori@metla.fi

Even if forest industries have not been the forerunners in the globalization process, foreign direct investment (FDI) by forest companies has increased rapidly in the 1990s. A central question then is to what extent FDI and traditional trade in the forest sector are substitutes or complements to each other, for example, does FDI lead to increased or decreased exports from the home country in the long-run. This paper explores the dynamic relationship between foreign direct investment (FDI) and exports of forest industries with U.S., Finnish and Swedish data. Both short-term and long-term interrelationship between FDI and exports is studied, as well as the short-term and long-term effects of exchange rate movements and exchange rate variation.

The results show that for the U.S. forest industries, FDI generates more exports of forest products in the long-run. in the case of the Finnish and Swedish forest industries, it is the exports that seem to drive the investments abroad. The effects of exchange rate risk and movements on FDI were estimated to be low in the case of the U.S. and Finnish forest industries, and only moderate in the case of Swedish forest industries. The results suggest that initiatives toward freer trade may also spur increased FDI by forest industries.

Keywords: Globalization, trade, corporate strategies

INDEX

INTRODUCTION

This volume of Congress proceedings includes summaries of posters received by 31 May 2000. Minor changes may have occurred since that date. These proceedings are divided into three parts or sections:

Part 1 : Posters in the main poster hall

Part 2 : Posters presented in poster/panel and group sessions.

Part 3 : Posters displayed during sub-plenary sessions

Part 4 : Posters displayed in task forces

Special thanks to the authors for their contributions to the scientific programme of this Congress. Enjoy your stay in Malaysia.

Eric Teissier du Cros, chairman of the CSC

Note: The summaries have been published as received from the authors and reviewers, respectively, who have sole responsibility for their content.

Análisis de la composición florística y estructura para la vegetación del piso basal de la Zona Protectora La Cangreja, Mastatal de Puriscal

Vargas Luis Acosta, Monge Ruperto Quesada
Instituto Tecnológico de Costa Rica, Escuela de Ingeniería Forestal, Apdo 159, 7050 Cartago, Costa Rica
FAX: (00 506) 591 41 82, Email: plinia@sol.racsa.co.cr

El presente estudio consta de dos partes. Una primera orientada hacia el estudio de la composición florística y diversidad del bosque en el sector de la Zona Protectora La Cangreja y una segunda parte enfocada a estudiar la estructura del mismo y a la vez dejar establecido una red de parecelas permanentes de muestreo.

El área de estudio se ubica en las zonas de vida según la clasificación de Holdridge de bosque húmedo tropical y bosque muy húmedo tropical transición a premontano.

En el sitio se establecieron siete parcelas con un área total de 16 100 m^2, a través de éstas se logró determinar, que para el sitio estudiado el área basal es de 38,5 m^2/ha, la presencia de 591 áboles/ha en 148 especies/ha, un dosel que alcanza los 43,6 m de alto, para dar paso a un piso superior >29m de alto, un piso medio entre 14,5m y 29m, y el piso inferior con un altura < 14,5m.

El área mínima de muestreo obtenida es de 1 ha.

Por medio de los criterios de clases de frecuencia y el índice de Simpson (0,03) se determinó que el sitio es diverso, no así por los índices de Shannon (0,44) y riqueza (0,19) quienes lo catalogan como diversidad media. Esto es producto de las intervenciones del pasado, que han provocado la concentración del 86% del IVI en 10 especies en su mayoría heliófitas.

Con el inventario de flora se deteminaron 193 especies arbóreas distribuidas en 126 géneros y 56 familias, donde las familias más importantes por número de especies presentes son *Euphorbiaceae, Meliaceae, Lauraceae, Moraceae y Mimosaceae* con 8,11,13,16 y 17 especies respectivas.

El endemismo en el sitio es de un 7,25% a nivel arbóreo.

High Density Short Rotation System: A Potential Woodlot Technique for the Production of Fuelwood and Poles in Areas of Diminishing Forest Land Base

Charles Adu-Anning, Dominic Blay Jr.
Forestry Research Institute of Ghana (FORIG), University Post Office Box 63, Kumasi, Ghana
FAX: 233-51-60121, Email: forig@africaonline.com.gh

High density short rotation woodlot technique has been used in many tropical countries to produce fuelwood and pulpwood. However, in the West Africa sub-regions, especially Ghana, adequate studies have not been conducted on the production of fuelwood and pulpwood with this technique. Therefore trials were established in the Sudan and Derived savannah areas of Ghana to determine the effect of planting density on the growth and dry matter production litterfall and decomposition, nutrient sequestration and nutrient use efficiency and soil chemical properties of *Gmelina arborea* harvested on very short rotations. The spacing treatments allotted were 0.6m^2, 1.2m^2, 1.8m^2 and 2.4m^2 per tree of growing space. Harvesting was done at 20, 3- and 4-years after planting. Weeds were adequately suppressed by manual weeding. At two, three and four years, the 0.6m^2 treatment gave significantly ($P<0.001$) dry matter production for all component fractions (leaves, bark, wood and branches) and also total dry matter for *Gmelina arborea*. With respect to nutrient concentration the differences within the cutting cycles in the different spacing were significantly different for all the species ($P<0.05$). The concentrations in the tree component were in the order leaf > stembark > branches stemwood. The sequestration (kg/ha) in these components were also significant ($P<0.05$) and in the order stemwood > branches > stembark > leaf. Monthly leaf litterfall (g m^{-2} month-1) for *Gmelin*a in the four spacing were 0.6m^2> 1.2m^2> 1.8m^2> 2.4m^2. Decomposition rate for *Gmelina* litterfall was faster than Teak. The rates in the various spacing were 0.6m^2>1.8m^2>1.2m^2>2.4m^2 and differences were significant ($P=0.001$). Tree stocking and cutting cycle effects on soil chemical properties also indicate that pH levels declined with increasing cuttings years. Available phosphorus levels increased with increasing tree stocking. Magnesium also declined at the higher tree stocking density. It is concluded after preliminary analysis of spacing/cutting cycle interactions that the 0.6m^2 treatment yielded the greatest dry matter in all species during the two, three and four yearly cutting cycles. Also in terms of perha the 0.6m^2 treatment was the best in terms of dry matter production. With regard to the impact of tree stocking on litterfall, decomposition, nutrient sequestration and soil chemical properties, the results were positively correlated and the $0.6m^2$ spacing at four-yearly cutting cycle was the best.

Keywords: *Gmelina arborea* high density, short rotation, woodlot, fuelwoods.

Effects of Fertilizer and Previous Land Use on the Pools of Carbon, Nitrogen, and Phosphorus in Soils *from Eucalyptus globulus* Labill. Plantations in Southwestern Australia

R. T. Aggangan, A. M. O'Connell, B. Dell
Forestry and Environment Research Division, PCARRD, Los Banos, Laguna, Philippines
Tel: 63 49 536 0014 to 536 0020, FAX: 63 49 536 0016 or 536 0132, Email: ra@ultra.pcarrd.dost.gov.ph

The pools of carbon (C), nitrogen (N) and phosphorus (P) were measured in soils under *Eucalyptus globulus* plantations established on ex-pasture and ex-native forest sites. The *E. globulus* plantations were fertilized with N, P or N-and-P. The parameters measured in the plantation soils were compared with values obtained from adjacent pasture and native forest soils. Application of both N and P fertilizer significantly increased the pools of C, N, P, and C:N ratio in soil under the *E. globulus* plantation established on an ex-native forest site. The pools of N and P were also enhanced by N-and-P fertilization in soil from the ex-pasture plantation site, but fertilization had no effect on the amount of organic C or the C:N ratio. The results suggest that changes in the pools of C, N, and P were associated with previous land use. The native forest soil had higher levels of organic C, N and P than the ex-native forest plantation soil. However, both the native forest and ex-native forest plantation soils had high C:N ratios, reflecting the quality of the organic residue inputs entering these soils. The pasture soil had higher total organic C, total N and P concentrations than the ex-pasture plantation soil, but these two soils had similar C:N ratios. The results of this study suggest that fertilizer prescription for improving the growth of *E. globulus* plantations must consider past land use and fertilizer history.

Key words: Australia, Eucalyptus, plantations, sites, fertilizer.

Agroforestry Systems in Nepal: Lessons Learned and Challenges Ahead

Swoyambhu Ma Amatya
Ministry of Forests ad Soil Conservation, Department of Forest Research and Survey,
Babar Maha, Kathmandu, Nepal

Nepal is a relatively small country, of about 14.7 million ha, between India and China. Based on altitude, it has been divided into five physiographic zones: High Himal; High Mountains; Middle Mountains; Siwaliks; and Terai. Most people (>19 million) depend on agriculture and related business for their livelihood.

The aim of developing agroforestry within Nepal is to meet the present and future requirement of fuelwood, fodder, small timber and to protect environmental degradation. The topic of "Agroforestry" has recently received considerable attention. This is largely due to the evidence that trees and agricultural crops could be managed simultaneously and guarantee the sustainability of agricultural system. The agroforestry systems practised by the Nepalese farmers vary according to the physiographic zones. And within a given physiographic zone, it varies with location.

Past studies carried out on the existing agroforestry system in Nepal point towards the need for a closer study of indigenous agroforestry practices. Based on these studies, future agroforestry models should be developed taking institutional capability, research needs, and training and extension opportunities into consideration. Considering the current weakness in research, extension, and training in the area of agriculture, livestock, forestry, and natural resource management, the challenge of promoting agroforestry is formidable.

In the Nepalese context agroforestry systems have their own limitations. Some are institutional and others are socio-economic. In general, farm size holdings are too small to produce large marketable quantities of timber and other non-timber products. In addition, poor infrastructure restricts flourishing markets particularly in the hills. Perhaps one of the major limitations to agroforestry development in Nepal is the sheer complexity of both the ethnic and agro-ecological conditions. This limitation as far as practicable, should be overcome. This paper examines the lessons learned and the challenges ahead in developing agroforestry systems in Nepal.

Irrigation Requirement for Establishing Forest Plantation in the Semi- arid Zone of Israel

Nir Atzmon
The Volcani Center, Dept. Natural Resources, Post Box # 6, 50250 Bet-Dagan, Israel
Email: atzmon@agri.huji.ac.il

The need for afforestation, especially in semi-arid regions, is increasing rapidly world-wide due to the denudation of the land and the lack of wood and timber for fodder, fuel and construction. The success of those afforestation activities is directly related to the ability of forest seedling to establish under those unfavourable conditions. It is well accepted that the first dry season after planting is the most critical.

The aim of the present study was to test the possibility of ensure forest seedling survival and establishment by adding the minimum irrigation possible, during the first year after planting, for maximum survival. The experiments are done in the Northern Negev, latitude 31°25'N .

This area is characterized by rolling hills, 250-400 m above sea level. The soils are typical loess soils with low water infiltration capacity. The mean annual rainfall of the area is 250mm. The winters are relatively mild and the summers are hot and dry. Site preparation included contour mounding for water harvesting, and weed control by spraying simazine and outs. One year old seedling of *Eucalyptus turcuata*, *Prosopis* sp and *Acacia* sp. Were planted in within the furrow with distance of 6 m between seedlings. Watering was done manually I-4 times during the dry season. The study includes soil water content analysis using depth moisture gauge, plant grow measurements, and roots exposure. The most prominent result at the end of the first growing, season was that no significant differences in survival was found between seedlings that were watered only once (end of April) and seedlings that were watered 4 times. It seems the irrigation done at the dry season allow the roots to continue their penetration into the ground to more wet layers and thereby to ensure their survival. Different species showed different root morphology and different root growth rates.

Growth of *Eucalyptus grandis* in Response to Nutrients in the Western Ghats, Kerala, India

M. Balagopalan, P. Rugmini
Kerala Forest Research Institute, Peechi-680 653 Kerala, India
Email: libkfri@ md 2.vsnl.net.in

Sixteen fertiliser combinations of N, P and K and nine silvicultural treatments comprising three each of pit sizes, spacing and skinning in factorial combination were applied to *Eucalyptus grandis* planted at Vallakkadavu in the Western Ghats, Kerala, India. Treatments were aimed to ensure that growth was not limited by lack of nutrients in plots of different silvicultural treatments during the first three years after planting. The fertilisers, Urea, Mussorie rock phosphate and Muriate of potash were applied for N, P and K respectively, at the time of planting in June 1992 in the planting pit and in furrows in October 92, June 93 and October 93, the latter two with double the dose of those applied in the first year. The furrows were 5-10cm deep, 15-25 cm away around the plant and then filled with soil. Fertiliser treatments had significantly and substantially increased growth in mean height during the study period, 36 months and basal area at 36th month after planting. There was no interaction between fertiliser combinations and silvicultural treatments.

The trees in the plots receiving the best nutrient combination, N2 P2 K1 i.e., 30g of N, 30g of P and 15g of K/plant, which is equivalent to 163kg of Urea, 375kg of Mussorie rock phosphate and 73kg of Muriate of potash/ha, were 1.2 times taller and had 1.5 times more basal area than those in unfertilised plots.

More detailed growth estimates showed fertiliser inputs had substantially increased the volume of trees. After 3 years, the best fertiliser treatment had increased the volume from 8.37 m^3 to 12.42 m^3/ha. Tree growth in unfertilised plots in this study was severely inhibited by low soil nutrient supply.

Seed Production and Seed Quality in Dry Dipterocarp and Mixed Deciduous Forest in Huai Kha Khaeng (Thailand)

L. Bernasconi, Calamini, G., Firusbakt, L., Salbitano F.
Institute of Silviculture, Via S. Bonaventura, 13, I-50145 Firenze, Italy
Tel: +39.055.30231246, FAX: +39.055.307263, Email: salbitano@cesit1.unifi.it

The present study was carried out in the frame of a research project funded by the European Union on "Ecology and sustainable semi-natural sylvicultural management of indigenous forest of Central South East Asia". The research deals with the understanding of early regeneration processes by focusing on seed ecology. General aim of the research is to contribute to the knowledge improvement on the regeneration ecology of the dominant species in natural dry forests in SEA to serve to outline semi-natural sylvicultural programs. Specific objectives are: to study the spatio-temporal features of seed production and dispersal; to observe the damage types on the seeds and relative frequencies during different phases of seed rain; to standardise a quantitative and qualitative classification of seeds in order to highlight morphological parameters, seedlot viability frequency, germination ability, damage type and severity (damage effects on seed viability and on germination success are also considered); to observe the early stages of germination per seed class.

The study was carried out in the Thung Yai- Huai Kha Khaeng Wildlife Sanctuary (central-western Thailand), the largest protected area in South East Asia. The survey area is located at an altitude ranging between 200 and 300 a.s.l. The climate is characterized by three seasons: hot and dry during the February-April period, hot and damp from May to October, cool and dry from November to January. The average yearly rainfall is 1448mm and it's variation ranges from 1105mm to 2003mm (extreme values recorded in 16 years at Khao Nang Rung weather station).

Average yearly temperature is 25.5°C (1980-1997). The monthly average of maximum temperatures varies between 30°C and 36°C, the monthly average of minimum temperatures instead varies between 12°C and 25°C. Seeds were collected a. on ground, b. directly from the tree crowns, c. by using seed traps, in order to evaluate the seed production both per individual trees and per canopy unit. The collection of seeds was taken out every 5 days for the recalcitrant seeds of *Shorea* and every 10 days for the other species. Seed dispersal was observed by seed traps and plots on ground, placed at increasing distances from the stem of isolated trees along the four cardinal directions.

Seed quality was evaluated by external observation. Four seed quality classes were detected, i.e. Healthy seed (Absence of visible damage); Insect damage (Entrance holes, presence of larvae inside the seed); Rodent damage (Evidence of rodent bites on seed); Fungi damage (Necrosis and withering of seed portions).

Seeds were examined one by one, attributed to one of the four classes and then counted. Seeds were classified on the basis of weight (all species), diameter and length of the main wing (only *Dipterocarpaceae*). Afterwards, such class-grouping system was used to extract samples by which proceed on with germination and viability tests. The species with recalcitrant seeds (*Shorea obtusa-Shorea siamensis*) disseminate at the beginning of rainy season, otherwise the other species observed (*Pterocarpus macrocarpus, Legerstroemia calyculata, Hymenodictyon excelsum, Vitex limonifolia*) do it during dry season. The rate of healthy and damaged seeds vary significantly during the period of seed production and remarkable differences can be observed between seeds collected directly from the tree crowns and on ground. The insect larvae are the main responsible of the damages found on the seeds. The germination is in general high for all species and even damaged seeds showed appreciable germination rate.

The Potential of Some Indigenous Dipterocarp Tree Species for large-scale Industrial Tree Plantations in Malaysia

Bin Mohamad Borhan
Forest Research Institute Malaysia (FRIM), Regional Center for Forest Management, Kepong, 52109 Kuala Lumpur, Malaysia

Keywords: Wood-based industry, dipterocarps, silviculture, stumpage value.

The wood-based industry in Peninsular Malaysia is facing a very challenging future arising from an acute shortage in the supply of quality timber raw material. The sharp decline in local log production from natural mixed dipterocarp forest during the past decade was due mainly to the tapering off in the opening of new forest areas for agriculture, stricter adherence to annual logging coups and curbs on illegal logging. Amongst the strategies adopted by the authorities concerned to stem any further deterioration of the industry include upgrading the management and quality of the remaining natural forests and the establishment of large-scale industrial plantation of "fast growing" tree species. Unfortunately, the currently on-going

Compensatory Forest Plantation project (CFPP) using fast growing exotic tree species is through to be inadequate and has yet to live up to its early promises. In view of this, there is an increasing trend now to look seriously into the potential of some prime and fast growing natural indigenous timber tree species (especially the Dipterocarps) which may provide the real answer to the raw material supply problem for our wood-based industry in the future. Already many misconceptions surrounding these indigenous tree species have been successfully dispelled through consistent R&D efforts conducted both in Malaysia and elsewhere and confidence in these species is increasing. The paper is based on a study of 15 selected dipterocarp tree species which are known to show great potential as candidates for large-scale industrial tree plantation. Amongst the factors considered in the analysis include their silviculture, nursery practices, growth rates as well as economics.

Nitrogen and Phosphorus Fertilization Effects on Forest Growth and Nutrient Cycling in Two Secondary Tropical Dry Forests in Mexico

Julio Campo, Ceccon, Eliane; Vazquez-Yanes, Carlos
Instituto de Ecología, Depto. de Ecología Funcional y Aplicada, A. P. 70-275, UNAM 04510 Ciudad Universitaria, Mexico
FAX: (525) 56 16 1976, Email: jcampo@miranda.Ecología.unam.mx

Tropical dry forests in the Yucatan Peninsula have been transformed at high rates into henequen plantations. The Mayan cultivated the henequen (sisal) *Agave fourcroydes*, a native agave, since the pre-Colombian period. Henequen was considered "green gold" and, by the 60s, 50% of the regional labour force was employed in its cultivation. In the 70s when synthetic fiber was introduced, henequen production was greatly reduced until its final collapse in 1992. Nowadays there is a mosaic landscape characterized by a coexistence of some henequen plantations and extensive areas of secondary tropical dry forests. The long-term henequen cultivation has reduced the nutrient pools in soils to levels that probably inhibit the natural forest succession.

The importance of the effects of low levels of nutrients on plant growth in tropical forest succession has been discussed more often than it has been exactly determined. In order to study the influence of nutrient limitation during the secondary succession in Yucatan dry forest, two forest sites of about 10 and 40-years old respectively, were fertilized with N, P, and nitrogen plus phosphorus. There were sixteen 12 x 12m plots per site, four plots per treatment and control. The secondary forests are located in the surroundings of Conkal village. In each of these forests, we measured tree trunk growth, litterfall production, nutrient fluxes from the aboveground vegetation and nutrient turnover in forest soil before and after fertilization.

Litterfall production showed a strong seasonal pattern. This production was similar in both sites without fertilization. However, forest soil carbon turnover was lower in 10-years site than in 40-years site. Litterfall production and nutrient turnover in forest soil were found to change after fertilization. Our preliminary results, after the first year of fertilization, strongly suggest that secondary forest production be limited by the availability of phosphorus.

Effect of a Gap-understory Gradient on Early Development of Scots Pine and Norway Spruce Seedlings

Michelle deChantal, Kari Leinonen and Timo Kuuluvainen
University of Helsinki, Department of Forest Ecology, P.O. Box 24, FIN-00014 Helsinki, Finland
Tel: +358-9-191 7696, FAX: +358-9-191 7605, Email: Michelle.deChantal@helsinki.fi

Small-scale gap disturbance is an integral part of the natural dynamics of boreal forests. As such, it has been suggested that sustainable forest management should aim at reproducing the structural heterogeneity created by natural disturbances. Accordingly, and due to increased public concern about ecosystem diversity and sustainable forestry practices, foresters are turning to small-scale alternative silvicultural methods to manage forests. As a result, more regeneration area is in a gap-understory environment. Small-scale silviculture contributes to increase the amount of forest edges, which in turn affects the microenvironment for regeneration, especially light. Light influence seedling development and gives rise to different competition situations and survival strategies. Both size and morphology play an important role in determining succession dynamics after a disturbance, conferring a competitive advantage at the regeneration stage and promoting production.

We studied the early development of *Pinus sylvestris* L. and *Picea abies* (L.) Karst. seedlings growing along a gap-understory gradient in a boreal Norway spruce forest. The effects of radiation, seed pre-treatment by moist chilling and seedbed microsite soil preparation (inverted pyramids) on aboveground size and morphology of seedlings were described for the first two growing seasons. Shade intolerant *P. sylvestris* responded more to increased radiation than shade tolerant *P. abies*. Two-year-old *P. sylvestris* underwent a 7-fold increase in aboveground dry biomass from the understory to the centre of the gap, whereas *P. abies* experienced a 2.5-fold increase. Moist chilling and microsite preparation resulted in additional increases in aboveground dry biomass for both species. With increasing radiation, one- and two-year-old *P. sylvestris* allocated photosynthetic carbon such that they built up 46% and 56% more aboveground dry biomass in needles compared to stem, respectively. The biomass distribution for one-year-old *P. abies* changed from shade to sun, such that the proportion of biomass found in needles increased by 26%. For two-year-old seedlings, the pattern of biomass distribution was almost constant. With increasing radiation, the total leaf area of one- and two-year-old *P. sylvestris* underwent 8- and 13-fold increases, while *P. abies* showed 3- and 5-fold increases, respectively. The specific leaf area of one- and two-year-old *P. sylvestris* decreased by 15% and 30%, and mean needle length increased 1.9- and 3-fold with increasing radiation, respectively. On the contrary, radiation did not affect the specific leaf area and mean needle length of *P. abies*.

Although early development is important for later success, the results from this study cannot predict that *P. sylvestris* will outcompete *P. abies* in similar gap environments. This is because the subsequent development of seedlings is also affected by other factors, such as competition by ground vegetation and herbivory. This effect, as well as early seedling growth, is likely to be strongly dependent on within-gap position, since competition with mature trees retards the growth of ground vegetation in gap edges. It is possible that these contrasting factors affecting seedling growth and survival can lead to some type of within-gap partitioning between species. To verify this hypothesis would require tests of longer duration.

Aspen Forest Stands of the North-west of Russia are a Potential Base for Forest Stock Improvement

N. N. Dekatov, Pirogov N.A
Saint-Petersburg Research Institute, Institutsky pr., 21, 194021 Saint-Petersburg, Russia
FAX: (812) 552-80-42, Email: spb330@spb.sitek.net

In the 1930s and 1940s significant territories of coniferous forest stands in the north-western region of Russia with high site quality of locality underwent intensive clear cuttings. Today considerable areas of these territories are covered by aspen stands. This is due to the fact that no silvicultural activities favoring reforestation and growth of the coniferous species in the cutover areas were carried out. Because of its defects aspen (*Populus tremula* L.) timber has a limited market which leads to accumulation of mature and overmature forest stands. Aspen stands comprise some 20% of the area where harvestable forests grow, and occupy the most productive soils, which could have otherwise given plenty of sound wood if only conifers grew there. As aspen stands grow on the most productive soils, forestry incurs losses as a result of low output of merchantable wood from these areas. Considerable areas of aspen stands have an undergrowth under its canopy that includes coniferous species. If properly managed, these stands could be converted to higher value spruce and mixed-species stands. Today, it is therefore very important to develop systems for utilization and management of these stands for their transformation. We have conducted field research, which have shown that aspen stands vary distinctly and so should be treated differently. The type of forestry management in the aspen stands area is determined on the basis of the following criteria:

- age and condition of the young spruce growth, i.e., its growth potential after the cutting of the aspen canopy;
- its stand density and distribution within the site, which both determine the cutting technology to be selected;
- the amount of the broad-leaved canopy which can be removed safely without causing dramatic ecological changes within the site.

Ecology and Reproductive Biology of Pondberry (*Lindera Melissifolia* [Walt] Blume)

Margaret Devall, Nathan Schiff
USDA Forest Service, Center for Bottomland Hardwood Research, P.O. Box 227, MS 38776 Stoneville, USA
Tel: 601/686-3161, FAX: 601/686-3195, Email: mdevall/srs_stoneville@fs.fed.us

Pondberry (*Lindera melissifolia*) is a shrub of the southern United States that grows in seasonally flooded wetlands and on the edges of sinks and ponds. It has been listed as an endangered species since 1986, and fewer than 50 populations are known. Many of the existing pondberry colonies are small and occupy only a portion of the apparently suitable habitat. The species has been affected by habitat destruction and alteration, especially timber cutting, clearing of land, and drainage or flooding of wetlands. In addition, stem dieback is a problem and sexual reproduction is sparse in some populations.

Pondberry is a stoloniferous, clonal shrub that grows to a maximum of 2 meters in height. It is a dioecious species with small yellow flowers that bloom in spring. Pondberry has always been a rare species, and knowledge of its ecology and reproductive biology is lacking. Male plants outnumber females; female clones are smaller than male clones, and are sometimes absent from stands. Seed production can be erratic.

We will report the results of three years of research on the ecology, seedling biology, and reproductive biology of the species. We studied pondberry populations in Mississippi and Arkansas and visited populations several other states. The most vigorous pondberry populations we observed occurred in locations with abundant light. Stem dieback appears to be widespread in populations. We have isolated three fungal pathogens from stems. Six insect species were found in association with pondberry, but do not appear to be a limiting factor for the plant. Fruit production can be abundant, but as in many other clonal species, few seedlings occur even when seed production is high.

Individual stems can be easily transplanted, and multiply rapidly. Opportunities for dispersal are very limited now due to land use of areas surrounding pondberry populations and to changes in hydrology. The hydrology of the pondberry habitat has changed, so areas that were suitable in the past are now less than ideal and some populations are not thriving. However potted plants in the greenhouse are flourishing, indicating that the plant grows well under the proper conditions. Many populations occur in small wooded areas that have not been cut and planted with crops only because they are slightly lower in elevation than the surrounding agricultural land, thus the plant's ability to spread or to migrate to more favorable habitats is limited. Because of the conditions in which it occurs, the survival of this species may depend on man’s intervention and introduction of the species to new areas or areas where populations existed in the past.

Bamboo (*Bambusa arundinacea* (Retz.) Willd.) Hedgerow Systems in Kerala, India: Root Distribution and Root Competition for Phosphorus with Adjacent Teak and Malabar White Pine Trees

B. N. Divakara, B. Mohan Kumar, P.V. Balachandran and N.V. Kamalam
Kerala Agricultural University, College of Forestry, Radiotracer Laboratory, Vellanikkara, Thrissur, 680654 Kerala, India
Tel: 0487-370050, FAX: +91-487-370019, Email: bm.kumar@vsnl.com

Root distribution of bamboo (*Bambusa arundinacea*) and root competition between bamboo and associated tree components in two mixed-species systems were evaluated using modified logarithmic spiral trenching and 32P soil injection techniques respectively.

To characterise the root distribution pattern, 18 boundary planted bamboo clumps were randomly selected. Based on diameter, the clumps were classified into small (1.0-2.5m), medium (2.5-4.0m) and large (>4.0m). Logarithmic spiral trenches were dug around the clumps (10m long). The number of severed roots exposed on both sides of the trench was assessed by placing 50 x 50m quadrats against the vertical sides of the trench at 1-m intervals.

For 32P soil injection, two binary associations (*Tectona grandis* L.f-bamboo and vateria *Vateria indica* Linn.-bamboo) were chosen. Thirty-six experimental units (eighteen each for teak-bamboo and vateria-bamboo) were selected considering the range of lateral distances between teak/vateria with the corresponding bamboo clump (grouped into 1 m or 1.5 m classes). 32P solution was applied at rate of 116.92 MBq per plant through eight equi-spaced PVC access tubes at 50 cm radial distance (either at 25 cm or 50 cm depth; randomised block design with three replications). The most recently matured leaves from the treated and neighbouring plants were radio-assayed at 15, 31 and 45 days after application of 32P following the Cerenkov counting technique.

Excavation studies indicate that root density declined with increasing depth and lateral distance. Clump size is a cardinal determinant of lateral spread of roots (with 83% of the large clump extending roots beyond 10 m while only 30% of the small clumps extended roots up to 10 m). Number of roots in small clumps ranged from 446 m^{-2} at 0-2 m distance (43% of total) to 36 roots m^{-2} at 8-10 m (3.5%). Medium clumps recorded 467 roots m^{-2}

(46%) at 2-4 m and 92 m^{-2} (9%) at 8 -10 m. The respective figures for large clumps were 386 roots m^{-2} (43%) at 2-4 m and 90 m^{-2} (10%) at 8-10 m. Nearly 85-90% of the roots excavated was less than 2mm in diameter. Linear regression linking root density with lateral distance for bamboo clumps gave reasonably good predictions (R2>0.53).

Significant differences in 32P absorption by treated teak and vateria as a function of lateral distance to bamboo clumps within the range of lateral distances tried (1.5 to 4.5 m in teak bamboo and 2 to 6.5 m in vateria bamboo combination) were not detected. Implicit in this is probably the non-discriminatory nature of bamboo clumps with respect to root proliferation in this zone. Absorption of 32P by neighbouring bamboo clumps also was not statistically significant except at 45 days after application (vateria-bamboo). Highest 32P counts were recorded by bamboo clumps in the 1-3 m lateral distance zone. Although there was a decreasing trend in 32P absorption as the lateral distance increased, no predictable pattern was discernible.

In general 32P absorption by bamboo was higher when the same was applied at 50-cm depth in vateria-bamboo combination. This would imply that even deep placement of the fertilisers may not ease competition from nearby (<6.5m) bamboo clumps. Inter-specific root competition with under-planted crops can, however, be avoided by planting 8-9m away from the base of the bamboo clumps.

The Use of Different Tree Species for the Afforestation of Problematic Sites

Achim Dohrenbusch, J. Kumke und G. Mackenthun
University of Göttingen, Institute of Silviculture and Forest Ecology, Buesgenweg 1, D-37077 Goettingen, Germany
FAX: +49-551-393270, Email: adohren@gwdg.de

In central Europe a change of forest management can be observed. One important objective of this management is to increase the portion of broad-leaved species on the total forest area. Beside a slow change of conifer stands into broad-leaved stands, the afforestation of free fields gives the possibility to reach the goal in a shorter time. Therefore a long-term investigation was established in a low mountain range area in northern Germany. In the Solling mountains, a highly loaded forest site with acid soil and harsh climatic conditions in 500 m over sea level was selected. There is an average annual input of 30 kg sulfur and 40 kg nitrogen per hectar. The growth of ten different tree species was investigated over a seven year period. The forest stand has been established on three differently treated sites:

- intensive site preparation, with deep ploughing and extreme amounts of fertilizer in order to create optimal site conditions
- liming with a common intensity (4 t/ha)
- untreated control site

Already during the first years after the stand establishment there are huge differences in the survival rate of the 10 tested tree species. Above all pioneer species like black alder and birch were able to grow in a normal way. Noble fir (*Abies procera*), Ash (*Fraxinus exelsior*) and Norway-maple *(Acer platanoides*) showed very high rates of mortality, the mortality of European beech (*Fagus sylvatica*) and Sycamore-maple (*Acer pseudoplatanus*) was lower. In addition to the lower mortality rate, the pioneer species were at least one meter higher than the other tree species. Furthermore the practice experiment show, that the tree species react in a very different way on supporting treatments. For European beech and Douglas fir (*Pseudotsuga menziesii*) already a normal liming treatment could improve the life conditions, whereas ash and both maple species showed a distinct improvement only after an extreme site preparation with deep plouging and big quanitities of fertilizer, that are not realistic for practical application on a grand scale. The natural regeneration of quick-beam *(Sorbus aucuparia*), Norway spruce (*Picea abies*) and birch (*Betula verruccosa*) was the better, the poorer the soil conditions was. Only willow (*Salix caprea*) had higher densities on soils with better nutrient conditions.

The differences of the nutrient content of leaves and needles were more determined by the species than by the site treatment. Compared to the control, only calcium and magnesium showed significant higher concentrations within the leaves on the limed sites.

Structural Elements of the Pedunculate Oak's Crown as an Important Factor in Forestry Management in Croatia

Tomislav Dubravac, Vlado Krejci
Forest Research Institute, Cvjetno naselje 41, HR-10450 Jastrebarsko, Croatia
Tel: +385-1-6150742, FAX: +385-1-6150742, Email: tomislavd@jaska.sumins.hr

The tree crowns and forest soils are the main factors for all life activities in the stand. The effect that the tree crown has on the stand is manifold. Of all the structural elements, the tree crown, as one of the most susceptible and most obvious indicators of the physiological state of the stand, presents an interesting medium for observation and research. In the broad sense of the word, the structure of the crown means the size and shape of the crown, its growth and development, its arrangement in space and time and its proportions in relation to the remainder of the tree's parts. During the past thirty years, as part of ecological-management research of forest types in Croatia, studying the crown's structure has held an important place. Issues include researching the intensity of growth and development of the crown both horizontally and vertically in relation to dbh and the age of the stand, the period of maximum growth of the crown and the laws that govern them. Subsequently, the crown's shape, its area and volume, the site index, the amount of crown and horizontal projections on the ground and the crown complex are researched as important conditional factors for natural regeneration.

Searching for laws between the variables, i.e. expressing empirical equations, is an important area of research for foresters. This aim can be attained if the following questions are answered: What type and how strong is the relationship (correlation) between certain elements of the crown's structure and the tree's diameter? Further, the interdependence of the researched variables with other parts of the tree has to be established and the most acceptable equation function has to be found, i.e. a regression model. Finally, a mean morphological shape of the pedunculate oak's and common hornbeam's crown structure has to be expressed. Researching the laws governing changes in the width, length and area of the crown with an increase in the trunk's diameter is of a linear character and its dependence can be expressed by a linear equation. The volume of the crown according to diameter classes changes its size whose laws change can be expressed by a non-linear regression in the form of an exponential function. The form quotient of the crown is 0.56. The relative development of the crown's length is 45% of the tree's height and the relative development of the crown's diameter (the relationship between the tree's diameter and the crown's diameter) is on average 17 fold. Growth in the crown's diameter in an average stand's tree has a maximum value of 15.69 cm, where the tree's diameter is 8 cm, its age 17 years and the soil's ground covering of the crown is 70%, and is a good prerequisite to natural regeneration. Interception is highest in middle-aged (21.9%) and lowest in young stands (2.3%). Precipitation flow down the tree per 1 m^2 in the crowns of young trees is 23.9 times greater than in mature trees. The obtained laws can be utilised to advise about correct and timely management, increase the amount of information available about the state of stands, solve current problems in the forestry profession and increase awareness about the role and significance of the crown in the forest’s development.

The Dynamics of the Vertical Development of Tree Crowns and Trunks in Homogeneous and Mixed Pedunculate Oak Stands in Croatia

Tomislav Dubravac, Vlado Krejci & Dijana Vuletic
Forest Research Institute, Cvjetno naselje 41, HR-10450 Jastrebarsko, Croatia
Tel: +385-1-6150742, FAX: +385-1-6150742, Email: tomislavd@jaska.sumins.hr

The crown length is an important indicator of developmental stand conditions. An increase in the crown length increases its volume, as well as its assimilatory mechanism and production of tree substances, while the relationship between the trunk and the crown changes in favour of the crown. The share of the crown to the tree's total height, in deciduous trees, is approximately 30% and is a good indicator of forestry management and a prerequisite of good natural renewal. Observing the crown development as one of the stand structural elements is a point of interest for all foresters, especially in determining the time, intensity and duration of the sylviculture, as well as its growth.

This paper shows the intensity of the vertical development of the tree crown and trunk in relation to the breast height diameter and the age of the stand, in addition to observing differences in the length of the tree crowns and trunks in homogeneous and mixed pedunculate oak stands. Research was undertaken in the associations of pedunculate oak and common hornbeam (*Carpino betuli-Quercetum roboris* Anic ex Raus 1969) and the pedunculate oak and great green weed (*Genisto elatae-Quercetum roboris* Ht. 1938). For both associations fifty sample plots were chosen for investigation. The age categories were between 20 and 120 (140) years. Data processing was done in the same manner for all plots. Correlative and regressive analyse was carried for tree crowns and trunks length. The aim was to find a mathematical expression that reflects the spreading and variability of the data.

Preliminary research that was carried out in homogeneous oak stands show that the share of crowns in the total tree length is uniform throughout all developmental stages, excluding regeneration, and is 45% of the tree height. Further more, the crown length increases as the diameter and the stand age increase up to the fertilisation period. Vertical development is most prominent in young stands, slower in middle aged stands and weak in old stands.

The length of the trunk, as well as the tree diameter, is one element that influences the share of useful tree volume. The development of the trunk length of young trees is very intensive, then decreases and with the formation of the permanent crown ceases. Once the permanent crown is formed only the diameter will increase.

Establishment of Seed Production Areas For Teak At Mata Ayer Forest Reserve, Perlis, Malaysia

Lok Eng Hai, Ab Rasip Ab Ghani and Ong Tai Hock
Forest Research Institute Malaysia (FRIM), Forest Product Technology Division,
Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, Email: Lokeh@frim.gov.my

Establishment of seed stand or seed production areas (SPA) is an effective method of producing improved seed in a large quantity to meet the immediate demand such as teak. Five plots each covering about 0.5 ha were established on 20 years old stands at Mata Ayer Forest Reserve, Perlis, Malaysia and this activity has been given high priority with the seeds collected mainly used for forest plantation establishment in the country. The stands of trees that have been upgraded and managed for seed production are based on their frequency of superior phenotypes. Several criteria used in the selection activities and establishment technique are described. Progeny obtained from these SPA stands are also being tested and results obtained are promising.

Keywords: *Tectona grandis* phenotypes, selection, production area, progeny and stands.

Establishment Techniques and Early Growth Performance of Teak On Decking Site

Lok Eng Hai, Ong Tai Hock
Forest Research Institute Malaysia (FRIM), Forest Product Technology Division,
Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, Email: Lokeh@frim.gov.my

Teak, *Tectona grandis*, is one of the recommended forest plantation species and is widely planted in the country. However, due to the variation in various soil types and conditions these species does not strive well and at times failed. Often most forest plantations are established on sites which are known to be neglected, degraded or compact such as the decking area, water-logged, lateritic, sandy and heavily eroded sites which are poor in fertility and growth rate. Such sites required high management costs, good silvicultural practices and intensive labour.

Hence, this poster describes the appropriate three different planting methods via deep furrow, big hole and normal standard practices applied on a decking site which has been left idle was formerly a log yard. The growth performance of the two and a half years old teak are also being studied and early results obtained are promising with the proper planting technique used.

Keywords: Teak, Soil variation, degraded, decking, silvicultural practices.

Performance of Selected Mesophytic in the Raised Lands of the Sundarbans Mangrove Forest of Bangladesh

M. Faizuddin
Bangladesh Forest Research Institute, Khulna-9000
Muzgunni, Bangladesh
Tel: 880-41-762927, FAX: 880-41-762927

Sundarbans, the largest single tract of natural mangrove forest of the world, is located at the southern extremity of the Ganges River Delta bordering the Bay of Bengal. It occupies an area of about 10,000 sq. km including both Bangladesh and Indian parts. The forest in Bangladesh territory covers an area of 6,017 sq. km and lies between 21°28`-22°30`North latitude and 89°-90° East longitude.

The forest is very rich in biotic diversity supporting 334 plant species, 400 species of fishes, 35 species of reptiles, 270 species of birds and 42 species of mammals. Unlike most other mangrove forests the tree vegetation of the Sundarbans is not dominated by the *Rhizophoraceae* family. *Heritiera fomes* (63.8%) and *Excoecaria agallocha* (17%) are the two most extensively occurring tree species.

The Sundarbans plays an important role in the national economy of the country by supplying a remarkable quantity of timber, fuelwood, thatching materials, raw materials for newsprint and hardboard mills, fishes, honey crabs, etc. It contributes about 40% to the total revenue income of the Forest Department.

The Sundarbans has been under scientific management for more than 100 years. Future stocking of the forest is dependent on the natural regeneration. The productivity of the forest is very low (1.12 m^3/ha/yr) in comparison to other mangrove forests of the world.

The reason for low productivity of the forest may be due to slow growth of the main species (*H. fomes*), poor regeneration in some parts of the forest, poor control on the management systems etc. Areas with poor regeneration are increasing day by day and these areas are covered with some non-commercial species which are called Non Commercial Cover (NCC). According to ODA inventory report (1985), about 2% of the area of the Sundarbans are NCC. NCC is found in two forms such as;

a) raised land where there is no or very little tidal inundation, specially found in the north and north eastern parts of the forest and

b) depressed land where there is a stagnation of water, found specially in the western parts of the forest.

Raised NCC lands are unsuitable for mangrove species as these areas are seldom inundated by tidal surges. Mangrove Silviculture Division of the Bangladesh Forest Research Institute has been trying to introduce commercially important mesophytic species to cover those areas. Since 1986 to 1992 experimental trial plantations were made with 19 mesophytic species in different locations. These species are *Lagerstremia speciosa*, *Samanea saman, Albizia procera, A. lebbeck, Acacia nilotica, A. catechu, Swietenia macrophyla, Cassia siamea, Dalbergia sissoo, Toona ciliata, Leucaena leucocephala, Melia azedarach, Aazadiracta indica, Calophyllum inophyllum, Tamarindus indica, Polyalthia longifolia, Anthocephallus cadamba, Diospyros perigrina* and *Caesalpinia pulchirrima*. Out of 19 species, 3 species namely *L. speciosa, S. saman* and *A. procera* were found promising and recommended for the pilot plantation trial. Accordingly plantations were raised with these 3 species at different locations in 1992, 1993 and 1994. Survival and growth performance data recorded in June, 1998 were analysed. The results show *L. speciosa* as the most suitable species for the plantation in the raised areas of the Sundarbans for its good survival (78%-91%) and growth (height growth 0.95–1.05 m/yr and diameter increment 4.02–4.53 cm/yr) in ever location.

Reaction Ability of Silver Fir and Norway Spruce in the Dynaric Region of Slovenia

Franc Ferlin
Slovenian Forestry Institute, Vecna pot 2, 1000 Ljubljana, Slovenia
Tel: +386-61-2007831, FAX: +386-61-27-35-89, Email: franc.ferlin@gozdis.si.

Keywords: silver fir, Norway spruce, reaction ability, ring width trends, understory trees.

The main objective of the study was to investigate the recent growth reaction ability (for sociological rank changes) of the understory silver fir and Norway spruce trees in natural and selectively managed Dynaric silver fir-beech (*Omphalodo-Fagetum*) and spruce-silver fir forest (*Ribeso alpini-Piceetum*). The results shall illuminate the ecological perspective of natural silver fir and Norway spruce and the perspective of selection forest management under current environmental conditions.

The study area is located in the south-eastern part of the Dynaric region in Slovenia. The interference climate with relatively intensive rainfalls (above 1600mm per year) and moderate annual average temperatures (between 5 and 8°C) are characteristic for this area. For the study 8 research plots (size from 0.25-2.0 ha) were chosen: four plots in the silver fir-beech forest (altitude 800-900m), two plots in silver fir-beech forest with natural Norway spruce (attitude the same, site-climate more cold and wet), and the last two plots in spruce-silver fir forest (altitude 1150-1300 m). One of the silver fir-beech plots was located in the protection belt of the virgin forest (Rajhenau), and one of the spruce-silver fir plots in natural forest (Goteniski Sneznik). On each plot, 45 to 75 trees were selected (randomly if not all of them). Besides usual dendrometrical and silvicultural variables also the developmental tendency, vitality/health condition and light/shade condition of trees were assessed. Two increment cores were taken (up to the pith) from each of the selected tree for dendrochronological analyses.

The main results of the study are:

1) The ages of the understory silver fir and Norway spruce trees are surprisingly high at both sites: up to >240 years for silver fir at the silver fir-beech site and up to >340 years for both tree species at the silver fir-beech site (with Norway spruce) and spruce-silver fir site. The maximum ages of understory trees does not differ very much between selection and virgin/ natural forest.

2) The recent growth response to light of the released (and not seriously damaged) understory trees is still very strong (the diameter and height increment are strongly increasing), irrespective of their high physiological age or long suppression period in the past. The understory silver fir and Norway spruce growth behaviour is very similar. Understory silver fir and spruce trees could therefore be very perspective for selection forest management.

3) Although the long-term ring width trends of the understory trees do not differ significantly between silver fir and Norway spruce, the recent ring width trends of dominant trees are generally different (last 30 or more years): declining for silver fir and increasing for Norway spruce. Comparison between stands of various development history suggests that the type and intensity of forest management is the primary factor responsible for different dominant silver fir and Norway spruce growth trends.

4) From ecological and environmental point of view the optimum silvicultural technique for this forest ecosystems would be the single tree selection ("Einzelplenterung") for silver fir and single to group-wise selection ("Gruppenplenterung") for Norway spruce also under current environmental conditions.

Development of *Triplochiton sclerexlyon* (Wawa K. Schum) as a Plantation Species by Cuttings

K. Frimpong Mensah, T. Asiedu Amaning
University of Science and Technology, Institute of Renewable Natural Resources, Kumasi, Ghana
FAX: 233-51-60137, Email: ust lib@ust.gn.apc.org

Among the primary endemic species that contribute substantially to Ghana's timber export earnings is *Triplochiton scleroxilon* (K. Schum), (Wawa), accounting for about 22% of the total cubic volume of the major timber product exports. The exploitation of Wawa is due to its abundance in almost all the forest types in Ghana and West Africa is general. Though Wawa has multiplicity of uses, the species is well known to produce seeds irregularly, both on annual and seasonal basis, a major constraints to having enough seeds for replanting. Vegetative propagation techniques have been developed for the species to encourage reforestation efforts. This study describes the application of low technology propagation system using cuttings.

Two experiments were carried out: (i) testing of rooting performance from cuttings of 2 year old, 4 year old and 8 year old stockplants (banded and unbanded), and (ii) growth (height, diameter) performance of rooted cuttings on different mixtures of sand, loam, and sawdust. No rooting was observed in 8 year old cuttings. Blanching had no significant effect on rooting. Highest rooting percentage was in 2 year old cuttings.

Growth medium of 25% sand, 25% loam, 50% rotted sawdust produced significant growth (height and diameter) (P=0.05 ANOVA) and biomass accumulation (leaf, root).

The results indicate that the most suitable cutting material for vegetative propagation of *T. scleroxylon* is 2 year stock plants and rooted cuttings performed best on growth medium of 50% rotted sawdust. Use of juvenile stockplants and seedling growth medium rich in organic nutrients may be recommended for use in propagation of *T.scleroxylon* cuttings.

A Shelterwood System for Regeneration of *Picea abies* (L.) Karst in Sweden

Dan Glode, Ulf Sikström
The Forestry Research Institute of Sweden, SkogForsk, Uppsala Science Park, S-751 83 Uppsala, Sweden
Tel: +46 18 18 85 98, FAX: +46 18 18 86 00, Email: dan.glode@skogforsk.se

Regeneration of Norway spruce *Picea abies* [L]. Karst. under shelterwood is a silvicultural system that demands knowledge, activity and endurance. On an appropriate site and with a well planned silvicultural program the net income can be higher than from clear-cutting, scarifying and planting. This is mostly due to that the regeneration cost decrease more than the logging cost increase in the shelterwood system. However, incomplete regeneration, windthrow and damage done to the regeneration during felling of the shelterwood can result in a lower net income than from the clear-cutting system.

Some of the advantages with the shelterwood system compared with the clear-cutting system are: (i) reduced risk for frost damage on the seedlings; (ii) a less heightened ground-water level in the regeneration stage; (iii) suppression of the field vegetation, which facilitate seedling establishment and growth. The most feasible sites are usually moist and fertile and located in low parts of the terrain, i.e. where the above mentioned advantages are most clearly outspoken. In addition, a shelterwood induce less environmental changes compared to a clear-cut, e.g. for air humidity, shadow and wind speed. This is especially important in stands where species adopted to long forestry continuity are present. Many of these species are rare and are not likely to survive a clear-cut.

The logging operations included in the system are: Preparatory-, Seed-, Removal- and Final cutting. When the new generation of conifer plants is established the final cutting should be carried out at a suitable time in order to minimise physiological damage due to, e.g. changes in light and humidity, as well as logging-related damage to the regeneration. The final cutting can be done with both single- and two-grip harvester systems with an acceptable amount of damage in the regeneration. However, it is necessary that the logging is careful and that the stand is not too dense and the regeneration not too sparse. On average 40-60% of the original seedlings will be damaged or killed.

Windthrow usually occurs during the first five years after the logging operation and can be a severe problem. On an average, 10-20% of the shelterwood trees will be windthrown. In order to minimise the probability for windthrow, the seed-cut should not exceed 40% of the trees, corresponding to about 30% of the standing volume, when thinning from below. Preferably the highest trees with a long green-crown length should be left and trees with a short green-crown length should be cut.

Indigenous Woody Species in Grassland Areas of Northeastern Luzon, Philippines: An Alternative for Grassland Rehabilitation

Ma. Visitacion D. Guingab
Isabela State University, College of Forestry and Environmental Management, Isabela, Philippines

Five grassland sites in Northeastern Luzon, Philippines were studied to identify indigenous woody species and determine their potentials for rehabilitating degraded grassland. Sixty two (62) species belonging to fifty (50) genera and twenty nine (29) families were identified in the woody patches of grassland areas in five localities classified as 57 trees and 5 shrubs. Among these, three (3) are promising species for reforestation namely: *Afzelia rhomboidea* (*Leguminosa*e), *Pterocarpus indicus* (*Legurninosae*) and *Vitex parviflora* (*Verbenanceae*) while eleven (11) others have potential in grassland rehabilitation based on the following characteristics they possess: a) most of them have multiple usage capable of providing products and services in addition to fuelwood and timber; b) since all are native species, they adapt well to the site, establish easily and require little care; c) they are capable of growing in extreme environment such as infertile soils, low moisture and exposure to frequent grassland fires and strong typhoons; and d) some have the ability to fix atmospheric nitrogen, ability to coppice and fast growing. These are *Albizzia procera* (*Leguminasae*), *Alstonia scholaris* (*Apocynaceae*), *Erythrina orientalis* (*Leguminosae*), *Polyscias nodosa* (*Araliaceae*), *Trema orientalis* (*Ulmaceae*), *Antidesma ilocaman* (*Euphorbiaceae*), *Mallotus philippinensis* (*Euphorbiaceae*), *Bauhinia malabarica* (*Leguminosae*), *Canarium aspersum* (*Burseraceae*), *Diospyros pilosanthera* (*Ebenaceae*) and *Streblus asper* (*Moraceae*).

Productivity of Grasses in Relation to Site Quality in *Pinus roxburghii* Sargent Plantations

Bhupendar N. Gupta, D. Dalai
Dr. Y. S. Parmar University of Horticulture and Forestry, Post Box # New Forest, H. P. -173 230 , Nauni, Solan, India
Tel: 91-0135-759382, FAX: 91+1972+52242, Email: Guptab@yspuhf.hp.nic.in

The present study was conducted during the 1996 growing season (June-October), in Solan Forest Division of India's Himachal Pradesh. It is located between latitudes 30-31°N and longitudes 76-77°E and the region's climate is sub-tropical. Two sites were selected. Site I is a good site quality and site II is a poor site quality. Site quality was determined by the height intercept method. The aboveground biomass of the grasses was determined by the harvest method and belowground biomass was estimated by excavating a monolith of 25x25x30 cm, from each quadrat taken at a fortnightly interval starting on 15th June. The important grass species recorded in the study were *Themeda anathera, Chrysopogon montanus, Heteropogon contortus* and *Panicum maximum*.

The total aboveground biomass on sampling dates varied from 10,1 q/ha to 23,5 q/ha in site I and from 9,8 q/ha to 27,6 q/ha in site II. In both sites the peak biomass was recorded around mid-August. In site I the aboveground biomass showed a gradual increase until mid-August and in site II, except in mid-July, a similar pattern was noticed. At peak biomass stage *Chrysopogon montanus* contributed with 26,7 q/ha (96%) to the total aboveground biomass in site I and with 15 q/ha (54%) in site II. The percentual contribution of *Chrysopogon montanus*, *Heteropogon contortus* and *Panicum maximum* was 90, 40 and 3, respectively, in site I and 64, 27 and 9, respectively, in site II. During the study period, *Themeda anathera* aboveground biomass, was significantly different, on both sites, in mid-August, end-August and end-September but on the other dates it was equal. During the study period, *Chrysopogon montanus*, *Heteropogon contortus* and *Panicum maximum* aboveground biomass were significantly different on both sites.

The total below-ground biomass of grasses on different sampling dates varied from 9,6 q/ha to 17 q/ha on site I and 7,9 q/ha to 17,8 q/ha on site II. It was recorded that below-ground biomass increased gradually from June to mid-August after it showed an irregular trend. At peak biomassa stage, *Chrysopogon montanus* contributed with 16,6 q/ha (97%) to the total below-ground biomass on site I, whereas on site II besides *Chrysopogon montanus* (73%), *Panicum maximum* (14%) and *Heteropogon contortus* (12%) also contributed significantly to the total below-ground biomass.

Thus, it was found that the difference in site quality based on the tree characteristics had no influence in total above or below- ground grass biomass but had an influence on the biomass production of individual grasses and thereby their contribution to the total biomass of the community. An attempt was made to correlate the site quality and aboveground biomass with rainfall and basal area of the grasses. It was found that rainfall explained, in site I and in site II, respectively 25% and 34% of the aboveground biomass variation. Basal area of the grasses accounted, in site I and in site II, respectively for 49% and 30% of the above-ground biomass variation.

Natural Reproduction of *Quercus serrata* Coppice Forests by the Mother Tree Method

Ryoji Hashimoto, Nobuyuki Abe
Iwate University, Department of Agronomy and Forestry,
3-18-8 Ueda, Iwate 020-8550 Morioka, Japan
FAX: 81-19-621-6139, Email: hashimot@iwate-u.ac.jp

Deciduous coppice forests dominated by *Quercus serrata* are widely distributed around cities and farm and mountain villages in Japan. In these areas the afforestation by conifers was made actively during 1950's to 1970's. But recently the new trend towards natural reproduction by making full use of native broad-leaved tree species have been growing among forestry experts and regional people. The mother tree method have a number of advantages; e.g. easily performed, enable to shorten the regeneration period and so on. Various fundamental studies and technical tests were carried out in order to examine applicability of the mother tree method for *Q. serrata*. The canopy trees produced good seed crop almost every two years, bumper seed crop at intervals of 6 or 8 years. Larger number of mature seeds were supplied at years when the trees bore more seeds. Most of seeds fell right under tree crowns or near around them and collected mainly at low spots on the ground surface. The seed fall was followed by leaf fall and the leaves also collected in the same manner to cover seeds. So seeds could avoid desiccation damage. Seedlings showed, already at current year stage, high photosynthetic ability in leaves, 60-70% of young trees, and the photoinhibition of photosynthesis was not observed. Daytime stomatal conductance of current year seedlings was kept relatively high even in non-rain fall periods in summer, probably due to marked development of their root system. At the following year weeds and shrubs started to grow thick and suppressed certain parts of the seedlings. It was, however, concluded that the regeneration of *Q. serrata* would succeed finally if the growth of bamboo grasses could be restricted artificially. The use of a backhoe was extremely effective for removing the under-ground system of bamboo grasses etc. Although soils were compacted by using such heavy machinery, the soil compaction did not strongly influence the photosynthetic performance and growth reaction of the seedlings.

Bosques tropicales secundarios en transición

Lionel Hernández
Universidad Nacional Experimental de Guyana,
Av. Las Américas Torre General de Seguros Piso 3,
Puerto Ordaz, Venezuela
FAX: 0058 86 225673, Email: lhernand@uneg.edu.ve

Este trabajo trata sobre la estructura y composición florística de vegetación boscosa secundaria submesotérmica en el Escudo Guayanés al Sudeste de Venezuela, y es parte del proyecto "Dinámica Bosque-Sabana" en la Gran Sabana, a fin de analizar los cambios en la vegetación boscosa. Bajo el clima húmedo regional no ocurre una cobertura continua de bosque siempreverde; más bien predomina un mosaico de bosques, sabanas y una vegetación transicional entre ambas formaciones. Se ha postulado que ese mosaico representa una etapa transitoria de un proceso dinámico de cambio de los bosques hacia sabanas, ocasionado principalmente por una combinación de fragilidad latente y baja capacidad de recuperación de la vegetación boscosa, en donde los incendios forestales durante los años extremadamente secos son los principales agentes desencadenadores. Los factores externos que usualmente perturban los bosques son los incendios no controlados y la agricultura migratoria. Los resultados sobre vegetación secundaria post-conuco confirman el habitual cambio en la estructura y la diversidad arbórea a través del tiempo, sin embargo se detectó una diferenciación de esas características en función de las condiciones de sitio así como del tipo y frecuencia de perturbaciones agrícolas. En cuanto a la vegetación secundaria post-incendio se puede diferenciar entre comunidades secundarias resultantes de eventos perturbadores singulares de incendios ocurridos durante sequías excepcionales y aquellas comunidades surgidas a partir de incendios reiterados en el límite bosque-sabana. Cabe señalar que en ambas variantes se ha podido constatar una tendencia hacia un proceso de degradación de la vegetación boscosa secundaria, en vez del habitual proceso de recuperación sucesional. En estos bosques no sólo es notoria la falta de especies pioneras especializadas, sino también la escasez de esciófitas. Más bien la mayor parte de las especies aparentan poseer un comportamiento poco especializado, o sea bastante flexible en lo que respecta a su tolerancia o necesidad de luz. Ello parece indicar una adaptación de las especies a ecosistemas forestales con un alto nivel de perturbación. La restringida estabilidad del sistema determina una fuerte dinámica, lo que implica una alta probabilidad de variación de las condiciones e incidencia de la luz, durante el lapso de la vida promedio de un árbol. Por lo tanto, una especialización estricta de especies como árbol esciófito bajo estas circunstancias sería muy desfavorable, mientras que un comportamiento como oportunista sería más viable para su supervivencia. La amplia distribución de la mayoría de las especies en los distintos tipos de bosques y la relativamente alta afinidad florística entre los distintos tipos de bosque indican una adaptación de gran parte de sus especies a diferentes condiciones de sitio. En vista de la carencia de suficiente información sobre requerimientos de agua, nutrientes y luz no se pudo distinguir realmente cuando el factor limitante para la ocurrencia de una especie es la incidencia de luz o las condiciones de sitio. Evidente parece ser sólo la ausencia de especies pioneras típicas, que normalmente son exigentes, no solamente con la luz, sino también en relación al suministro de nutrientes, como por ejemplo especies de los géneros: *Cecropia*, *Roupala* y *Schefflera*, que posiblemente sean excluidas, debido a los suelos extremadamente oligotróficos.

Taper Variation among Progenies of *Acacia mearnsii* de Wild and its Implication in the Tree Volume Estimation

Antonio R. Higa, Admir L. Mora, Augusto A. Simon, Pedro P. Stein
Federal University fo Paraná, Rua Bom Jesus 650, CEP 80.035-010 Curitiba, Brazil
Tel: +(41)232 9084, FAX: +(41)232 9084, Email: arhiga@floresta.ufpr.br

This paper aims to determine the taper variation among progenies of *Acacia mearnsii* De Wild. (black wattle) and to discuss its implications in the tree volume estimation. Black wattle is an important forest tree species in Rio Grande do Sul State, Brazil. The total area planted with this species is estimated in 120 thousand ha with an annual plantation rate of 13 thousand ha. 75% of the total plantation area is located in small farms, in varied agroforestry systems. These farmers plant agricultural crops (mainly cassava, corn, beans or watermelon) associated with black wattle trees in the first two years. When the trees are three or four years old, the grass regenerated understore is used to feed the cattle introduced in the forest. The main products of the black wattle forests are bark, demanded by the tannin industries, wood, used as an energy source by the local population, and chips, demanded by pulp industries. Estimation of tree volume during the rotation period is an important tool used by the foresters not only for experimental reasons, but also, to keep control of the forest stock for administrative purposes. The methodology most used to estimate the black wattle tree volume is based on the estimation of the cylindrical volume multiplied by an average taper value. However, measuring the black wattle tree height planted in a high density forest (2000 trees/ha) is a difficult task for trees taller than 9 m of height. This study was based on 135 trees of 46 open-pollinated black wattle families, planted in Piratini County, Rio Grande do Sul State, Brazil (31002' LS, 52057' LW and 220 m. a.s.l). The trees were four years of age and belonged to a replication of a progeny test planted in the randomized block design. The average taper values of the 135 trees measured was 0.517 with a coefficient of variation of 14.9%. There were statistically significant differences (95% of probability) among progenies in relation to the taper values. Regression analysis among the cubed volume and the volumes obtained by different methodologies emphasized the need to use an equation adjusted for these population. Based on the results of this study, it was concluded that the volume of black wattle trees estimated using equations based only on diameter values (DBH) was accurate (r^2=0,87) and less time consuming, therefore, should be adopted in the black wattle tree improvement program carried out in Southern Brazil.

Rehabilitation of Degraded Peat Swamp Forest

Shamsudin Ibrahim, Ismail Parlan
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Email: sham@frim.gov.my

Keywords: Peat swamp forest, rehabilitation, native species, nursery practice

Degradation of peat swamp forests has been closely associated with human activities especially uncontrolled logging. These degraded areas need to be rehabilitated to help restore productivity, improve peat swamp forest environments, and maintaining their role as sources of high quality timber. Adequate high quality planting material is currently a major constraint in rehabilitating degraded peat swamp forests, and research on appropriate planting techniques using suitable species is crucial. The study site was conducted in Compartment 101, Raja Musa Forest Reserve in Batang Berjuntai, Selangor. The area experiences fire on a regular basis and was occupied by grass, *mainly Imperata cylindrica* (lalang). Four different methods of planting and six different peat swamp forest species were used in this study. Growth (height and diameter), survival and mortality data of the seedlings, as well as foliage samples, were taken every three months during the course of the study. Planting materials were successfully raised using seeds and wildings. It was found that planting materials of peat swamp forest species can be raised using normal soil potting mixture in the nursery. Handling of these species in the nursery does not require special care, and their management in the nursery was similar to that for dryland species. Seedlings of peat swamp forest species had fewer problems with disease and fungus. The findings showed that these species can be raised with minimum care as long as we have sources of the plants (seeds and wildings).

Recycling of Wood Ash - Effects on Stem Growth in Swedish Coniferous Stands on Mineral Soils

Staffan Jacobson, Hagos Lundström & Sten Nordlund
The Forestry Research Institute of Sweden, Uppsala Science Park, S-751 83 Uppsala, Sweden
Tel: +46 18 18 85 47, FAX: +46 18 18 86 00, Email: staffan@skogforsk.se

During the last decade, the interest in utilizing logging residues for bioenergy has increased in Sweden. The use of such residues for energy production generates large amounts of wood ash, which at present are being dumped. This dumping is not unproblematic. It is space-demanding, and involves the risk of strong bases and heavy metals being leached out contaminating the ground water.

A more intense harvesting results in an increased export of nutrients and soil acidification. To prevent, or reduce, the negative effects of intensive biomass harvesting, it would be of value to recirculate the nutrients contained in the wood ash. Wood ash has a high pH (ANC), and a major part of most macro- and micro nutrients (except for N) from the biomass is retained in an inorganic form.

With the object to study whether the stem-growth of coniferous trees is affected by applying wood ash, a series of field experiments was established in middle-aged Scots pine (*Pinus sylvestris* L.) and Norway spruce (*Picea abies* (L.) Karst) stands on mineral soil. Stabilized wood ash in doses of 1, 3 and 6 tons ha-1, as well as a combined ash + N treatment, was studied.

Preliminary results indicate that the addition of wood ash increased stemwood growth on fertile sites in south Sweden and decreased growth on less fertile sites further north. The number of experiments is still small, but results agree well with experiences from liming.

Despite the anthropogenic input, N is still the growth-limiting nutrient for the vast majority of the Swedish forests, and the addition of wood ash probably influences the supply of inorganic nitrogen available for tree growth. The addition of wood ash on the fertile sites, with N-rich forest soil, such as moder/mull soils, probably resulted in an increased net mineralisation of N in the soil organic layer, while it in the more N-poor forest soils probably led to an increased N-immobilisation. The C:N ratio in humus seems to be a good measure from which to judge if a pH increase in the soil leads to an increased or decreased net mineralisation.

Reclamation of River-damaged Areas through Agro-forestry in Nepal

Shesh Kanta Kafle
UNDP/LGP, Nepal
FAX: 977-1-527601, Email: gyan@vishnu.ccsl.com.np

Keywords: agroforestry, montane regions, Nepal, silvipastoral systems, rehabilitation, *Dalbergia sissoo*, *Acacia catechu*

Land degradation due to flooding has become a major threat to the foothills of middle mountainous region and Terai part of Nepal, leading to the deterioration of socio-economic conditions and of natural ecosystems. Agroforestry practices have been promoted in those areas with the twin objectives of countering land degradation problems and meeting the demands of local people for fuelwood, fodder, and small timber. The present study assessed the effectiveness of such practices in the riverside areas of the midhills region in reclaiming the degraded lands, considering vegetation establishment, land productivity and control of weed infestation (*Imperata cylindrica, Saccharum munja*) as the bases for evaluation. Data were gathered from the field measurements and observations. In addition, data pertaining to crop yields were collected using semi-structured questionnaires. Results of two years' study showed that *Dalbergia sissoo* could be successfully intercropped with *Zea mays, Solanum tuberosum, Cajanus cajan* and *Phaseolus vulgaris* in river affected areas. There was no significant difference in growth performance of *D. sissoo* planted in river-affected areas and unaffected areas. Yields of various crops have also been documented. Three treatments adopted to control infestation of

Imperata cylindrica and *Saccharum munja*: (1) land preparation using power tiller, (2) dense plantation of riverine tree species at 1 x 1 m spacing, and (3) silvipastural management (i.e., protection of existing grasslands from excess grazing and planting *D. sissoo* and *Acacia Catechu* at 4 x 4 m spacing). Of these treatments, the dense tree plantation was most appropriate from both the economic as well as ecological standpoints. Species composition was found to have changed in the silvipasture plots. Land preparation using power tiller was found to be an effective approach to eradicate *Imperata cylindrica* and *Saccharum munja*, although it was not economically feasible and transportation of the power tiller was also difficult in remote areas.

Stand Structure and Spatial Pattern of Commercial Species in Logged and Unlogged Venezuelan Forest

Ludwig Kammescheidt
University of Göttingen, Institute of Tropical Silviculture, Büsgenweg 1, 37077 Göttingen, Germany
Fax: +49 551 39 4019, Email: lkammes@ufobi6.uni-forst.gwdg.de

The impact of logging on the stand structure and spatial pattern of commercial species was studied along a chronosequence of 5-19yr old logged stands in the Forest Reserve of Caparo, Venezuela. For comparison, a mature forest stand was surveyed. A systematic sampling design was applied. On average, 10.2 trees/ha with a bole volume of 66.5 m^3/ha were removed. Up to the mid 1980s, covered by this study, only *Bombacopsis quinata, Swietenia macrophylla, Cedrela odorata and Cordia apurensis* were logged. The 5-yr, 8-yr and 19-yr old logged stands showed a mean basal area of 17.8 m^2/ha, 21.3 m^2/ha and 22.2 m^2/ha, respectively, whereas 33.2 m^2/ha were measured in the mature forest. The share of undamaged trees in the basal area increased from 30.8% in the 5-yr old logged stand to 43.9% in the oldest logged stand. The number of emergent trees (>3m height) was considerably reduced by logging; even 19 years after logging only 8 stems/ha were found in this height class comparing to 51 stems/ha in the mature forest. *B. quinata*, the most important timber species in the study area, occurred with only two heavily deformed individuals in the logged stands. Juveniles of *B. quinata* were rare (< 10 stems/ha) in both logged and unlogged stands. A similar situation was found in *C. odorata* and *S. macrophylla*. In contrast, *C. apurensis* was well represented in small size classes in logged and unlogged areas. A second cutting cycle will be based on a variety of medium- and small-sized shade-tolerant and light-demanding species which were regularly distributed in the unlogged and logged area. However, the spatial patterns of seedlings and saplings of these species did not show any clear trend. Nineteen years after logging, only one third (61.3m^3/ha) of the commercial bole volume of the mature forest (185.3m^3/ha) was attained.

Stand Characteristics and Natural Regeneration of *Kalopanax septemlobus* Growing at Kangwon Province, Korea

Ho-sang Kang, Don Koo Lee
Seoul National University, Department of Forest Resources, College of Agriculture and Life Sciences, 441-744 Suwon, Korea R.
Email: silvi@chollian.net

Kalopanax septemlobus is a deciduous tree whose height and diameter at breast height (DBH) sometimes exceed 30m and 1.8, respectively. The importance of *K. septemlobus* in Korea has been recognized these days due to several reasons. Timber quality is better than any other woody species of which reason makes this tree species expensive in timber market. In addition, *K. septemlobus* produces saponin, one of the second metabolic products that could be effective for several medicinal and edible uses. Although *K. septemlobus* deserves many good things for human life, there has been no previous research on its ecological characters. The objective of this study was to understand the characteristics of stand distribution and factors affecting natural regeneration of *K. septemlobus* growing with other hardwoods in Kangwon Province, Korea. We have researched the seed quality by X-ray photography and site characteristics, which are altitude, slope, aspect, elevation, moisture and nutrient content of soil. The plot was established by 20 X 20m and all individual trees > 2.0cm in DBH were measured for the vegetation composition, and compare to the topographical and soil characteristics. *K. septemlobus* was spottily distributed at the high elevation and in good nutrient soil conditions mixed with *Quercus, Acer, Betula* and *Carpinus* species. Its distribution patterns were clustered at the early stage, but, the mature trees were randomly distributed only in one or two individuals. The seedling grew fast under good light conditions, and showed shade tolerance at the early stage. The growth of *K. septemlobus* continued from April till August when measured for girth band at Mt. Kyebang. The dominant tree grew by 6.1mm per year whereas suppressed one under other trees showed almost no growth. The natural regeneration of *K. septemlobus* in natural hardwood forests was very difficult because of its low seed viability and its germination. The seed viability of *K. septemlobus* was 34.5% under good light condition in forests, whereas 19.6% inside forests. The height growth of *K. septemlobus* seedlings showed a reverse-J shaped curve, which might induce high mortality. Such mortality was resulted from severely competing herbs or seedlings of other species and also browsing by wild animals.

Economic Analysis of Forestry Plantations on Degraded Sites

Parvinder S. Kaushal, Rajesh K Rana
Parmar University of Horticulture and Forestry, Regional Center, NAEB, 173 230 HP Nauni-Solan, India
Tel: +91 1792 52487(O), FAX: +91-1792 52242, Email: pkaushal@yspuhf.hp.nic.in

The present paper studies economics of forestry plantations in three degraded sites viz. eroded soils, water-logged soils and alkaline & saline soils. Such plantations were maintained by the farmers on their farm lands in order to meet various household and agriculture needs. The study is based on the survey and interviews with the farmers of the area under consideration. Plantations in all the degraded sites under study being sparce, the estimations were done per 100 trees, rather than area basis. In order to assess profitability of the plantations, Net Present Worth (NPW) and Benefit-Cost Ratio (B-C Ratio) were determined at 12 % rate of returns, as the farmers of the area are getting long term agricultural loans at 12% interest per annum.

Eroded sites are characterised by low soil depth, oftenly exposed hard rock and nutrient deficit landmass. Special site specific benefit-cost studies for such plantations were conducted in Suan river catchment area of Una district in Himachal Pradesh, India, for the plantations of *Dalbergia sissoo*, *Albizzia lebbeck*, *Toona ciliata* and *Grewia optiva*. Plantations of all the species under consideration in eroded soils were profitable. *Grewia optiva* being very popular and useful fodder species of the area, yielded the highest NPW (US$ 240) followed by the *Dalbergia sissoo* (US$ 112), *Toona ciliata* (US$ 122.73) and *Albizzia lebbeck* (US$ 79.8). However, the B-C ratio was found to be the highest for *Dalbergia sissoo* (2.59) followed by *Toona ciliata* (2.58), *Grewia optiva* (2.35) and *Albizzia lebbeck* (1.97).

The water-logged soils of Una district in Himachal Pradesh, India, have existing plantations of *Dalbergia sissoo*, *Acacia arabica*, *Populus* and *Eucalyptus* spp. The plantations of all the four species under reference were profitable. *Populus* spp. and *Eucalyptus* spp. being short duration (8 years) crops yielded significantly higher NPW (US $ 318.2 and US $ 228.3, respectively) and B-C ratio (4.18 and 6.18, respectively) as compared to long rotation (25 years) *Dalbergia sissoo* and *Acacia arabica*. The total undiscounted benefits of *Dalbergia sissoo* (US$ 1788) and *Acacia arabica* (US$ 1798) were, however, considerably higher than *Populus* spp. (US$ 919) and *Eucalyptus* spp. (US$ 597.8).

Alkaline and saline soils pose a great problem for cultivation of many crops in many parts of India. Growth as well as survival of forestry plantations in such lands is adversely affected. This study was done in one of the districts largely affected by this type of soils (Karnal, Haryana, India). Plantations of different species studied were *Eucalyptus* spp., *Acacia nilotica*, *Zyzyphus* spp. *Morus alba*, *Dalbergia sissoo*, *Sesbania aegyptica* and *Prosopis* spp. The plantations of all the seven species under study were not profitable to grow under alkaline and saline soils. NPW and B-C Ratio criteria of economic analysis indicate the plantations of *Eucalyptus* spp. *Acacia nilotica*, *Zyzyphus* spp. *Dalbergia sissoo* and *Prosopis* spp. were profitable while *Morus alba* and *Sesbania aegyptica* were non-profitable. *Eucalyptus* had the highest NPW (US$ 448.80) while *Morus alba* had the lowest NPW (US$ -30.83). On the other hand the B-C ratio was the highest for *Eucalyptus* (4.97) and the lowest (0.74) for *Sesbania aegyptica*. *Eucalyptus* was found to be the highly profitable species due to its fast growth and reduced supply of wood in present days. The economic analysis of these site specific plantations related to marketed benefits provided information on profitability of various local tree species. However, many non-marketed benefits of these plantations will further increase profitability of such plantations.

1 US $ = Rs. 42.00 (Rs. = Indian Rupees)

Rehabilitation of Degraded Tropical Forest Ecosystems

Shigeo Kobayashi
CIFOR, Jalan Situ Gede, 16680 Bogor Barat, Indonesia
Tel: +62-251-622622, FAX: +62-251-622100, Email: s.kobayashi@cgiar.org

1. Background and Justification

Tropical forests are decreasing at the rate of 16.9 million ha/yr due mainly to clearing for agriculture and shifting cultivation. Moreover, timber harvesting results in more than 5 million ha of tropical forest becoming secondary forests every year without any adequate management. The decrease and degradation of the tropical forests affect not only the production of timber but also global environments.

Many environmental changes are initiated by forest harvesting including site degradation, reduced water supply, soil loss and greenhouse gas emission. What is needed at the present time is the assessment of harvesting impacts which significantly influence rehabilitation methods. A growth in population and rapid economic expansion have resulted an escalation in demand for wood products. Increased supply of wood from plantation forests has the potential to reduce pressure on natural forest resources as well as contributing to environmental care and economic advancement for landholders in the tropics. Short-rotation plantations will show changes in nutrient storage and cycling processes. The clarified scientific information enables managers to devise silvicultural systems which enhance soil properties important to sustainable production and minimise deleterious effects associated with short rotation. Therefore, "Rehabilitation of Degraded Tropical Forest Ecosystems" as the CIFOR research project was proposed and started in 1996.

2. Research Activities

Following research activities have been proposed and started in 1997 collaborated with seven institutions such as UNMUL-Indonesia, FCFUM-Argentina, PNGFRI-Papua New Guinea, INIA-Peru, UPM-Malaysia, KUFF-Thailand, and EMBRAPA-Brazil.

(1) Evaluation of forest harvesting impacts on the forest ecosystems: (i) evaluate logging and yarding methods on disturbance of forest ecosystems, (ii) analyse the demography of regenerated tree population, (iii) model a/de-gradation processes in forest ecosystems.

(2) Development of methods to rehabilitate logged-over forests and degraded forest lands: (i) treatments accelerating natural regeneration, (ii) development of enrichment planting methods.

(3) Development of silvicultural techniques on degraded forest lands: (i) development of species-site matching methods, (ii) management options for sustained productivity, (iii) social and economic acceptability of management options.

3. Experimental Site related with Activities

UNMUL is carrying out the study of two different harvesting intensities + forest fire at Lowland mixed Dipterocarp forest -9 ha in Bukit Soeharto, East Kalimantan, Indonesia. FCFUM is studying two different harvesting intensities with bamboo at YABOTI Sub-tropical forest -72 ha in Guarani Forest Reserve, Misiones, Argentina. PNGFRI is carrying out the study of three different refining intensities + enrichment planting at Logged over lowland mixed evergreen forest -150 ha in Oomsis and Bulolo, Papua New Guinea. INIA initiates the study of mixed species plantation at the abandoned agriculture and pasture grasslands and secondary forests (purmas) in Campo Verde and Nueva Requena, Pucallpa, Peru. UPM is studying the three Gap plantings and three line plantings + mixed planting at logged over mixed Dipterocarp forest -12 ha in Pasoh, Malaysia. EMBRAPA is carrying out the study of clearcutting + 7 site preparation: site management + organic residue and litter treatments, undergrowth treatment, tillage, fertilisation at 7 year old *Eucalyptus grandis* –16 ha in Sao Miguel and Mogi Guacu, Sao Paulo, Brazil. KUFF is studying tree different thinning intensities and one clear cutting + intercropping at 17 year old Teak -4.32 ha in Thong Pha Phun, Kancganaburi, Thailand.

4. Final Outputs

Rehabilitation is aimed to improve biological diversity, increasing commercial value for the timber production, increasing non-timber products, increasing forest functions, improve fertility and improve soil physical properties etc. Technical developments are expected for reducing logging impacts, sustainable forest management, accelerating natural regeneration, species selection – site matching, enrichment, sustainable site management and catalytic plantation. Socioeconomical developments are also expected that rehabilitated production forest and environmental forest, local community participation and socio-economic acceptability.

The Management Problems in Planting of *Haloxylon* spp. in Iran

Ali Ahmad Korori, Khoshnevis M., Maghouli F., Matinizadeh M., Moraghebi F., Salehi P. and Teimouri M.
Research Institute of Forests and Rangelands, Ecophysiology and Biotechnolgoy Group.
Forest Department, Post Box # 13185-116, Tehran, Iran
FAX: +98-261-663482, Email: shirvany@hotahari.ut.ac.ir

Haloxylon spp. are very important for erosion control in sandy hills and deserts. Over the past 16 years in Iran, one of the major problems that has arisen is the weakening (yellowing) of these trees, especially during the summer season, in trees between 12-16 years of age. Ecological, ecophysiological and physiogenetic research conducted between 1993 and 1998 has sought answers to causes of this problem. Our research included initial studies of natural and artificial habitats of *Haloxylon* in which ecological parameters were measured, including climatic, edaphic and geographic parameters as well as plant community composition. Research plots (with area 5000 m2) were selected for physiological studies. Parameters such as height, diameter, healthy conditions and natural regeneration were studied in all of trees in each plot. At least one soil profile was described in each of the plots. In each of the plots, four green, four yellow and four green-yellow trees were selected at end of summer. One and two-year-old branches were sampled for studying alteration of cations, anions and enzymes in each season. Further sampling was done from 1- and 2-year-old branches of green and yellow trees for genetics studies at the end of summer. Genetics studies were done by analysis of peroxidase and esterase enzymes. Results showed problems of management including: 1- Monoculture of *Haloxylon*; 2- Unsuitable distance in planting; 3- Intraspecies competition; 4- Use of unsuitable seeds for planting; 5- Uncontrolled grazing by camel in natural *Haloxylon* habitat.

Testing the Effects of Fertilization and Liming for the Restoration of Forest Stands in Air-polluted Regions

Jiri Kulhavy
Mendel University of Agriculture and Forestry, Institute of Forest Ecology,
Zemedelsk 3, 613 00 Brno, Czech Republic
Tel: 00420 5 4513 4180, FAX: 00420 5 4513 4180,
Email: kulhavy@mendelu.cz

The present condition of Norway spruce stands in air-polluted regions of the Czech Republic is not satisfactory. The pollution manifests itself in the increased defoliation and frequent occurrence of symptoms characterizing the direct effect of air pollution. Yellowing of stands due to the long-term effects of acid depositions and the following decrease of bases in soil are very evident. Based on the reasons it is clear that inevitable revitalization measures will be necessary in the future.

The aim of the study was to test the application of PHOTOMAG+ (pure solution of magnesium monohydrogencarbonate Mg (HCO3) and dolomitic limestone for improving the condition of forest stands in selected areas. Aerial application of PHOTOMAG+ and liming were carried out in three spruce stands 78-98 years old situated at 1000-1200 m altitude of the Jeseníky Mts.and 30-50 yr old stands at 700-800 m in the Krusne hory Mts. (Erzgebirge). The stands exhibited marked symptoms of yellowing (Mg deficit) and a relatively high degree of defoliation before application. The proportion of trees showing yellowing and the proportion of yellowing needles were recorded in particular. Yellowing intensity was highest in older needle year-classes (≥ 3rd-4th needle year-class). In a short time after its application (4 months), PHOTOMAG+ significantly increased the value of efficiency of primary photochemistry of photosystem 2, induced increased reparation of damage of the inner photosynthetic apparatus of needles and markedly stimulated photosynthetic assimilation of CO_2 (particularly due to the increased ability to utilize lower values of radiation). The preparation did not significantly affect the structural components of the photochemical apparatus and this fact manifested itself in small changes of values in the rate of transport of electrons. Some 15 months after PHOTOMAG+ application, a perceptible but not significantly positive effect of improved photosynthesis was recorded as well as an evident tendency in ceasing its effects.

PHOTOMAG+ application caused a significant increase in Mg and Ca content in needles and im-proved balance in nutrition. With respect to the considerable deficit of these elements, however, the dose used was not able to replenish the elements to the level necessary for sufficient nutrition. As for micro-elements, the level of Zn and partly also Cu nutrition was improved.

PHOTOMAG+ application caused increase in the content of total and available (Mehlich II) Mg and Ca in soil and a positive change in soil pH occurred to a more acceptable level from the viewpoint of requirements for the uptake of nutrients by forest trees and for decomposition processes in soil.

Significantly positive effects of Photomag application were found of previous applications of dolomite limestone. In spite of the fact that the application of dolomite limestone was carried out in 1992, its effects were significant in the higher content of Ca and Mg both in needles and soil, in the better bal-ance of nutrition and in the lower occurrence of yellowing symptoms. The effect of the application of dolomitic limestone in the Krusne hory Mts., with respect to a short period which elapsed from the time of liming, manifests itself in the decrease of acidity in the upper layer of soil being negligible as for mineral nutrition improvement. It is possible to conclude that revitalization measures in Norway spruce stands in the region are highly substantiated. The results show that PHOTOMAG+ and crushed dolomite lime-stone application can improve health conditions of stands in air-polluted regions. PHOTOMAG+ applica-tion can be recommended for increasing the resistance of young stands, where the initial symptoms of Mg deficiency are observed or where it is necessary to delay the dieback of stands fulfilling the protection role in the course of their regeneration.

Structural Development and Silvicultural System *of Pinus densiflora* Stands in Kyushu, Southern Japan

Takashi Kunisaki
Iwate University, Department of Agronomy and Forestry, 020-8550 Morioka, Japan
Tel: +81-19-621-6279, FAX: +81-19-621-6279, Email: kunisaki@iwate-u.ac.jp

This study describes the stand structure and individual tree growth of *Pinus densiflora* (Pd) secondary stands, on 6 sites in the *Abies firma* (Af) and *Tsuga sieboldii* (Ts) forest zone between cool and warm temperate zone. The study objectives are to clarify quantitatively the structural development pattern and to design an extensive silvicultural system of Pd stands.

The stands has high basal area of Pd, Ts and Af but few broadleave trees. Stands stratification is as follows: Pd in the uper layer; Ts, Af and tall broadleave trees in the intermediate layer; Ts, Af, tall broadleave trees and shrubs in the understory. Pd didn't exist in intermediate and understory layers, because it is a intolerant species. Age differences between sample trees of different heights, from each Pd, Ts and Af single cohort stand, is less than 10 years.

At stand starting stage, Pd upper layer trees has the greatest height and dbh growth rates. Af, Ts and broadleave intermediate trees has lower growth rates. Differences in height and dbh among Pd, Ts and Af increases with stand development. However, height growth rates for Pd, Ts and Af became about the same after Pd reaches 40 years.

At stem exclusion stage, above 40 years, species dominance status changes with stand development. Pd decreases, and Ts, Af and tall broadleave trees increases. Size dbh hierarchy and height distribution for Pd populations simplifies, but for Ts and Af populations developes with stand development. Differences in dbh among Pd, Ts and Af increases, but differences in height are steady and decreases with stand development. In the future, Pd stands shifts to Ts and Af stands, because the height difference among Pd, Ts and Af decreases with stand development and Pd is supressed by Ts and Af under interspecific competition for light at ages above 80 years.

An extensive silvicultural system was designed for Pd stands. Target Pd timber production is as follows: log diameter bigger than 40 cm and log length greater than 4 m. The target Pd population is as follows: rotation age, 150 years; mean dbh, 57 cm; mean height, 26 m; stand density, 150 trees/ha; stand volume, 437 m^3/ha. The silvicultural type is the clear cut spatially dispersed and natural seeding regeneration. The tending operations, weeding, cutting of woody vines and cleaning are conducted at stand starting stage. Population density is controlled through natural thinning at stem exclusion stage. When stand is 80 years old or stand density is close to target density, Ts and Af trees higher than 12 m are cut to prevent decreasing Pd stand density following competition for light among Pd, Ts and Af. When the stand age is 150 years, Pd stands are clear cut and new Pd stands are created by natural seeding regeneration. This makes it possible to conduct Pd sustainable timber production.

Mast Fruiting as a Dynamical Feature of Flowering and Subsequent Survival to Mature Acorns, in a Japanese Deciduous Oak, *Quercus mongolica* var. *grosseserrata*

Shigeo Kuramoto
Shikoku Research Center, Forestry and Forest Products Research Institute,
Asakura-Nishimachi 2-915, 780-8077 Kochi-city, Japan
Tel: +81+88+844+1121, FAX: +81+88+844+1130,
Email: shkura@ffpri-skk.affrc.go.jp

Keywords: Mast fruiting; Acorn; Fruit set, Oak

In order to understand the proximate causing of mast fruiting, I studied mast fruiting pattern for *Quercus mongolica* var. *grosseserrata*, a major canopy tree in cool-temperate forests in Japan, with special reference to flowering and subsequent flower survival to acorn maturation. I observed flower and acorn production on shoots, and survival of flowers to mature acorn, at crown surface of trees growing a natural deciduous broad-leaved forest in northern Japan from 1990 to 1996. I also estimated pollen production in the stand using litter traps, as the indicator of pollen supply under natural condition. To detect the effects of pollination success on acorn production, I also conducted artificial pollination experiments.

Female flowers were produced every year although showed yearly fluctuation. Pollen production followed same trend of female flowers. Acorn production, however, was intermittent and restricted in some years, such as 1992 and 1994. Annual acorn production was correlated with survivorship of flowers to mature acorns (hereafter; Fruit set), not with flower abundance. Fruit set varied annually, and higher in mast years compared to non-mast years. Key factor analysis revealed the importance of early stage survival as the determinant of the annual acorn production. In non-mast years, artificial pollen supply increased survival of flowers in early stage, not acorn production. In mast year, however, higher early stage survival under natural condition as well as that on under artificial pollen supply, resulted large acorn production.

These facts suggest that pollination failure is the important cause of non-mast years because of severe flower abscission. Because pollination failure was irrespective of pollen production, external factors especially weather conditions at the pollination must be considered as the determinant of pollination success. It was implied that initial acorn crop which was determined by pollination success might affect the Fruit set. Success of pollination, and high fruit set after pollination, which was related high pollination success, can be required for mast years.

Patterns of Putative Ectomycorrhizal Basidiome Production in a Lowland Rain Forest in Peninsular Malaysia

Su-See Lee, R. Watling
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603-6365531, Email: leess@frim.gov.my

Keywords: Ectomycorrhizas, basidiome production, rain forest, tropics, Peninsular Malaysia

The rain forests of Peninsular Malaysia are dominated by the ectomycorrhizal *Dipterocarpaceae*, one of the most important families of timber trees in South East Asia. As with other host plants ectomycorrhizal fungi have been demonstrated to enhance uptake of phosphorus and improve seedling growth of some dipterocarp species. In the northern hemisphere ectomycorrhizal fungi are also known to play important roles as indicators of ecosystem health and monitors of soil disturbance.

The main groups of ectomycorrhizal fungi involved in the symbiotic association with dipterocarps are members of the *Amanitales*, *Boletales*, *Cantharellales*, *Russulales* and several hypogeous taxa, all members of the *Basidiomycot*a. Between 1992 and 1997 collections of putative ectomycorrhizal fungi were made in Pasoh Forest Reserve, a lowland dipterocarp forest located approximately 140 km south-east of Kuala Lumpur, the capital of Malaysia under the auspices of various joint collaborative projects. The main aim of these collections was to examine the frequency of basidiomes of putative ectomycorrhizal fungi in logged and unlogged lowland rain forest. Collections were made during March in each year and additionally in early September 1995 and late August 1996, coinciding with the two predicted annual rainy seasons of February-March and July-August. During each visit of about three days duration, collections were made along the Main Trail, Nature Trail, around Ecological Plot 1 and the Arboretum. Beginning from 1995, collections were extended to the newly established regeneration plots, A-E.

A total of 290 species, distributed in 19 families were recorded with many of the collections being new to science. For the purposes of comparing basidiome fruiting patterns in this presentation, collections made from the regeneration plots are excluded. Although collections were made at approximately the same time(s) each year, the number of species collected each year varied considerably from a low of 45 species in 1993 to a high of 107 in 1995. While the higher number of species encountered in 1995 may be attributed to two collections that year, this did not hold true for the following year when only 53 species were recorded despite collections being made in March and late August. In fact, the number of species found in just one short visit in 1992 (87 species) far exceeded the numbers recorded in 1996. As in Europe and North America, erratic fruiting appears to be a feature of the Malaysian lowland rain forest. It is unclear as to why this occurs. The following are possible reasons for this phenomenon: the frequency and abundance of fruiting may be influenced by seasonal or local weather patterns and/or host-fungus relationships; the fungal mycelia could require a certain length of time for accumulation of sufficient energy for basidiome production; grazing or feeding intensity by animals could influence fruiting. Members of the *Russulaceae* were always the most numerous in each year's collections with the exception of 1997 when surprisingly only 4 species of this family were collected. Much work remains to be conducted on the taxonomy of the Malaysian *Russulaceae* as many of the collections have distinctive differences in morphology and life-strategies from the temperate and West African taxa. Members of the *Boletaceae* and the *Amanitaceae* were the next most frequently collected species followed by members of the *Cantharellaceae* and *Cortinariaceae.* Members of the other families were less frequently encountered and often only single specimens were found. Several hypogeous fungi were also recorded, refuting the claim that such fungi are absent from tropical rain forest. Ideally a much longer period of study than that available to the present researchers is required to obtain more meaningful results.

Nitrogen Supply Effects of Seabuckthorn *(Hippophae rhamnoides* L.) in Poplar Plantations in Dry Subhumid Area of China

Shirong Liu
Chinese Academy of Forestry, Research Institute of Forest Ecology, Environment and Protection, 100091 Beijing, China
FAX: 86-010-62884972, Email: liusr@prot.forestry.ac.cn

Poplar is a fast-growing and high-yielding tree species in dry subhumid area of China, but its growth is affected by nutrient and water stresses. This species is being managed over successive rotations with continuous cropping. Introduction of the seabuckthorn into pure poplar plantations may lead to significant changes in organic matter decomposition and nutrient recycling, and hence to an increase in tree growth and biomass production. The objectives of the study were: to determine responses of soil nutrient availability and nutrient cycling processes of poplar plantations mixed with seabuckthorn; and how these responses vary with mixing patterns or poplar varieties.

Nitrogen supply effects of seabuckthorn in poplar plantations in a dry subhumid area of China were examined over 3 years in different poplar varieties (*Populus* 'Xiaohei', *P.* 'Zaoling06' and *P. euramericane* cv. 'N3061'), and in two different mixing designs (individual- or strip-mixing patterns). The positive effect of seabuckthorn on tree growth was found in the poplar plantations, irrespective of poplar variety or mixing pattern. The aboveground net primary productivity were significantly larger (27% to 113%) in the mixed stands than in the pure stands, regardless of poplar variety or mixing pattern. The increases was due largely to the contribution of the mixed seabuckthorn plants, accounting for 20% to 41% of the total above-ground net productivity. The concentrations of N, P and K were found to be significantly higher in the seabuckthorn leaves than in the poplar leaves. Nutrient concentrations in poplar tissues were frequently larger in the mixed stands than in the pure stands, but the nutrient concentrations varied with elements and varieties. The concentrations of soil total N and available N were 86-164% and 19-36% higher in the mixed stands than in the pure stands. The enhanced growth was not always correlated with foliar N concentration, but related to the increased annual amount of N uptake. The annual nutrient returns in the poplar mixed stands were enhanced, as the ratios of annual nutrient return to uptake were higher in mixed stands than in pure stands. This implied that there was a large amount of nutrients involving in the nutrient recycling processes in the poplar stands when mixed with seabuckthorn.

In conclusion, a growth response to the occurrence of seabuckthorn was possible in poplar plantations under the nutrient-deficient and seasonal drought stress in the dry subhumid climate of China. The growth enhancement of poplar tree was largely attributed to the increased availability of soil nutrients, especially N. The increased N availability was the result of one or more of the followings: the increased N inputs into the soil through N -fixation by root nodule, good-quality litter fall, and rapid nutrient recycling. Seabuckthorn acts as an N pump and plays an important role in maintaining sufficiently stable N availability in concert with rapid poplar growth. Seabuckthorn was characterized by its high ratio of leaf to stem, relatively rapid turnover, and high tissue nutrient concentrations, as well as its important function of N-fixation. The importance of seabuckthorn in modifying soil chemical processes and elemental cycling would be signified in view of long-term site productivity and sustainable productivity in poplar plantations, in particular, under successive rotations with continuous cropping on the same sites.

Influence du Pâturage, par Trois Ruminants Domestiques, sur la Dynamique de la Végétation du Nord de la Côte d'Ivoire

Dominique Louppe, N'Klo Ouattara , Coulibaly Zoumana & Jean Cesar
CIRAD-Forêt, BP 5035, 34032 Montpellier, Cedex 1, France
Tel: +33-4-67615800, FAX: +33-4-67593755, Email: dominique.louppe@cirad.fr

Mots-clés: savanes soudano-guineennes, pâturage, bovins, ovins, caprins, vegetation herbacée et ligneuse, Côte d'Ivoire

Dans le Nord de la Côte d'Ivoire, les troupeaux sont dirigés vers des espaces boisées et quelques jachères eges qui sont les principales ressources fourragères actuelles en raison de l'extension des superficies cultivées. Ces espaces étaient source de bois d'oeuvre, de l'énergie, des ressources alimentaires, de la pharmacopée, etc. car ils servaient de biotope et de nombreuses espèces animales et végétales. Il est urgent d’aménager durablement ces espaces menaceés pour garantir l'avenir des formations boisées et la perennité des produits que les hommes en retirent. Pour cet aménagement durable, la connaissance de l'impact du betail sur la végétation est essentiel.

L'étude a été menée dans les environs de Korhogo. Le climat y est de type soudanais humide. L'unique saison des pluies, de mai à octobre, apporte 1.200mm d'eau. Les regimes alimentaires des bovins, ovins et caprins ont ete étudies dans un dispositif experimental récent (1995) par la methode des "coups de dents" décrite par Guerin en 1988. L'impact de deux troupeaux, l'un exclusivement bovin l'autre mixte: bovins + ovins + caprins, sur la végétation herbacée et ligneuse est analysé comparativement et une mise en defens. La registration des arbres a, tout particulierement, etait suivie par comptages, mesures et cartographie sur des parcelles unitaires de un are (5 pour chaque troupeau + 10 mises en défens). Apres trois anneés, il est possible d'estimer l'effet du pâturage sur la régénération des especes, et s'il y a un risque de modification irreversible du milieu.

Les bovins consomment préférentiellement, 90% les graminées, les ovins mangent 80% d'herbacées et les caprins 80% de ligneux et subligneux.

Apres trois ans, le développement de la végétation ligneuse est fortement reduit par le troupeau mixte. L'abroutissement, par les caprins essentiellement, des branches basses et l'écorage plus ou moins important des troncs, ralentissent la croissance des arbustes. La consommation des jeunes semis, sauf pour quelques rares especes particulières, empêche la reconstitution de la strate arbustive.

Au contraire, l'espace est récolonie par les ligneux dans les parcelles bovines exclusifs. Le houppier des plants dejà installes se développe sans contrainte. Pourtant, la régénération des ligneux ne peut pousser et le tapis herbacé est fortement degradé par la surconsommation des graminés les plus appetées. La mise en defens favorise la croissance, lente, des régénérations des ligneux.

Afzelia africana: une Essence Précieuse et Plastique

Dominique Louppe
CIRAD-Forêt, BP 5035, 34032 Montpellier, Cedex 1, France
Tel: +33-4-67615800, FAX: +33-4-67593755, Email: dominique.louppe@cirad.fr

Afzelia africana est un grand arbre de la famille des Césalpiniacées dont le bois, de grande qualité, est recherché par les industriels du bois sous le nom de “lingué” ou parfois de “doussié”. Son fût, généralement droit et cylindrique, est court en zone de savane et long et parfaitement élagué en zone forestière. De plus, c’est une espèce à usages multiples au feuillage fourrager, aux graines oléagineuses fréquemment utilisées en médecine traditionnelle.

L'aire naturelle d'*Afzelia africana*, en Afrique occidentale et centrale, est vaste. C’est une des rares espèces arborées dont l'aire de répartition va des zones sèches (précipitations de 900mm/an) jusqu'à la forêt dense semi-décidue. Ce n’est pas une essence grégaire. Les arbres sont généralement disséminés, très rarement en bouquets. En milieu naturel, cette espèce ectomycorhizienne montre une grande plasticité vis-à-vis des conditions pédologiques. Néanmoins, plus le climat est sec, plus elle recherche des sols profonds, bien draînés et approvisionnés en eau.
Cependant, *Afzelia africana* risque de disparaître car cette espèce est très sensible aux feux qui empêchent sa régénération naturelle.

L’élevage en pépinière est aisé et court (plants en pots) si un prétraitement adéquat est appliqué aux graines. Des essais en plantation en plein, sans ombrage, ont été réalisés en Côte d’Ivoire, aussi bien en zone de savane, de forêt dense semi-décidue que de forêt dense sempervirente. En zone de savane, la croissance initiale est lente (2,6 m de hauteur en moyenne à 8 ans) mais fortement influencée par les conditions de sol : elle peut atteindre 1 cm par an en diamètre sur termitière où les sols sont les plus fertiles. En zone de forêt dense semi-décidue, la hauteur moyenne est de 16 m à 17 ans avec une croissance de 0,7 cm par an sur le diamètre. En forêt sempervirente, elle atteint 19 m de hauteur au même âge. Dans les deux derniers cas, en zone forestière, le fût libre, droit et cylindrique, peut atteindre 10 m.
On peut escompter une utilisation industrielle de qualité des bois issus de plantations. Bien que sa croissance soit assez modeste, la valeur du bois et son aptitude à croître en peuplements mono-spécifiques, font de *Afzelia africana* une bonne essence de reboisement économiquement intéressante en milieu favorable.

Mots-clés: *Afzelia africana*, bois, plantation, croissance.

Isoberlinia doka: une Essence Méconnue et Abondante pour une Production Durable de Bois d'Oeuvre en Forêts Claires Soudano-Guinéennes

Dominique Louppe
CIRAD-Forêt, BP 5035, 34032 Montpellier, Cedex 1, France
Tel: +33-4-67615800, FAX: +33-4-67593755, Email: dominique.louppe@cirad.fr

Isoberlinia doka Craib & Stapf. est un grand arbre de la famille des Césalpiniacées qui peut dépasser 23 mètres de hauteur et 70 cm de diamètre. C’est un arbre des forêts claires soudano-guinéennes

d'Afrique de l'Ouest, où il domine fréquemment au sein des forêts denses sèches dégradées par le passage répété des feux.

Le fût est généralement droit et cylindrique. Le bois parfait, brun rosé, présente des veines gris violacé d'un bel effet esthétique. Le rendement au sciage sous écorce est de 52% avec aubier et de 31% pour le bois parfait seul. C'est un bois mi-lourd, mi-dur et moyennement nerveux mais cassant. Il est utilisable pour les panneaux, la menuiserie et l'ébénisterie. Néanmoins, il est peu utilisé faute d'unités de transformation et de valorisation dans son aire naturelle.

Cette essence est délicate à élever en pépinière et sa croissance est particulièrement lente en plantation : en moyenne moins de 2 mètres à six ans au sein de parcelles de recherche bien entretenues.

En forêt naturelle au Nord de la Côte d'Ivoire, celle de Badénou par exemple, *Isoberlinia doka* est l'essence dominante tant en nombre d'individus à l'hectare qu'en volume sur pied. Cependant, le peuplement d'*Isoberlinia* est déséquilibré par une régénération réduite du fait de passages très fréquents du feu. Cette insuffisance de régénération ne permet pas de garantir l'avenir de cette espèce.

Il est impératif de supprimer les feux pour permettre à *Isoberlinia* de se régénérer. Après exploitation à blanc-étoc de la forêt et trois années de protection, on observe une forte régénération de *Isoberlinia*, aussi bien par rejets et drageons que par semis. Par contre, dans la savane boisée non exploitée, sous le couvert des arbres, les semis naturels et les drageons sont rares ; les rejets proviennent essentiellement de souches régulièrement endommagées par les feux.

Ainsi, dans les espaces régulièrement parcourus par les feux de brousse, l'espèce reste néanmoins abondante dans la strate de régénération car les souches résistent aux feux courants. Par contre, ces souches et les jeunes plants traumatisés ne donneront jamais de bois d'oeuvre même si les feux sont arrêtés. Les déformations subies dans le jeune âge semblent rédhibitoires et se concrétisent à l'âge adulte par une pourriture humide du bois de coeur, parfois sur deux ou trois mètres de haut.

Mots-clés: *Isoberlinia doka*, bois, croissance, régénération, aménagement.

Mixed Stands Silviculture and Management in Portugal - Preliminary Results

Jaime Sales Luis, Angelo Carvalho Oliveira and Maria do Loreto Monteiro
UTAD-Florestal, 5000 Vila Real, Portugal
FAX: 351-59-350480, Email: jfsl@utad.pt

In Europe there is a renewed interest in the mixed-species stands creation and, when the sites permit, in the steady change from pure to mixed-species stands, of softwood with broadleaves. This interest is due to the knowledge that mixed-species stands are, in general, ecologicaly more stable and less susceptible to the risks of natural catastrophes (wind, fire), provide a better quality A-horizon soils, improve the natural stand regeneration conditions and, guarantee the benefits from associate forest products.

In Portugal, three research studies are being developed whose results will allow a definition of mixed stands silvicultural and management models, providing an important contribution for the social, economic and aesthetical valuation of the rural landscape. A set of six research plots, organized in a randomized block design with two replications, were measured in Rossas, Bragança (northeastern Portugal). These plots are designed to analyse the *Castanea sativa* productivity under different species composition and management alternatives: control; selective removal of *Pinus pinaster*, selection and tending of *Castanea sativa* crop trees; removal of *Pinus pinaster*, selection and tending of *Castanea sativa* crop trees. *Pinus pinaster* top height (15m) at plot installation age (24yrs) places the study location in a medium-high site class (20m at 50yrs). The basal area increment (95-98), for the control plots, is 0.9 m^2/ha for *Castanea sativa* and 1.6 m^2/ha for *Pinus pinaster*.

A set of twenty one research plots, organized in a replacement series of a substitutive randomized block design, with seven types of mixtures and three replications, were measured in Bemlhevai, Bragança (northeastern Portugal). These plots are designed to analyse the growth and potential productivity of *Castanea sativa* and *Pseudotsuga menziesii* mixed stands and the long-term individual performance of *Castanea sativa* component. *Castanea sativa* top height values range from 3.1 to 9.1 m, in monoculture, and from 2.6 to 9.4 m in mixture. For *Pseudotsuga menziesii*, these values range from 3.2-11.7m in monoculture, and from 2.8-12.9m in mixture. A clear benefit on both species productivity is steadly increasing with time in mixtures 1, 2 and 3, in which the interspecific competition effect is

present, corresponding to relative yield total values greater than 1,0. From the economic point of view, the most productive mixtures (1 and 2) are also very competitive when compared with the traditional solution of *Castanea sativa* monocultures in most mountain regions.

A set of three research plots were installed and measured in Lousã mountain (central Portugal), covered with *Pinus pinaster*, *Castanea sativa* and *Quercus* spp. These plots were designed to analyse species composition changes under different thinning alternatives: control; 30% removal of crown cover; 50% removal of crown cover, providing mixed compositions, ecologicaly and environmental more balanced, in the scope of a modern multifunctional silviculture that harmonizes the wood production with other social forest benefits. *Pinus pinaster* is dominant in all the plots, with an average of 90% in basal area and ranging from 44 to 71% in number of trees, but only with an average of 37% in crown cover. The crown cover removal under the different thinning alternatives requires an accurate selection criteria, using plots crown charts, in order to mantain a dynamic balance in the species composition.

Present Status of Cropland Agroforestry Systems of the Northern Bangladesh

Md. Millat-e-Mustafa
University of Chittagong, Institute of Forestry and Environmental Sciences, 4331 Chittagong, Bangladesh
Tel: 00 88 031 714914, FAX: 00 88 031 714914, Email: sakif64@hotmail.com

Keywords: Cropland, Bangladesh, component, arrangement pattern, interaction, rotation

An exploratory survey to assess the present status of cropland agroforestry systems of the Northern Bangladesh with respect to component, arrangement pattern, tree density, interactions of the components and management interventions adopted by the farmers were carried out over a period of one year (1999). From the 26 districts of the Northern Bangladesh, one district (Jhenidah) was picked randomly followed by the random selection of a village (Sabek Binni) within it. The village Sabek Binni shares important environmental, farming system and socioeconomic characteristics widely found in Jhenidah district. A complete list of the farmers with cropland agroforestry of Sabek Binni was made and 30 farmers were selected randomly from this list for detailed study. A species inventory followed by PRA techniques involving combination of semi-structured interview, participatory observation, and group discussions were adopted to collect the data.

The 30 crop fields surveyed varied in size from 0.24-0.85 ha with a mean of 0.58 ha (sd±m=3.89). Farmers grew different varieties of rice, wheat, and seasonal vegetables (e.g., *Phaseolus spp., Dolichos lablab, Ipomoea batatus, Colocasia antiquorum,* and *Cucumis sativus*) in their crop fields, either in mixture with trees or in patches, all primarily for household consumption and for sale in case of any remaining surplus. *Mangifera indica, Phoenix sylvestris, Acacia nilotica* and *Dalbergia sissoo* were deliberately retained in the crop fields, and recorded from all the farms surveyed. Apparently, these were the species preferred by the farmers for multiple outputs and commercial values in the region. Three types of arrangement patterns of trees in the crop fields were identified: alley cropping, scattered planting and border planting. The arrangement patterns depended on the types of the trees grown and size of the lands. Fruit trees were usually grown in larger sized lands (≥0.4 ha in size) in alleys with regular spacing (2.7 m x 13.5 m for *Phoenix sylvestris* and 4.5m x 13.5m for *Mangifera indica*). Timber species were grown in smaller sized lands (<0.4 ha) with scattered distribution. In both cases, a minimum of 9m patch surrounding the plot from the aisle was retained for growing agricultural crops. Border planting was restricted only in the common aisle of two successive lands owned by the same landlord and both fruit and timber trees were grown in mixture with a tree to tree distance of 4.5-9m in line. Mean tree density ha^{-1} varied from 61-102, 40-52, and 50-70 for the arrangement patterns alley cropping, scattered planting, and border planting respectively. Farmers were well aware about the competitive interactions between the components. Farmers opined that with the augmentation of tree canopy and root system, crop losses became significant after 3-5 years of tree planting due to competition for light and nutrients. Farmers maintained a regular pruning schedule to keep competition for light and nutrients between trees and crops to a minimum. Moreover, different tree based products (e.g. fruits, molasses, raw materials of handicrafts, fuel, timber etc.) which were becoming available at that stage compensated their crop losses even many folds. Farmers maintained rotations of 12-15 years for *Acacia nilotica* and *Dalbergia sissoo*; 20-25 years for *Phoenix sylvestris*; and 40-45 years for *Mangifera indica* in the crop fields.

Evaluation of Thinning Effects on the Productivity and Regeneration in Conifer Plantations, Using the Canopy Dynamic Model

Hiromi Mizunaga
Kagoshima University, Faculty of Agriculture, 1-21-24 Koorimoto, 890-0062 Kagoshima, Japan
Tel: +81-99-285-8572, FAX: +81-99-285-8572, Email: mizunaga@env.agri.kagoshima-u.ac.jp

Keywords: thinning, canopy structure, conifer plantation, gap

The thinning makes changes on the stand structure, productivity and microclimate in the stand through the changes of the canopy structure, like the creation of the artificial canopy gaps. The author constructed the canopy dynamic model for simulating the changes of foliage distribution, stem volume increments and spatial distribution of photosynthetic photon flux density (PPFD) in the stand during the closure of thinning gaps. The aim of the model is to evaluate the efficiency of different sorts of thinning in the plantations of conifer species, mainly *Cryptomeria japonica* or *Chamaecyparis obtusa*.

The model was composed of following four integrative parts.

1) The three-dimensional shape of canopy surface was simulated from the three-dimensional positions of the tree apex and the crown form, which was represented by the simple formula.

2) The plot was divided into small (0.2m x 0.2m x 0.2m) cubes. The foliage-mass density within the small cube in the canopy was determined from the location of the cube (the vertical distance from crown surface and the horizontal distance from the stem), and the tree size. Hence, the foliage distribution within the individual crown or within the stand could be estimated from the location of the stem base, the tree height, and Dbh of individual tree.

3) The stem volume increments and the stability of the crowns, which may relate with the resistance to the wind damages or heavy snow damages, were determined from the foliage distribution in individual trees.

4) The spatial distribution of PPFD in the stand was simulated from the estimated hemispheric diagram based on the spatial distribution of foliage and stems, and the topology of the ground.

The verification of this model suggested its availability as follows.

1) The simulated reduction of canopy gap ratio after thinning showed similar pattern and the speed to the actual reduction, which were reported previously.

2) The simulated foliage mass, stem volume increments and production diagram of individual trees corresponded to the measured values.

3) The PPFD in the stand was simulated well in daily totals. The model also predicted a frequency pattern of PPFD with sufficient accuracy for evaluating the thinning effects on light availability. Consequently, it is possible to predict the foliage distribution, the stem volume increments, and the light availability in the stand, although the model requires only the three-dimensional position of the bases and initial heights of individual trees as the individual data. The practical information for thinning effects on the productivity of stem volume, the stability of crowns, and the light availability at the forest floor was obtained by running the simulation model with different thinning intensities or types, as follows.

1) The increment of stem volume increased with thinning intensity. The line thinning showed less effect on the foliage weight that other thinning type did.

2) The shifting upward of foliage distribution accompanying with tree-height-growth was reduced with an increasing in the thinning intensity.

3) The line thinning enlarged the eccentricity of crowns more than other thinning type did, showing the tendency to lose the horizontal stability of crowns.

4) Spatial variance of the assimilation rate of seedlings was estimated in the plantation which was thinned by line thinning. The gap size influenced on the assimilation rate of seedlings beneath the canopy gap, while around the gap, it had a little influence on the changing pattern of the assimilation rates with the distance from gap edge.

Effet du Délianage sur la Régénération Naturelle en Forêt Dense Humide Soumise à un Traitement d'Éclaircie

Anatole N'Guessan, Fako Doumbia & Aim, Diahulssie
CNRA, 08 BP 33 Abidjan 08, Côte d'Ivoire
Tel: +225-44 28 58, FAX: +225-44 21 08, Email: louppe@africaonline.co.ci

Mots-clés: forêt dense humide, régénération naturelle, pérennisation, délianage, eclaircie, Côte d'Ivoire.

La régénération naturelle est l'élément principal de la pérennisation d'une forêt. Les processus de régénération apparaissent dans des conditions naturelles (chutes d'arbres) ou suite aux interventions humaines (exploitation forestière). Cette étude, débutée en 1993, a pour but d'apprécier l'impact du délianage sur la régénération naturelle en forêt dense sempervirente. Elle entre dans le cadre des recherches visant à offrir des conditions favorables optimales à la régénération naturelle.

Quatre années après la mise en place de ce dispositif, les résultats partiels obtenus sont les suivants: (1) on observe une disparition progressive des lianes quel que soit le traitement (éclaircie ou témoins non éclaircie); (2) le délianage favorise une régénération naturelle des essences principales dans les parcelles éclaircies avec un taux d'augmentation de 2%. Cette régénération est plus importante dans les parcelles éclaircies que dans les parcelles témoins non éclaircies. C'est l'inverse en ce qui concerne les essences secondaires; (3) le délianage semble favoriser l'apparition de nouvelles essences principales telles *que Pycnanthus angolensis* (Ilomba), *Piptadeniastrum africanum* (Dabema), *Lovoa trichilioïdes* (Dibetou), *Canarium schweinfurthii* (Aiélé) et *Eribrema oblonga* (Bi).

Rehabilitation Techniques for Degraded Mixed Dipterocarp Forest in Consideration of Ecological Process

Yasuyuki Okimori
Biological Environment Institute, KANSO Co. Ltd, 8-4 Ujimatafuri, 611-0021 Uji, Japan
Tel: +81-774-21-5001, FAX: +81-774-21-5005, Email: yasoki@aol.com

Secondary forests have been spreading by mechanized logging, illegal logging and slush-and-burn agriculture in mixed dipterocarp forests. Proper methods of rehabilitation technique are needed to prevent degradation of these secondary forests. Objective of this research is to study effects of several rehabilitation methods on different types of degraded vegetation by means of, particularly, enhancing natural regeneration and application of enrichment planting in collaboration with Gadjah Mada University. The research station was in Jambi province, central Sumatra, Indonesia.

Tree vegetation around the research station is roughly classified into residual forest after logging, secondary forests after abandonment of slush-and-burn agriculture, rubber plantation, *Imperata cylindrica* grassland, etc. Methods of reforestation should be adapted to the degraded conditions of vegetations and their aims at reforestation. Some methods have been considered like an enrichment planting of dominant species, a mix-planting of dipterocarps with fast-growing species, an underplanting by natural pioneer trees, etc. 1) Releasing trees for creating artificial gaps enhance the growth of natural dipterocarp saplings, however the population structure may not become steady. 2) Enrichment planting exceeds the natural sapling growth under the forest. The species and releasing intensity should be best in moderate light intensity. 3) Mixed planting of dipterocarp seedlings with fast-growing trees or rubber trees. Both of the above methods are applicable to rehabilitate the logged-over forest as a practical method. Combination should be more considered on silvicultural system between the enhancement of natural saplings and the enrichment plantings. Further, our project has effectively combine seedling production of dipterocarps by practical inoculation method of ectomycorrhizal fungi.

The important thing is how to integrate these ecological techniques to the actual reforestation and rehabilitation projects in consideration of cost-performance. These problems also shall be discussed using some cases.

Regeneration of *Cryptomeria japonica* on Stumps in Natural *C. japonica* Forest in Northern East Region of Japan

Takayuki Ota, Takeshi Seki and Shozo Nakamura
Tohoku Research Center, Forestry and Forest Product Research Institute, 72 Nabeyashiki, Shimokuriyagawa, 020-0123 Morioka city, Japan
Tel: +81-19-648-3942, FAX: +81-19-641-6747, Email: takaota@ffpri-thk.affrc.go.jp

It is well known that fallen logs and stumps are often important regeneration sites for conifer species. To clarify the mechanism of regeneration of *Cryptomeria japonica* on stumps, a research plot (1.05 ha) was established in Sado natural forest reserve in Akita pref., Japan. Elevation of this plot is 950m a.s.l. and average annual temperature is 5.3°C. Snow depth in winter is about 4m.

DBHs (diameter at breast height) and heights of trees (DBH > 5 cm) were measured in 1992. In this forest, many *C. japonica* were seen on stumps. The regeneration sites were divided into 3 categories; forest floor, fallen logs and stumps. The size of all stumps and logs was measured. The density of trees of *C. japonica* and other species in each regeneration site was compared. Main species in this plot were *C. japonica* and *Fagus crenata*. *C. japonica* occupied 28% of population and 70% of relative basal area. Though the area of stumps is 3% of this plot, 45% of *C. japonica* trees grew on stumps. The density of *C. japonica* trees is 26 times as much as that on the forest floor. The area of fallen logs is 3% of this plot and only one *C. japonica* tree was seen there. Only one tree of *F. crenata* grew on stumps and no trees were seen on logs. So in this forest, stumps are used mostly by *C.*

japonica but neither the forest floor nor fallen logs are suitable regeneration sites for *C. japonica*.

Stumps were classified in 3 types according to vegetation on them: stumps on which *C. japonica* grew, stumps where broad leaved trees grew, and stumps on which no trees grew. The mean diameter and mean height of 3 types of stumps was compared.

Though we could not see any significant difference of mean diameter of stumps in these three classes, the mean height of stumps on which *C. japonica* grew was significantly higher than that of the other two stump classes. It is suggested that the height of stumps is an important factor whether *C. japonica* trees regenerate on them or not.

Seed fall and the dynamics of current seedlings of *C. japonica* have been researched in 32 quadrats (2 x 2 m) on the ground and 14 stumps for 4 years. In winter, under the snow cover, 60% of current seedlings were killed on the ground, though the rate was 20% on stumps.

Survival rate of *C. japonica* seedlings in 3 years is 2% on ground and 20% on stumps. These results confirm our findings regarding the importance of stumps, and stump height, on the regeneration patterns of *C. japonica* in this study.

Underlying Causes of Tropical Deforestation by Modeling Stock and Change Variables at Subnational Level

Matti Palo, Erkki Lehto and Jussi Uusivuori
Finnish Forest Research Institute (METLA), Unioninkatu 40 A, FIN-00170 Helsinki, Finland
Tel: +358 9 857051, FAX: +358 9 85705 717, Email: Matti.Palo@metla.fi

Underlying causes of tropical deforestation were examined in this study. Empirical analysis was based on FORIS Database by FAO and on National Bureau of Economic Research data of Harvard University. FAO data included original random year observations from 1953 to 1991 on forest areas at subnational level. At the largest data set case, 477 observations were used. This is 5-6 times more than we have seen used in other similar deforestation modeling.

Both stock variables (forest area, forest cover, nonforest area, nonforest cover) and change variables (forest area and forest cover changes) were used as dependent variables in the modeling. Reliable change variables are in limited supply. We used 54 subnational observations from 13 Asian and Latin American countries. Independent stock variables included sizes of national and subnational population, national income (GDP) levels, sizes of ecological zones, data reliability estimates plus geographic dummies. Whereas in change modeling we applied only national and subnational population and national GDP as independent variables.

We used multiple regression analysis with ordinary least squares (OLS). All the variables were transformed into natural logarithms. In the stock variable modeling we used first only stock variables and then respectively only their ratio-variables. Regular statistical tests with residual analysis were carried out. In order to rank the independent variables in the order of causality we computed standardized regression coefficients for the independent stock variables.

Our results show that increasing population and GDP expand deforestation at low income levels. This result comes out both from our stock and change variable modeling. This is our prime finding which has global relevance, because other studies have not produced convincing results in this front so far. This causal relationship has been under debate both in the Intergovernmental Panel on Forests and in the Intergovernmental Forum on Forests in the United Nations. We, however maintain a hypothesis, that after a certain per capita income level threshold point, increasing income will start slowing down deforestation and expanding forest area (environmental Kuznets-curve).

Furthermore, the results suggest that ecological conditions as well as the quality of data play decisive roles in deforestation. Ecological conditions are linked to economic accessibility of forests, while the quality of forest data may be linked to the general information infrastructure of a region and hence reflects risks inherent to economic agents in the deforestation processes. One specific value of our modeling is that we experimented with twelve different independent variables. A major debate in deforestation modeling has concerned the relevant choice of the dependent variable. Our six variants of valid deforestation variables proved operational. The respective change variables of population and GDP supported our hypothesis of these relationships. We learned from the stock variable modeling, that when we can identify the factors which control the variation of forest area or relative forest cover at the subnational level, we can also understand better the underlying causes of deforestation. After all deforestation is defined as a decrease in forest area.

Testing Afforestation Methods with *Pinus halepensis* in a Semiarid Mediterranean Site

A. Roldan, J.I. Querejeta and V. Castillo
CEBAS-CSIC, Avenida de la Fama, 1. Apdo. 4195, 30080 Murcia, Spain
Tel: +34 968215717, FAX: +34968266613, Email: aroldan@natura.cebas.csic.es

A factorial field experiment was conducted in a degraded semiarid site of SE Spain, during 6 years, to test the effectiveness of mycorrhization and several soil preparation techniques on afforestation with *Pinus halepensis*. The mycorrhizal treatments tested were nursery inoculation with *Pisolithus arhizus* and forest soil addition to the planting holes. The soil preparation treatments were terracing (mechanical and manual) and addition of organic amendment (Urban Solid Residues).

One year after planting, the study revealed significant differences in mycorrhization levels, frequency of mycorrhizal species, fine root production and growth between the inoculated seedlings and the non-inoculated controls. Inoculation with *P. arhizus* gave better pine growth and mycorrhization rates than the addition of forest soil. Both mycorrhization treatments were particularly effective in combination with mechanical terracing. The pines survival rate was significantly higher in the subsoiled mechanical terraces than in the manual terraces, due to the much greater efficiency of the former to increase the water availability into the soil profile.

The addition of the organic amendment, corrected many of the negative effects that mechanical terracing usually exerts on the physical and chemical properties of soils and fostered the hydrological benefit associated with this land preparation method. The organic amendment had no apparent negative influence on the seedlings mycorrhization level and significantly improved pine growth. Six years after plantation, the *Pinus halepensis* seedlings showed a maximum development in the mechanical terraces with USR, where fertility levels were the highest, soil physical properties were the most favourable and soil moisture availability was the greatest among the land preparation methods tested. The seedlings growth increase with the treatments can be due to the change in soil conditions (increased fertility and soil aireation) and probably to a mycorrhization effect upon water relations, although this has not been clearly demonstrated. The results obtained show that both the survival and the growth of *Pinus halepensis* seedlings can be improved, assuring the success of afforestations even under such harsh drought conditions as those recorded in the experimental area during the 1994, 1995 and 1998 seasons.

Seed and Seedlings Management for Sustainable Dipterocarp Plantations

Shyamal K. Roy, Pinaki Sinha
Jahangirnagar University, Department of Botany, Savar, Dhaka, Bangladesh
FAX: 880-2-833054, Email: shkroy@juniv.edu

Dipterocarps, the rainforest tree species of South and Southeast Asia, are of great economic importance because of their timber. In Bangladesh *Shorea robusta* and *Dipterocarpus turbinatus* are the prime species of *Dipterocarpaceae*. These species are generally propagated by seeds, which are difficult to germinate and lose their viability within a few days. We devised a method for large scale production of plantlets and their propagation all the year round. Seed of *S. robusta* and *D turbinatus* were collected at full maturity. They were kept on the soil at a shady place. Within two days seeds were found to have germinated. Each germinating seed was then placed on the polythylene bag containing alluvial soil and compost (4:1). After six months when the plantlets wer 40-50 cm in height, they were transferred to another place. In an open place soil was dug out upto 25 cm depth. A thick black polyethylene sheet was spread on the pit. Polybags containing plants were kept on it at a distance of 15 cm from each other and filled up with alluvial soil and compost (4:1). After one year the plants were 125-150 cm in height and the roots, instead of penetratig the soil, spead on the plyethylene sheet. The technique was convenient since when the plants were uprooted from the bed for transplanting in the field, practically no injury occurred and 95-100% plants survived. The technique is quite applicable to obtain large scale high quality seedlings and feasible in sustainable management for plantations.

The Urban Forest of Tomorrow - Pre-commercial Thinning Adapted for Use in Urban Areas in Sweden

Dan Rydberg
SLU, Department of Silviculture, S-901 83 Umea, Sweden
Tel: +46 90 786 56 20, FAX: +46 09 786 76 69, Email: Dan.Rydberg@ssko.slu.se

The Swedish urban forests originate mainly from the old production forests and are characterised by the forestry in practise at the time of urbanisation. Forests in the central parts of older urban areas are therefore generally old and senile, while forests situated in newly urbanised suburbs are relatively younger, with proportionally more young stands. In many instances, the areas of young growth in urban green areas of Sweden are in urgent need of management. The aim of this study is to demonstrate the creation of multi-functional urban forests by means of silvicultural thinning techniques to enhance the biodiversity of a regenerating mixed young forest. Twelve different small forest compartments were identified on 2.1 ha of 20-year old forest, all of which were subjected to their first silvicultural thinning. Every forest type services a specific function. The twelve compartments consists of the Rowan Forest, The Children's Forest, the Glade, the High Forest-like Pine Forest, the Untended Forest, the Mixed Forest, the "Walk the Dog" Forest, the Birch Forest, the Ever Juvenile Forest, the Willow Forest, the Multilayered Spruce Forest and the Aspen Forest. For each forest type silvicultural prescriptions are recommended to achieve and sustain the amenity requirements of an urban forest. A variety of silvicultural treatments are suggested for all of these categories in order to create and maintain forest structures adapted to the actual functional use of the forest.

A Soil Seed Bank in a Mature Conifer Plantation in Japan and its Development after Logging

Atsushi Sakai, Ryuichi Tabuchi, Shigeo Kuramoto, Takeshi Sakai and Sigeho Sato
Shikoku Research Center, Forestry and Forest Products Research Institute,
Asakura Nishi-machi 2-915, 780-8077 Kochi, Japan
Tel: +81-88-844-1121, FAX: +81-888-44-1130, Email: golgo@ffpri-skk.affrc.go.jp

Keywords: Soil seed bank; Conifer plantation; Secondary succession

We conducted a study on the composition of buried viable seeds and their development after logging in a mature conifer plantation in order to understand the mechanism of secondary succession. The study site is located in a 76-year-old (in 1998) *Cryptomeria japonica*-*Chamaecyparis obtusa* mixed plantation. Canopy trees were felled on December 1997 and harvested on April 1998. Study sites were established both in the logged area and the reserved control area on March 1998. Integrated insolation in the reserved site was ca. 7% of that in the logged site. For seed bank analyses, soil samples (0.06 m^2 x 5cm in depth) were collected (n=35 for the reserved site and n=30 for the logged site). Each sample was put into a planter and incubated at the nursery for 120 days. Germinated seeds were identified and then removed. Quadrats (1 m^2) were established for seedling census both in the logged site (8 quadrats) and the reserved site (12 quadrats). Emerged seedlings of all woody species and large herbaceous species were tagged once on a monthly basis from May to October in 1998 and their numbers and the heights were recorded. We regarded the number of the emerged seedlings in the planter as the number of buried viable seeds in the field.

The density of buried viable seeds was 1.075 m^{-2} (62 species) for the reserved site and 1.792 m^{-2} (57 sp.) for the logged site. The dominant species of both sites was *Hydrangea luteo-venosa*. Several herbaceous species and *Rubus* spp. were also dominant. The large difference on species composition between soil seed bank and actual vegetation was observed. The soil seed bank was composed of 62 species in the reserved site, while actual vegetation on forest floor was composed of 87 species. There were thirty species common both in the soil seed bank and in the actual vegetation. However, 18 species out of those 30 common species produced no seeds in 1998. It implies the buried viable seeds of many species would be dispersed from the exterior of the study site or possibly dispersed in the interior of the study site when plantation were established or when thinning was carried out.

The density of current-year seedlings was 12.4 m^{-2} (18 species) for the reserved site and 33.4 m^{-2} (28 species) for the logged site. *Abies firma* (8.0 seedling m^{-2}) was dominant in the reserved site, although several pioneer species such as *Macleaya cordata* (4.0 seedling m^{-2}), *Mollotus japonicus* (3.8 seedling m^{-2}) and *Rhus javanica* (2.8 seedling m^{-2}) were dominant in the logged site. The percentage of emerged seedlings to the population of the buried viable seed was 7.7% for the logged site and 1.7% for the reserved site. In spite of the high density of buried viable seeds, most of them did not emerge even in the logged site.

In the logged site, current-year seedlings showed rapid height growth. Two exotic species, *Crassocephaium crepidioides* (mean height=94.3cm) and *Erechtites hieracifolia* (H=126.0cm), were abundant among them, although the densities of seedlings were small. *Mollotus japonicus* (H=25.5cm), *Macleaya cordata* (H=16.8cm) and *Rhus javanica* (H=15.8cm) followed them. In contrast, no seedlings grow over 10cm in height in the reserved site. It is suggested that dominant species after logging is not correlated closely with the density of their buried viable seeds.

Growth and Propagation of Selected Species of *Nepenthes*

H. B. Sani, Dal Awa, K Meekiong, WA Fariza
University Malaysia Sarawak, Faculty of Resource Science and Technology, 94300 Sarawak, Malaysia
FAX: 6082-672275, Email: awi@mailhost.unimas.my

Keywords: *Nepenthes,* growth performance, vegetative propagation, micro-propagation

Nepenthes (commonly known as pitcher plants) of which there are 17 species recorded in Sarawak, thrive on the marginal soil along the roadside and secondary forests. Although they have been gazetted as "protected species" in Sarawak, they are nonetheless harvested extensively for use in traditional medicine and for sale as ornamentals. Preliminary studies were carried out to examine the growth performance of *Nepenthes ampullaria* Jack and *N. mirabilis* (Lour) under low light intensities (shade) and the potential of producing the plants through vegetative propagation by tissue culture and rooting of cuttings. The results showed that *Nepenthes* could survive under low light intensities (85% shade) with no significant reduction in photosynthesis rate and its growth. In fact, the plants grown under low light intensities produced more and larger leaves as well as more and longer pitcher compared to those grown under direct sun light. Vegetative propagation using nodal cuttings showed great potential as an alternative to propagate the species with 42.5% overall rooting success for *N. mirabilis*, 22.5% for *N. ampullaria* and 19.2% for *N. rafflesiana* with the application of industrial rooting hormones. *Nepenthes mirabilis* produced the best results with over 60% cuttings treated with Seradix-1R rooted, followed by *N. rafflesiana* (60% using Seradix-2 R). Experiment on micro-propagation through seeds managed to get 25% of the seed germinated on ½ MS with 6% sucrose media and these seedling were either grew into single seedling or form callus (+ 5.0/L, 2,4-D). The major problem encountered during in vitro germination was the high contamination of seeds by fungi and bacteria although the seeds were surfaced sterilized by soaking the seeds in 30% Chlorox R for 20 minutes. Once the seeds germinated there was no more contamination. Each callus seed produced 150-300 shoots and they were subcultured on ½ MS + 2mg/l IBA.0 5mg/l BAP. After four subcultures it is possible to generate about 150,000 new plantlets in 48 weeks.

Role of Tree Stands in the Rehabilitation of Degraded Lands of Auroville, India

S. Saravanan, C.Buvaneswaran and R.Jambulingam
Institute of Forest Genetics and Tree Breeding, PB 1061, 641 002 Coimbatore, India
Tel: 0422: 431540, 435541, 450302, FAX: 91-0422-430549, Email: ifgtb@satyam.net.in

Agricultural development in the country has converted vast areas of forestland to meet demands on food production. Large chunks of such converted lands were mismanaged in the past without recourse to scientific methods of soil and water conservation. This brought degradation of these lands to the level of abandonment. Protection forestry is now extended to such agrarian regions through planting of fast growing exotics and other indigenous tree species supported by meaningful soil conservation strategies for the past two to three decades. The result of such endeavor against severe odds is the successful greening of wastelands of Auroville, Tamilnadu, India. Investigations were undertaken to assess the long-term effect of these tree planting activities on the amelioration of the highly degraded lands. The study was carried out in 20-year-old mixed stand dominated by *Entrerolobium cyclocarpum* and in the adjacent open area which has not yet been afforested. The objectives of this study were to observe the possible changes, if any, in the microclimatic conditions and the status of microbial proliferation. The productivity of this stand was estimated using biometrical observations made on the trees existing in the demarcated sample plots. Soil temperature was recorded periodically at two different depths (at 5 and 10 cm depths) both under tree stands and in the open site. Similarly soil moisture was estimated gravimetrically both under tree stand and in the open at the two different soil depths. Air temperature was also recorded in these two study sites. Soil samples were collected at two different depths both under tree stand and in the open for enumerating the population of bacteria, actinoomycetes and fungi adopting standard procedure (Parkinson et al. 1971). Tree stand registered mean height of 16.4 m and basal area of 330 m^2/ha. The net primary productivity of this tree stand was 21.2 t/ha/yr. Besides this productivity, the tree stands ameliorated the microclimatic conditions of the site which in turn supported proliferation of microbial population. While the mean monthly soil temperature in the barren site reached 42.3°C. The fluctuation of soil temperature (the difference in the soil temperature recorded at 8 and 12 hrs.) on an average was highest (12.8°C) in the treeless open ground and was only 2.6°C. under the tree canopies at 5 cm depth. Further, the tree stand restricted the fluctuation of air temperature from 6.6 to 9.0°C.

Tree stand enhanced the soil moisture content to 2.8% from that of in the open site (0.7%). This ameliorative effect of tree stands caused proliferation of soil microflora, which serve as an index of site enhancement Increased bacterial population were noticeable under tree stands (5.3 x 106 per gm. of soil) as compared to the barren soil (1.8 x 106 per g soil). In general the treeless site supported low population (12 x 105 per g soil) of actinomycetes compared to the afforested site (21 x 105 per g soil). Similarly, the soils under tree stand harboured more fungal population (21.3 x 104 per g soil) than the barren soil (13.7 x 104 per g soil).

Biomass Production in an Age Series of *Bambusa bambos* Plantations

Piramanayag Shanmughavel, K. Francis
Bharathiar University, Dept. Botany, 641 046
Coimbatore, India
FAX: 091 422 422387, Email: shanvel_99yahoo.com or botany@bharathi.ernet.in

Keywords: Biomass, age series, *Bambusa bambos*. Plantations mean periodic increment, net primary production.

Bamboo is one of the most useful plants known to mankind and approximately 2.5 billion people, mostly the poor in developing counties, depend on it for a wide range of uses and livelihoods. Sustained availability can be ensured only by raising extensive bomboo plantations. The growth and biomass production in age series (1-10 years) of *Bambusa bambos* plantations were studied and compared with its growth in natural and plantation stands. Culm recruitment was monsoon dependent and was enhanced by light rains preceding the onset of monsoon. The average daily height growth was 30 cm and independent of monsoon rainfall.

In order to estimate the total biomass in relation to organic productivity, 15 culms were randomly selected from each age group. For reasons of economy the rhizome was excavated only from three in each age group. After felling, the total height of each culm, diameter at breast height (DBH), basal area and number of nodes were measured and subdivided into leaves, branches, culm and rhizome. Fresh weight of components was estimated in the field and sub-samples from each component was brought to the laboratory in plastic bags. The sub-samples were then oven dried at 103 + 2°C at constant weight. From the oven dry weight of the samples the total standing biomass of each age group was calculated by multiplying the total number of the bamboos of different ages with the average dry weight of the sample.

There was linear increase of the total biomass of all compartments with the age of the plantations. Biomass was distributed between culms (81%), branches (14%), leaves (1%) and rhizome (4%). The total biomass ranges from 2.3 t/ha (1 year) to 297,9 t/ha (6 years) and then decreased to 15,6 t/ha (10 years). The number of culms produced per clump its height and DBH was found increased up to 6 year, later it found decreased. Ultimately the accumulation of biomass also decreased after 6 years. The mean annual biomass production was 49,6 t/ha/year over the 6 period. The mean periodic increment and net primary production was highest in the 5 year, during which a peak of 124 t/ha/year in net primary production was obtained.

Changes in Plant Species Diversity in a Restoration Sequence of *Quercus variabilis* Forest Stands in Baotianman Mountain

Zuomin Shi, Cheng Ruimei
Chinese Academy of Forestry, Institute of Forest Ecology, Environment and Protection, 100091 Beijing, China
FAX: 0086-10-62881937, Email: Shizm@fee.forestry.ac.cn

Changes in plant species diversity in a restoration sequence of *Quercus variabilis* forest stands in Baotianman Mountain were studied. The result show that species richness and species diversity indices of different layers in forest stands with different restoration time are as follows: herb layer>shrub layer>tree layer. Most differences between species diversity of tree layer, shrub layer and herb layer in the forest stands were not significant. Only differences between species richness of tree layer and herb layer and that of shrub layer and herb layer were significant. Differences of tree species diversity among the forest stands were more significant, differences of shrub species diversity were significant, and differences of herb species diversity were not significant.

Seedling Survival and Growth of Canopy Trees Across Openings of a Sri Lankan Rain Forest.

B. M. P. Singhakumara, P. Mark S. Ashton
University of Sri Jayawardenapura, Department of Forestry and Environmental Science,
Nugegoda, Sri Lanka
Email: singha@eueka.lk

The basis for the management of native forests is an understanding of the micro-site requirements necessary for satisfactory regeneration establishment of late-serial canopy trees. This study examines the performance of planted seedlings for the development of enrichment planting guidelines, and for constructing treatments to test natural regeneration methods in mixed-dipterocarp forests of the hill region of southwest Sri Lanka. Four canopy tree species were planted in mixture in five micro-sites that represented the understorey-gap continuum. This was replicated across three canopy openings that were located in different parts of the rain forest topography (ridge, middle-slope, valley). We selected two species of *Mesua* (*M. thwaitesii, M. ferrea*) and two species of *Dipterocarpus* (*D. hispidus, D. zeylanicus*). Micro-sites were located in the forest understorey on the southern side of the canopy opening; on the outside southern edge of the canopy opening; the opening center; on the outside northern edge; and the northern understorey adjacent to the canopy opening. Seedlings were planted and monitored for growth and survival over a two year period after which a sub-sample was taken for estimation of dry mass and proportional allocation to root, leaves and stem. The remaining seedlings were monitored for growth and survival for a further two years. Results demonstrate clear differences in survival and growth among species in relation to micro-site. Both *Dipterocarpus* spp. had low survival in the forest understorey as compared to *Mesua* spp. Trends in understorey mortality were most pronounced on the ridge site for all species, except *M. ferrea*, and least pronounced in the valley site. *M. ferrea* had greatest growth and mass, with greater allocation to roots, in the ridge understorey micro-sites as compared to the other species. *D. zeylanicus* exhibited the greatest height growth (after 2 and 4 years) and dry mass of all species, but this was restricted to the centers of the canopy openings on the valley and middle-slope sites. *M. thwiatesii* had greater growth than the other species in understorey sites of the valley. Results suggest *Dipterocarpus* spp. to be intermediate in shade-tolerance, with over 90% of the seedlings dying after 4 years beneath the forest canopy. Higher rates of mortality were recorded in those circumstances for *D. hispidus* than *D. zeylanicus*. Both *Mesua* spp. were more shade-tolerant, but *M. ferrea* was the most tolerant of dry sites in the forest understorey, as compared to the other species tested. Differences among species are discussed in relation to their known site affinities within the forest. Finally enrichment planting guidelines are suggested.

Factors Influencing the Degradation of Natural Forests and Conservation Programmes in Karnataka State, India

V. Sivaram, R. Shubharani
Bangalore University, Department of Botany, Post - Graduate Centre, 563101 Kolar, India
FAX: 91-080-3219295, Email: cenfound@sparrl.com

Karnataka state is situated in the South -West of the Indian peninsula with an area of 192000 sq. kms. (19.2 million ha) and a population of about 44.8 million (1991). With an average growth rate of 2.066 percent per annum during 1981-91, Karnataka is one of the fastest growing states in India. The population projections are 49.18 million for 1996 and 53.73 million for 2001. It was estimated that an area of 38324 sq. kms. is under the control of Karnataka forest department, more than 50 percent of the area of forests is highly degraded because of the overexploitation. In Karnataka only 10 % of the total geographical area is under good tree cover. The majority of the rural population are entirely depending on the forests for fuel wood and other basic needs. The poster comprehensively reports on the reason for forest degradation in the state and the measures taken by the government, and the national and international non-governmental organisations (NGO's) to protect the natural resources. The strategies for conservation and sustainable management of forests in Karnataka are discussed in detail.

Agrosilvicultural Models for Small Farmers in the Coastal Region of Paraná State, Brazil

Irene Costas Stridsberg
Universidade do Contestado-Canoinhas, Caixa Postal, 01, 994960-000 Canoinhas, Santa Catarina, Brazil
Email: sirene@mps.com.br

Keywords: Brazil, agroforestry, farm models, sustainable forest management

The aim of the study was to develop agroforestry models for low income small farm owners in the coastal region of Paraná state. The analysis determined the best combination of forestry and traditional agricultural crops, with the level of technology available to low income small farm owners. Incomes improve when the forestry activity is focused on the market for medicinal usage of the tree, excluding traditional wood products. Sustained yield management of native wood species with characters adequate for medicinal utilization opens up a gateway for a harmonic life between man and nature.

The study examined the economic returns from a base model reflecting the current system, and three distinct agroforestry models. The base model included income from agriculture, traditional forestry extraction and wage income, for a property with 16 ha, of which 2.6 ha was in legal forest reserve. Gross monthly per capita income was R$51.26. The first agroforestry model included agricultural income, wage labor and forestry income from extraction of medicinal plants; monthly per capita income was calculated to be R$74.85.The second agroforestry model included agricultural income, wage labor and a more sustainable agroforestry model of medicinal plant production and extraction; this provided income of R$116.42. Finally, the third agroforestry model included agricultural income, wage income, sustainable medicinal plant production, and forest enrichment; income was still higher, at R$187.02, leaving ample income available for other household investment purposes.

The authors drew several conclusions from this study about the opportunities for agroforestry in the Parana economic and biophysical environment:

1. The inclusion of medicinal products in small farm profits significantly changes household income level, making possible greater investment and growth in productive activities.

2. Participation in the medicinal product markets creates a strong incentive for conservation and presernvation of natural resources in the biome.

3. The current situation forces households to seek off-farm employment, which is contributing to impoverishment, marginalization and rural exodus towards the urban centres.

4. The current methods of protection do not offer viable alternatives for economic survival of the native population of these protected areas. The situation of conflict between humans and nature continues.

Storage of Dipterocarp Seedlings at a Slow Growth Phase as Planting Stock for Plantation Programmes

Fui Ying Tsan
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 03-6342633, FAX: 03-6367753, Email: tsanfy@frim.gov.my

Most of the dipterocarp species that are economically important produce recalcitrant seeds where storage of these seeds is almost impossible. Storage of the seedlings of these species at a slow growth phase has yet to be an alternative for the continuous supply of planting material for plantation and reforestation purposes. Factors that are of main concerns for storage of seedlings are the quality of such seedlings during storage and the potential of the stored seedlings to resume rapid growth on return to normal growth condition. Field studies are also necessary to determine the ultimate quality of such stored seedlings as planting stock.

Many recalcitrant-seeded species are shade tolerators. Seedlings of shade tolerators have the capacity to acclimatize to dense shade where they grow very slowly. Germinated dipterocarp seeds of *Dryobalanops aromatica, Hopea odorata*, *Shorea assamica* and *Shorea leprosula* were found to develop into seedlings when sown on the forest floor and remain at a slow growth phase for periods ranging from one to two years under relative light intensities ranging from 10% to 15%. It is similar to the wildings developed from seeds dispersed from the mother trees. These seedlings were able to retain above 80% survival rates and resume normal growth when transferred into polybags and placed in the nursery for recovery. *Shorea ovalis* seedlings, however, showed suspended growth under such condition. In spite of the excellent medium for the growth of seedlings, storage of seedlings on the forest floor was not practical as high mortality rate of above 20% was recorded due to damage by animals and fungal infestation. It is suggested to simulate the same low radiation growth environment in shade houses. This approach should allow sunlight to penetrate in the form of sunflecks and avoid excessive water vapour around the seedlings. Hundreds of seedlings can be maintained within a metre square area in root trainers depending on the size of the seedlings.

Cold storage of seedlings, on the other hand, is an established practice for many forest and ornamental species in the temperate countries where environmental conditions and seedling dormancy are major constraints to lifting and planting operations. In the tropical region, preliminary work found that the dipterocarp seedlings could not tolerate temperatures below 10°C. Further research showed that cold storage incorporated with light is even more beneficial to the seedlings. Above 80% of the seedlings of *Dipterocarpus cortunus, H. odorata, Shorea curtisii, S. leprosula*, *Shorea longisperma* and *S. ovalis* could be maintained at a suspended growth state for periods ranging from three to six months in a growth chamber of 16°C under low radiation of approximately 5 $\mu mol/m^2/s$ provided by a daylight lamp. When the cotyledons shed, these seedlings suffered from starvation. Survival rates ranging from 60% to 95% were obtained depending on the species following retrieval of these seedlings from storage condition for recovery in the nursery. For the sustainable growth of seedlings, it is necessary to grow the seedlings in the cold chamber at above their lowest safe temperatures and light compensation points for a positive carbon (C) balance. The photoperiod, however, should be held in several sessions daily if necessary to reduce the heating up in the growth chamber.

The growth of the dipterocarp seedlings in the polybags placed in the nursery can also be controlled by some growth inhibitors to avoid root bound seedlings. Seedlings of *H. odorata* could be maintained as slow growing seedlings by means of up to two applications of paclobutrazol at rates of 0.5 and 1 g/l done at an interval of three months from the age of four-month old and upwards. They could fully recover from the slow growth phase within a period of three months when application of the growth regulator was ceased and fertilizer was applied to enhance the seedling growth. The seedlings following the third application of this growth retardant showed persistent growth inhibition even after the studied recovery period. Application of gibberellic acid may be necessary to facilitate the recovery of these seedlings from the persistent growth inhibition.

Biomass Production and Nutrient Dynamics Under High Density Short Rotation Energy Plantations in North Western Hill Region of India

K. S. Verma, V. K. Mishra. H. S. Saralch and B.K. Nayak
College of Forestry, Dept . of Silviculture and Agroforestry, UHF P.O.Nauni, 173230 Solan, India
Tel: +91 1792 52422©,52270 (o), FAX: 91-1792-52242, Email: verma_ks@ yspuhf.hp.nic.in

Short rotation forestry is an old silvicultural practice but its commercial use in the Indian sub-continent is recent. During the last two decades fast growing tree species, especially fuelwood species, have been grown to meet the energy needs of the fast increasing human population. The two distinct objectives of energy plantations are: i) increased biomass production in a short period and ii) amelioration of marginal lands. Total aboveground biomass production and nutrient dynamics under high density plantations raised at two different locations viz.; submontane subtropical low hills (upto 914 m. a.msl) and sub temperate sub humid mid hills (915-1523 m. a.msl) were evaluated. At location 1 in low hills *Eucalyptus tereticornis* (Smith); *Melia azedarach* L. and *Leucaena Leucocephala* (Lam.) de Wit were grown each at four densities: 5000, 10,000, 15,000, and 20,000 plants ha^{-1} for nine years. At location 2 in mid hills, only *Eucalyptus tercticornis* was grown at three densities: 27,777, 12,345 and 6,944 plants ha^{-1} for six and half years.

Aboveground biomass computed on per tree as well as per ha basis differ significantly with the species and density both. *Leucaena* accumulated more biomass per tree than *Eucalyptus* and *Melia*. The contribution of stem to above ground biomass irrespective of species and plant density ranged between 60.8-81.3%. Total aboveground biomass on per ha. basis was highest in leucaena (186.63 MT) which was 153% higher than *Eucalyptus* and 328% than *Melia*. Nutrient concentration (N, P, K, Ca, Mg) and their accumulation were significantly higher in leucaena. Soil pH, EC, organic carbon, available N, P, K, exchangeable Ca, and Mg were more in planted than unplanted plots.

At location 2 in mid-hills *Eucalyptus* biomass per tree decreased significantly with the increase in density. Biomass per ha, however, increased. Total biomass at maximum density was 2.5 times higher than the lowest and 1.75 times than the intermediate. The average productivity expressed as ton ha^{-1} yr^{-1} was 18.15, 10.12 and 7.07 as the density decreased from maximum to minimum. Soil organic carbon content increased with the increase in plant density, whereas N, P, K, Ca & Mg content in soil decreased. Depthwise distribution of soil organic carbon, N, P, K, Ca and Mg decreased with the increase in soil depth irrespective of plant density however, pH decreased. Relationship between biomass production and the available nutrient elements in soils have indicated that *Eucalyptus* absorbed more of the N from 0-30 and 30-60 cm soil depths and did not show specific preference to any of the soil depth for P, K and Ca . The correlation coefficient values yet , were high for the above two depths than 60-90cm. The correlation coefficient values between leaf nutrient concentration and the available nutrients in soils at different depths have also shown that trees absorbed more N, P and K from 0-30 and 30-60cm soil depths. Nutrient cycling studies i.e. retention, release and uptake have established that retention increased linearly as the plant density increased. The different tree components retained larger amount of nutrients and the release through leaf and non-leaf litter was negligible. In case of the total amount released through leaf and non-leaf litter was just 6% of the total uptake.

Species Introduction of *Monocalyptus* to Southwestern China

Huoran Wang, Yongqi Zheng
Chinese Academy of Forestry, 100091 Beijing, China
FAX: (00) 86 10 62872015, Email:
wanghr@rif.forestry.ac.cn

Monocalyptus is the second largest subgenus in the genus *Eucalyptus* L'Heritier. It includes 134 species and 9 subspecies. Most of them are important species in the Australian forests for timber production, such as *E. regnan*s F. Muell., the highest angiosperm plant on the Earth and *Eucalyptus obliqua* L' Herit. The high economical value and high productivity of many *Monocalyptus* species have attracted a lot of interests in planting the species in many other countries outside Australia. However, examples of successful introduction of *Monocalyptus* species are only a few. Up to date, a few countries in the Southern Hemisphere like South Africa and New Zealand have shown limited success in planting *Monocalyptu*s. Therefore, species transfer of *Monocalyptus* is of great implication in ecophytogeography.

A species screening trial was established in Yipinglang Forest Farm in the central part of Yunnan Province, China with 11 species of *Monocalyptus*. The climate at the experiment site is mild with annual mean temperature of 18 centigrade degree, mean temperature of July, the hottest month, of 21-27 centigrade degree, mean temperature of January, the coldest month, of 8-10 centigrade degree and 250 days of frost free. The four seasons are not clearly distinguished with prolonged dry period from November to April. The trail set was located at the lower part of the slope, and previously occupied by natural forest vegetation that was dominated by *Pinus yunnanensis* Franch. in association with oaks and other hardwoods. The soil was yellowish red and well drained with a pH value of 5.5-6.0. 7-year results showed that *E. regnans, E. obliqua, E. delegatensis, E. elata, E. fraxinoides, E. triflora, E. fastigata, E. dendromorpha* and *E. muelleriana* were adapted to the local environments. The growth performance of these species is very promising in comparison with *E. globulus*, a landrace planted at adjacent plots at the same time. *E. fraxinoides* displayed the best growth performance and tree form, with an average annual height increment of 2 m and an average annual diameter increment of more than 3 cm. Species with average annual height increment of about 2 m are *E. fastigata*, *E. delegatensis*, *E. muelleriana* and *E. regnans*. The annual height increment of some individuals of these species was as high as 3 m. Several factors affecting growing *Monocalyptus* species in China were discussed. Site condition and microenvironment were identified as the critical factors that constraint planting of *Monocalyptus* species. Site selection would be essential part for a successful planting program with *Monocalyptus*. Temperature may be a factor more critical than precipitation for the species transfer of *Monocalyptus*. An expanded multi-site species/provenance trial of *Monocalyptus* species was recommended for further study.

The Forest Restoration and Sustainable Forest Management in the Three Gorge Reservoir Region in China

Xiao Wenfa, Ma Juan Cheng Ruimei
Chinese Academy of Forestry, Research Institute of Forest Ecology and Environment Protection, Wan Shou Shan Hou, 100091 Beijing, China
FAX: +86 10 62889555, Email:
xiaowenf@fee.forestry.ac.cn

Seriously disturbed by human beings, the forest vegetation and the degradation of the ecological environment in the Three-Gorge Reservoir Region in China are analyzed. Based on the diversity of the regional climate, the geomorphology and topography and the forest biology, the strategies for the sustainable forest management are discussed. (1) The forest vegetation distribution patterns are shown. Seriously disturbed by human beings, the vegetation in the Region is sparse and uneven with an unclear vertical distribution. Little forest vegetation distributes below the elevation of 800m. 17.5% of the land on the slop above 25 degrees are cultivated. *Pinus massoniana* and *Biota orientalis*, also the main forest species in the sparse forest grown by aero-sow and artificial planting, take the largest areas in the region. The species diversity is decreasing seriously. (2) The environmental problems, mainly the land degradation, the decrease of land productivity and the water and soil erosion caused by the disturbance of human activities such as the irrational land use and forest cutting, are analyzed and assessed. The soil erosion volume is up to 290 million tons per year. (3) Based on the forest shelter engineering in the middle-up stream of the Yangtze river, the strategies for the regional forest restoration and sustainable management mainly including closing the mountain and raising forest, returning the cultivated land on the slops above 25 degrees to forest, developing the firewood for energy and building the forestry management system with the multiple functions and mixed management models are discussed and assessed.

Effects of Land Use Change on Water Quantity and Quality in Penang State , Malaysia

Chan Ngai Weng
Universiti Sains Malaysia, 11800 Penang, Malaysia

Penang is one of the most rapidly development and urbanising states in Malaysia. Land use changes have been rapid, largely from the forest to agriculture at the turn of the 19th century. After independence, however, rapid urbanisation, housing and commercial and industrial developments have further accelerated land use change from forest and agriculture. These changes have significant effects on the water resources of the states, both in terms of quantity and quality. Since the 1930s, rainfall in the catchment areas in the late hills has gradually declined from an average of about nearly 4,000mm to bout 2,500mm in the late 1990s. in the urban centres such as Georgetown, however, greater air population has slightly increased rainfall amounts but the rainfall over the urban areas are of no use in terms of water resources as the majority of rainfall in urban catchments are not trapped and retained but run off as overland flow. The rainfall- evaporation analysis also revealed that the amount of effective rainfall is often much lower than the total gauged rainfall. Furthermore, water quality has also declined considerably since the middle of the 19th century. Almost all rivers near the foothills (which are urbanised) consist of water that are too polluted to be of any use for water supply purposes. Hence, the major water catchments on the island have intakes on hill slopes before the rivers enter the foothills and the coastal plains. Coupled with the fact that Penang has very few water catchments, the state is faced with a "water insecurity" situation as it currently draws about 80% of its water demand from the Muda River which has its origins in Kedah. Despite the completion of the Teluk Behang Dam in the year 2000, the dam is expected to meet only about 45% of the water needs of the island, and Penang will still be insecure in terms of water. Penang's insecure water situation was laid bare during the prolonged dry spell of the 1997/98 El Niño, resulting in severe water stress. Hence, Penang is extremely susceptible to water stress. While urban areas cannot be reafforested, the authorities must take steps to reafforest farmed areas, illegality development and other deforested catchment land. Given the large area of catchment land under private ownership, the state should consider acquiring such land to stop illegal developments. Greater monitoring and enforcement of all developments on catchment land is necessary. Comprehensive river basin catchment management should be practised, ideally led by the Perbadanan Bekalan Air Pulau Pinang. More significantly, all catchment land should be gazetted immediately to prevent further destruction. Local plans such as the Penang Hill Local Plan may be used as a for of land use control. The water authorities must now revise the conventional strategy of Supply Management (increasing supply) to one of Demand Management (reducing demand and wastage). Finally, Penang should also consider looking at the option of inter-state water transfer with its water rich neighbours.

Eco-physiological Characteristics of *Sabina vulgaris* in Mu-Us Desert, China.

Ken Yoshikawa, Linhe Wang and Nobuhito Ohte
Okayama University, Faculty of Agriculture, 700-8530 Okayama, Japan
Tel: +81-86-251-8376, FAX: +81-86-251-8388, Email: kenchan@cc.okayama-u.ac.jp

Eco-pyshiological aspects of *Sabina vulgaris (Juniperus, Cupressaceae)*, evergreen coniferous shrub, were measured in Mu-Us desert to analyze the characteristics of trees for the revegetation in semi-arid region. Mu-Us desert is located in the south of Ordos plateau and the north of loess highland. Annual precipitation is 350mm and monthly mean temperature ranges from 21.8° in July to -11.4° in January. Even in such cold semi-arid region, *S.vulgaris* constructs dense and compact patches on fixed sand dune. Although the maximum height of trees is less than 2m, their branches are creeping on the ground and can stabilize the sand surface against strong wind in early spring. However, most of *S.vulgaris* communities in Mu-Us desert were destroyed by the reclamation initiated after the independence of China. Now only 10% of Mu-Us desert is covered by *S.vulgaris*. In 1988, a permanent experimental plot (200m * 400m) was established on fixed sand dune in Mu-Us desert to study the dynamics of *S. vulgaris* community and some eco-physiological characteristics of xerophytes plants, such *as S. vulgaris* and *Artemisia ordosica*, growing in semi-arid condition.

The topographic map of the plot and the distribution map of *S. vulgaris* patches in the plot were made. Twenty four sample patches were selected in the plot for intimate experiments. Four wooden stakes were paled at the periphery of each sample patch and the growth rate of creeping shoots to four directions (north, south, east and west) were measured from these stakes at once a year. To reveal the effects of long-term water stress on *S. vulgaris*, 72 seedlings were planted in gravel culture medium and the osmotic potential of Hoergland culture solution was controlled by the content of polyethyleneglycol (PEG).

Competing with *A. ordosica*, all sample patches enlarged continuously for ten years. The mean radial growth rate was about 11 cm/yr. The density of branches in the center part of patch begin to decrease after the patch radius exceeds about 8m. It means that most of the patches begin to deteriorate in 70 to 80 years after the establishment of seedling. The distance of the ground level of each patch from the groundwater level was ranged from 20cm to 5m according to the undulation of the fix sand dune surface. By the measurement of vertical root distribution and the analysis of ^{13}C in needles of several patches growing on different ground levels from the groundwater, it seems that patches growing on the lower part of fix sand dune are supported by the groundwater and others on the higher level are growing by only rainwater. Seedlings growing under chronic water stress for several years in a greenhouse showed a remarkable drought adaptation in both the stomatal and the cuticle transpiration rates.

Growing Shelter Belt Forest System-An Effective Way to Combating Desertification

Lixiang Zang, Zhang Feng
Forestry Research Institute of Chifeng Municipality, 024006 Chifeng, China

Chifeng municipality of Inner Mongolia, The People's Republic of China, is located at the interface section of Hunshandandake Desert and Kerqin sands where sand dunes and loess hills are integrated forming huge scale landscapes of desertification. Soil and water erosion imposes a constant severe threat to the overall development of the whole region. Within the territory of Chifeng Municipality, desert takes up 2,420,000 ha, nearly 62% of its total. Desertification proccess in Chifeng used to be accelerated at an alarming speed due to the long time effects of population growth, extensive cultivation, overgrazing, clearance of forest for wood and fuel consumption and many other irreversible damage to the natural vegetation. Hazards of desertification, such as persistant drought, heavy sand storms, devastating floods, and all other kinds of harmful events, intensify as the time increase. It is not a rare occurrence that farmfield being destroyed over night by heavy sandstorms, rangeland degraded or even completely covered with moving sand dunes. In some places the endless advancing sands destroy major transportation facilities and water projects, forcing numerous local inhabitants abandon their homes. It is estimated that 231 kms of major highway, 3891 country houses 1768 ha farmfield, 390,000 ha of rangeland were lost during 1958-1988 in only four counties in Kerqin desert region. It is very clear that people in desertification-pron area are facing a deteriorating situation with the actively advancing sands. Serious soil and and water erosion as the leading factor contributes to desertification in Chifeng protecture for its low and scarce vegetation, strong wind and heavy dust in spring and rainstorms in the summer. There are about 964,000 ha of land suffering extremely severe erosion. It is observed that there is 0.3 to 10 cm depth of earth washed away from hills and rolling land each year, that equals 12000 tons of soil loss per km^2. Based on the principle of taking suitable measures to site-specific condition, afforestation on loess hills for desert control had been conducted in a systematic way, planning and designing coordinately and tackling local problem comprehensively, in order to change the bold landscape into a new ecosystem characterized by thriving both forestry and livestock production. From the standpoint of all-inclusive agriculture, a new way of land arrangement was designed to replace the tradition of reclamation abandonment, a plundering way of land usage. By the new way, hills and gentle slopes are reorganized in utilization which roughly results in balance among agriculture, forestry and animal husbandry. In afforestation, three types of arrangements, shelter belt network shelter belt, and block stand, are basically taken from the consideration of making shelter belts play full function in run-off obstruction, controlling water and siol erosion, and making belts store up as much water as possible. These measures are expected to be favourable to forest growth and the rational utilization of of cultivated hillsides as well.

Influence of Potassium on the Growth and Root Characteristics of Three Timber Seedlings Grown in Soil Containing VA- Mycorrhizae

K. S. Abouelkhair, O.A. Badran, V. Gianinazzi-Pearson, S. Gianinazzi, P. Giot and P. Andre.
Alexandria University, Department of Forestry & Wood, Alexandria, Egypt

Acacia saligna, *Casaurina glauca* and *Cupressus sempervirens* seedlings, grown in soil containing the vesicular arbuscular mycorrhizal fungus *Acaulospora trappei*, were used to study the effect of potassium levels (0, 20, 40, 80 and 160 mg K/l) on seedling growth and root characteristics. Treatment with 20 mg K/l added to the soil (containing 1.2 meq K/l) gave the highest dry weight of leaves, stems and total dry weight. The root volume, root length and root surface area of *A. saligna* seedlings were highest with a potassium level of 20 mg/l. Increasing K levels up to 160 mg/l reduced these root characteristics. The root volume, root length and root surface area of *C. glauca* seedlings were highest with the 80 mg K/l treatment. However, the alternative K treatments did not significantly affect the other growth characteristics of *C. glauca*. For *C. sempervirens*, the highest height and dry weight of stems were obtained with the 80 mg K/l treatment. Root length and root surface area were highest with a treatment of 20 mg K/l), whereas the weight of roots, volume and radius were highest with the treatment of 80 mg K/l. However, these characteristics were significantly larger than the control for increasing K additions up to 160 mg/l. We conclude that addition of K fertilizer as potassium sulphate to newly reclaimed soils, containing *Acaulospora trappei*, would improve growth of fast growing tree seedlings by increasing root growth characteristics.

The Reasons for Earlywood and Latewood Formation

G. F. Antonova
Siberian Branch of Russian Academy of Science
Email: dndr@ifor.krasnoyarsk.su

Wood quality is determined by the proportion of earlywood and latewood tracheids, as well as by the morphological attributes of these cells. Morphogenesis of both kinds of tracheids is similar with the growth of primary walls in the radial expansion zone and deposition of secondary wall substances in the zone of secondary wall thickening. However, the terminal characteristics of earlywood and latewood tracheids differ considerably. The reasons of these distinctions were analyzed from measurements of cell development during wood formation in *Pinus sylvestris* L. and *Larix sibirica* Ldb. These two conifers are dominant species in the forests of Middle Siberia.

Observations were obtained on 10-12 trees with estimated ages of 50 to 60 years based on external and internal development. The mean numbers of cells within each of the two previous annual rings of each tree were similar and had a normal distribution. The durations and rates of xylem cell formation, primary wall growth and secondary wall thickening of earlywood and latewood tracheids were measured during the seasonal period of wood formation. The effects of air temperature and precipitation on each process were also studied. Radial diameter growth of earlywood tracheids in both pine and larch occurs mainly during June, with latewood tracheid development occurring in July. Secondary wall thickening of earlywood cells occurs in June-July, and in latewood cells such thickening occurs during August and the first half of September.

Hydrothermal conditions during xylem cell growth can considerably influence the morphological characteristics of tracheids. Each of the processes determining wood formation has its own optimum temperature range outside of which the process rate decreases. The developments of radial diameter and wall thickness have different air temperature maxima. The favorable mean daily temperature for radial diameter development in both pine and larch is 21-22°C, whereas, maximum thickness of tracheids is reached at temperatures of 15-16°C. The effects of day and night temperature on radial diameter and wall thickness differed. Distinctions in the temperature and moisture requirements for primary and secondary cell wall development appear to be related to differences in endogenous events leading to these developments. Radial diameters, as well as wall thicknesses of both kinds of tracheids, are larger in larch than for pine tracheids. The transition from earlywood to latewood cell formation is induced by internal water deficit of the cambial tissue and by changes in the linkage between cellulose microfibrills and xyloglucans. Internal water stress results in latewood tracheids having smaller radial diameters and greater length than earlywood cells.

Growth Responses of Palasan Seedlings, *Calamus merrillii* Becc., to Different Light Intensities and Watering Regimes

Aida Baja-Lapis
Ecosystems Research and Development Bureau, 4031 Laguna, Philippines
Tel: (63) 49 536 2850, FAX: (63) 49 536 2850, Email: lapis@uic.net.ph

The growth responses of palasan (*Calamus merrillii* Becc.) under different light intensities and watering regimes were studied under nursery conditions. Three light intensities of high light (100% sunlight), medium light (80-90% sunlight) and low light (50-60% sunlight) were imposed on palasan seedlings. Among the treatments, low light resulted in high biomass gain. This was attained because of large leaflet areas developed, more leaves produced and high chlorophyll content.

Biochemical and anatomical parameters were also determined. Photosynthetic responses were obtained with a LICOR 6200 closed-photosynthesis system. Photosynthetically active radiation, stomatal conductance, internal CO_2, relative humidity, leaf and air temperatures, and maximum net photosynthetic rate were measured. The results showed positive photosynthetic responses of palasan under low light intensity. Data from measurements were statistically analyzed by the analysis of variance method. Correlation and regression analyses were used to elucidate relationships among variables.

The light requirements for favorable seedling growth were shown to be at about 50-60% of sunlight. A 2-day watering interval favored growth as determined from biomass, height increment and root collar diameter measurements. Frequent watering gave high net assimilation rates and low starch and sugar contents in palasan leaflets. The plant relative water content did not vary under the different watering regimes, reflecting an efficient balancing of moisture in the test plant perhaps induced by stomatal closure. Likewise, moisture conservation may have been favored by the waxy surfaces of leaflets, a morphological feature of palasan. The cultural requirements for favorable growth of palasan in the nursery include low light intensity and watering at 2-day intervals instead of the usual daily watering used in the past.

Coupling a Diffusion Resistance Type Short Time Step Model With Structural Forest Growth Model

Frank Berninger, Risto Sievänen, Eero Nikinmaa, Pekka Nygren
University of Helsinki, Department of Forest Ecology, Post Box # 28, 00014 Helsinki, Finland
FAX: +358-70858648, Email: Frank.Berninger@Helsinki.fi

While structurally explicit growth models are enhancing the realism of three-dimensional descriptions of tree growth, their computational complexity makes it difficult to maintain a full range of complexity for all physiological processes. Also, some feedback mechanisms cannot be adequately described on a short time basis.

LIGNUM is a spatially explicit three-dimensional tree growth model based on functional balance and pipe model theory. The model was originally developed for Scots pine in Finland with long time steps. Subsequent applications to pruned *Gliricidia sepium* in Guadeloupe, West Indies required shortened time steps and the explicit introduction of post-pruning nitrogen fixation and labile carbohydrate reserve dynamics. The LIGNUM model describes the flow of labile carbon and nitrogen between a shoot and a root compartment. All growth processes depend on sugar and nitrogen concentrations in the compartments. Depending on the labile carbohydrate concentrations the reserve compartments are either filled or emptied.

The coupling of a diffusion resistance model for net carbon uptake by foliage with short time steps with the slower pipe model requires the combination of different processes that run at different time steps. Allocation between different aboveground biomass parts is controlled by allocation keys derived from the pipe model theory in LIGNUM. The long time step model keeps track of pipe length, the three-dimensional architecture and runs a light interception model at regular intervals. Application of the model to *Gliricidia sepium* after coppicing is demonstrated.

Effects of Climate Change on the Seed Production of *Gliricidia sepium* (Jacq.) Walp. Germplasm Collection in VISCA and its Implication for Genetic Improvement: A Preliminary Study

Ernesto C. Bumatay
Visyas State College Of Agriculture, Department of Forestry, 6521-A Baybay, Leyte, Philippines
Tel: 521-2027, 588-692, FAX: (632) 525-6849, Email: vicarp@mozcom.com

Gliricidia sepium grows well even in very inproverished soil condition. However, planting them directly using either seeds or cuttings in the field resulted in higher mortality rate. Thus, it is ideal to raise seedling in the nursery to ensure high survival rate. In the establishment of the germplasm collection of *Gliricidia sepium* (Jacq.) Walp. in the Visayas State College of Agriculture (VISCA), Philippines, mature seeds and branches of *G. Sepium* were collected from representative populations in different localities and abroad. Accessions were planted in CRD design with no replication. The seeds and cutting collection were raised in the nursery for 40 days and then hardened before transplanting in the field at a distance of 1m x 1m. Data on percentage survival of seedlings and cuttings were recorded two weeks after transplanting. Plant height and stem diameter was measured after outplanting and every three (3) months thereafter, and every six (6) months after the trees had reached one (1) year of age. Observation of each accession was made by taking note of morphological characteristics of the *G. sepium* germplasm collection. The experiments were conducted in 1990. Visual observation showed that most of the local accessions collected were bushy, shrubby and short-stuttered much so with those propagated through cuttings. On the other hand, foreign accessions performed well in terms of growth and were noted for their arboreal characteristics with lesser side branching. The leaf characteristics among local accessions were usually broad and oblong in shape compared to foreign accessions, which were small to large in size and elliptically shaped. Number of leaflets per rachis varies from branch to branch and tree to tree. In terms of plant growth and biomass production, the different accessions showed promising result. Prominent among the accessions propagated through seeds were Gs6 and Gs14 having a total plant height of 15.18m, a DBH of 11.80 cm and a biomass production of 0.1660 cubic meter, respectively at 72 months of growth. On the other hand, foremost among those accessions propagated through cuttings was Gc26, having a total plant height of 13.22 m, a DBH of 10.2 cm and a biomass production of 0.1088 cubic meter at 72 month of growth. Like other tree species, *Gliricidia sepium* succumbed to the attack of some pests and diseases. Among the insect pests identified were aphids, mealy bugs and ground termites while the identified diseases were stem canker and leaf spots. These infestations and infection affected the growth of the different trees in the germplasm collection.

Effects of ECM and AM, Alone or in Competition, on Root Colonization and Growth of *Eucalyptus globulus* and *E. urophylla*

T. Yinglong Chen, Mark Brundrett, Nicholus Malajczuk,
Mingqin Gong, and Bernie Dell
The Chinese Academy of Forestry, The Research Institute of Tropical Forestry,
510520 Longdong, Guangzhou, China
Tel: +86-20-87030121, FAX: (+86) 20 87725622, Email: yinglongchen@hotmail.com

A glasshouse experiment examined the effects of competition between ectomycorrhizal (ECM) and arbuscular mycorrhizal (AM) fungi on root colonization and growth of *Eucalyptus globulus* and *E. urophylla*. *Eucalyptus* seedlings were inoculated with spores of the ECM fungus *Laccaria lateritia* alone, or in combination with pot culture inoculum of one of 3 AM fungi (*Glomus, Acaulospora* and *Scutellospora* isolates). In addition, soils from a new plantation site were used as inoculum for comparison as their relative importance at inoculum level is uncertain. Both ECM and AM fungi effectively formed associations with seedlings, though mycorrhizal root lengths varied considerably with plant age up to 16 weeks. AM fungi were initially able to colonize roots more rapidly from pot culture inoculum than the ECM fungus *Laccaria* could from spores. However, once established *Laccaria* became a more aggressive colonizer of new roots than any of the AM fungi. When both types of fungi were present, ECM root colonization levels increased substantially after 8 weeks, as the proportion of roots with AM declined. The relative susceptibility of *Eucalyptus* roots to these two associations apparently also changed as seedlings became older. AM colonization levels declined in the absence of ECM fungi after seedlings were 8 weeks old. The soil P levels, corresponding to a growth response curve for eucalypts in that soil, were used and relatively substantial growth responses to mycorrhizas at the lowest P level were obtained. All inoculated treatments, whether alone or in combination, stimulated plant growth relative to controls at the low P level. Plants inoculated with *Laccaria* alone or in combination with AM fungi gave the largest growth response. AM fungi alone also resulted in some growth promotion, especially for *E. urophylla*. Ectomycorrhizal fungi had a major impact on root system form - substantially reducing the proportion of fine roots (specific root length), but this did not occur when only AM fungi were present.

Estimating Genetic Parameters for Half-sib Progenies in Five Populations of Erva-mate (*Ilex paraguariensis* St. Hill) in Juvenile Age for the Trait Plant Height

J. S. C. Fernandes, Ushiwata, S.; Daminelli, R..; Gabardo, J.; Kobiyama, M.; Maccari, A.; Prevedello, C.; Resende, R.; Resende, M.; Sturion, J.
UFPR, Departamento de Genética, Caixa Postal 19071, CEP 81531-990 Curitiba, Brazil
FAX: +55-041-266-2042, Email: cunha@bio.ufpr.br

This trial is part of a project done in partnership between EMBRAPA/CNPF and the Genetics Department of the UFPR. The aim is to estimate genetic parameters for phenotypic characteristics from five populations of "erva-mate"-*Ilex paraguariensis* St. Hil. and develop other studies considered important for the culture. The populations were collected among different sites in the States of Paraná and Rio Grande do Sul, and were set up at the UFPR farm of Canguiri. The trial design was an 8x8 balanced lattice, with 9 repetitions, 6 plants per plot, and a total of 3,456 plants (64 half-sib progenies). The traits evaluated were mortality at the age of 4 and 12 months, and plant height at 12 months, from the date the trial was set up. Preliminary evaluations of the chemical properties of the soil where the trial was carried out were also performed. The results showed that plant height was not affected by the chemical properties of the soil. The mortality rate at 4 months was not affected by progenies nor by populations. At twelve months, strong differences in mortality rate was observed among populations. The populations from Barão de Cotegipe, State of Rio Grande do Sul, showed the lowest mortality rate. Significant effects for plant height were detected among populations and also among the progenies within them. Barão de Cotegipe showed the highest individual narrow sense heritability and average for plant height. Therefore at least the Barão de Cotegipe site deserves more attention since information from another source also reported the plant height trait having a positive and significant correlation with biomass in more advanced ages.

Continuous Diagnosis and Design of Agroforest Systems in Two Micro-Watersheds of Araponga, Zona da Mata, Minas Gerais, Brazil

Fernando Silveira Franco, Laercio Couto, Irene Maria Cardoso, Cassio Murilo Trovatto, Elias Silva, and Osmar Villas Boas
Universidade Federal de Vicosa, Departamento de Engenharia Florestal,
36570.000 Vicosa, Minas Gerais, Brazil
FAX: (031) 899-2478, Email: fsfranco@alunos.ufv.br

The study area for this work encompasses the rural communities of Araponga Municipality in the watersheds of two streams, the São Joaquim and the Boné, in the Serra do Brigadeiro of Minas Gerais state, Brazil. The Serra do Brigadeiro is part of the Zona da Mata, which itself is part of the Atlantic Forest of southeastern Brazil. These areas are also part of current activity of the Center for Alternative Technology of the Zona da Mata (CTA/ZM) in conjunction with the Araponga Rural Workers Syndicate (STR). The selected sites are representative of the general conditions of the Araponga Municipality.

Our method of diagnosis and design of agroforest systems was adapted from the Rural Participatory Diagnosis Systems, the Diagnosis and Design of the International Council of Research in Agroforestry (ICRAF), and other approaches that utilize participatory techniques in the collection of data and related information. The geographically referenced data obtained for diagnosis were stored and analyzed using a Geographic Information System (GIS) that delineated two small watersheds into locally specific and environmentally appropriate agroforest systems. The GIS system (IDRISI 4.1) operates on personal microcomputers with minimal sophistication.

The participatory diagnosis methodology retained information from the local farmers, facilitating understanding of their systems of production, their principal problems and causes of those problems, as well as furnishing aids for planning and implementing agroforest systems. The farmers participated in all stages of the diagnosis and design process.

Agroforest systems have great potential in both ecological and socio-economic terms to resolve diverse challenges in the study region that are acceptable and adoptable by the farmers. For these reasons, it is necessary to have a systematic focus involving the participation of the farmers in the entire process and emphasizing the importance of trees in the production system.

Although this work conforms to the design and implementation features of some agroforest systems currently being monitored by the CTA/ZM, the STR, and the Federal University of Vicosa, we expect that these systems can be modified and improved. Evaluations of diagnosis and design of our agroforest systems will be on-going by virtue of this work's dynamic nature. Thus, the present work will have continuity along with possible extensions into other studies.

Although this work conforms to the design and implementation features of some agroforest systems currently being monitored by the CTA/ZM, the STR, and the Federal University of Vicosa, we expect that these systems can be modified and improved. Evaluations of diagnosis and design of our agroforest systems will be on-going by virtue of this work's dynamic nature. Physiological Studies of Biomass Production in Fuel-wood Tree Species under Agro-climatic Conditions of Palampur in Northwest Himalaya

Gopichand
Institute of Himalayan Bioresource Technology, 176 061 Palampur (H.P.), India
FAX: +81-1894-30433, Email: director@csihbl.ren.nic.in

The rapid depletion in forests and the need for fossil fuel alternatives have focused attention on renewable energy sources such as plant biomass. The growth and biomass production of a few local as well as exotic fuel-wood species were studied in short rotation, high-density plantations at Palampur (elevation of 1300 m msl, at 32.06 N and 78.18 E) in the northwestern Himalaya.

Meteorological data for the five years, 1993-1997, show an average annual rainfall of 1737mm, and the mean monthly temperatures recorded in January and June were 5.8 and 29.1°C, respectively. Average relative humidity was 55% and the average solar insulation is 6.8 hr/day. The environmental conditions of this region are a very important determinant of growth and biomass production of tree species.

A Split Plot Design experiment with 10 tree species as the main treatment, spacing (1x1m and 1x0.71m) as a sub-treatment, 4 fertilizer levels of N:P:K as a sub-sub treatment, and with three replicates was established. *Populus deltoides*, known for its fast growth, was taken as the standard for comparison. Growth parameters and physiological observations were recorded up to three years under various environmental conditions such as low and high light intensities and cloudy weather during the course of the study. The trees were harvested after three years, and fresh and dry weights were measured. Significant differences in photosynthesis rate, transpiration rate, stomatal conductance and water potential were obtained between various treatments.

From April to June, vertical and radial growth increased by 20% to 50%, whereas, in the months of July-August, growth was 225% higher than during the initial period in spite of decreasing period of bright sunlight. During September to October, growth was low at 10-15%. In deciduous species, growth did not occur during the winter months of October to March. If winter extended beyond March, growth was reduced in all tree species.

Biomass production in *Salix tetrasperma* was appreciably lower than for the other species. Species with narrow leaves such as *Melia*, *Eucalyptus*, *Robinia* and *Albizia* showed 25% to 50% higher photosynthesis rates than plant species with wide leaves such as *Trewia nudiflora, Populus deltoides and Morus alba*. Plant growth is a reflection of net photosynthesis rate integrated over time. However, in spite of a lower photosynthesis rate, *Grevillea robusta* showed excellent aerial growth, which may be due to a "sun fleck" effect. After 36 months of growth, *Eucalyptus* gave the significantly highest dry weight of about 160 tons/ha.

Indian Forest Gene Resources - Need for Integration of Emerging Conservation research

Bhupendar N. Gupta
Dr. Y. S. Parmar University of Horticulture and Forestry, Post Box # New Forest, H. P. -173 230 , Nauni, Solan, India
Tel: 91-0135-759382, FAX: 91+1972+52242, Email: Guptab@yspuhf.hp.nic.in

The Indian region is endowed with a diversity of approximately 45,000 species of plants, which approximately constitutes 12 percent of the global plant diversity. India's forest cover occupies an area of 64 million ha and includes 16 distinct major forest groups, each of which is divided into as many as 250 sub-types. Indian forests contain approximately 600 arborescent taxa representing 75 families with 260 genera important to commercial forestry. These taxa represent a mixture of Indo-Malayan, European, Sino-Japanese, Mediterranean, and African elements. Through cross pollinations, these taxa have produced enormous variability contributing to India's biodiversity and forest gene resources. A vast range of morphological variation occurs in important commercial species, e.g., *Cedrus deodara, Acacia catechu*, and *Tectona grandis*.

Forestry research to widen the gene base of commercially important species, while subsequently conserving genetic resources has been limited. Recent advances in forestry-related sciences have not been applied and integrated to commercial forestry programs. In order to sustain, manage, and conserve Indian forest tree genetic resources the following steps are important: (I) characterization of significant centers of forest gene resources by using remote sensors and integrating a geographic information system; (ii) quantitative assessment of the conservation status of species, and identification of critical index species and their sensitive parameters; (iii) biochemical characterization of population structure; (iv) multiplication and restoration of critically threatened taxa using recent trends in biotechnology; and (v) development of seed-gene, pollen and tissue culture gene banks for conservation. There is a need for inter-institutional support and networking among the international institutions working on common objectives toward the management and conservation of Indian forest gene resources.

Changes in Population Structure and Genetic Diversity of *Shorea curtisii* Dyer ex King due to Selective Logging

W. S. Ho, Wickneswari, R. and Mahani, M.C.
Universiti Kebangsaan Malaysia, Faculty of Life Sciences, Department of Genetics,
43600 UKM Bangi Selangor, Malaysia
Tel: 603-8292214, Email: p13549@pkpel.cc.ukm.my

Effects of a single selective logging event on the genetic diversity of *Shorea curtisii* at different age cohorts viz. seedlings, saplings, poles and adult trees, were determined using six simple sequence repeats (SSRs) loci. A total of 67 samples of *S. curtisii* were collected from compartment 48 (2-year old logged stand) and 27 samples from compartment 40 (unlogged stand) in the Serting Tambahan Forest Reserve, Negeri Sembilan, Malaysia. The reduction in basal area of trees above 1 cm diameter at breast height (dbh) after logging was about 42.3% compared to the unlogged stand. The mean basal area and tree density for seedlings and saplings (< 5 cm dbh) in the logged stand increased by 79.2% and 39.5%, respectively, over the unlogged stand, indicating that logging practices favour the regeneration process in the logged stand.

Genetic diversity increased by 28.8% in the seedlings after a single selective logging event while a reduction of 8.6-13.2% occurred in other age cohorts. Hypothetical multilocus gametic diversity was reduced by about 42% in adult trees after selective logging. Latent genetic adaptive potential of the adult trees decreased to about 63%, suggesting that the ability of this gene pool to adapt to changing environmental conditions may have been compromised. In contrast, the hypothetical multilocus gametic diversity and latent genetic adaptive potential increased in the seedlings by about 77% and 84%, respectively. This suggests that seedlings have the potential to produce genetically diverse gametes with the capability for colonisation or adaptation to long-term changed environments. About 66% of the genotypes detected in seedlings and saplings in the logged stand most probably originated from adult trees in the nearby unlogged or logged stands within the forest reserve.

Changes in genetic diversity of this species due to selective logging imply that gene pools of naturally regenerated progeny stands may be quite different from the original parental stands. Therefore, it is prudent to revise the current silvicultural decision-making process early to ensure minimal decline in productivity and genetic diversity in the regenerating stands.

Keywords: selective logging, regeneration, population structure, genetic diversity, microsatellites

Identification of Gibberellin in the Female Flowers, Male Flowers and Needles of *Cryptomeria japonica*

Tamaki Honma
Tottori University, Department of Forest Product Science, Faculty of Agriculture, 4-101 Minani Koyama-cho, Tottori 680-8553 Tottori-shi, Japan
Tel: +81-857-31-6767, FAX: +81-857-31-6767, Email: thonma@muses.muses.tottori-u.ac.jp

Cryptomeria japonica (sugi) is a monoecious tree species that forms unisexual flowers at different periods: male flowers from late June to early July and female flowers from late July to early August. Flower bud formation of both male and female is promoted by gibberellin (GA) treatment. GA treatment promotes the formation of male flowers from early June to early July changing to promotion of female flowers from early August to early September. These observations suggest that

flower formation of *C. japonica* is possibly regulated by endogenous GAs, and that the physiological conditions of trees is closely connected with the development of male or female flower responses to GAs. Since both male and female flowers develop in needle tips, endogenous GAs in needles may affect the sexual differentiation of flowers.

Several research groups have surveyed the endogenous GAs in conifers, and various GAs have been identified in the early-non-hydroxylation biosynthetic pathway. However, rather few GAs have been identified in the early-13-hydroxylation biosynthetic pathway of conifers. We obtained similar findings in a survey of endogenous GAs in the pollen of *C. japonica*. Detection of GA9, GA12 and GA15 was obtained with a combination of dwarf rice assay (Tan-ginbozu), Enzyme-Linked Immunosorbent Assay (ELISA) and GC/MS, whereas, GA1 and GA3 were detected by ELISA alone. We analyzed endogenous GAs in the male flowers, female flowers and needles of *C. japonica*. The occurrence of GA1, GA3, GA5 and GA20 in the female flowers, GA1, GA3, GA4, GA5, GA9, GA12, GA15 and GA20 in the male flowers and GA1, GA3, GA4, GA5 and GA20 in the needles were suggested by dwarf rice assay (Tan-ginbozu) and/or ELISA. These GAs were confirmed by GC/MS or GC/SIM.

The early-13-hydroxylation biosynthetic pathway is predominant in vegetative tissue and female flowers, whereas, both the early-13-hydroxylation biosynthetic and the early-non-hydroxylation biosynthetic pathways are predominant in male flowers. The occurrence of GA1 and GA3 as the major GAs in vegetative tissues and female flowers suggests the organ specificity of GA biosynthesis as is found in rice. GA3 increased in needles during the periods of male and female flower formation. This result suggests that formation of male and female flowers is promoted by endogenous GA3 as well as by the exogenous GA treatment. GA1 increased in needles during shoot elongation suggesting that GA1 promotes vegetative growth in *C. japonica*, whereas, GA3 promotes reproductive growth.

Effect of *Acacia nilotica* Leachates on Germination and Initial Growth of Field Crops

M. S. Hooda, Anil Kumar
CCS Haryana Agricultural University, Department of Forestry, 125 004 Hisar, India
FAX: 91-1662-34952, Email: hau@hau.ren.nic.in

The bioassay studies were conducted in the Department of Forestry, Chaudhary Charan Singh Haryana Agricultural University, Hisar. The extracts of leaf, flower, pod, root and mixed of *Acacia nilotica* (Var. *indica*) were prepared with five concentrations . The per cent germination of all the crops was observed more than the control (0% concentration) at 25 and 50% concentrations in root and flower extracts. However, among extracts, the poor germination of all the crops was recorded at 25 and .. [abstract incomplete]

Effect of Lime on Growth. Nodulation and Biomass Producton of *Leucaena leucocephala* Seedlings in the Nursery

Mohammed Kamal Hossain, M. O. Faruque and U. K. Aryal
Chittagong University, Institute of Forestry and Environmental Sciences, 4331 Chittagong, Bangladesh
Tel: 880-31-726310, FAX: 880-31-610004, Email: ifescu@globalctg.net

The effects of applications of different amounts of lime on the growth, nodulation and biomass production of *Leucaena leucocephala* seedlings were investigated in a nursery experiment. L. leucocephala, a multipurpose tree species is known to be very sensitive to the acid soils of the hilly areas of Bangladesh. Lime was applied at rates of 0 (T0-control), 10 (T1), 20 (T2), 30 (T3) and 40 t/ha (T4). Application of lime considerably increased soil pH from 5.5 in the control treatment to the highest recorded value of 6.9 in the T4 treatment. Application of lime also significantly improved the growth, nodulation and biomass production of the seedlings. The highest values for stem height (89.7 cm) and root length (76.9 cm) were recorded in T2 after 10 weeks of seedling growth. Collar diameter was highest (83mm) in treatments T1 and T3, and root diameter was highest (7.7 cm) in the T0 treatment. Nodule number was highest (20) in treatment T1 followed by T2 (19). Similarly, dry weight of stem (8.9 g) , root (7.9 g) and total dry weight of the seedlings (23.4 g) were highest in treatment T1. Leaf dry weight (6.9 g) was highest in the T2 treatment. Root-Shoot ratio (2.3) was highest in treatment T3, with Quality Index (1.916) being highest in the T1 treatment. Height

increment per week (7.85 cm) was greatest in the T2 treatment. It is concluded that a lime application of 10-20 t/ha to soils with pH values of approximately 5.5 significantly increases soil pH and enhances the growth performance of *L. leucocephala* seedlings.

Water use by some forest plantations species in the tropics

José Kallarackal, C.K. Somen
Kerala Forest Research Institute, Plant Physiology Division, Peechi 680 653 Thrissur, India
Tel: +91-487-782037 (O), FAX: +91-487-782249,
Email: libkfri@md2.vsnl.net.in

Criticism of water use by forest plantations has been made by several environmental groups. Exotic plantations, like eucalypts, have been criticised for their excessive water use in the tropics. A detailed study on the water consumption of *Eucalyptus tereticornis*, *E. grandis*, *Acacia auriculiformis*, *Anacardium occidentale* and *Tectona grandis* has been conducted in the State of Kerala. Some of the above species are exotics and others are natives. Plantation water consumption was estimated with the Penman-Monteith model. Some of the salient results from the study are the following:

1. *Eucalyptus tereticornis* is an excessive water consumer with very little stomatal regulation during the dry season.
2. *Eucalyptus grandis* has a good stomatal control mechanism that reduces excessive loss of water.
3. *Acacia auriculiformis* has well-developed stomatal control mechanisms that reduce water loss during the dry season. However, the species transpires actively under high soil water availability conditions.
4. *Anacardium occidentale* has a stomatal mechanism similar to *Eucalyptus tereticornis*.
5. *Tectona grandis* conserves water by its deciduous habit in the dry season. However, it consumes excessive water during the post monsoon season.
6. Plantation water use in tropical areas with seasonal rainfall may only be a critical issue in the dry season.
7. It is important to choose suitable exotic species for plantations in the tropics if excessive water consumption needs to be avoided.

An extension of this study showed that the eucalypt roots invaded the water table of the study area, explaining the high water consumption by the eucalypts during the dry season. Excessive water consumption can be reduced to some extent by increasing tree spacing in plantations. *Eucalyptus urophylla* has higher water use efficiency in comparison to some of the other eucalypt species currently grown in plantations in India.

Early Selection of Sitka Spruce Using Farm-Field Site Technique

Dinesh Karki
Department of Forest Research and Survey, Post Box # 3339, Kathmandu, Nepal
Email: foresc@wlink.com.np

Early selection is used to identify the superior genotypes long before they have reached the rotation age. It increases the genetic gain through shortening the generation interval and cost of progeny testing programme. However, co-ancestry problem associated with the quick turn-over of generation is the subject of major concern among the tree breeders.

Data collected by the Tree Improvement Branch of the British Forestry Commission's Northern Research Station were analysed. In retrospective progeny test 32 open pollinated families were planted in fertile and uniform farm-field site using intensive site preparation and close spacing. The same families had previously out-planted in two forest based sites. Farm-field plantations were of four years and forest based plantations were of eight years.

The most important parameters required for reliable early selection are high heritability and strong juvenile-mature correlation. Analysis of study showed low heritability and weak juvenile-mature correlation for all measured traits. Families with best performance at younger farm-field site were not consistently good performers at older forest based sites. A high genotype environment interaction was observed between farm-field sites and forest based sites.

Both farm-field sites and forest based sites were far from ideal. The poor site selection is possibly the main reason for the disappointing results. However, the results of this study do not undermine the possibility of future research on successful early selection of Sitka spruce (*Picea sitchensis*) in Britain.

Interactions in the Mycorrhizosphere of an Altimontane Norway Spruce Forest Undergoing Natural Regeneration

Hojka Kraigher, Tadeja Trost, Urska Vilhar & Jurij Diaci
Slovenian Forestry Institute, Slovenia
FAX: +386 61 273 589, Email: hojka.kraigher@gozdis.si

Natural regeneration of Norway spruce has been studied in an altimontane autochtonous Norway spruce stand on permanent forest research plots in the east Julian Alps in west Slovenia. Sampling plots (0.5 x 0.5 m) were distributed in wind-rose directions (N, E, S, W) at every 2 m in three developmental phases (old growth-F, young regeneration center-D, clear-cut-G). In 45 soil samples (274 ml, 0-18 cm deep) 61,000 root tips were counted, 1 to 3% of which were nonmycorrhizal. Old unidentifiable ectomycorrhizal types were observed on 52% (F), 70% (D) and 81% (G) of all root tips. From the other, i.e. vital types of ectomycorrhizae, 20 (F), 10 (D) and 5 (G) types were identified on each of the plots. Most ectomycorrhizae are undescribed types for which the identity of the fungal partner is not known. The number of roots and diversity indices were correlated with the presence of natural spruce seedlings and their survival. Data and correlations are compared with the influences of the relative direct irradiance and winter dessication on the plots. Possible biodiversity impacts on plant production and processes in the forest ecosystem will be discussed.

Growth, Nutrition and Photosynthesis ofEectomycorrhizal (EM) and Arbuscular Mycorrhizal (AM) Tropical Tree Seedlings

W. U. Kriebitzsch, Ch.Then
Institute for World Forestry, Federal Research Centre for Forestry and Forest Products,
Leuschnerstr. 91, Hamburg, Germany
FAX: +49-40-73962-480, Email: oecokri@aixh0101.holz.uni-hamburg.de

The objective of this work is to gather information on the autecology of the EM tree species to integrate them into rehabilitation programmes for degraded land. These species mainly grow on very poor soils in nature and thus seem to be suitable for reforestation of strongly devastated sites. Answers to the following questions are of unique importance: What are the light and nutrient demands of seedlings in their juvenile stages? Is there any difference in shade tolerance between ectomycorrhizal and endomycorrhizal species? What are the effects of fertiliser treatments and of mycorrhizal infection on the ecophysiological behaviour of these species? Are there any differences in the adaptability of the investigated tree species for different light intensities?

The investigation of different growth parameters shows clear differences between the tree species with VA- and EM-mycorrhiza, however also great differences in each group. All parameters show a great impact of irradiance on plant development. The seedlings of the VA-tree species are better shade-adapted than those of the EM-tree species. *O. alata* has an intermediate behaviour between the groups.

The seedlings of all VA-tree species have relatively high demands on the supply with basic cations. This holds also true for the EM-tree species *M. bisulcata*, but not for *T. moreliana*. The demand to single elements are distinctly different between the species. Evidently especially nitrogen is the growth - limiting nutrient in the discussed experiments. The phosphorus contents in the leaves are particular high in the MYK treatment due to enhanced P- absorption and/or partly to P accumulation as a consequence of reduced growth and biomass production in the MYK treatment.

The VA-tree species have higher demands on water supply as the EM-tree species. *M. bisulcata* shows a particular high adaptability to dry conditions. EM hyphae and mantle improve water storage and supply, which could be responsible for the high specific leaf area of M. bisulcata and the low water use efficiency values of all three investigated tree species in the MYK treatment, compared with the COM treatment, which in its turn is typical for moist sites. On the other hand the improved water supply can enable the EM- species to grow on very dry soils.

The VA-tree species are distinguished by a high productivity, which is conform with the high nutrient and water demands. High mycorrhizal infection rates produce high carbon sinks. Therefore dry weight, leaf area and photosynthetic capacity of *M. bisulcata* and of *O. alata* are reduced in the MYK treatment. Possibly improved biomass data for *T. moreliana* in this treatment are an effect of an extreme positive benefit/cost ratio of EM- symbiosis of this species.

Distribution and Genetic Diversity the Case *of Terminalia Paniculata* (*Combretaceae*)

Krishnan
India

The Western Ghats Forests in India are considered as one of the biggest Biodiversity hot sports in the world. The past management during colonial era and subsequent management interventions has caused disturbance of the Western Ghats Forest ecosystems, resulting in the change in the loss of genetic diversity and vegetation structure. At present, in the semi-evergreen forest and moist deciduous forest of Western Ghats Forest, the *Terminalia paniculata* is a dominant species. However the fire and grazing in the Western Ghats Forest has contributed for the loss of genetic diversity of many species. To estimate the loss of genetic diversity in the Western Ghats Forest, the *T. paniculata* was chosen as it is an important dominant species. The field inventory was done to measure the distribution of this species in different sites to estimate the species richness and diversity in the site. Further samples of mature leaves were collected from the trees and seedlings in every sample plot and proteins were extracted. Further total genomic DNA was extracted and purification was done with ethanol gradient at-20°C over night. The following restriction enzymes were used: Eco RI, Eco RV and Hind III. The DNA digested was loaded to 0.8% agarose gel with ethidium bromide and run for 2 hours. The bands were visualised under UV light and interpreted. From the studies it is evident that, the regeneration and genetic diversity of *T. paniculata* is poor in the disturbed sites as compared to the undisturbed sites.

Morpho-Physiological Direction in Forest Tree Breeding: its Characteristics, Methodical Basis, and Perspectives of Development

Gregory T. Krynytsky
Ukrainian State University of Forestry and Wood Technology,
103 Gen.Chuprynky str., UA-290057 Lviv, Ukraine
Tel: +00380-322-971765, FAX: +00380-322-971765,
Email: krynytsk@forest.lviv.ua

Modern tendencies of the development of the genetic and breeding investigations in the forest phytocoenoses allow to separate a new morpho-physiological direction, that forming on the bounder of the Forest Breeding and the plant physiology.

The morpho-physiological direction in the forest breeding is aimed at the study of the physiological-biochemical aspects of the genotypes vital activity in the concrete conditions of the environment. This direction foresees also the transition from the genetic-breeding investigations by the scheme "genotype-accumulation of the phytomass (or other breeding trait)" to the complex investigations: "genotype-concrete environment conditions-physiological-biochemical processes-accumulation of the phytomass". The principal difference of this direction from other ones is such, that the breeding process is aimed in this case not at the genotype only but at the genotype with taking into consideration the mechanisms of its realization in the concrete environmental conditions. The morpho-physiological direction foresees the breeding to the reciprocal action in the system "genotype-environment". This reciprocal action becomes apparent by the intensity of the physiological-biochemical processes. This way it is provided the organic connection of the forest breeding with the trees plant's physiology and the development of the breeding investigation with taking into consideration of the physiological-genetic regularities of the productive process.

It is worth while to include in the system of the genetic-breeding tests of the morpho-physiological direction:

- physiological-biochemical indicators, that reflected the general level of the metabolism and vitality of plants: bio-potentials, bio-electrical reactions to the dosed external irritant, impedance, polar capacity;
- physiological-biochemical indicators, that determined the production process: photosynthesis, temp respiration, photo-respiration, pigment contents;
- molecular-genetic criterions; terpens, isozymes etc.

As the additional criterions it should used the morpho-anatomic indicators of the leaf apparatus, biometrical indicators of trees and other physiological-biochemical traits.

For the receiving of the correct results it is necessary to carry out the frequent measurings and to time them to the main phenological phases and to difference after the enthogenesis stages.

The considerable increase of the effectiveness of the breeding could be achieves by the conducting of the investigations of the dynamics of the physiological- biochemical processes at the same time with the static measurings. It should be the transition from the static system of the indicators to the static-dynamic one, in which the physiological-biochemical parameters (as markers) become more greater importance. Therefore it is proposed for the decision of the different genetic-breeding tasks the new indicator-the degree of junction, correlation of changes (dynamics) of the physiological-biochemical processes in the time of the investigated objects.

The morpho-physiological direction in the forest breeding foresees three stages of the selection. It is recommended at the first stage to distinguish two trees categories by the morpho-physiological indicators - high-productive and low-productive trees. By the conducting of the deepened breeding works it is proposed to carry out the second selection among high-productive trees on the plus genotype and the increased level of vitality on the physiological-biochemical and the molecular-genetic parameters.

The third stage of selection foresees the examination on the high productivity of the plus trees, selected at the second stage on progenies.

The morpho-physiological direction in the forest breeding foresees three stages of the selection. It is recommended at the first stage to distinguish two trees categories by the morpho-physiological indicators – high-productive and low-productive trees. By the conducting of the deepened breeding works it is proposed to carry out the second selection among high-productive trees on the plus genotype and the increased level of vitality on the physiological-biochemical and the molecular-genetic parameters.

The third stage of selection foresees the examination on the high productivity of the plus trees, selected at the second stage on progenies.

The morpho-physiological direction of the investigations corresponds to the modern tendencies of the forestry and forest management development. One of the main tasks is the investigation of the individual variability of the trees in the populations of the main forest species by the intensity of the primary physiological-biochemical processes, that provides the active growth, the accumulation of the phytomass and the biological firmness of the plants.

Induction of Lammas Shoot Formation and Flowering in Japanese Red Pine by Heating in Spring

Tatsuya Kushida, Hiroshi Nagata
Mie University, Fac.of Bioresources, 1515 kamihama-cho, 514-8507 Mie, Japan
Tel: +81-59-232-1211 ext. 2536, FAX: +81-59-231-9517, Email: kushipie@u-net.or.jp
s8kusht@maric.bio.mie-u.ac.jp

Potted two-year-old seedlings of Japanese red pine (*Pinus densiflora*) were transferred into a greenhouse, which had an adjusted minimal temperature of 18°C, from the outdoors on February 20th, March 7th, and 22nd, 1990, before the initiation of spring flush. On May 22nd 1990, these seedlings were returned to the outdoors. The earlier the seedlings were transferred into the greenhouse, the earlier the second flush started, the greater the percentages of lammas shoot elongating, and the larger the lengths of terminal buds (the amounts of the secondary flush). In a second experiment, potted seedlings were divided into two groups. The first group included 139 seedlings grown in the greenhouse under the condition of a minimal temperature of 18°C from March 6 to June 4, 1990 (heated treatment), and the second group included 237 seedlings grown under outdoor conditions (non-heated treatment). The terminal buds of seedlings in both treatments were periodically sampled and the numbers of leaf primordia formed in the buds were counted under a microscope. In the heated seedlings, more than 90 leaf primordia were observed in August when rapid internodal elongation in the buds occurred. No internodal elongation occurred in more than 90 leaf primordia observed in the non-heated seedlings in September under short-day conditions. It is concluded that lammas shoots in Japanese red pine are the elongated buds with 90 through 100 leaf primordial that develop under 14 hours day length or more. However, many studies attribute the causes of the lammas shoot formation to the nutritional condition, soil water content, accumulation of stored substances inside the tree, day length and temperature. From our experiments, it is clear that those factors are secondary and indirectly relate to the formation of lammas shoots through their influence on the formation rate of leaf primordia. In a third experiment, potted seedlings were carried into the greenhouse on February 20th, March 2nd, 12th, and 22nd 1995. They were returned to the outdoors on May 21st. The earlier the seedlings were carried into the greenhouse, the greater the percentages of lammas shoots that elongated and the greater the lengths of terminal buds. The numbers of male flowers in the heated seedlings were more abundant than for the outdoor seedlings, while the numbers of female flowers in the heated seedlings were fewer. The elongation of terminal buds resulting from lammas shoot formation seemed to be related to the differentiation of the male flowers. The number of male flowers was infrequent in excessively elongated buds. Few seedlings had both male and female flowers in either heated or non-heated treatments.

Cloning of S-ACC Synthase and T-ACC Oxidase Genes and Expression of Antisense Constructs in Transgenic Plants

Mingliang Li
Chinese Academy of Forestry, Molecular Genetic Laboratory,
The Institute of Forestry, 100091 Beijing, China
Tel: +86-10-62889641, FAX: +86-10-62872015, Email: mlli@rif.forestry.ac.cn

This research project was aimed at obtaining an ACC synthase gene-homolog from *Populus deltoides*, constructing an expression vector containing an antisense fusion gene of ACC synthase and ACC oxidase, and obtaining transgenic plants in which ethylene production during flower senescence and fruit ripening were inhibited by antisense RNA.

A 1.5kb cDNA fragment of ACC synthase was amplified from cDNA of soybean and a 0.9kb cDNA fragment of ACC oxidase was amplified from cDNA of tomato through the polymerase chain reaction (PCR), cloned, and a fusion of the ACC synthase and the ACC oxidase genes constructed. The ACC synthase and ACC oxidase genes and their fusion gene were inserted into a binary vector, pBin438, in an inverted orientation between the CaMV 35S promoter and Nos 3? termination sequence, to construct expression vectors pBAACS, pBAACO and pBAACSO. The fusion gene was also inserted into pBI121, in sense orientation, to construct the expression vector pBSACSO. A genomic library of *Populus deltoides* was screened to obtain the ACC synthase gene of *Populus deltoides* using a cDNA of Soybean ACC synthase as a probe.

Transgenic *Populus deltoides* containing one of the three antisense genes, or the sense fusion of ACC synthase with ACC oxidase, and transgenic lily (*Lilium brounii* L.), babys-breath (*Gypsophila paniculata*), carnation (*Dianthus fragrans* Fisch), date (*Zizyphus jujuba* Mill. Var cui and *Zizyphus jujuba* Mill. Var Xiang), and kiwi-fruit (*Actinida chinensis* Planch var. Hayward) containing the antisense fusion gene, were obtained, respectively, by Agrobacterium-mediated transformation of leaves (except the sense fusion transgenic *Populus*, which was transformed by a partial bombardment method). Both PCR detection and Southern blot analysis confirmed the successful integration of a single antisense gene or a single sense gene in the genome of the transgenic plants, and more than 15 plants of each species were obtained. The results from reverse transcription PCR (RT-PCR) of RNAs isolated from the transgenic plant leaves confirmed that antisense RNA was present in the antisense transgenic plants, and that sense fusion RNA was present in the sense transgenic plants. The amount of ethylene released from the antisense transgenic plants was much lower than that released from non-transformed control plants, especially for the transgenic plants containing the antisense fusion gene, from which the amount of ethylene released was less than 9% of that from the control plants. Leaf senescence was delayed in these ethylene-deficient plants. The amount of ethylene released from some of the transgenic poplars containing the sense fusion gene was at different level, some released more ethylene and some released less ethylene than non-transformed controls. The effects of the antisense fusion gene on flower senescence and fruit ripening in transgenic plants are currently being tested.

Effects of RNA Editing on the Phylogeny Reconstruction Based on CoxI Gene

Meng-Zhu Lu, Alfred Szmidt and Xiao-Ru Wang
Chinese Academy of Forestry, Research Institute of Forestry, 100091 Beijing, China
Tel: +86 10 62888862, FAX: +86 10 62872015, Email: lumz@rif.forestry.ac.cn

CoxI genomic and cDNA sequences from gymnosperms and angiosperms were used to study the effects of RNA editing on gene evolution and phylogeny reconstruction. In six gymnosperms harboring edited coxI gene the number of nucleotide substitutions at 1st, 2nd and 3rd codon positions was similar. In contrast, in angiosperms, the number of nucleotide substitutions at 1st and 2nd codon positions was much lower than at the 3rd. The coxI gene in long-lived gymnosperms evolved much faster than in annual angiosperms. This accelerated rate of nucleotide substitution in gymnosperms is due to accumulation of T-C substitutions at edited sites that can randomly appear at all three codon positions. Editing predominantly occurred at 1st and 2nd codon positions as a result of selection against nonsynonymous T-C substitutions and other types of mutations. The tree topologies for the investigated species based on genomic DNA data were in concordance with their taxonomic positions. The trees based on polymorphic edited sites agreed with trees derived from complete sequence information. This indicates that edited sites are reliable sources of phylogenetic information especially for species that contain many edited sites. However, the fast evolution rate of coxI gene in gymnosperms has caused the long branches in the phylogenetic trees. The inclusion of the species with a processed paralog i.e., edited form of the coxI gene, affected the topology of phylogenetic trees, especially when the taxon with a processed paralog was closely related to the other species analyzed.

Effects of AMF Alkaline Phosphatase Activities on *Hippophae rhamnoides* Drought-Resistance under Water Stress Conditions

Tang Ming
Northwest Forestry University, Faculty of Forest Products and Engineering,
712100 Yangling Shaanxi, China
FAX: 029-7082093

The relationship of AMF alkaline phosphatase (ALP) activity and drought resistance of the mycorrhizal fungus *Hippophae rhamnoides* was studied under water stress conditions with histochemical techniques. Total hyphae and functional hyphae provide the base for the active hyphae, and amounts of these hyphae decrease in the order of total hyphae > functional hyphae > active hyphae. Active hyphae play an important role in biomass accumulation of the host tree. Active hyphae with ALP activity have a beneficial effect on *Hippophae rhamnoides* growth and its drought resistance. In addition, high ALP activity is related to an increase in the fresh weight of the host trees and a reduction in wilting. The direct participation of ALP in the exchange of phosphorus nutrient substances with host trees can improve the nutrition and water status conditions of trees as well as their drought resistance.

Interspecific Hybridization between *Populus alba* Oliv. and P. *euphrotica* L. using *In Vitro* Technique

A. Jafari Mofidabadi, A.R. Modir-Rahmati
Research Institue of Forests and Rangelands, Post Box # 13185-116, Tehran, Iran

An *in vitro* method was used to produce hybrid plants between *Populus alba* L. and *P. euphratica* OLIV in two directions. Developed ovaries and ovuels were isolated from *P. alba* L. female branches which were pollinated with *P. euphratica* pollen grains by using twig and pot breeding technique. The same procedure were carried out in the case of *P. euphratica* OLIV female branches with *Populus alba* L. pollen grain. Isolated ovaries and ovules of both crosses were then transferred to growth regulator free half concentrated MS agar medium for embryo germination. Fourteen days old *Populus alba* L. ovary and ovule embryos produced the highest plantlets, while 45 days old ovary and ovule embryos of *P. euphratica* OLIV were necessary to obtain hybrid plants. Maximum two to three plantlets were observed in both *Populus alba* L. and *P. euphrotica* OLIV ovary culture. More than 90% of pollinated *P. euphrotica* OLIV and *Populus alba* L. ovules successfully produced plantlets, whereas the efficiency of pollinated ovaries to produce plantlets was 70% for *Populus alba* L. and 67% for *P. euphrotica* OLIV. Plantlets were cultured in the same medium within jars, before being transferred to potting soil. Seventy five interspecific *P. alba* L.x *P. euphratica* Oliv and twenty six of *P. euphratica* OLIV x *Populus alba* L. Hybrid plants were successfully acclimatized in greenhouse.

Agroforestry in Dry Areas

M. Mohiuddin
University of Chittagong, Institute of Forestry & Environmental Sciences, Chittagong, Bangladesh

Limitation of soil water is one of the most important plant stress variables in many parts of the world, particularly in monsoon and savannah climates. The tree and crop component species of an agroforestry practice in a dry area may compete with each other for soil water leading to a negative interaction between the components. However, differential responses of trees and field crops to drying soil could overcome this situation. Understanding the competition and complementarity between component plant species in an agroforestry system with limited soil water supply may aid design of a system with enhanced productivity.

Competition for water can cause leaf water potential and stomatal conductance of component species to be reduced. However, competition for soil water may be reduced if a deep-rooted component is able to transport water from deep moist subsoil to the surface soil enhancing available water for a shallow rooted component. Conversely reduced development of root mass in a drying soil may lead to reduction in the competitive ability of that component species.

The key to effective agroforestry practice in dry areas is the efficient use of water throughout the soil profile. Increase in the root/shoot ratio and deep penetration of roots in gradually drying soil together with differential ecophysiological characteristics of the component species could facilitate maximum root exploration and water use throughout the soil profile. In addition, reduction of stomatal conductance and leaf expansion during soil drying can reduce transpiration resulting in the conservation of available soil water. Suitable choices of complimentary species components in agroforestry could facilitate sustainable production in dry areas.

Diversity of Arbuscular Mycorrhizal Fungi and their Associations with Angiosperms of the Western Ghats Region of Southern India

T. Muthukumar, K. Udaiyan and K. Vasantha
Bharathiar University, Departmant of Botany ,Microbiology Laboratory, 641 046 Coimbatore, India
FAX: 091-422-422387, Email: tmkum@yahoo.com

The Western Ghats extend for about 1600 km from the Tapti River in the North to the peninsular tip in the south. This is a floristically rich region next to the Himalayas, and is one of the 18 areas in the world recognized for high biodiversity. Mycorrhizae have long been known to be important in symbiotic relationships with many forest species. Most plants in natural ecosystems rely on mycorrhizae for the uptake of water and nutrients; these associations are obligate for many tropical plants. The diversity of arbuscular mycorrhizal (AM) fungi of the Western Ghats was investigated. We examined the soil and root systems of 329 angiosperms, representing 60 families, from three vegetation types of seasonal forests, scrublands and grasslands.

The incidence of mycorrhizae in the 329 angiosperms was significantly higher than that reported for other ecosystems. AM associations were identified in 308 species, with 159 of these being recorded for the first time. In addition, AM associations were found in families that typically lack mycorrhizae. A total of 36 AM fungal species were identified as follows: 4 *Acaulospora*, 2 *Gigaspora*, 21 *Glomus*, 4 *Slerocystis* and 5 *Scutellospora* species. Five *Glomus* species were previously undescribed and two are an addition to the Indian Glomales. The mycorrhizal status of the plant species seems to be associated with plant life form and life cycle patterns. Similarly, the fungal richness and spore populations of AM fungi tended to depend on the vegetation types. The importance of conserving AM fungal diversity and preserving their role in natural ecosystems of the Western Ghats is discussed.

Studies on the Biochemistry of Nitrogen Fixation in *Acacia Catechu* and *Robinia Pseudoacacia* L.

Nath Kaur Amarjit
Dr. Y.S. Parmar University of Horticulture and Social Sciences, Dept of Biotechnology, 173 230 Nauni-Solan, India
Email: asc@yspuhf.hp.nic.in

Robinia Pseudoacacia, a fast growing tree legume, has been successfully grown in the degraded hill conditions of the Himalayas. This species is planted on dry sites that experience water deficiency during summer and winter. Studies of water stress effects on various biochemical parameters in nodules and leaves of three-month old seedlings of *R. pseudoacacia* were undertaken. Water stress applied for 3, 7 and 10 days followed by re-watering for the same number of days gave signs of recovery from water stress in all the seedlings. However, the seedlings subjected to 10 days of water stress showed complete wilting followed by re-emergence of leaves, regeneration of nodules and recovery of biochemical parameters after re-watering. These results indicate that seedlings of *R. pseudoacacia* are capable of enduring short periods of water deficit shocks during transplanting.

The regulation of sucrose hydrolysis and utilization of hexose were investigated with partially purified alkaline invertase from developing nodules of *R. pseudoacacia*. The enzyme was purified 78 fold with 71% recovery. Sucrose seems to be the main factor controlling invertase activity.

Acacia Catechu willdenow, a nitrogen fixing tree legume of the west Himalayan sub-tropical zone and Shiwalik Hill area, occurs widely on degraded sites. Apart from its utility in agroforestry, it is widely used for the extraction of tannin. In addition to the process of symbiotic nitrogen fixation, leguminous crops also make use of nitrate assimilation for meeting their nitrogen requirements. Nitrogen metabolism of A. catechu seedlings was studied after 5, 10 and 15 days of daily application of 20 mM nitrate. The results suggest that application of nitrate (20 mM) for short periods (15 days), before seedlings are transplanted for afforestation, is beneficial. The survival rate of nitrate-treated seedlings may be improved. The long-term effect of applied nitrate affects the partitioning of photosynthates.

Metabolism of phosphoenol pyruvate in developing nodules of *A. catechu* was studied on 4 to 5 month-old seedlings that had well a developed tap root and lateral roots. Nodules at this stage of development were healthy and showed no sign of degeneration. The activities of enzymes involved in carbon metabolism viz., NAD-malate dehydrogenase, NAD (P) isocitrate dehydrogenase and pyruvate kinase were highest at this stage. Seedling survival rate was 100% when transplanted at this stage. However, by the end of November, when leaves started falling, nodules showed signs of degeneration. Attempts were also made to partially purify and characterize the above mentioned enzymes at this stage.

Genetic Variation on Growth and Selected Wood Properties of *Acacia auriculiformis* Provenances

Mohd M. Noor, Nor Aini A. S. and Kamis A
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia

A trial at Universiti Putra Malaysia (UPM) Serdang, Malaysia consisting of twenty eight provenances of *Acacia auriculiformis* A. Cunn. ex. Benth was assessed at four years for total height, diameter at breast height, specific gravity and fibre length. Of these provenances, 7 were from Queensland (QLD), 15 from the Northern Territory (NT) and 6 from Papua New Guinea (PNG). The provenances and geographic regions differed significantly at $p<0.05$ in their growth performance. Generally the Queensland provenances recorded the best growth in both height and diameter followed by the Northern Territorry and Papua New Guinea Provenances. The mean total heights for provenances from Queensland, Northern Territory and Papua New Guinea were 13.38m, 12.37m and 11.89m respectively. The mean diameters at breast height for provenances from Queensland, Northern Territory and Papua New Guinea were 12.6 cm, 11.04cm and 10.69cm respectively.

A similar pattern of variation was found in the wood properties except for wood specific gravity where there was no significant difference encountered between the three geographic regions. However, there were significant variation between provenances on both wood properties studied. The mean specific gravity ranged from 0.53 for the provenance from Balamuk on Bensbach (PNG) to 0.61 for the provenance from South Balamuk (PNG). The mean fibre length ranged from 0.865mm for the provenance from Balamuk on Bensbach (PNG) to 0.993mm for the provenance from Coen River (QLD).

Generally, the percentages of variance components due to between and within provenances were high for growth and wood properties. Most of the genetic variation was contributed by the variation of the traits between individuals within provenances. This was shown in the residual variance components of all traits that ranged from 32-71%. Based on the basic information obtained on the genetic variation of this species, the alternative selection strategy recommended for the species is through selecting more individuals within provenance levels from all geographic regions.

Keywords: Geographic region, Provenance, genetic variation, total height, diameter at breast height, specific gravity, fibre length, variance component

Effects of Aluminum on Growth and Physiology of Woody Plants

Asayo Oda, Fukuju Yamamoto
Tottori University, Department of Forest Science, 680-8553 Koyama, Tottori, Japan
FAX: +81-857-31-5347, Email: fukuju@muses.tottori-u.ac.jp

We have found that aluminum application to hydroponic solutions increased the root dry weights of *Betula grossa* and *Quercus myrsinaefolia* seedlings. These experiments have now been extended to a more detailed study of growth of aluminum-treated species, with emphasis on relationships between phosphorus and aluminum in culture solutions.

Experiment 1: Two-year-old seedlings of each of *Eucalyptus viminalis*, *Quercus acutissima* and *Cinnamomum camphora* were used in this experiment. Culture solutions (pH 4) containing 0, 0.05, 0.5, 5 and 50 mM Al were prepared. The seedlings were cultured for 35 days and dry weights of leaves, stems, and roots were determined separately. In each species treated with 5 mM Al, dry weights of both shoots and roots were greater than those of other concentrations of Al. Newly-formed roots of *Q. acutissima* and *C.*

camphora in the solution containing 5 mM Al were the largest among all of the plant parts.

Experiment 2: To determine interactive effects of P and Al on growth, 1/5 Hoagland medium without P was prepared. Using this medium, 19 different culture media (pH 4) were prepared by mixing 0, 0.02, 0.2 and 2 mM P and 0, 0.05, 0.5, 5 and 10 mM Al in all combinations. The control medium containing P but no Al was pH 5.8. Two-year-old *E. viminalis* and *Q. acutissima* seedlings were cultured for 4 and 7 weeks, respectively. One half of E. *viminalis* seedlings cultured under 0, 0.02, and 0.2 mM P in combination with 10mM Al died within 4 weeks. The biomass of both shoots and roots in the surviving E. *viminalis* seedlings was reduced. In the *Q. acutissima* seedlings the dry weight of new roots increased in the solutions containing 0.5, 5, and 10 mM Al. However, the application of 2 mM P to the solutions containing 0.5 or 5 mM Al suppressed the seedling dry weight increment. All of *Q. acutissima* seedlings cultured in 10 mM Al solution with or without P survived and the dry weights of new roots increased. These results suggest that the root formation in the seedlings cultured with soluble Al is highly related to the reduction of toxic effects of Al in shoots of seedlings.

Experiment 3: To determine the effect of Al on the growth of P- or Ca-deficient plants, 1-year-old *Q. acutissima* seedlings were cultured for 9 weeks in 3 different hydroponic solutions as: 1) 1/5 Hoagland medium; 2) 1/5 Hoagland medium without P; and 3) 1/5 Hoagland medium without Ca. At Day 64, the seedlings from each of these hydroponic treatments were divided into three groups and transplanted to three different media (pH 4) containing 0, 0.27, 2.7 mM Al, respectively, and cultured for 6 weeks. The seedlings were harvested, the dry weights of plant parts were determined, and Al, Ca, P, Na, Mg, Ca and K contents of each part were analyzed. In the Ca-deficient solution without Al, the rate of root elongation declined within 9 weeks. The dry weights of new roots significantly increased after 6 weeks in the solution without Ca and containing 2.7 mM Al. The biomass of both shoots and roots was reduced in the P-deficient medium containing 2.7 mM Al. Under the treatment of 2.7 mM Al, high levels of Al were detected in roots and leaves. These results indicate that the presence of Al in plants increases P uptake into roots and excludes Ca from the roots.

Clonal Propagation Technology for Neem (*Azadirachta Indica* A. Juss) to Improve Productivity

K. Palanisamy
Institute of Forest Genetics and Tree Breeding, R.S. Puram, 641 002 Coimbatore, India

Neem (*Azadirachta Indica* A. Juss) is a globally important tree species. The azadirachtin obtained from it is used as an environmentally safe insecticide. It is an evergreen tree but it shows complete leaf fall for short duration (10 days) followed by bud break). Clonal propagation technology through branch cutting of the mature neem tree is the standard propagation technique. Cuttings (20cm length and 1.0 cm diameter) collected from mature trees (25 to 30 years) are treated with 1000ppm IBA (indole butyric acid) and when cut during leaf fall/bud break, give rise to greater than 80% rooting. At other times rooting is only 0 to 20% effective. It is presumed that some root forming substances are synthesized from the emerging new sprouts, which induce root formation. There is a direct relationship between peroxidase activity and adventitious rooting in neem. High root formation coincided with less peroxidase activity and poor rooting with maximum activity, and the peroxidase can be used as a biochemical marker for rooting potential in neem cuttings. Cuttings from the lower, middle and upper crown of the tree did not show any significant variation in rooting. The juvenile cuttings collected from two year old seedlings gave good rooting in most of the season. Air-layering technique in neem tree was also developed and it was successful (>90%) but only during the rainy season. In neem, high seed yielders and high azadirachtin content are the main criteria for selection of superior trees. The propagules raised through cuttings from superior trees fruit after two years. This technology will be useful for mass multiplying the superior types for plantation and thereby augment the productivity. It is also helpful for establishing clonal seed orchard and breeding populations for further genetic improvement of the species.

Production of Transgenic Poplar with Antisense OMT Gene via *Agrobacterium tumefaciens*

Young-Goo Park, I.W.Sul, I.S.Ahn and D.I.Shin
Kyungpook National University, Department of Forestry, Lab. of Forest Genetics,
Department of Forestry, 702-701 Taegu, Korea R.
FAX: 82-53-950-6798, Email: ygpark@kyungpook.ac.kr

Lignin, a major component of secondary cell walls, is formed from polymerization of three cinnamic alcohol precursors, p-coumaryl, coniferyl, and syringyl alcohols. This provides rigidity and impermeability of the plant cell walls that serve as mechanical and chemical barriers against outer environments. The content of lignin in woody plants is especially important for the pulp and paper industries, since toxic chemical treatments are needed to remove the lignin closely associated with cellulose. Development of reduced lignin content in woody tissues by genetic engineering techniques has significant benefits by alleviating the environmental safety and operational costs of the delignification process. O-methyltransferase (OMT) is the best candidate enzyme for this genetic engineering purpose. This is a methylating enzyme involved in lignin biosynthesis that catalyzes the methylation process of both caffeic and 5-hydroxyferulic acids. Down regulation of the OMT gene by the antisense RNA technique will influence the expression of the OMT gene resulting in a reduction of the lignin content in plants. This research has been the focus of low-lignin poplar plant development using the antisense RNA OMT gene via the Agrobacterium transformation system.

Populus nigra x maximowiczii leaf segments were co-cultivated with *Agrobacterium tumefacience* harbouring plasmids with OMT antisense and neomycin phosphotransferase (NPTII) chimeric genes. Leaf segments from in vitro grown poplars were detached and infected with an Agrobacterium strain. Following co-cultivation, the leaf segments were cultured on MS basal medium without growth regulators for two days, followed by growth on MS medium with 2,4-D at 2 mg/l and antibiotics, such as cefotaxime and kanamycin. Calli were induced after 5 months under dark conditions; however, growth rates were very slow compared with control plants. After one year of antibiotic selection, calli were transferred to a regeneration medium (MS supplemented with BA at 4 mg/l and antibiotics) under light conditions. Following 6 months in culture, shoots produced calli, and putative transgenic plants were transferred to a hormone-free medium to accelerate their growth rate. Molecular analysis of transgenic poplars has been undertaken to confirm the presence of the foreign genes (NPTII and OMT). The putative transformed poplars currently show a phenotypically normal status. In this research, independent transgenic lines are being continuously selected to achieve poplar plants with low-lignin content.

Physiological effects of low concentration of SO_2 on *Eugenia grandis*

Elisabeth Philip
Forest Research Institute Malaysia, 52109 Kuala Lumpur, Malaysia
Email: philip@frim.gov.my

Atmospheric pollution in urban areas is a major environmental issue in many countries. In Malaysia, public authorities and experts are trying to improve air quality in these areas. Efforts have been taken by prohibiting open burning, and stringent checks on smoke emitted from industries and vehicles. However, with the rapid increase in industries and motor vehicles, it is difficult to curb the air pollution problem completely. It was reported that emission of sulphur dioxide from industries in 1999 was estimated to be 69,000 ton/year, is anticipated to double by the year 2000 (Leong and Lim, 1994) in Klang Valley, Klang Valley houses Kuala Lumpur, the national capital, industrial areas like Petaling Jaya and Shah Alam and a sea port.

Sulphur dioxide (SO_2) is one of the most deleterious atmospheric pollutants for plants. A review by Darrall (1989) suggested that SO_2 caused both acute and chronic injuries to plants. Physiological decline is more prevalent when plants were exposed to low levels of SO_2 concentrations. One of the criteria for early recognition of incipient pollution damage in plants is disturbance in photosynthesis and alteration in stomatal opening and closing (Larcher, 1995).

A two-year study was conducted in the urban environment of Shah Alam to evaluate *E. grandis* responses to urban air pollution. *E. grandis* was chosen due to its popular choice as a landscaping tree. It is fast becoming a popular way side tree due to its oblong crown with dark green leaves. It grows quickly when young and does not produce any buttresses or surface roots. In addition, this tree does not shed its leaves frequently and has a thick bark that enables it to withstand lalland fires.

Changes in plant performance were considered in relation to the status of ambient air quality in the study area. Assessment was conducted by comparing the physiological parameters; leaf gas exchange patterns of trees grown in polluted area; Shah Alam and control site, Pangkor Laut. Six trees were chosen in each site and monitored monthly.

Reductions in photosynthetic rates, stomatal conductance and transpiration were correlated to air pollution levels at different sites. The study showed that the SO_2 and NO_2 increased the mesophyll resistance and reduced the photosynthetic rates. In this case, there was no significant difference in stomatal limitations between the control and pollution exposed plants, thus implying the decreased photosynthetic rates in the treated plants were due to biochemical limitations. The A/C_i curve suggested that these pollutants had affected the primary carboxyls and electron transport in vivo. The increase in C_i in the treated plants further substantiated that the stomata were closing as a result of this. Thus, the mechanism of stomatal closure was a result of an increase in mesophyll resistance.

Interactions Of *Acacia nilotica* Willd. Ex. Del. on *Oryza sativa* Linn.

G. R. S. Reddy, A.K. Sah, U. Prakasam and Amit Sahai
Tropical Forest Research Institute, Post Box # R.F.R.C. Mandla Road, Jabalpur, India
FAX: 91-761-321759, Email: alkamit@hotmail.com

The germination responses of rice (*Oryza sativa* Linn.) seed treated with fresh aqueous extracts from live babul (*Acacia nilotica* Willd. Ex. Del.) bulk samples derived from leaves, stem, twigs, root, flowers and seed were determined. Results indicated a positive germination response with lower concentrations of extract and inhibitive effects with higher concentrations. However, a pot culture study revealed that shoot and root lengths of rice were significantly reduced as the concentration of extracts increased. Nevertheless, seedling dry weight per plant and total biomass per pot were significantly higher as extract concentrations increased. In contrast, grain yield per plant increased in pots treated with dried litter powder up to 50 g per pot and 7.5% fresh extract concentration. Grain yields declined at higher levels of litter powder and fresh extract treatment.

Isolation of Differently Expressed cDNA Following Laser and Blade Cutting of Axillary Buds from Woody Species

A. Rodrigues, M. Salom, Pais
ICAT, Laboratory of Plant Biotechnology
Tel: (351 1) 757 36 25, Email: arod@fc.ul.pt

In a previous study on sectioning of *Persea indica* and *Arbutus unedo*, with laser beam and with surgical blade, it has been verified that a laser beam can be used as a good alternative to surgical blade sectioning of plant material in order to induce buds to break dormancy and to promote shoot development in micropropagation of woody species during winter time. The effect of laser cutting of the explants on axillary bud development seems to depend on the species used and on the period of the year for explants cutting. When the cutting is performed in November or December, cutting with a laser beam promotes break of dormancy and faster development of axillary buds. However, when the explants cutting is done in February, shoot development seems, in general, independent of the cutting method.

In vitro plants from *P. indica* and *A. unedo* even when kept under similar photoperiod and temperature conditions along the year, present, during winter time, some degree of dormancy which bring difficulties whenever in vitro multiplication programs has to be performed in winter time. This does not seem to be the case of *Populus alba* that presents, all over the year, a similar behaviour in terms of shoot bud development. In this species, the bud development in vitro was independent of the cutting method.

DDRT-PCR studies performed on *Persea indica* (an evergreen plant presenting high degree of bud dormancy *in vivo* and in vitro) and on *Populus alba* (a deciduous plant, presenting a low degree of dormancy *in vivo* and no dormancy *in vitro*) enabled the isolation, until now, of two differentially expressed cDNAs from explants of *Persea indica* and three explants from explants of *Populus* alba, when shoots were sectioned in November. The relationship between the expressed / repressed genes with the sectioning method is being evaluated. The characterisation of these cDNAs as well gene(s) expression at the cells/tissues levels and its possible role in bud development following cutting will be presented and discussed.

Change of Composition and Maintenance of Free Amino Acids in Tissues and Organs of *Pinus sylvestris* Under Flooding

Ludmyla Romanova, M Yermolaeva
V.N.Sukachev Institute of Forest, Siberian Branch RAS, 660036 Krasnoyarsk, Russia
FAX: (3912) 433686, Email: dndr@ifor.krasnoyarsk..su

During the period of intensive cambial activity, the composition and maintenance of free amino acids in tissues and organs of *Pinus sylvestris* were studied in three plots on a raised bog with differing aeration conditions in the soil root layer. Trees growing in a nearby pine-lichen forest were taken as control. Free amino acids accumulated in tissues of pine growing in the raised bog. As aeration of the root layer decreased amino acids increased in the tissues of roots and underground organs. The special role of glutamic acid in free amino acid metabolism was shown by the high proportion of glutamic acid (up to 43%) in the free amino acids of tissue samples collected during vegetative growth. Root anaerobiosis in pine resulted in high contents of alanine, proline and gamma-aminobutyric acid in tissues. These amino acids are closely connected with the Krebs cycle reactions, and under anaerobic conditions these reactions are slowed down. Utilization of amino acids in anaerobic metabolism may be limited by energetic difficulties or the absence of oxidative de-amination. The ability of pine trees to reuse internal reserves of organic nitrogen appear to be an important adaptive property for the vitality of pine under natural hypoxic stress. The study is supported by the Russian Foundation of Fundamental Research (grant 98-04-48136).

Interactions of *Dalbergia sissoo* Roxb. and *Cajanus cajan* (Linn.) Cradish

Amit Sahai, G.R.S. Reddy, Alka Bhargava and U. Prakasam
Tropika Forest Research Institute, Post Box # R.F.R.C.-482012, Mandla Road, Jabalpur, India
FAX: 91-761-321759, Email: alkamit@envfor.delhi.nic.in

The germination of perennial pigeon pea seed was studied through bioassay, using both aqueous and ether extracts of *Dalbergia sissoo*. Extracts were obtained from separate plant parts viz., leaves, stem, twigs, flowers, root and seed, as well as from the whole plant. Germination was inhibited by both lower and higher concentrations of fresh extracts obtained from live bulk samples. This inhibition was relatively low in lower concentration and high in higher concentrations. The highest inhibition of germination was up to 48.5%. Shoot length and seedling dry weight decreased up to a maximum of 24.1 and 16.9% of control values, respectively with extract treatment. Root length was promoted up to 9.6% with 5.0% fresh extract; however, this response gradually decreased after four weeks.

Pot culture studies with pigeon pea were conducted for three consecutive years using six levels of well-decomposed litter followed by fresh extracts of *D. sissoo* obtained as described above. Litter was adding every year at 3 levels in proportion to the litterfall obtained at a *D. sissoo* agroforestry field trial and at three levels above the normal for extrapolation of results. The density of seedlings was lower in pots receiving higher extract concentration than with lower concentration. Plant height, number of branches, number of leaves, number of flowers, 100-seed weight, root and shoot biomass and total biomass were also determined. Plant height increased with higher extract concentrations as was found for the number of branches, number of leaves, number of flowers, root and shoot biomass and total biomass per plant. However, the total yield per pot seems to be higher with the third and fourth level of litter treatments than with either lower or higher extract concentrations. Maximum biomass was found with litter applications between 30 to 40 g/pot, being equivalent to 2.4 to 3.2 t/ha, which is the litterfall rate in the fifth year of an agroforestry system. Higher levels of litter and fresh extracts caused a reduction in yield which suggests that litter levels in excess of about 3 t/ha should be avoided by removing excess litter from fields and using it as manure in other locations. The 100-seed weight was highest in the second year under higher concentrations of litter.

The field growth data on interactions have revealed that the growth of both the crops *D. sissoo* at 5m x 5m and pigeon pea at 1m x 1m are positively correlated up to three years from establishment of the agroforestry system. In the fourth year the pigeon-pea crop has been resown and the yield results have not yet been determined.

The inhibitive actions of fresh and decomposed litter have been related to the presence of certain allelochemicals such as phenolics and tannins. It was observed that phenolics and germination % are negatively correlated in bioassay experiments, whereas in pot culture, tannins and phenolics are negatively correlated with germination but not to the extent of the bioassay results.

Central America and the Dominican Republic Strengthen their Supplies of Genetically Improved Seeds

Rodolfo Salazar
CATIE, Turrialba, Costa Rica
FAX: (506) 556 7766, Email: rsalazar@catie.ac.cr

Forest cover in Guatemala, Honduras, El Salvador, Nicaragua, Costa Rica, Panama and the Dominican Republic is characterized by a wide diversity of broadleaf and coniferous species. Lack of planning on the wise use of land, harvest for timber and other forest products and population growth among other factors, have caused destruction of a great part of these natural forests; the negative impacts of this process are well-known.

A way to diminish some of the negative effects caused by the destruction of the forest cover is to promote reforestation. For this activity to be successful, it is necessary to define objectives, select the species, and use reproductive material of improved genetic quality, along with intensive silvicultural management, in order to guarantee higher production.

The Tropical Agricultural Center for Research and Higher Education (CATIE), located in Turrialba, Costa Rica, through the implementation of research and transfer projects on silviculture of plantations, has been supporting the above seven countries during the last 20 years. As a result of this cooperation process, native as well as introduced species with potential to promote the development of silviculture have been identified.

One of the problems being faced in the promotion of forestry plantations has been the lack of genetically improved material of priority species. Many of the plantations have been established using material of unknown origin, or without being genetically assessed.

Thus, CATIE took the responsibility of providing the necessary support to the seven countries in order to improve the genetic and physiological quality of seed of the priority species being grown, and with the economic support of the Danish Agency for International Development (Danida), it started the implementation of the Tree Seed Project (PROSEFOR) in September 1992.

During these six years, PROSEFOR has been working intensively in a joint effort with national institutions responsible for the forestry sector, in order to enable National Tree Seed Banks to satisfy national demand for genetically improved seed.

Through technical assistance and training, a complete process has been developed to identify and select the best seed sources of priority species in each country. Subsequently, technical management of these sources was initiated to improve the genetic quality of the seed to be produced. Presently, 310 seed sources of 78 priority species have been selected. Most of these seed sources have already supplied seed to the users.

To complement this important task, PROSEFOR has simultaneously strengthened National Tree Seed Banks in order to improve seed collection, processing, storing and distribution systems. Nowadays, each country has its own seed source register, which guarantees that the user will receive basic information on site and seed source characteristics.

Allelopathy in Agroforestry Systems: Interference of *Populus* and *Dalbergia* with Wheat and Maize

Harminder Pal Singh, R. K. Kohli and Daizy R. Batish
Panjab University, Department of Botany, 160 014
Chandigarh, India
Tel: +91-172-546666, 547777, FAX: +91-172-541409,
Email: hpsingh_01@hotmail.com

Agroforestry, a traditional and widely practiced land use system in India, is presently being recognized as a well-developed science of resource management. Current research in this science is directed toward understanding ecological and economic aspects based on major key factors such as sustainability, profitability, complexity and competitiveness. In the tropics, including India, the practice of agroforestry has advanced rapidly in recent years. Most of the studies have shown beneficial aspects of agroforestry. Nevertheless, some negative aspects of tree-crop combinations, such as competition among roots, shading effects and allelopathy, are also being realized. Hence, an ideal agroforestry model will have a balance between the positive and negative aspects. Allelopathy, which is now an established science in many managed and natural ecosystems, has also been investigated in many agro-ecosystems where trees are planted with crops without much planning. Since, trees are the dominant and long-lived components, their inhibitory effects on the adjoining crops cannot be ignored. In India, fast growing trees like *Eucalyptus*, *Populus* and *Leucaena* are favoured for agroforestry, and these genera have been extensively planted in agricultural fields with the aim of gaining short-term profitability.

A study was conducted in fields with 2-row shelterbelts of *Populus deltoides* and *Dalbergia sissoo*. A poorer performance of crops, particularly wheat and maize, was observed in the fields sheltered by *P. deltoides* as compared to *D. sissoo*. The inhibitory effect was observed close to the tree line rather than at distances away from the tree line. This decline in growth and yield of crops was attributed to allelopathy, particularly caused by senescent and decayed leaves, which fall abundantly and accumulate on the soil surface as litter. The allelochemicals from this litter layer are released either through leaching and/or through microbial decay. Upon release, the allelochemicals adversely affect germination, growth and yield of crops. In laboratory bioassay studies, the aqueous leachates of fresh, senescent and decaying leaves of *P. deltoides* significantly decreased germination and growth of wheat and maize. These leachates contained significant amounts of phenolics, which have also been extracted from the soil under *P. deltoides*. These studies show that *P. deltoides* is an allelopathic tree and crops grown in association with *P. deltoides* should be thoroughly screened for their susceptibility to allelochemicals. The understanding of allelopathic phenomena is essential in agroforestry ecosystems in order to obtain suitable crop production.

Initiation of Rooting in Stem Cuttings of *Salvia officinalis* L. through Growth Regulator Treatments in the Western Himalayas

Meenu Sood, J.M. Singh Rastogi & L.J. Srivastava
Dr. Y.S. Parmar University of Horticulture and Social Sciences and Forestry,
Department of Forest Products, 173 230 HP Solan, India
FAX: 91-01792-52242, Email: fpu@yspuhf.hp.nic.in

Salvia officinalis L. is a new essential oil bearing crop in Western Himalayas. It is one of the most important culinary herb. Its oil finds use in perfumes as a deodorant, in insecticidal preparations, for the treatment of gingivitis and as a carminative. It is also extensively employed in the food industry as a standard spice. It was introduced from Germany through the National Bureau of Plant Genetic Resources, New Delhi, India in mid-hill zone of Himachal Pradesh. *Salvia officinalis*, being an exotic species, has shown weak performance for rooting of stem cuttings and seed germination under Indian conditions. Hence, the present studies were conducted on the rooting of stem cuttings by taking GA3, IBA, IAA and NAA hormones and treating stem cuttings with 0, 1000, 1500 and 2000 ppm concentrations using the quick dip method for 10 and 20 seconds. Treatments with growth-promoting substances significantly promoted rooting in all cuttings over untreated cuttings. Among the different treatments, cuttings treated with 1500 ppm of IAA for 10 seconds took the least time for rooting (81/3 days), stimulated the highest percentage of rooting (84.3%), and also promoted large numbers of roots (40.7) with increased length (31.1 cm).

Genetic Engineering in the Improvement of Forest Trees: a Review

D. K. Srivastava
Dr. Y.S. Parmar University of Horticulture and Social Sciences, Dept. Biotechnology, (H.P.)- 173 230 Solan, India
Email: A.S.Chandel [asc@yspuhf.hp.nic.in]

Forest tree genetic improvement is a relatively long process limited by the rate of growth of the species involved and by the quantity of improved seeds that can be obtained through each breeding cycle. It is also a costly process because it requires the establishment of seed orchards, complex breeding plots, and often, programmes to accelerate flowering. Plant genetic engineering makes it possible to shortcut this process by allowing the isolation of specific gene(s) and transfer of single gene traits, and by using tissue culture procedures permit the production of an unlimited number of plantlets. The different approaches for transferring the foreign genes into plant cells may be divided into direct and indirect techniques. Apart from microprojectiles, with direct gene transfer methods (electroporation, microinjection, PEG-mediated and liposome-mediated delivery) the isolation of protoplasts is required. The indirect approach employs *Agrobacterium*-mediated gene transfer, using its different plasmid vectors (Ti and Ri). This system is based on the natural capacity of *Agrobacterium* to integrate its T-DNA into the plant genome. Considering its efficiency, the *Agrobacterium* system is certainly the method of choice, if the plant to be transformed is within its host range. The advantages are that complex explants, not only protoplasts, can be transformed, and that the genes are stably integrated into the plant genome and inherited in a dominant Mendelian fashion.

The development of efficient genetic transformation systems for forest tree species is of great importance to forest biotechnology. Forest tree genetic engineering is a logical complement to forest tree breeding, with the difference that it is more precise and focused. Reliable protocols for genetic transformation of forest tree species have been developed using Agrobacterium-mediated gene transfer techniques in *Allocasuorina, Azadiracta, Eucalyptus, Juglans, Larix, Populus, Robinia and Santalum*. Most research to date has been focused on the engineering of traits that relate directly to the traditional roles of industry in forestry, such as control of insects, weeds, plant diseases and lignin content. Progress has been rapid and genes conferring some of these traits have already been successfully introduced into *Populus* species. Traits such as lignin content can be manipulated through the introduction of gene(s) and could allow the production of wood tailored for specific industrial uses. As more becomes known about the molecular biology of forest tree species, more opportunities will be identified for improving forest tree growth.

Construction of *Populus deltoides* Marsh x *P. cathayana* Rehd. Molecular Linkage Map

Xiaohua Su, Zhang Qiwen, Zheng Xianwu, Li Jinhua, Stephen Harrish and B. Lurley
The Research Institute of Forestry, Chinese Academy of Forestry,
Wan Shou Shan, 100091 Beijing, China
FAX: 010-62872015, Email: suxh@rif.forestry.ac.cn

A molecular linkage map was constructed for *P. deltoides* Marsh x *P. cathayana* Rehd. based on random amplified polymorphic DNA (RAPD) markers. The mapping pedigree consisted of three generations with the F1 produced by interspecific hybridization between a *P. deltoides* female and a *P. cathayana* male. Three-hundred random 10-mer RAPD primers were screened in amplification reactions using DNA isolated from the parents and a sample of their F1 recombinant-inbred population. Of these primers, 180 revealed at least one polymorphic RAPD locus which could be used in mapping. We identified 20 linkage groups spanning 1900 cM (110 RAPD markers) with an average distance of 17 cM between markers. Linkage groups ranged from 188 to 37 cM in length and included 3 to 10 markers, respectively. This map should facilitate the identification of markers that 'tag' genes for pest and disease resistance and other traits in poplar. This is the first genetic map for *P. deltoides* x *P. cathayana*, and an important step towards the molecular breeding of poplar.

Keywords: Molecular linkage map, RAPD, *Populus deltoides* Marsh, *P. cathayana* Rehd.

Biochemical Response of Siberian Conifers to Water Deficit

Nina E. Sudachkova, I.L.Milyutina, G.P.Semenova
V.N.Sukachev Institute of Forest SB RAS, 660036 Krasnoyarsk, Russia
FAX: (3912)433686, Email: dndr@ifor.krasnoyarsk.su

The productivity of forest stands in Russia varies over a wide range, reaching a maximum only in the most favourable climatic conditions. About one half of all wood stocks in the country is located in Siberia, where productivity of the economic forest species is limited for a large part of the forest territory by natural limiting factors. Water deficit is a dominant limiting factor, particularly in the southern boundary area of the Siberian forest. Biochemical responses to water deficit were examined in *Pinus sylvestris* L. and *Larix sibirica* Ledeb. in three habitats in eastern Siberia with varying precipitation. Annual precipitation at the three study areas ranged from 460mm in Krasnoyarsk to 350-360mm in the southern locations of Minusinsk and Khakasia. Total and protein nitrogen, free amino acids, starch and the low molecular carbohydrate content in needle, xylem and inner bark of stem and rough roots, as well as, the cellulose and lignin content in stem and root xylem samples were determined.

Pine and larch trees from Krasnoyarsk populations exceed growth parameters of trees from southern populations in diameter and height increment by 30-40%. Drought caused sugar accumulation with higher monosaccharide concentrations in root bark and the cambial zone of pine trees subjected to greater water deficit. The content of non-protein forms of nitrogen, in particular, free amino acids also increased in reserve bark tissues, photosynthetic tissues and in the cambial zone. Total nitrogen and especially protein content were higher in root bark than stem bark of larch but not for the pine. In stem and root xylem of pine reserve carbohydrate compounds were dominant, whereas, proteins were dominant in larch xylem. Water deficit had no influence on the content of cellulose and lignin in the xylem of either species.

We suggest that the tissues of current shoots may be used for identification of biochemical indices of water stress in pine and larch. The combined concentrations of arginine, ornithine and citrulline in current shoots increased with decrease in the water content of the 20-cm surface soil layer, whereas, the sum of glutamic acid, proline and gamma-aminobutyric acid concentrations decreased with decrease in soil water content. The proline proportion in free amino acids increased under drought impact only in some tissues. The maximal concentration of this amino acid was found in current year shoots and did not exceed 0.1% of tissue mass. This concentration is insufficient to supply a significant osmotic effect usually attributed to proline. The study is supported by the Russian Foundation of Fundamental Research (grant 98-0448136).

Assessing Genetic Diversity of Two Different Timber Species (*Shorea parvifolia* and *Eusideroxylon zwagerii)* in Central Kalimantan Using DNA Markers

Enny Sudarmonowati, N. S. Hartati, Ulfah J. Siregar
Indonesian Institute of Sciences (LIPI), R&D Centre for Biotechnology,
Jl Raya Bogor Km. 46, 16911 Cibinong, Indonesia
Tel: 62-21-8754587, FAX: 62-21-8754625, Email: u.siregar@cgiar.org

Genetic diversity of *Shorea parvifolia* and *Eusideroxylon zwageriio* on two sites in Central Kalimantan, Indonesia, was assessed using DNA markers. Genetic diversity parameters, (number of alleles per locus, effective number of alleles per locus, number of polymorphic loci, Shannon's diversity index and Nei's gene diversity), were calculated based on four RAPD (random amplified polymorphic DNA) markers. AFLPs (amplified fragment length polymorphisms), were also used on some samples for a comparison to RAPDs. Results of RAPD analysis showed that more than 80% of the loci of *S. parvifolia* are polymorphic, whereas for *E. zwagerii* it is more than 90%. Despite logging in one site the levels of genetic diversity of both species found in two sites were similar to that of other countries.

Effects of the Application of Plant Hormones and Plant Growth Regulators on Growth and Flushing of Dormant buds in *Aesculus turbinata* seedlings

Shingo Taniguchi, Tamaki Honma and Fukuju Yamamoto
Tottori University, Department of Forest Science, 680-8553 Koyama, Tottori, Japan
FAX: +81-857-31-5347, Email: fukuju@muses.tottori-u.ac.jp

The present study deals with the effects of application of 10 different kinds of plant hormones and plant growth regulators (PGRs), including GAs (GA_3 and GA_4), IAA, trans-zeatin (t-Z), (+)-abscisic acid (ABA), Ethrel (ET), 24-epi-brassinoride (24-epi-BR), (±)-jasmonic acidmethyl ester (±)-JA-Me), uniconazole-P and AMO-1618, on growth and flushing of dormant buds in 2-year-old *Aesculus turbinata* seedlings. Seven different concentrations of PGRs from 0.0001 to 500 µg/10 µl (50% acetone solution) were prepared and each 10 µl solution was applied to the apical bud of each seedling by injection with a micro-liter syringe. Four seedlings were used for the same treatment. A 10 µl of 50% acetone solution was also applied to seedlings as a control. The treatments were started on June 6, 1998 and repeated 4 times at 7-day intervals.

The application of GA_3 and GA_4 at higher concentrations increased the growth of apical buds. However, the growth was suppressed by the applications of low concentrations of IAA, high concentrations of t-Z, (+)-ABA, Ethrel, uniconazole-P and AMO-1618. The growth of lateral buds was accelerated by the applications of high levels of GAs, uniconazole-P, and AMO-1618. These results suggest that the GAs are essential in the growth of dormant buds in *A. turbinata* seedlings.

The applications of GAs, IAA, (±)-JA-Me and Ethrel enhanced the flushing of dormant buds at various concentrations, suggesting the roles of these PGRs in bud breaking. In IAA-applied seedlings, the apex of apical buds became round shaped. The leaflets on apical buds abscised in the IAA or Ethrel treated seedlings.

Reproductive Potential of Siberian Forest Forming Conifer Species in Destructive Forest Ecosystems

I. N. Tretyakova
V.N. Sukachev Institute of Forest, Russian Academy, Siberiasn Branch, Academgorodok, 660036 Krasnoyarsk, Russia
FAX: 8(3912) 433686, Email: dndr@ifor.krasnoyarsk.su

The extreme conditions in Siberia (unfavourable ecological factors, region of geophysical anomalies) influence greatly on viability and productivity of forestforming tree species. The change of crown structure, defoliation of needles and decrease of viability of generative organs are considered to be a response of conifer species to unfavourable ecologicalfactors. The loss of apical dominance, the appearance of subapical zone of degradation in shoots of male sexualization (*Abies*) as well as appearance of various tumors on trunk, branches and roots can be considered as biological parameters of species response under ecological stress. Another parameter of unfavourable ecological conditions is the viability of generative organs. Reproductive potential of species (seed productivity, quality of pollen and seeds) decreases under these conditions. It hampers the natural regeneration. The genetical study and selection of conifers in the region with unfavourable ecological condirions with help of parameters of generative organs, crown structure and devoliation of needles allow to determine species sensitive (*Abies*) and species resistent (*Larix*) as well as show resistent, productivity genotypes and tree mutants. The selection and breeding of genotypes which have not change in crown structurea and produced fertile pollen and seeds will promote Siberian forest composition. Thus, the habitus of trees and the their reproductive activity allow to evaluate the atate of forests under unfavourable ecological conditions.

QTL Detection and Candidate Genes Mapping for Marker-assisted Selection in *Eucalyptus*

Daniel Verhaegen, Jean Marc Gion, Mireille Poitel, Jacqueline Grima-Pettenati, Henri Bailleres and Christophe Plomion
CIRAD-Forêt, BP 5035 Campus de Baillarguet, 34032 Montpellier Cedex, France
Email: verhaegen@hpbaill.cirad.fr

The forestry department of CIRAD is developing clonal varieties of *Eucalyptus* for the tropical region of Congo. The breeding programme is based on a reciprocal recurrent selection scheme between *E. urophylla* and E. *grandis*. Quantitative genetics methods are successfully used througout the selection process. However there is still interesting information that remains unaccessible to the breeders (e.g. the number of major genes controlling trait variation, their effects, etc.). We are now using the genetic mapping approach to adress these questions for economically important traits (growth, stem form, cutting rate, physical and chemical wood properties). The objective of this study is to give some preliminary results on the following specific questions:

1- are selection criteria under oligogenic control with mendelian components (QTLs) that could be manipulated by the breeders ?

2 - what about QTL stability across ages and genetic backgrounds ?

3 - what is the biological meaning of QTL ?

Saturated genetic maps of two parental elite trees were first constructed using the two-way pseudotestcross mapping strategy based on dominant markers segregating in 200 interspecific F1 progenies. These maps comprised 269 and 236 RAPD markers for the *Eucalyptus urophylla* and *Eucalyptus grandis* individual parents, respectively. For the afro-mentioned traits, several regions controlling part of the phenotypic variation were identified by interval mapping. Because growth and stem form were studied from the plantation in 1992 to the exploitation in 1998, QTL x Age interaction could be analyzed. Some QTLs were found to be stable after 3 years of growth (half rotation age).

The maps are now being completed with candidate genes potentially involved in the trait variation. For wood quality (density, growth strains, lignin content and S/G ratio), 5 genes of the lignification pathway (PAL, COMT, CCoAOMT, CCR, and CAD) have been mapped using SSCP (single strand conformation polymorphism). Four other genes (C4H, 4CL, C3H, F5H) will be studied in the near future. For growth and cutting rate, two genes in relation with cellular division and rooting ability (EgTub and EgPar) have also been mapped. The relationship between these genes and trait variation is under analysis. If co-localisation between these genes and QTL are obtained, then we will look for linkage disequilibrium between alleles of candidate genes and allele of QTL, in the population. The association between RAPD polymorphism and trait variation was also evaluated in a broader genetic background (12 x 12 factorial design), for wood density and vigour. Such molecular information should ultimately be useful firstly to assist the selection of parents for further generations of breeding, and secondly to choose the best trees in the best families, to be vegetatively propagated for clonal varieties production.

The Growth and Initial Photosynthetic Processes of *Pinus sibirica*

Nina Vorobjeva, Vladislav Vorobjev, Albina Zotikova and Julia Sobolevskaya
Russian Academy of Sciences, Siberian Branch, Institute of Forest, The Filial, Academichesky prospect 2, 634021 Tomsk, Russia
Tel: 7 3822 258907, FAX: +7 3822 258855, Email: root@ienc.tomsk.su

The activity of the photosynthetic apparatus is a genetically determined function that is important in growth, productivity and organism adaptive capacity. Chloroplast functional activity was studied in fast-growing and slow-growing seedlings of *Pinus sibirica* under different growth conditions, including extreme conditons for tree growth. The rates of ferricyanide photoreduction and the noncyclic photophosphorylation reaction were greater for fast-growing seedlings than for slow-growing ones. Fast-growing seedlings had higher basic and coupled electron stream (in presence of ADP and inorganic P) than in slow-growing seedlings. The "photosynthetic control" and R/2e ratio, that provide an index of noncyclic photophosphorylation of electron streams coupling all chain reactions with photophosphorylation, were not essentially different between the two seedling groups. The reaction of ferricyanide photoreduction is described by the electron stream in the photosynthetic chain connected with Photosystem II (PHS II) and the activity of phosphorylase determining ATP production. The initial processes of photosynthesis in *Pinus sibirica* seedlings are connected to the growth and electron stream reaction of PHS II. Fast-growing seedlings produce more energy-active photosynthetic apparatus.

An increase in altitude influences plastid formation and quantities of photosynthetic pigments. Needles of *P. sibirica* growing in subalpine areas contain lower amounts of pigment and carrotinoids. The content of chlorophylls is reduced up to 23% at the expense of chlorophyll b. This shows some distinction in the heterogeneity of pigment forms connected with PHS II and the light-harvesting complex (LHC). Changes in a pigment complex not only involve the total content of green and yellow pigments, but also their ratio. The ratio of chlorophyll a/b increases from 2.3 to 3.0 with altitude, and the chlorophyll content in the LHC may be reduced by 23%. In contrast, the chlorophyll content in Photosystem 1and PHS 11 may be increased by 15.6% with altitude. A preferential decrease of chlorophyll b and increase of the ratio of chlorophyll a/b supports the assumption that the LHC role in formation of grana declines with increase in altitude. Assimilation reactions of *P. sibirica* also vary with changes in a pigment complex caused by anthropogenic factors. Change in the ratio of pigment components may be an adaptation to changes in environmental conditions. These changes also appear to be a reason for assimilate accumulation in the plant. The functional activity of chloroplasts was investigated with measurements of the reaction rates of ferricyanide photoreduction and non-cyclic photosphorylation of needles. These measurements revealed some specific dependence between the primary photoactive processes in a plant and the site of growth activity. Photoactivity of chloroplasts decreases with an increase of basic electron transport and electron-coupled transport rates. The activity of the C-hyll reaction in the presence of the phosphate-acceptor system is evidence for potentially high reduction activity of chloropasts and for effective coupling of electron transport with photophosphorylation. Differences in chloroplast functional activity result from the distinction between photosystem organization and the content of reaction centers of PHS II. Differences in chloroplast funtional activity at the different elevations may represent some adaptation of the photosyntetic apparatus of *P. sibirica*.

Change in Sex Expression in Clones of *Casuarina Equisetifolia* Forst

Kannan Chandra Sekhara Warrier, K.G. Ajith Kumar,
Rekha R. Warrier and K. Gurumurthi
Institue of Forest Genetics and Tree Breeding, R.S. Puram. P.O., 641 002 Coimbatore, Tamil Nadu, India
FAX: 91 0422 430549, Email:
kannanwarrier@hotmail.com

Flowering pattern in sex identified clones, of *Casuarina Equisetifolia* Forst. grown as hedges in the clone bank of Institute of Forest Genetic and Tree Breeding, Coimbatore, India revealed that sex change occurs in this species. The population assembled and rooted ramets from three year old trees selected from Chengalpet and Chidambaram area of Tamil Nadu, India consisted of constants males, constant females and monoecious individuals at the time of introduction during 1992 and remained so till 1997. The data on flowering collected during the months of September, 1997 and March, 1998 showed that content males, constant females and bisexuals accounted for 59.26% and 4% of the population respectively. Six clones (11% of the population) changed their sex in various ways. Four clones viz., CHCE 1003, CHCE 2903, CHCE 0109 and CPCE 3702 were females originally changed their sex to bisexuals. Clones CHCE 0401 and CPCE 3501 were originally males and transformed into monoecious plants by producing female cones approximately five years after introduction. Continuous hedging may bring out plasticity of sex expression in a small percentage of population.

Modeling and Experimental Research of Canopy Structure, Photosynthesis, and Transpiration of *Cunninghamia lanceolata* (Lamb). Hook. Stands

Xiao Wenfa
Chinese Academy of Forestry, Research Institute of Forest Ecology and Environment Protection,
Wan Shou Shan Hou, 100091 Beijing, China
FAX: +86 10 62889555, Email:
xiaowenf@fee.forestry.ac.cn

Cunninghamia lanceolata (Lamb.) Hook. (Chinese fir) is an important timber and native species in southern China. The physiological and ecological basis for productivity in Chinese fir is investigated since little research has been conducted in past decades. Canopy structure, light [including Photosynthetically Active Radiation (PAR)] distribution, photosynthesis and transpiration of three Chinese fir stands at the Subtropical Forestry Experimental Center of the Chinese Academy of Forestry in Fen-Yi County, Jiangxi Province were determined and modeled. A bottom-up method used in the research gave the following results.

First, linear relationships were found between branch length, branch inclination, and the height of the branch. The canopy layers with densest leaves shifted upward from 8-year-old to 13-year-old crowns, and the relationship between relative leaf area density and branch height fitted a Beta distribution model.

Second, the distributions of total solar radiation and PAR in relation to canopy structure were determined along with the energy budgets of the three different Chinese fir stands. Close relationships between nitrogen content of needles and soil water content with photosynthesis of the three different stands were obtained.

Third, measurements of daily and seasonal changes of photosynthesis, respiration and transpiration were made with a LI-6200 portable photosynthesis system. The relationships of PAR, temperature, and humidity with stomatal conductance, photosynthesis, respiration, and transpiration of needles of different ages in different crown layers were described and modeled. The basic photosynthetic characteristics, including light-compensation, light-saturation, maximum photosynthesis rates and transpiration ratio, of needles of different ages and different position in a branch were determined.

Finally, a simplified model of radiation transmission and light-photosynthesis curves (A-PAR curves) of needles of different ages in different layers of the canopy were obtained. The simulation model of net photosynthesis rate and transpiration rate of Chinese fir plantations was developed from the field data, the A-PAR curves, and the aerodynamic characteristics and energy balance of the stand. Leaf level responses from the LI-6200 system were successfully integrated to the canopy scale, and the model gave reasonable outputs. Simulation modeling is a new development in production ecology of plantation forestry in China. The combination of modeling with the experimental results provided a new approach and direction for calculating and evaluating the productivity of Chinese fir plantations and other forest plantations.

Effects of Depth of Flooding on Growth, Stem Morphology and Anatomy of *Taxodium distichum* Seedlings.

Fukuju Yamamoto
Tottori University, Department of Forest Science, 680-8553 Koyama, Tottori, Japan
FAX: +81-857-31-5347, Email: fukuju@muses.tottori-u.ac.jp

The aims of this study are to examine the influence of depth of flooding on growth, stem morphology and anatomy of baldcypress (*Taxodium distichum*) seedlings. The effects of gravitropic stimuli on the anatomical characteristics of flood-induced hyperplastic stems are also studied.

I. Depth of flooding study: Twenty-eight, 3-year old baldcypress seedlings were divided into 4 groups of 7 plants, and each group received one of four treatments: (1) unflooded seedlings, (2) flooded seedlings at 3 cm above the ground level, (3) flooded seedlings at 38 cm above the ground level, and (4) submerged seedlings above shoot apices. The 15-week flooding treatment was initiated on May 18, 1998. After the determination of height and diameter increment, the seedlings were harvested, separated into leaves, stems and roots, and their dry weights were determined. Stem segments also were sampled for microscopic observations from each seedling at 3 cm and 23 cm above the ground level. The following results were obtained: (1) Flooding at 3 cm above the ground level stimulated the biomass increment of the seedlings. The seedlings submerged above shoot apices survived but showed little growth. (2) Flooding enhanced diameter increment of submerged portions of stems. The position of the most vigorous diameter increment was located just beneath the water level and raised as the water level was raised. (3) The tracheids in hyperplastic stem portions were expanded in both radial and tangential directions. However, flooding reduced the thickness of the tracheid walls.

II. Study of gravitropic stimuli: Forty-eight, 3-year old baldcypress seedlings were divided into 4 groups of 12 plants, and each group received one of four treatments: (1) unflooded, untilted control seedlings, (2) seedlings flooded at 28 cm above the ground level, (3) seedlings tilted at 45ø, and (4) seedlings flooded at 18 cm above the ground level and tilted at 45ø. The 8-week flooding and tilting treatments were initiated on May 24, 1998. At Day 10, 5 seedlings of each group were harvested for determination of the amount of ethylene released from the stems using gas chromatography. On July 27, the seedlings were harvested, separated into leaves, stems and roots, and their dry weights were determined. The following results were obtained:

(1) The rate of angle recovery from of stem inclination was greater in the flooded and tilted seedlings than that of the unflooded and tilted seedlings. (2) In the unflooded, tilted seedlings the diameter increment was vigorous in the vertical direction of inclined stems, whereas that was vigorous in horizontal direction in the flooded, tilted seedlings. (3) Compression wood tracheids were formed on the lower side of inclined stems of the unflooded, tilted seedlings. In the flooded, tilted seedlings thin-walled tracheids with expanded cell diameter were observed on the upper and the lateral sides of inclined stems. Compression wood was formed on the lower side. (4) Ethylene production was remarkable in the flooded seedlings. Tilting did not affect ethylene production.

Studies on the Mechanism and the Artificial Induction of Foxtailing in *Pinus spp.*

Y. Yurugi, H. Nagata
Mie University, Department of Forest Resources, Faculty of Bioresources, Kamihamacho 1515, 814-8507 Tsu, Mie, Japan
FAX: +81-59-231-9517, Email: yurugi@bio.mie-u.ac.jp

Pine trees in the tropics and subtropics often exhibit the continuous growth of the shoots throughout the year, being understood as the phenomenon of foxtailing. In contrast, *Pinus densiflora* SIEB. et ZUCC., a species of the temperate zone, normally shows the periodic development of lateral buds. We investigated whether the pine trees from temperate and subtropical zones can be changed between periodic and continuous growth by changing the photoperiodic and/or air temperature conditions.

Young plants of *P. densiflora* exposed to a 20-h photoperiodic condition, showed the continuous growth of the shoots without the formation of lateral buds during an experimental period of 28 months. P.luchuensis MAYR, a species seen to grow in Okinawa (the subtropical zone in Japan), showed the periodic growth of the shoots as the plants were grown with a 20-h photoperiod. When the plants were grown with 12-h and 13-h photoperiods, 80% of the pines continued to grow the shoots, which was the highest occurrence among treatments.

The periodic growth pattern of the subtropical pine with a 12-h photoperiod however disappeared when the growth chamber temperature was controlled at 25°C in daytime and 15°C at nighttime. The present study suggests that differences between *P. densiflora* and *P. luchuensis* in their growth patterns were related to the length of photoperiod and ambient temperature and associated changes in the correlative inhibition between the internode elongation and primordia differentiation of leaves in the apexes.

Keywords: Coppice; Replanted sites; Commercial plantations; *Eucalyptus*; Congo

Since 1978, 42,000 ha of clonal *Eucalyptus* plantations have been established in the Pointe-Noire region for pulp production. These plantations, owned by ECO sa (*Eucalyptus* du Congo Societe Anonyme), are based on two natural hybrids (E.PFI and E.12 ABL* *saligna*). As felling age is 7 years, management of coppice appeared very early as a main issue. More than 10 trials focusing on this goal have been therefore established since 1985. Moreover, complementary experiments were set up to compare coppice and replanted sites production.

The trees can be cut at ground level, without impact on latter coppice production. From 4 months after cutting, there are marked differences in growth between coppice shoots. These differences increase with age: from 2-3 years the only two bigger shoots per stump, that represent 70% of the total basal area, keep on growing. Coppice reduction increases growth of the remaining shoots. This operation can be carried out during the first year, as soon as the dominant shoots can be identified (from 4 to 9 months old). Optimal coppice reduction intensity depends on soil fertility and stump density: as observed with planted crop, the maximum production is obtained between 600 stems/ha in the low fertility sites and 800 stems/ha in the best sites. As initial stand densities vary between 400 to 800 stems/ha, one to two shoots per stump must be selected. Secondary coppice shoots have to be controlled, manually with bush knife, or chemically using glyphosate (Round up). This last manner allows weed control at the same time, with an application of 3 to 4 litres of glyphosate perha , mixed in 250 to 350 litres of water. It provides the best results for shoot control and stem growth and induces the lowest costs. A fertilisation of 200 to 250 kg/ha N-P-K (13-13-21) must be applied one year after the harvesting of the previous stand (planted crop or coppice).

Coppice stumps can be weakened with a 40% glyphosate solution (Round up). The solution must be applied by spray at a dose of 25-30 ml/stump, just after stem harvest i.e. less than one hour. No return time is then necessary. A site replanted with the previous clone exhibits about the same mean annual increment as coppice. Moreover the loss of production during the period between harvesting and planting must be taken into account. It appears therefore that a plot may be replanted only if a much better vegetal material can be used (*E. urophylla* * *E. grandis* vs natural hybrid). These results contribute to manage efficiently the congolese commercial plantations consisting at present of 9,000 ha of planted crop, 18,000 ha of coppice and 15,000 ha of replanted sites.

Asexual Propagation and Mycrorrhizal Inoculation of Selected Dipterocarps in the Philippines

Loretto U. de la Cruz
UPLB College of Forestry and Natural Resources, Institute of Renewable Natural Resources, Laguna, Philippines
Tel: (6349) 536 2557, FAX: (6349) 536 2721, Email: ludc@lb.msc.net.ph

Keywords: Asexual propagation; Mycorrhiza, Dipterocarps

The rapid disappearance of dipterocarps in the Philippines requires immediate steps to reestablish these ecologically and economically important forest species. However, efforts to reestablish dipterocarp stands are hampered by lack of quality planting materials. This is due to irregularity in seed production, short viability of seeds, and lack of appropriate seed technologies. Moreover, the degraded nature of soils in logged-over areas make dipterocarp establishment difficult.

Two promising technologies involving the reestablishment of forest trees are asexual propagation using cuttings and mycorrhizal inoculation. Asexual propagation enables the production of clones of selected trees even during non-seed years, while mycorrhizal inoculation helps in the establishment of the clones in degraded soils. However, the two technologies have to be tested in dipterocarps.

This study aimed to develop appropriate technologies for asexual propagation using cuttings and mycorrhizal inoculation of selected dipterocarp species. Four separate experiments were conducted to determine the effect of growth hormones (no Hormone, IBA at 10 ppm, and Rootone F), number of leaves of cuttings (0, 1, 2, and 3 leaves per cutting), or cutting positions on donor plant (1st and 2nd, 3rd and 4th, 5th and 6th, and 7th and 8th nodes below the terminal shoot) on rooting of dipterocarp cuttings. Initial effects of mycorrhizal inoculation using rooted cuttings were assessed in terms of height growth. All experiments were conducted in a screenhouse under 20% sunlight. The cuttings were rooted in sand-soil medium in polyethylene covered basins maintained at 85-95% relative humidity.

Dipterocarp species varied in their response to hormone treatments. In *P. malaanonan*, best rooting (78%) was achieved using Rootone F powder, while 10 ppm IBA did not improve rooting over that of control. In *S. contorta*, Rootone F and IBA slightly improved rooting by 98% compared to control (84%). In *A. thurifera*, IBA (95%) was comparable to the control (90%) but Rootone F (64%) depressed rooting. In *H. manggacapui*, all treatments gave 95% rooting.

Number of leaves on cuttings showed significant effect on the rooting of dipterocarps. In all species tested, leafless cuttings did not root at all. Best rooting of *A. thurifera, S. contorta and S. guiso* occurred if cuttings contained 2-3 leaves, while best rooting of *D. grandiflorus* occurred in 1-leaf cuttings.

Shoot proliferation of three potential tropical plantation tree species

Keywords: Micropropagation, *Acacia auriculiformis*, *Acacia crassicarpa*, *Azadirachta excelsa*, 6-benzylaminopurine, Multiple shoots.

It has become increasingly important to reforest and preserve individual germplasm for continuous supply of elite genetic material for breeding and raw material for the industries. Extensive afforestation programs with the establishment of large-scale-forest plantation have been undertaken in many countries. This is to meet the rapidly growing demand for wood supply especially the hardwoods. Tropical trees species like *Azadirachta excelsa*, *Acacia crassicarpa and Acacia. auriculiformis* have been identified as potential plantation tree species, which have good wood quality, good growth performance and broader market prospects. Eventhough, these species can be propagated by seeds there is a need for vegetative propagation if rapid breeding is to be done especially for *A. excelsa* which produces recalcitrant seeds. *A. crassicarpa* on the other hand, only produced seeds once in two to three years. While for *A.auriculiformis*, most of the good form trees produce very small amount of seeds as a result from their small crown and few branches. The conventional methods of tree improvement and selection offer only limited possibilities of meeting the rapidly growing demands. In this regard, vegetative propagation is worth special attention particularly tissue culture. Micropropagation through tissue culture technique offers an alternative tool to propagate selected trees for plantation purposes. Therefore, this experiment aimed to study the possibility of micropropagating *A. crassicarpa, A. auriculiformis* and *A. excelsa* via shoot proliferation.

Nodal stem segment and young leaves *of A. crassicarpa* and *A. excelsa* obtained from 2-3 months old seedlings and 7 months-old seedlings respectively were used as explants in this study. However, explants for A.auriculiformis were obtained from nodal stem segment of 5 month-old seedlings and 6 year-old plus trees. They were cultured in three types of medium viz Murashige and Skoog (MS) Gamborg (B5) and Woody Plant medium (WPM) supplemented with 5 concentrations of 6-benzylaminopurine (BAP). Multiple shoots developed from nodal stem segment explants of each species except for leaf explants which was cultured in the medium supplemented with 0.5 – 6.0 mg/1 BAP. For *A. crassicarpa,* the highest mean number of shoots (4.3≅4) and the longest mean root length (4.9≅5 mm) were obtained from the medium supplemented with 2.0 mg/L BAP. As for *A. excelsa*, the highest mean number of shoots (1.6≅2) and the longest mean shoot length (2.7≅3mm) were also obtained from the medium supplemented with 2.0 mg/L BAP. Besides callus formation, nodal stem segment explants from both species also tend to produce callus when cultured on the medium supplemented with BAP. As for *A. excelsa*, the highest mean number of shoots (1.6≅2) and the longest mean shoot length (2.7≅3 mm) were also obtained from the medium supplemented with 2.0 mg/L BAP. Besides callus formation, nodal stem segment explants from both species also tend to produce callus when cultured on the medium supplemented with BAP. For A. *crassicarpa*, formation of callus was observed on the medium supplemented with higher concentration of BAP (10.0 mg/L) and the intensity of callus produced was very low (+). The calli produced were compact and light green in colour. As for *A. excelsa*, the callus produced was compact and white brownish in colour, and was produced at a higher intensity (+++).. For *A.auriculiformis*, low concentrations of BAP (0.1 – 0.5 mg/L) were sufficient for shoot initiation. However, longer gestation period was observed for the explants taken from mature tree before the shoots initiated can start multiplying. It can be concluded that the large scale micropropagation of these species are possible and thus it is an excellent tool to complement the conventiaonal vegetative propagation of multiplying selected trees.

Somatic Embryogenesis in *Pinus gerardiana* Wall

Ramesh C. Thakur, Ishii K
Dr. Y S Parmar University of Horticulture and Forestry,
Dept. of Tree Improvement and Genetic Resources,
173230 Solan (HP), India
Tel: +91-1792-22834, FAX: +91-1792-52242, Email: rcthakur@mailcity.com

Keywords: Edible nuts; *In vitro*; Osmotic potential; *Pinus gerardiana*; Somatic embryogenesis

Somatic embryogenesis refers to methods whereby embryos are produced *in vitro* from small pieces of plant tissue or individual cells. The embryos are referred to as somatic because they are derived from the somatic (vegetative) tissue, rather than from the sexual process. Propagation through somatic embryogenesis has the capability to capture all genetic gain of desirable individuals. Moreover, it has a great potential to produce large number of clones for reforestation purposes. Also, the capacity to induce somatic embryos from somatic tissue of mature trees is very important as it may lead to rejuvenation.

Pinus gerardiana Wall., a conifer of dry temperate Western Himalayas, is highly valued for its edible nuts. The nuts of this species are highly nutritious and have aphrodisiac value. Due to over exploitation and low regeneration capabilities, the species has become threatened during the last few decades. Keeping in view the great regenerative potential of somatic embryogenesis, this species was studied for its somatic embryogenesis. Aseptically removed mature zygotic embryos were used as the explants for these studies. Zygotic embryos were placed on basal culture medium for conifer somatic embryogenesis supplemented with 3.0 mg/l Naphthaleneacetic Acid (NAA) and 1.5 mg/l N6-Benzyladenine (BA) for embryogenetic tissue initiation. The initial cultures were kept in dark at 25+2 0C. The embryogenetic tissues obtained from initial cultures were maintained on the same medium but with reduced hormones i.e. 1.0 mg/l NAA and 0.75 mg/l BA. Somatic embryos were developed and matured by using a higher osmotic potential by adding maltose, Polyethylene Glycol (PEG) and Abscisic Acid (ABA). Development medium did not contain any hormones. Good quality somatic embryos were obtained by this process.

The process of somatic embryogenesis in this species clearly offers an important tool to assist in genetic improvement of this important conifer of dry temperate region of Western Himalayas. The system is not only developed for clonal propagation, but also as a interface for genetic engineering techniques for the purpose of producing transgenic clonal planting stock of this conifer.

Somatic Embryos Induction of *Cyclobalanopsis glauca*

Ya-Nan Wang, Yeou-Hsuan Chang.
Department of Forestry, College of Agriculture, National Taiwan University. Taipei, Taiwan, Republic of China.
Tel:886-2-23630231ext2512, Fax:886-2-23629615, E-mail:m627@ccms.ntu.edu.tw

Keywords: Somatic embryo; *Cyclobalanopsis glauca*

Immature embryos of *Cyclobalanopsis glauca* were transferred onto MS basal medium supplemented with 1 mg/l NAA and 0.5 mg/l BA to get the seedlings *in vitro*.

Three kinds of materials were used for callus induction: (i) immature embryos, (ii) cotyledon and (iii) hypocotyls of *in vitro* seedlings. The results indicated that both immature embryos and hypocotyls on MS basal medium with 1 mg/l NAA and cotyledon on MS basal medium with 0.5 mg/l 2,4-D gave the better induction. However, among these three kinds of materials, the greatest amount of calli were induced by immature embryos. Additionally, callus characteristics were observed to vary according to the type of plant growth regulators used . We found that the embryogenic callus induced on the medium with 2,4-D could be used as suitable materials for suspension culture.

The formation of the few somatic embryos from the embryogenic callus of hypocotyls and cotyledon was investigated. The results indicated that direct somatic embryos could be induced from the embryogenic callus obtained from immature embryos. Supplementing the culture medium with 0.5-1 mg/l ABA, improved the growth of the somatic embryo.

Investigation of Wood Specific Gravity Variation of Hornbeam (*Carpinus Betulus* L.) from Different Origins.

Seyed F. Emadian, A. Kelidari
Mazandaran University, Department of Forestry, Post Box # 578, Sari, Iran
Tel: 98-1598-2981, FAX: 98-21-8891014, Email: via wolfrum

Keywords: hornbeam, *Carpinus Betulus*, wood specific gravity.

Hornbeam (*C betulus* L.) is one of the major forest species in northern Iran. It covers over 31% of total timberlands of the region. Among other native hardwood species, hornbeam has the longest fiber length. Thus, hornbeam has been considered to be a suitable candidate species for the pulp and paper industry of Iran. For these reasons developing a tree breeding program for this species to improve such economic traits as fiber length and wood specific gravity (WSG) is desirable and economically justifiable.

In this investigation variation of WSG of hornbeam from three different ranges of altitudes at two geographic regions were studied. The ranges of altitudes were low (0-250 m), medium (400-550 m) and high (900-1000 m) above the sea level, and the geographic regions were Noushahr and Shastkola, which are about 300 km apart from each other. Hence, in this study, a total of 6 locations were selected to be searched for sampling purpose. At each location a total of 30 trees with the best phenotype were used for sampling. The samples were obtained using an increment borer. Wood specific gravity was determined using volumetric technique. A nested design was used for statistical analysis, along with Duncan's multiple range test to compare the mean values. The results showed that out of the total variation of WSG found in hornbeam, individual trees within altitudinal range, altitudinal range within geographic region and geographic region accounted for 83.5%, 12% and 0.08% of the variation respectively. The overall means for WSG in Noushahr and Shastkola regions were 0.763 and 0.768 g/cm^3, respectively, which were not significantly different from each other. Moreover, there was not any significant difference among WSG values in the low, medium and high altitudinal ranges of Shastkola region (0.756, 0.756 and 0.758 g/cm^3 respectively). However, in Noushahr region, the WSG value in the medium altitudinal range (0.813 g/cm^3) was significantly different (at 0.05 statistical level) from those in the low and high altitudinal ranges (0.740 and 0.751

g/cm^3). The results of this study suggest that using the individual tree selection method in the correct geographic region could achieve a significant genetic gain for WSG of hornbeam.

Intra Species Genetic Variability of *Picea abies* (L.) Karst. and *Picea abies* var. *Misicii* Mat. et Pav.

Milic Matovic, Vera Lavadinovic
Faculty of Natural Sciences, Institute for Biology, Kragujevac, Yugoslavia
Email: inszasum@EUnet.yu

The species *Picea abies* (L.) karst. has the greatest morphological variability in the family *Pinaceae*, which results in the description of a high number of intraspecific taxa. Vidakovic (1982) cites, after Krüssmann (1972), more than a hundred cultivars and forms. In the characteristics of these forms there is not a single description that corresponds wholly to the morphological characteristics of the "mutant" spruce (Matovic 1988; Matovic et al. 1994; Matovic and Vujkovic 1994a, 1994b). This paper compares some morphological and quantitative characteristics of the "mutant" and the common spruce (*Picea abies*) growing in the same stand. During the last field investigations (1994) from the mutant spruce site at the mountain Kamena Gora near Prijepolje, additional data and material were collected on the common spruce. In addition to the description of the habit, data have been obtained for needle length and thickness, annual growth increment, levels of branching and the number of needles per centimeter of branch length. The unusual spruce was described as an unnamed "new mutant form". Based on these descriptions, this mutant form has been ascribed to the taxonomic level of variety, and has been named *Picea abies* var. *misicii* - Misic's spruce, in honor of the prominent researcher of the flora and vegetation in Serbia - Dr. Vojislav Misic.

The state of the stand where *P. abies* var. misicii grows has changed compared to the first description obtained by Matovic when he discovered the stand in 1984. The regenerated vegetation, most likely vegetative, has been cut along with many adjacent common spruce trees. From the previous state of the stand, only a few broadleaf species remain in the tree layer (*Populus tremula* L., *Acer pseudoplatanus* L., *Sorbus aucuparia* L., *Betula pendula* Roth.), along with one *P. abies* var. *misicii* and one common spruce. The two spruce trees are approximately of the same age, height and basal diameter.

The girth of Misic's spruce is 98 cm at 40 cm above ground, and the bole forks at a height of 70 cm. Needle lengths on shoots of the same age, grown in 1992, 1993, 1994, are regularly longer (15.3 to 21.7mm) than needles (12.2 to 16.8mm) of the adjacent common spruce. Needle diameters from different parts of the canopy of the adjacent common spruce range between 0.7 to 1.2mm, and were smaller than the 1.1 to 2.0mm needle diameters of Misic's spruce. The number of needles per one cm of shoot length for the adjacent common spruce (48 to 76 range, average 59) is twice that of the mutant spruce (21 to 34 range, average 29). The top of the crown of Misic's spruce is widely conical, and from the upper third, crown edges curve gradually downward so that the crown is widest at the middle of the bole.

In Misic's spruce, a higher number of primary branches occur in the whorl of the older part of the stem than in the younger part, which has 2-3 branches per whorl. The majority of primary branches make a mildly acute angle compared to the stem, being almost pleiotropic. Some branches deviate significantly from the radial position of a whorl. These include branches that develop subsequently within or out of the whorl, and branches of later orders up to the tertiary level. These unique characteristics distinguish the mutant spruce from almost all of the members of the genus, family, and perhaps even wider.

Genetic Variations of Allozyme in Natural Stands of Hiba (*Thujopusis dolabrata* var .hondae.) in Tohoku Region

Jin'ya Nasu
Forest Tree Breeding Center, Kansai Breeding Office, Uetsukinaka 1043 Shoocho Katsutagun, Okayama, Japan
FAX: 081-0868-38-5139, Email: nasu@affrc.go.jp

1. Introduction

Hiba (*Thujopusis dolabrata* var *hondae*) is major forest tree species in Tohoku Region. It is distributed form Tosika-pen. in Hokkaido to Noto-pen. in Honshu. For the conservation of genetic resources, forest-trees must be conserved mainly in situ as population in the field, because of the extremely long time required for rotation of a generation , and consequently for their evaluations and utilization for genetic improvements. Recently, the genetic variation within and among populations of forest tree species have been investigated using allozyme loci encoding enzyme systems as genetic makers. In this study, the genetic variation and differentiation within and among natural hiba stands at the allelic level using the 7 putative loci as maker genes were investigated so as to have basic information for making of a study of the methodologies of in situ conservation of hiba as a genetic resource.

2. Materials and methods

Leaf samples of individual trees for this study were collected form 4 natural hiba stands (Kawai Sado Natsuse Hiyama). Those were collected 40 to 60 individuals for each of 4 natural hiba stands between October and April. Samples were stored at -60 until isozyme analysis was conducted. Isozyme analyzed by Polyacrylamide vertical slab gel electrophoresis. It was conducted following the procedures of Tsumura and Ohba (1993). Enzyme systems were stained: shikimate dehydrogenase (ShDH), eucine aminopeptidase (LAP) 6-phosphogluconete dehydrogenase (6PG), lucokinase (GK), lutamate oxaloacetate transaminase (GOT), osphoglucoisomerase (PGI). From these, 7 putative loci with a total 19 alleles were inferred.

The following statistics were used to estimate genetic diversity with in each population: 1) the proportion of polymorphic loci (Pl,95% criterion); 2) the effective number of alleles per locus (Ne); 3) the average observed hetrozygosity (Ho).

3. Results

The 7 putative loci were polymorphic (95% criterion). The2-test was carried out at every polymorphic loci to investigate the deviation form Hardy-Weinberg equilibrium . The results of the tests were not significant at 7 putative loci. The values of Pl ,Ne, Ho were calculated (Table 1)

Table 1The average of P_l ,N_e, H_o in 4 natural stands of Thujopsis dolabrata var .hondae

	kawai	Sado	Natsuse	Hiyama	Mean
P_l	0.86	0.57	0.86	0.71	0.75
N_e	1.54	1.40	1.42	1.61	1.49
H_o	0.33	0.25	0.28	0.34	0.30

The Character of Genetic Variation in Siberian Stone Pine Seedlings

Elena A. Petrova, Nina A. Vorobjeva
Institute for Ecology of Natural Complexes SB, Tomsk, Russia

The development of methods for sustainable use and conservation of biological resources in forest ecosystems requires extensive studies of the forest species genofond. The molecular genetic methods, in particular electrophoresis of isozymes, allowed a genetic variation in tree species to be evaluate, and near 50 conifer species have been described in recent year (Kani Isik et al., 1997).

236 Siberian stone pine seedlings (the progeny of 25 trees growing in the Altai Mountain, 450m a.s.l.) were investigated by starch-gel electrophoresis. Methods of enzyme extraction, electrophoresis and histochemical enzyme staining followed the Goncharenko et al. (1989). The vegetative tissue was used in the experiment, and it was difficult to determine some isozyme fractions. The genotypes of seedlings were detected on the 22 loci coding 14 enzyme systems. 15 loci appeared to be monomorphic, 7-polymorphic.

All the analysed loci have been found in Hardy-Wainberg equilibrium. The averaged value of the heterozygosity to be expected (He) is 0.271, the observed heterozygosity (Ho) was 0.225 in the sample of Siberian stone pine seedlings. So, we observed some insignificant deficiency in heterozygotes. It should be noted that null-alleles have been found in two analysed loci (Lap-2 and Skdh-1), which does not allow heterozygous genotypes to be identified in diploid tissue. This in its turn might lead to distortions in criteria of heterozygosity.

Chloroplast DNA Polymorphism in Italian Natural Populations of European Aspen (*P. tremula* L.)

Daniela Salvini, Daniela Taurchini, Silvia Fineschi and Maria Emilia Malvolti
CNR Istituto per l'Agroselvicoltura, v.le Marconi 2, I-05010 Porano, Italy
FAX: +39-0763-374330, Email: agroselv@ias.tr.cnr.it

In order to estimate inter- and intra-population genetic variability of *Populus tremula* L., an analysis of chloroplast DNA polymorphism was carried out on natural populations from northern, central and southern Italy. European aspen is a widespread species, distributed in the whole Eurasian continent. It spreads from the Mediterranean countries in the south to Scandinavia in the north and from Spain to the

Pacific Asian coastal regions. Unlike other poplar species, which are appreciated for the production of wood and pulp, European aspen is usually not cultivated and its economic value is mostly related to the possibility to obtain inter-specific crosses. Besides, its occurrence in forested areas is only sporadic and its presence in Italy is mostly restricted to some mountainous areas, where this aspen has often decreased following reforestation with other species. On the other hand, due to its pioneer behaviour, P. *tremula* has a particular ecological relevance; its capacity of gr owing on abandoned and degraded soils, as well as on soils destroyed by fires, might be exploited for habitat restoration. For these reasons it is of particular ecological interest. The study of genetic diversity on this species may constitute a basic knowledge background for genetic resource conservation programmes. The work was carried out by studying chloroplast DNA polymorphism in order to obtain information both on genetic diversity and on geographic structure of variability. This latter level of information is peculiar of cytoplasmic markers (chloroplast and mitochondrial DNA), as they are - with only few exceptions - uniparentally inherited. As most of other Angiosperms poplars shows maternal inheritance of chloroplast DNA and, therefore, the variation of this marker follows the direction of the seed component of the gene flow. Leaf and bud samples were collected in ten different areas all over Italy (four in the north, three in the centre and three in the south). A special care was taken in collecti oplast DNA was observed not only among different populations but also within the populations.

Keywords: *Populus tremula*, chloroplast DNA, genetic diversity

Allozyme Variation in Natural Populations of Chir pine (*Pinus roxburghii* Sarg.) in Himachal Pradesh

Kamal Sharma, Bernd Degen, Georg von Wuehlisch and N. B. Singh
India

The present studies were conducted selecting eight natural populations of *Pinus roxburghii* in Himachal Pradesh covering Shiwalik and Himalayan ranges of species distribution. Eleven enzyme systems; ACO, AAT, GDH, IDH, LAP, MDH, PGI, 6PGDH and SKDH were analysed using starch gel electrophoresis to assess the genetic variability within and among the populations.

For the eleven enzyme systems studied, 25 gene loci were identified out of which 18 (72%) were polymorphic. Most of the polymorphic loci showed segregation pattern according to Mendelian expectation of 1:1 gametic segregation. In total, 50 alleles were found to code for 25 gene loci. The allelic diversity of the gene pool was low (1.130). The range of hypothetical gametic diversity among the populations was large (9.591-56.581). The actual heterozygosity for populations ranged between 0.096 and 0.169 with a mean value of 0.147. Three populations showed significant positive fixation indices in seeds. Whereas highly significant negative fixation indices were recorded in parent trees in all the populations. A low amount of allelic differentiation among the populations was reflected by the mean gene pool value, δ=0.045 which means on an average the populations differed from their complement populations by 4.5% of the effective number of alleles. A small differentiation among populations and large variation within populations reflected by small value of GST (0.041) revealed that 96% of the total genetic variation resided within the populations and only 4% among the populations.

2.02.00 Genetic improvement

Genetic improvement and sustainable forest management

Juan Alba Landa, Lilia del Carmen Mendizabal Hernandez y
Virginia Rebolledo Camacho
Centro de Genética Forestal, Apartado Postal 551, Mexico
Tel: (28) 12 13 57, FAX: (28) 12 13 57, Email: zabal@speedy.coacade.uv.mx

Approximately 0.7% of the forest are lost annually in the world and Mexico is one of the more deforested countries, it has an estimated loss of 600 000 Ha annually, not only in tree surface but also in genetic characteristics susceptible to be handled in order to support the forest productivity and satisfy the society’s necessities.

Many conservation strategies have been proposed to avoid the loss of these resources, because the natural forest permanency is important in the species distinctive genome in all its natural distribution range that support the variation and permitting adaptation and evolution to new environments. However, generally these strategies have not considered that the forest conservation needs a future management vision that will be sustainable now and under the actual improvement system but considering the necessities of the growing population that maybe need other products that we do not use nowadays. If the forest management continue to be dysgenic, we are not able to preserve the genetic information for the future product requirements.

To get a sustainable forest management requires strategies that allow the use and preservation of variation: one strategy is the genetic improvement which allows to select at field level desired tree characteristics by seeds collection or vegetative explants to probe them in species, provenance or provenance/progeny trials. With this strategy the tree preservation and forest management for other tree products extraction is necessary.

However, the natural forest is too exploited, in such way that the preservation of the original parental sources during the period required to perform the genetic tests is difficult. So it is very important to develop a strategy to protect the desired characters, in order to get identical replicas from a single tree tested in different and obtain a high productivity to provide efficiently commercial and recreation products and services and decrease the wind, rain and noise effects. With this strategy is possible to improvement the environment quality and the human life quality.

In Veracruz state, Mexico there is a forest genetic improvement program. Many stands, seeds production areas of four species to immediately better quality seeds collection had been established. 7 species, 32 provenances and 375 families had been evaluated in 16 provenance and progeny tests. We will obtain a lot of quality seeds in these trials to use it in the appropriated sites. However we have a great challenge to define the size site for this species and know the movement of the specific genetic characters for specific purposes.

Flowering and Fruiting Phenology in an Exotic Population of *Grevillea robusta*: Implications for Improved Seed Production

Antoine Kalinganire, C. E. Harwood, M.U Slee & A. J. Simons
Australian National University, Department of Forestry, PO Box E4008, ACT 2604 Kingston Canberra, Australia
Tel: + 61 2 6281 8359, FAX: + 61 2 6281 8266, Email: antoine.kalinganire@ffp.csiro.au

The flowering and fruiting process within *Grevillea robusta* was carried out in a 5-year-old provenance-progeny trial at Malava, western Kenya. Field studies involved a detailed examination of patterns of flowering and fruiting, including the flower structure and development. The studies were carried out at the individual tree, family and provenance levels. The structure of the inflorescences and the nectar reward suggest the species is most likely bird- or mammal pollinated. Inflorescence production peaked in October for most trees, although there was considerable variation between trees with respect to the total number of inflorescences produced and length of flowering season. Within a family, the relative contributions of individual trees to pollen flow and fruit production may change with time. The variation in flowering patterns creates temporal changes in the distributions of potentially mating individuals in the stand. It was found that the heavy flowerers are the heavy fruit producers. The effect of this variation in flowering on the genetic quality of the progeny is important with a narrow genetic base for the seed produced. The study found no evidence of weather effect on flowering period and intensity. However, it is suggested that the environmental conditions at Malava are marginal for flowering for *G. robusta*.

Age Trend of Genetic Parameters on Height Growth *of A. mangium* in South Kalimantan - Its Implications for Selection Strategies in Seedling Seed Orchard

Susumu Kurinobu, Arif Nissatmanto and Hisao Kawasaki
Tree Breeding Center, Kyushu Regional Breeding Office Forest, 2320 Suya, 861-1102 Kumamoto, Japan
FAX: +81-96-242-3151, Email: kurinobu@mailer.cc.affrc.go.jp

Assessing the age trend of genetic parameters is essential in determining an optimum selection strategy for a seedling seed orchard, because the selections in the orchard have to be practiced much earlier than rotation age. It is well known that genetic gain by this type of selection is primarily dependent on the size of heritability and genetic correlation between selection age and harvest age. However, age trend of the parameters and expected gain at rotation age have not yet been reported on *A. mangium*, although seedling seed orchards of this species are widely used for genetic improvement in the tropics.

In this report, an optimum age for selection of *A. mangium* was investigated by analyzing height data measured repeatedly up to five years of age in two seedling seed orchards in South Kalimantan. In the orchards, a population from Queensland (QLD) and that from Papua New Guinea (PNG) were

tested separately. Data used for the analysis included 11 sets of measurements started at four months after planting up to 56 months. They were fitted individually to the height growth curve of Richards function, then they were extrapolated until rotation age of eight years. Adjusted data and those of extrapolated parts were subject to analysis of variance and covariance to derive selection index for evaluating early selection in the orchard. Genetic variance increased exponentially in relation to stand height until three to four years of age when they started to decline slightly in QLD and sharply dropped in PNG populations. Age-age genetic correlations were generally higher than the phenotypic correlations due to the decline of genetic variance, whereas the correlation between the first year height and that of rotation age reached almost zero in both populations. Genetic gain at rotation age was predicted as an indirect response by selection index with changing the age of selection. Expected gains by early selection were found to be very small at rotation age, even though it will bring some amount of gain at around the age of selection. On the other hand the selection during the latter half period of rotation will bring slightly greater gain at the rotation age with diminishing the gain in the early growth. Thus the final selection for the second generation plus trees might be better to start at around five years of age for this species.

Douglas-fir Provenance Tests in Serbia

Vera Lavadinovic, Milos Koprivica
Institute of Forestry, State Enterprise for Forest Management "Srbijasume", Kneza Viseslava 3, 11030 Belgrade, Yugoslavia
Email: inszasum@EUnet.yu

To test the introduced coniferous species, Institute of Forestry in Belgrade established two Douglas-fir (*Pseudotsuga menziesii* Mirb. (Franco) provenance tests at different sites. To assess the genetic potential, provenance diversity and adaptation of the introduced species, Douglas-fir seed was collected from the stands in a part of the natural range of the species, from New Mexico to British Columbia. The range of latitude is from 32°9, to 49°, longitude from 105°7, to 124°, and altitude from 150 to 2682m.

The first test on Mt. Juhor in central Serbia consists of 2° provenances on beech (*Fagetum submontanum* Jov.) site, extending between 43°47, and 43°55, north latitude and between 18°52, and 18°58, east longitude, at the altitude of 600-700m. Parent rock is composed of schists, soil type is acid brown (dystric cambisol) over gneiss, it is sandy, loamy, brown, deep, light, fresh and humus. The climate of the locality is predominantly temperate continental with cold winters and rather warm summers.

The second test plot includes 29 provenances covering the greatest part of Douglas-fir natural range. The experiment was established as a random block system in the natural site of Hungarian oak and Turkey oak (*Quercetum farnneto-cerris* Rud.) at the altitude of 370m. The geographical position of the sample plot Tanda is 44°14, north latitude and 22°09, east longitude. The climate of this locality can be characterized as subhumid to humid. The soil type is eutric brown soil (eutric cambisol).

To get more complete information about Douglas-fir adaptability, variability and suitability, during the study period, the following parameters were measured, observed and analyzed: plant survival, plant height, height increment, diameter of root collar, phenological characteristics and frost hardiness.

By the end of the second year, the percentage of Douglas-fir seedling survival was from 5.3% to 51.9%. Four-year-old seedlings were transplanted in two sample plots where the percentage of twelve-year-old plant survival ranged between 46.9 and 87.5%. Root collar diameter was from 4.9-12.0 cm, height from 2.1-5.6 m and height increment from 43-91 cm. The observation of bud break showed that the earliest bud break of twelve-year old Douglas-fir provenances begins on April 20th and the latest on May 25th. During the study period there were no frost damages in any of the sample plots.

Geographic Variation in Casuarina equisetifolia subsp. Equisetifolia Provenances Grown in Northern Australia

Khongsak Pinyopusarerk, E.R. Williams
CSIRO Forestry and Forest Products, Post Box # E4008, 2604 Kingston, ACT, Australia
Email: khongsak.pinyopusarerk@ffp.csiro.au

Casuarina Equisetifolia subsp. *equisetifolia* is a nitrogen-fixing tree of considerable social, economic and environmental importance in tropical/subtropical littoral zones of Asia, the Pacific and Africa. The species has a wide natural range, occurring on subtropical and tropical coastlines from throughout Malesia to northern Australia, Melanesia and Polynesia. It is frequently used in agroforestry systems, for soil stabilisation and reclamation work and in coastal protection and rehabilitation. Despite its wide natural distribution range, widespread planting and known morphological variation, very little has been done to explore and exploit the genetic variability within the species. A provenance trial of 59 provenances and landraces of *C. equisetifolia* was established in February 1994 at Weipa, north Queensland, Australia. Provenances were from natural stands in Australia/the Pacific and South East Asia whilst landraces are from Africa and Asia. Height and diameter growth together with 12 morphological characteristics (axis persistence; stem straightness; density, thickness, angle and length of permanent branches; length and thickness of deciduous branchlets; stem and foliage damage; and flowering and fruiting) were assessed 30 months after outplanting. There were significant differences between provenances and landraces in most characteristics assessed. Natural provenances from eastern Malaysia and Thailand generally grew faster than other sources but lacked stem straightness whilst Kenyan seedlots, though inferior in growth, were superior in stem form. Natural provenances from Australia and the Pacific region showed lower growth and poor stem form, but had lighter branches, short and fine deciduous branchlets. However, no one provenance showed superior performance for all characteristics, suggesting that inter-provenance hybridisation may be useful in genetic improvement programs. Principal component analyses for all assessed traits suggested a pattern of geographic variation among provenances from the natural distribution, with provenances from Australia and the Pacific Islands forming a separate group from those distributed in South East Asia. The wide geographic range and extensive cultivation of the species offer great potential for selection of genetic material for tree improvement programs.

Potential of Forest Genetic Improvement of *Eucalyptus urophylla* S. T. Blake on the Physical-Mechanical Properties of Wood for Sawmill

Laerte Scanavaca, José Nivaldo Garcia
R. D. Pedro II, 2247, 13416-770 Piracicaba/SP, Brazil
Tel: 55 19 4267542, FAX: 55 19 4222433, Email: lscanava@carpa.ciagri.usp.br

The FAO foresee that the world consumption of wood for sawmill will increase from 1.6 billion cubic metres registered in 1991 to 2.6 billion cubic metres by 2010, and that our national consumption shall increase from about 17 million cubic metres in 1990 to 59 million cubic metres until 2010 (increase of 350%). The motive of utilizing the reforestation wood are several, from the necessity of finding alternatives for brazilian native trees, subject to ecological pressure by environmental entities, to the high cost of forest extraction and freight due to long distances to consumer centers. There are enterprises which knowing the technical and the economical potential of reforestation wood, have already developed new lines of products (Vilela Filho, 1996).

Among species of *Eucalyptus*, the *Eucalyptus urophylla* is one of the most planted and with more potential of growth in Brazil. The *E. urophylla* is a species of Subgenus *Symphyormyrtus*, of high open forest, with gum or fibrous bark, with a good wood shape, density about 0,5 g/cm^3 and presents lignotuber, good budding at the second rotation and resistance to water absence. Besides that, it reacts to space variation and to fertilizer application and still possesses cline variation and ecotypes which are very important to the genetic improvement of the species (Ferreira, 1992).

Problems as growth tension, that causes fissure, warping, toughening, collapse and dimensional timber movement are some of the defects that make it difficult the use of rapid growth wood in sawmill. The work will be developed in an origin (9)/progeny (63) test, with a 19-year-old population of *E. urophylla* of Flores Island, managed to sawmill. It will be analysed the silvicultural characteristics: top of tree, bark, fruit, leaf, shape, strength, commercial volume, and technological characteristics: basic density, humidity, timber and piece extremity fissures, arching, resistance to normal traction and to parallel compression to the fibre, modulus of elasticity and flexibility, revenues on sawed green wood and secondly sawed wood.

We believe that it will be possible to correlate silvicultural and technological characteristics and to propose a program of genetic improvement based on these characteristics. This work is in process and we believe that we will have the results until the day of this symposium.

Methodologie de Suivi de Croissance de Plusieurs Provenances de *Khaya senegalensis* (Desr.) A. Juss. En Stations

Madjelia Some Dao
INERA/CNRST, Ouagadougou 03, 03 BP 7047 Burkina Faso, Burkina Faso
Tel: (226) 33 40 98, FAX: (226) 31 49 38, Email: madjelia@irbet.irbet.bf

Au Burkina Faso, les peuplements naturels de Khaya sont rares, la regéneration naturelle est absente et les plantations artificielles aux abords des avenues sont vieillissantes (G; W. Talkamp et al., 1992). Des études ont montré que l'espèce est un excellent bois d'oeuvre. Cependant, elle est beaucoup attaquée en pepinière comme dans les plantations par le borer des acajous: *Hypsila robusta* moore (CTFT-Burkina Faso, 1985). Des essais comparatifs de plusieures provenances de différents pays d'Afrique sont mis en place en 1988 dans différentes stations écologiques du Burkina Faso, par le Programme amélioration génétique afin d'identifier les meilleures selon les critères recherchés dans les scieries. Les variables mesurées, permettent d'évaluer la performance des provenances par rapport à la hauteur, au diamètre, aux niveaux de ramifications, à la rectitude du tronc et surtout au degré d'attaques des borers. Notre étude a montré l'adaptation de certaines provenances aux différentes conditions climatiques du Burkina et l'existence de plusieurs groupes par rapport à la qualité du bois recherché. Ces résultats sont interressants pour des travaux futurs en amélioration génétique.

2.02.00 / 2.08.00 Future of breeding and plantations in a sustainability-oriented world 1

Assessment of Forest Sustainability

Malilo H. Omari, Robert C. Albricht
P.O. Box 27, Singida, Tanzania
Email: Singidatcrs@maf.org

Tanzania has vast natural forest resources covering an area of about 33.5 million ha. These forests are subject to deforestation at a rate of 130000-400000 ha/yr occurring mostly on public or non- reserved forest land which is about 57% of the total forest area. The focus of forest management in these areas has traditionally been on valuable timber species and commercial forest products harvested under license.

In Singida Rural District tree planting and forest reservation was thought to be a solution not only for deforestation but also for satisfying local people's forest product needs. Exotic tree planting and campaign programmes were initiated in the early 70's with the Village Forest Programme (1971-1983) and were followed by a Community Forests Programme (1983-1992) and a Regional Forest Programme (1993-1995). Despite all these efforts forest degradation and deforestation have continued at an alarming pace.

Reserving forest areas in officially gazetted forest reserves is one strategy the government has used to prevent further deforestation. By the early 1980's the Mgori forest (study area) had been surveyed and demarcated by the government with the intention of officially gazetting it as a reserve. The villagers living around the Mgori forest objected to the gazettment as this threatened their livelihoods. In response to this threat Village Forest Committees were formed and management plans formulated. With the formal recognition of these management plans by the District council the local people regained control over their forest resources and collaborative forest management was the result.

The aim of this study was to compare the sustainability of forest (dry miombo woodland) in an area with collaborative/participatory forest management (Mgori) with an adjacent area where there is no collaborative/participatory management (Mungaa). Principles, criteria and indicators were used to compare the sustainability of the two forests. The principles, criteria and indicators were validated by field data gathered in and around both forests.

Conclusion:

Principles, criteria and indicators for sustainable forest management can be applied in miombo woodland to assess, monitor and evaluate the sustainability of forest and forest management. The results from this study suggest that collaborative/participatory forest management is more sustainable than non-collaborative / participatory forest management.

2.04.01 Conservation and management of forest gene resources

Strategy for Long-Term Conservation of Teak (*Tectona grandis*) Genetic Resources.

N.S. Nashatul Zaimah, Marzalina, M., Krishnapillay, B., Ang, K.C., Siti Hasanah, M.S., Zaiton, S., Fadzlinah, Z. and Hamsinah, H.
Forest Research Institute Malaysia (FRIM), Forest Plantation Division, Seed Technology Section, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603-6365573, Email: nashatul@frim.gov.my

Currently, there are several thousand forest tree species in the tropics with potential value. However only a few of these species have been included in *ex situ* conservation programs due to a variety of reasons. In general, the seed in an important form of genetic material that can be used in the conservation strategies. Erratic and recalcitrant behavior of seeds from certain species to conventional storage techniques is the most crucial problem to conservation.

Teak (*Tectona grandis*) is a well-known timber tree species mainly found in Southeast Asia including Malaysia. Teak has been tested for use in forest plantations in Malaysia. Long-term ex situ storage of teak germplasm is important in order to maintain the genetic diversity for use in subsequent breeding programs. Unfortunately, conventional methods of storage of teak seeds are not very suitable, as the seeds tend to deteriorate over time. Thus, another alternative method is to cryopreserve these seeds for long-term storage.

Several cryopreservation techniques were tested on teak seeds. They include air desiccation, encapsulation-dehydration and vitrification. All seeds (except control treatment) were maintained in liquid nitrogen (-196°C) and then subsequently thawed to evaluate their survival and capability to grow back into normal healthy seedlings.

Keywords: *ex situ* conservation, genetic diversity, breeding, cryopreservation, seedling survival

Ex-situ conservation of some endangered and wild medicinal plant species found in Indian forest ecosystems

P.E. Rajasekharan, S.R. Ambika and S. Gameshan
Division of Plant Genetic Resources, Indian Institute of Horticultural Research, Hessaraghatta Lake P.O., Bangalore-560 089, Karnataka State
Fax:+91-80-8466291, Email: bnguni@kar.nic.in

Different degrees of threats to biodiversity caused by several anthropogenic factors has resulted in the extinction of several medicinal plant species. Therefore, efficient conservation strategies need to be worked out to prevent this malady. *Rauvolfia serpentina*, *Tylophora indica* and *Kaempferia galanga species* were collected from Western ghat forest region of Kerala state in India and relocated to ex-situ ecosystems of Karnataka. Besides maintaining the species in field gene banks, attempts were made to bring them to aseptic conditions. Shoot tips and nodal explants were used to optimise protocols for in vitro multiplication of *R. serpentina* and *T. indica*. For in vitro multiplication of *Kaempferia galanga* sprouting buds were used. MS basal medium supplemented with BAP and NAA induced multiple shoots in the three species. Root formation occurred simultaneously along with shoots in *K. galanga* and *T. indica*. A separate medium (supplemented with IAA) was required for rooting in *R. serpentina*. The micropropagated plants were successfully field planted in the Karnataka ex situ ecosystem after hardening in glass house with varying survival rates recorded for different species. Slow growth experiments were carried out under Reduced Culture Condition (RCC) light and temperature. Vitro plants could be conserved for a duration of 6-12 months depending on the species. Post storage eco-rehabilitation studies for all species were carried out under ex-situ field conditions of Karnataka state ecosystem. In order to perceive any change after storage, total phenolics and alkaloid contents of treated and controls were estimated in two species (*T. indica* and *K. galanga*). No morphological changes were observed after in vitro storage in all the 3 species. Attempts were also made to reintroduce the species to the Kerala state forest ecosystem after multiplication.

Genetic Diversity, Genetic Effects of Forest Management and Natural Disturbance, Conservation and Sustainable Forest Management

O.P. Rajora
University of Alberta, Department of Renewable Resources, 751 General Services Building, T6G 2H1 Alberta, Canada
Tel: +1-780-492-4020, FAX: +1-780-492-4323, Email: Om.Rajora@ulberta.ca

Genetic diversity is the foundation of forest sustainability and ecosystem stability, as it is the basis of all biodiversity and provides raw material for adaptation, evolution and survival of species and individuals. The Canadian Standards Association has identified genetic diversity as one of the criteria/indicator for registration, certification and audit of sustainable forest management system. Forest management practices relying on forest harvesting and natural and/or artificial regeneration systems, including tree improvement, and natural disturbance, such as forest fires, can significantly impact gene pools and their genetic diversity in subsequent forest tree generations. Characterization of genetic diversity and biological processes that affect genetic diversity in forest tree populations and subsequently determining genetic impacts of various silvicultural management practices can provide resource managers with guidelines to manage for long-term forest sustainability and ecosystem health. Application of management practices without accounting for their genetic impacts can carry a risk of genetic degradation.

We have been conducting research on genetic diversity, genetic structure, mating system and other population genetic parameters in natural pristine populations, and determining impacts of forest management practices and forest fires on these genetic parameters in *Pinus strobus*, *Picea glauca* and *Picea mariana* using allozymes and DNA markers. Genetic diversity was found to be reduced by 25% to 50% in the postharvest residual gene pools of old-growth *P. strobus* harvested under a partial-cut (seed tree) system. In *Picea glauca*, natural stands showed the highest genetic diversity. Selections of phenotypically superior trees were found to have the lowest genetic diversity. Correspondingly, genetic diversity was significantly reduced in plantations when compared to natural stands. These results and other case studies have implications for conservation and sustainable management of forest genetic resources.

Gestion de ressources génétiques forestières à Madagascar

Lolona Ramamonjisoa
National Treeseed Centre, BP 5091, 101 Antananarivo, Madagascar
FAX: 261 20 22 412 41, Email: silonagf@bow.dts.mg

Mots clés: biodiversite, especes autochtones, génétiques, conservation, valorisation

Les forêts malgaches diminuent à un rythme sans précédent et ce sont des écosystèmes entiers qui sont menacés, des espèces animales et végétales qui disparaissent et les fonctions principales de la forêt qui ne sont plus remplies. Bref, c'est l'ensemble de la biodiversité qui se trouve être affecté.

Un problème moins souvent évoqué car moins visible mais tout aussi alarmant est la diminution rapide de la diversité génétique. Celle-ci est le soutien de la stabilité biologique et la base pour l'évolution naturelle et l'adaptation des espèces à des environnements changeants. Lorsque le "genepool" est érodé, l'espèce est condamnée tôt ou tard à disparaître.

Des capacités de récolte, de conservation et d'utilisation orientée des ressources génétiques forestières doivent être ainsi développées. Cela s'apparente à la mission d'une Centrale de semences forestières qui doit se doter d'un Plan National Intégré conçu pour l'orientation future à court, à moyen et à long terme de l'offre et de la demande en semences forestières avec un regard sur les actions de gestion de ressources génétiques.

La compréhension des dynamiques biologiques des populations dans lesquelles survivent les espèces ciblées est déterminante pour pouvoir prévoir la perte de gènes et de développer des stratégies pour les arrêter.

Il est aussi obligatoire de prendre connaissance de la variabilité génétique des espèces et de procéder à leur conservation et améliorer leur valorisation.

Un plan stratégique est mis sur pied et repose sur le principe de tentative de conciliation de l'écologie et de l'économie. Une logique argumentée composée de deux étapes est suivie pour le plan: étape de diagnostic et d'analyse et étape de définition des axes et objectifs stratégiques. La considération des options politiques et stratégiques nationales dans le domaine environnemental, concernant notamment les ressources naturelles et la biodiversité est mise en évidence. Il en est de même pour les aspects législatifs et juridiques reliables à la gestion des ressources génétiques.

Les essences forestières autochtones visées à Madagascar sont d'une part, celles qui sont dotées d'une importance capitale sur la biodiversité originelle de la flore malgache et d'autre part, celles qui offrent des produits forestiers d'une grande valeur socio-économique qui doivent en priorité rapporter aux communautés locales. Il s'agit des espèces nobles de la forêt naturelle malgache, notamment celles des deux genres *Dalbergia* et *Diospyros* tout en poursuivant les activités déjà initiées sur d'autres espèces comme le *Khaya madagascariensis*.

Notre étude de cas concerne cette dernière espèce avec laquelle un programme de conservation des ressources génétiques a été conduit depuis janvier 1995 et a abouti jusqu'à maintenant à une installation de conservation *ex-situ*. Le *Khaya madagascariensis* est très menacé de disparition à cause du défrichement car souvent elle colonise des terres utilisables en agriculture, d'une exploitation abusive pour la haute valeur technologique de son bois, et d'une cueillette destructive pour la propriété médicinale de son écorce.

Management and Conservation of Genetic Resources of *Quercus mongolica* var. *grosseserrata*

Masatoshi Ubukata, Naoei Itahana, and Kohzoh Kohno
Forest Tree Breeding Center Ebetsu, Hokkaido Breeding Office, 069-0836 Hokkaido, Japan
Tel: +81-11-386-5423, FAX: +81-11-386-5420, Email: ubuubu@affrc.go.jp

Quercus mongolica var. *grosseserrata* (*Fagaceae*) is a representative tree of the cool-temperate forests of Japan and is important as a source of commercial timber. Historically, the huge resources of oak in Hokkaido in the northern part of Japan have supplied the country with high quality oak timber. Natural regeneration usually occurs after large disturbances such as forest fires or typhoons. Regeneration success, however, is often not achieved where the forest floor is overgrown with dwarf bamboo (*Sasa kurilensis* or *Sasa senanensis*). In order to utilize *Q. mongolica* var. *grosseserrata* while conserving the genetic resources, a study was conducted to elucidate the genetic characteristics in this oak and to establish techniques for effective forest management in natural stands. Materials from forest tree conservation stands, individual trees, provenance test fields, and artificial hybrids were selected for study. These materials were evaluated by allozyme and cpDNA analyses, leaf characteristics, and phenology, in consideration of Hokkaido geography and inbreeding depression.

Allozyme analyses did not detect geographic differences, however, other characteristics revealed distinct differentiation between trees grown in the eastern part and the western part of Hokkaido. It was found that the natural oak stands have a genetic patch structure. In stands, about half of the individuals had produced many male flowers each year. Under artificial pollination, this oak showed self-incompatibility and high inbreeding depression indicating high pollen-dispersal and relatively limited acorn-dispersal. Closer management of the natural oak stands is proposed to establish mid-story advanced regeneration as isolated stands would be vulnerable to genetic reduction. Large trees should be selectively cut within a stand to maintain genetic diversity. When artificially regeneration is used, a local seed source should be used. Natural regeneration requires disturbance of the sasa cover by soil scarification.

Conservation and Management of Oak Genetic Resources Impacted by Oak Decline in Russia

Alexander S. Yakovlev, Igor A. Yakovlev
Mary State Technical University, Department of Plantation Silviculture, Ioshkar-Ola, pl. Lenina, 3, 424000, Russia
Tel: (8362)-55-21-30, FAX: (8362)-11-08-72, Email: yakovlev@mari-el.ru

Oaks in Russia are important ecological and economic species. The Forest Fund Inventory data of 1993 show the area of oak forest in the European part of Russia to be 3.72 Mha, including 1.34 Mha of high forest and 2.37Mha of coppice woodland. The main oak forest areas (% of total oak forest area) are concentrated in four economic regions: North-Caucasian (29.3%), Povolzhskij (22.9%), Central-Chernozemnij (15.9%) and Central (11.4%).

Pedunculate oak (*Quercus robur*) decline is currently causing significant loss of oak gene pool as well as decline in biodiversity of oak ecosystems. In the last 5 years, the total area of oak forest declined by nearly 0.175 Mha. The main reasons for oak decline are considered to be improper silviculture and over exploitation of oak forest during the last 3 centuries which has led to a decrease in stress tolerance of oaks. Further, extreme climate conditions, pests and diseases have added to oak decline over a wide area of Russia. Thus, effective measures for the recovery, management and conservation of oak genetic resources are needed.

A special conservation program for the pedunculate oak gene pool was developed in the Povolzhskij region. This program is based on a preliminary study of intraspecific variability in morphological traits and isoenzymes combined with a study of oak population structure, history and status in the region. Conservation measures of establishing genetic reserves and propagating selected superior oak trees are two key elements of the genetic resources program. A study of the selection and management history of oak groves originally intended for shipbuilding were reviewed, and oak groves in the best stand were selected for the establishment of oak gene reserves. These "shipbuilding" groves received special long-term management that makes them particularly suitable for setting a baseline of oak genetic resources.

Management of declining oak stands directed toward recovery, maintenance and improvement of the stands is another important aspect of our conservation program. Recovery is aimed at creating tolerant, multistoried mixed stands of oak and attendant species which favors oak growth. We have developed studies of natural and artificial regeneration with preference being given to enhancing natural regeneration based on the "gap" paradigm. This method consists of the formation of clearings (gaps) of 400-600 m^2 in the stand which receive litter scarification and management to favor self seeding and growth of seedlings. Future investigations will compare artificial recovery of oak with natural recovery after harvest by dividing a felling site into plot areas for artificial and natural regeneration. These plots will be large enough for four mature oak crown diameters which will allow development of mixed high tolerant oak stands.

Study on Variability within Pedunculate Oak Populations in the Middle Near Volga Region of Russia and Conclusions for Gene Conservation and Silviculture

Igor A Yakovlev
Mary State Technical university, Department of Plantation Silviculture, Komsomolskaya, d.155, kv.49, 424000 Ioshkar-Ola, ul, Russia
Tel: (8362)-55-21-30, FAX: (8362)-11-08-72, Email: yakovlev@mari-el.ru

The pedunculate oak (*Quercus robur* L.) populations indigenous to the Middle Near Volga region of Russia represent a valuable gene resource. These oak forests grow on the northeastern boundary of pedunculate oak's natural range in the Europe and have existed for a very long time. Oaks in this region are characterized by some peculiarities in intraspecific variability and genetic structure. Three phenological forms have been distinguished by differences in timing of autumn coloration and leaf fall. Progeny tests of the different forms show differences in early growth rate and demonstrate higher susceptibility to leaf damage. This study assessed intraspecific variability of trunk, branch, crown, bark, and leaf morphology. Two groups of populations were distinguished:

Privolzhskaja forest and Zavolzhskaja forest-steppe. The latter group is comprised of two subgroup populations growing in a forest-steppe zone of region: Mokshansko-Surskaja (highland) and Zavolzhskaja (high plain). Isoenzyme analysis detected 12 loci that revealed high genetic diversity of oak populations in this region. The mean percentage of polymorphic loci (58-66%), by 95% criterion, and the average number of alleles per loci (2.4-2.5) was determined. The observed heterozygosity varied from 16.1-17.8%, and the expected heterozygosity ranged from 16.2-18.4%. Thus, the observed heterozygosity was only slightly lower than expected and insignificant. Overall, genetic diversity of oak populations in this region is slightly higher than Finland populations, but was much lower than populations in Germany or France. The populations have uniform gene pools with intensive exchange of genes between them. Genetic distance (Nei) between them varied f rom 0.0016-0.0065 and Gst was 0.013. The concentration of variability within a population as opposed to between populations suggests that allocation of three large or four to five smaller genetic reserves over a variety of sites would adequately conserve a significant portion of the genetic variability.

Keywords: *Quercus robur*, progeny test, isoenzyme, heterozygosity, genetic variation

Conservation Potential for Trees and Shrubs in Arid and Semi-arid Areas of China

Jiang Zeping, Ma Wenyuan, Li Huiqing, and Wang Houran
Chinese Academy of Forestry, Sustainable Forestry Research Center, Wan Shou Shan Hou, 100091 Beijing, China
FAX: +86 10 62872015, Email: jiangzp@rif.forestry.ac.cn

The arid and semi-arid zones in China occupy 3.31 million square kilometers containing more than 1,000 woody plants that have a potentially important role in landscape rehabilitation and local economic development. Studies on the biology and ecology, particularly stress biology, have been conducted on major trees and shrubs. Drought-resistance and salt-resistance studies have been made of woody species from different genera including: *Calligonum, Tamarix, Haloxylon, Hedysarum, Canagana, Salix, Populus, and Hyppophae*, More than 70 species have being tested in 12 ecological sites for shelterbelts, cash crops, and green fodder respectively.

Provenance trials and genetic improvement experiments have been established for major species. Vegetative propagation by rooting cuttings, grafting, and tissue culture have made prominent progress for a number of species. Gene engineering techniques have been used in a few cases to identify and clone new genotypes of stress-resistant plant.

A number of trees and shrubs have been conserved in situ or ex situ. Seventeen botanical gardens and arboretums have been established in arid region, each containing approximately 300 to 500 woody plant species. Many studies have focused on the methodologies for plant gene conservation, as more than 20 woody plant species become endangered species.

Woody plant introduction and domestication is necessary in the region. Introduced species highly valued for shelterbelts and landscape rehabilitation are: *Populus euramericana*, *Pinus sylvestris* var. *mongolica*, *Hedysarum scoparium, Tamarix spp., Haloxylon ammodendron, Robinia Pseudoacacia,* and *Amorpha fruticosa*.

2.09.00 Seed physiology and technology

A Comparative Study on the Effects of Moisture Content and Temperature on the Storability of an Orthodox, Intermediate and Recalcitrant Forest Tree Seeds

N. Jayanthi, Hor, Y.L., Krishnapillay, B.
Forest Research Institute Malaysia (FRIM), Seed Technology Section, Forest Plantation Division, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603- 6365573, Email: jayanthi@frim.gov.my

Keywords: *Instia palembanica, Swietenia macrophylla, Hopea odorata*, shedding moisture, cryopreservation

Only two categories of seed storage behaviour, orthodox and recalcitrant, were recognized 30 years ago. Orthodox seeds are those that can be dried to low moisture content without affecting their viability, and that are tolerant of low temperature. In contrast, recalcitrant seeds are sensitive to drying, and die below a critical moisture content. Recalcitrant seeds are also very sensitive to low temperature. About 10 years ago a third storage category, intermediate, was introduced for seeds between orthodox and recalcitrant in terms of storage behaviour.

The effects of moisture content and temperature on the storability of examples of seeds from these categories, namely, *Instia palembanica* (orthodox), *Swietenia macrophylla* (intermediate) and *Hopea odorata* (recalcitrant) were studied. The objectives were to determine the critical and optimal moisture contents (MCs) and storage temperatures, to evaluate the combined effects of these two factors, and to investigate the potential for cryopreservation of these species.

The study was divided into 4 parts comprising 12 experiments. In Part 1, the effects of oven (35±0.2°C) drying seeds to various target MCs on germination and vigor (germination index and dry matter content) were evaluated. In Part 2, seeds at their shedding MCs were stored for 4 weeks over a range of temperatures, and germination percentage, germination index and dry matter production were assessed after 2 and 4 weeks. In Part 3, seeds were stored at selected MCs and temperatures for 9 months based on the results from Parts 1 and 2, so that the combined effects of optimal MC and temperature for could be determined; germination was tested after 1, 3, 6 and 9 months. In Part 4, the potential for cryopreservation of naked embryos was investigated.

From Parts 1 and 2, it was observed that seeds of *I. palembanica* (orthodox type) with a low shedding MC of 10%, tolerated dessication; the critical and optimal moisture levels were 6% and 8-10%, respectively. The intermediate-type seeds of *S. macrophylla*, the shedding moisture content of which was 37%, were much more sensitive and did not tolerate excessive dessication; the critical and optimal moisture levels were 15% and 25%, respectively. The recalcitrant-type seeds of *H. odorata* had a very high shedding moisture content of 48%, and were highly sensitive to even slight dessication; the critical and optimal moisture levels were also high, 29% and 32-35%, respectively.

From Part 3 it was found that orthodox seeds of *I. palembanica* withstood sub-freezing storage at –20°C, maintaining high viability for 4 weeks; the optimal storage conditions for this species were 8-10% MC and 5°C. Intermediate-type seeds of *S. macrophylla* also withood storage at -20°C, but the optimal storage conditions for this species were 25% MC and 15°C. Recalcitrant seeds of *H. odorata* were highly sensitive to low temperature and all seeds died at 5°C. Seeds of this species could not be stored by conventional methods and almost all seeds died within 3 months even under the optimal conditions of 32-35% MC and 20°C. Part 4 showed that embryos of orthodox *I. palembanica* could be directly frozen in liquid nitrogen at 10-11.9% MC, with 75% survival. More than 70% of *S. macrophylla* embryos similarly frozen at 18% (and lower) MC survived also. No embryos of *H. odorata* survived liquid nitrogen freezing irrespective of MC.

Thus, for orthodox species such as *I. palembanica*, whole seeds stored well at low MC and low temperature and embryos could be cryopreserved even at a shedding MC of 10%. For intermediate species such as *S. macrophylla*, MCs and temperature had to be higher for conventional storage, but embryos could be cryopreserved if dessicated to 18% or lower MC. Storage of recalcitrant species such as *H. odorata* was very difficult, with no whole seeds surviving conventional storage for 3 months even under optimal conditions, or cryopreservation at all MCs.

Effect of Pretreating Temperature on Seed Germination of *Idesia polycarpa*

Satoshi Kitaoka, Yutaka Yurugi, Sin-ichiro Ito and Hiroshi Nagata
Mie university, Lab. of silviculture, Fac. of Bioresources, 1515 Kamihama-cho, Tsu, 514-8507 Mie, Japan
Tel: +81-11-706-2592, FAX: +81-11-706-3450, Email: skitaoka@exfor.agr.hokudai.ac.jp

Idesia polycarpa is a tree species distributed between the Subtropical Zone and the Temperate Zone of Japan. To determine the variation in seed germination, especially the response to pretreatment temperatures, experiments were carried out using seeds collected from two provenances, Nago City in Okinawa prefecture (the Subtropical Zone) and Owase City in Mie prefecture (the Temperate Zone). Pretreatments comprised combinations of six temperatures of 5º, 7º, 10º (as prechilling), 15º, 17º and 20ºC (as conditioning) with five durations of 0 (control), 20, 40, 60 and 80 days. Germination of treated seeds was tested under a constant temperature of 25ºC for 24 days and alternating temperatures of 25º/15ºC, each for 12hr, for 30 days. Counts of germinated seeds were made at three days intervals.

Alternating temperatures were more effective than the constant temperature. Pretreatment at 5º and 7ºC inhibited the germination of Okinawa seeds, but promoted those of Mie provenance. When pretreated at 15º and 17ºC, the germination of Okinawa seeds was considerably promoted, and these temperatures were effective also for Mie seeds. From these results, it is speculated that Temperate Zone seeds of *Idesia polycarpa* in Mie prefecture have gained a chilling requirement while keeping their subtropical genetic character.

Viability Retention in *Pongania pinnata* (L.) Pierre and *Syzygium cumini* (L.) Skeels Seeds of Different Sizes

Sudhir Kumar, M.C. Arjunan, N.R. Ponnammal, B. Gurudev Singh, R. Parimalam and S.N. Vijayachandran
Institute of Forest Genetics and Tree Breeding, Post Box # 1061, R.S. Puram, 641 002 Coimbatore, India
Tel: 0422-431540, FAX: 91-0422-430549, Email: ifgtb@satyam.net.in

Keywords: moisture content, seed storage, protein, carbohydrate, lipid

Changes in the biochemical processes associated with seed deterioration are initiated before germination exhibits any decline. These include changes in storage compounds, respiratory pathways, enzyme activities, membranes and chromosomes. The poster reports changes associated with seed deterioration and viability retention in size-graded seeds of *Pongamia pinnata* (L.) Pierre and *Syzygium cumini* (L.) Skeels during storage.

Mature pods of *P. pinnata*, and fruits of *S. cumini*, were collected locally and extracted seeds were size graded according to length using sieves. For *P. pinnata*, seeds 2.6-3.2 cm long were classed as large, those 2.0-2.5 cm were medium, and those 1.6-1.9cm were small. Similarly, for *S.cumini*, seeds 1.4-1.6cm long were large, 1.0-1.3cm were medium, and 0.6-0.9cm were small. After grading, seeds were stored in cotton bags at room temperature, 29±2°*C*. To test viability retention, at 15 day-intervals samples of seeds of all sizes were removed from the storage bags and germinated on sterilized sand at 29±2°*C*. Seed moisture contents were determined from duplicate samples using the low constant-temperature oven method.

In *P. pinnata*, germination was 98, 86 and 70% in fresh large, medium and small seeds, respectively. After storage for 5 months, germination decreased to 54, 40 and 7%, respectively. Viability was retained in large seeds for 8 months, in medium seeds for 7 months and in small seeds for 5 months.

In *S. cumini*, germination was 98, 95 and 80% in fresh large, medium and small seeds, respectively. After 2 months of storage, germination decreased to 43, 41 and 11%, respectively. Viability was retained in large and medium seeds for 4 months, but for only 2 months in small seeds.

The moisture contents of fresh seeds of *P. pinnata* were 5.6, 6.3 and 7.2% in large, medium and small seeds, respectively. During storage (8months), moisture content in *P. pinnata* seeds decreased gradually. For *S. cumini*, the moisture contents of fresh seeds were 44.8, 45.7 and 46.8% in large, medium and small seeds, respectively. During storage (2 months), moisture contents of *S. cumini* seeds decreased rapidly.

Protein, carbohydrate and lipid contents were determined in fresh and stored seeds until they lost viability. In fresh seeds of *P. pinnata* protein, carbohydrate and lipid contents were in the order of 114.6, 22.7 mg/g and 24% in large; 96.9, 20.5 mg/g and 21% in medium, and 67.1, 18.2 mg/g and 17% in small seeds, respectively. Similarly, in fresh seeds of *S. cumini* protein, carbohydrate and lipid contents were 22.8, 20.6 mg/g and 0.6% in large, 20.1, 18.6 mg/g and 0.5% in medium, and 18.9, 16.8 mg/g and 0.4% in small seeds, respectively. In fresh seeds of both species, large seeds showed higher proportions of protein, carbohydrate and lipid content followed by medium and small seeds. In general, as storage duration increased, germination, moisture content, protein and carbohydrate levels decreased, while lipid contents increased, in all three seed sizes of both species.

Cross-sectional, Image-guided, Minimally-invasive Phytobiopsy

J A Vozzo, Ramesh Patel, Asmita Roy
U S Department of Agriculture, Forest Service, MS Starkville, USA
Tel: (662) 325-8654, FAX: (662) 325-3278, Email: jvozzo@cfr.msstate.edu

Keywords: computerized tomography, magnetic resonance imaging, chemical analyses

Using computerized tomography (CT) for biodensity of morphology, and magnetic resonance imaging (MRI) of mobile proton distributions for comparative physiology, a slightly invasive procedure allows quantitative chemical analyses. The supplemental procedures provide a useful comparison of dormant and germinated seed tissues to correlate form, function, and amount of metabolic substrate during treatments and storage trials.

CT uses thin, contiguous, nondestructive slices of single-plane images to identify and quantify in area and volume any tissues within a 5000 Hounsfield unit biodensity range. The data are expressed in either histograms of densities or numerical mapping of the same density units. MRI provides presence and distributions of the Hydrogen ion density for bulk water and/or fatty acid molecules. These mobile proton distributions are visually displayed by both area and volume (pixel and voxel determinations). The biopsy is sample extraction through a 1.0-3.0-mm bore penetrating the seedcoat. Chemical analyses are quantitative for elemental and organic changes in challenged tissue.

3.02.00 Effects of nursery and silvicultural operations on the environment and society

Energy Consumption and Emissions to the Air in Timber Production - a Life Cycle Inventory Approach from Seedling to Log in Northern Sweden

Yvonne Aldentun, Staffan Berg
SkogForsk, Uppsala Science Park, S-751 83 Uppsala, Sweden
Tel: +46 18188500, FAX: +46 18188600, Email: yvonne.aldentun@skogforsk.se

Keywords: Life cycle analysis; Timber production; Forest operations

Forestry has a major role in Swedish foreign trade and it is thus important to the economy and to employment. There is increased concern over environmental issues in forestry during the last decade. Cleaner timber production is not only beneficial for the environment, it might even improve market access for forest products. Knowledge about the environmental load from different forest operations is needed in bench-marking and serves as a quantitative base for certification. Such information also allows comparisons between different forest operation techniques or systems. Life cycle assessment is one tool to describe the impact of a product from cradle to grave.

A Life Cycle Inventory was carried out in a forestry district in northern Sweden, Lycksele förvaltning, Assi Domin AB. The aims of the study were to describe the energy consumption and the emissions to the air from timber production in order to provide data to be used in Life Cycle Assessments for various forest products.

Data were collected using a bottom-up approach to obtain detailed information about the entire chain of operations, e.g. container-seedling production, site preparation, planting, cleaning, fertilising, thinning and final felling. This means that production and transportation of necessary commodities to the nursery and also transportation of seedlings, machinery and labour to the work site were included in the study. All data were related to cubic meters of produced timber.

The approach used in the study made it possible to compare the various activities in the production chain with respect to their need of fossil fuels and emissions to the air. Carbon dioxide dominated the emissions, followed by nitrogen oxides. The logging operations required the largest amounts of fossil fuels. Logging was also a major source of emissions per cubic metre of timber. The use of energy and the emissions per m^3 timber from logging in thinnings exceeded the energy use and the emissions from logging in final felling. This was due both to a smaller diameter and larger distances between the trees to be cut in the thinning operation compared with the final felling operation. Site preparation was the most energy-consuming silvicultural operation, but it was still a minor user of fossil fuels compared to logging. The most important source of emissions in seedling production was the heating of the greenhouses.

Effect of Potting Media and Size of Root Trainers on *Shorea Leprosula* Seedlings

H. Aminah, Ab. Rasip Ab.Ghani, Abdul Khalim Abu Samah,
Kassim Elias & Yusof Yahya
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia

Keywords: Container-grown; Seedlings; Malaysia; Potting media

A factorial experiment, consisting of 6 potting media and 2 sizes of root trainers, was carried out in the nursery of the Forest Department District of Lentang, Pahang, Peninsular Malaysia. Potting media used were: 1) 100% coconut husk, 2) commercial peat mix, 3) oil palm mesocarp fibre. A further three media were prepared, consisting of each of the above media mixed with rice hulls in the ratio of 3:1. These mixtures were filled into two sizes of root trainers (500 & 700 cm^3) and were tested with *Shorea leprosula* seedlings. Height and diameter were measured and a survival count was made after six months of potting. Measurements taken at 6 months showed that increments in height (50.8 cm) and diameter (3.8mm) of *S. leprosula* were significantly better in plants raised in oil palm mesocarp fibre compared to the other potting media. No significant differences were observed in the height and diameter increments of plants grown in the two sizes of root trainers. In term of survival, high survival of more than 90% was obtained in all media. From the results obtained, decomposed oil palm mesocarp fibre has the potential to be used as a lightweight potting media for potting forest seedlings. It is easily obtainable and cheap, as it one of the wastes from oil palm mills. This lightweight medium will greatly facilitate transportation of seedlings to the planting site.

Performance of *Khaya Ivorensis* Rooted Cuttings in a Field Trial

Ab. Rasip Ab. Ghani, Ong Tai Hock
Forest research institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Email: Wong Wai Kin [wwaikin@frim.gov.my]

Keywords: Cuttings; Establishment; Malaysia; Growth

The performance of *Khaya Ivorensis* rooted cuttings was evaluated to assess the suitability of rooted cuttings as a source of planting material for plantation purposes. The cuttings were made from selected seedlings based on their vigour. The trial was conducted in Sg. Chinoh Estate, Perak, where the site has a moderate to shallow soil depth (less then 50-cm effective soil depth). The experiment was carried out on a randomized complete block design with three replications. Growth rates (height and diameter at breast height), survival, health, and response to wind throw were recorded. At 3.5 years, the mean total height of the rooted cuttings had reached 16.7 metres, with a mean diameter at breast height of 12.3 cm. The survival rate of the trees was high, i.e. more than 90%. After a heavy storm, only 3 trees (1.2%) were uprooted and 6 trees (2.4%) had their trunks snapped. Due to high survival rates, good growth and good resistance to wind throw, the potential of using rooted cuttings for mass production of *Khaya Ivorensis* is very promising.

Evaluation of Post-Harvest Establishment Techniques on the Initial Growth of *Eucalyptus grandis* hill. Ex maiden in the Northeast of Argentina

Ana M.. Lupi, Fernandez, R. A.; Reis, H; Bernio, J; Elizaul, J.; Reboratti, H.
EEA INTA Montecarlo Facultad de Ciencias Forestales, Eldorado Misiones, CC 4 (3384), Misiones Montecarlo, Argentina
Tel: +54 3751 480512, FAX: +54 3751 480057, Email: rfernandez@ceel.com.ar

Keywords: Site preparation, Slash management, Fertilization, *Eucalyptus grandis* Hill ex Maiden, Argentina.

The objective of this work was to study the effects of different site preparation techniques such as slash management, soil cultivation and fertilization on the growth of *Eucalyptus grandis* Hill ex Maiden. The study area was located on a Kandiudalf soil, in the Northeast of the Corrientes province, Argentina. The place was located at a longitude of 55°43'W, a latitude of 28°05'S, and an elevation about 100 m asl. The annual average temperature was 21°C and the annual average rainfall was 1700mm, with a uniform distribution.

From 1978 through to early 1997, the experimental site was planted with *E. grandis*. The experiment was established between September and November 1997, using a factorial design of 2x2x3 with four replications. The applied treatments were combinations of: (1) slash and litter management of burning or retaining the slash; (2) soil cultivation by subsoiling to 40 depth or ploughing to a depth of about 15cm; (3) fertilization of 0, 150, 300 g/seedling, with 15% N, 15% P_2O_5 and 15% K_2O fertilizer.

In August of 1997, the remaining slash and litter from the harvesting operation were sampled and they were classified according to size into two types of thin (those with diameter of less than 1 cm), and thick (those with diameter between 1 and 15 cm). Sub-samples from both classes were analyzed in laboratory for N, P, K, Ca, Mg, and Na concentrations. In September 1997, the slash management and soil cultivation treatments were applied; at the end of October, the trees were planted; and 20 days later, the fertilizer treatments were applied. In July 1998, leaf samples were collected to estimate the nutrients by each treatment.

The dry weight of the thick residual debris was the 7.80 tn.ha-1, whereas the weight of the thin residual debris was 16.74 t.ha^{-1}. The Ca, N, and Mg levels were quantitatively more important, with a total of 457.4; 68.6 and 39.4 Kg.ha^{-1}.

Statistical analysis of the growth, 9 months after planting, did not show any significant difference for ground-line diameter (GLD) or total height, between the slash and litter management treatments nor the soil cultivation treatments. However, the interaction between both factors was significant, with the best growth from ploughing combined with the burning treatment. With the fertilizer treatments, the statistical analysis showed significant differences (P= 0.01) between treatments, mainly in those that had been fertilized, compared with the control without fertilizer. The GLD was 5.4, 6.2 and 6.5 cm and the total height of the trees was 213.8, 273.2 and 288.8 cm for the fertilizer rates of 0, 150, and 300 g.seedling^{-1}, respectively.

The foliage concentrations of N, P, K, and Ca were similar to those reported in the literature for one-year-old leaves and the concentrations could be considered optimal for the growth of *E. grandis*.

3.02.00 Effects of nursery and silvicultural operations on the environment and society

Nitrate Leaching Potential of Slow Release Fertilizers in Bare-root Pine Nurseries

Ken McNabb
Auburn University, School of Forestry, AL 36849-5418 Auburn, USA
Tel: 334-844-1044, FAX: 334-844-1084, Email: mcnabb@forestry.aubum.edu

Keywords: Nitrate leaching; Nursery; United States of America; Bare root

The Southeastern United States produces about 1.2 billion bare-root pine seedlings annually, with 1-0 loblolly and slash pine (*P. taeda* and *elliottii*, respectively) accounting for 95% of this production. A typical fertilization regime in the region uses ammonium nitrate at 168 kg/ha of elemental nitrogen top-dressed in 5 applications of 33.6 kg N/ha during the summer months when shoot biomass expansion is highest. While this time-tested formula produces a seedling of acceptable morphology and quality, during the past decade there has been growing concern about the potential loss of nitrate (NO_3) to the environment through leaching. Slow-release fertilizers may possibly increase nitrogen use efficiency, and hence reduce nitrate losses, because they release nutrients more similarly to the actual use requirements of the plant.

A randomized, complete-block design, with 3 blocks and individual plots 40 feet long, was used to test two slow-release fertilizer materials and ammonium nitrate at equivalent rates of 224 kg N/ha N. The SLRs were two polymer-coated ureas; a 21-7-14, 270-day release, and a 13-13-13, 180-day release. They were applied in early April and worked to a 5 cm soil depth using a bed shaper. The ammonium nitrate was applied in 8 biweekly top-dress applications of 28 kg N/ha each. This particular nursery uses 336 kg N/ha liquid ammonium nitrate as its standard treatment and areas immediately adjacent to each of the experimental blocks were also sampled, allowing for a direct comparison with the granular fertilizers. Two zero tension lysimeters (16.5 cm diameter) were placed in each plot at a depth of 30 cm and sampled during the growing season according to rainfall amount.

The area received a total of 962mm of rainfall from April to January. Lysimeter samples were taken on 7 occasions during this period. There was considerable variability both in the amount of water collected in each lysimeter as well as the nitrate concentrations. Volumes collected in the 24 treatment plot lysimeters varied between 0 to 1.1 l. Water samples varied from 1 to 204 ppm nitrate concentration. Statistical analysis revealed the amount of water leached did not vary between treatment or block. There were significant differences, however, in the amount of nitrate leached, with averages of 26.0, 22.8, 10.0, and 2.4 kg/ha of nitrate leached during the sample period for the liquid, 180-day release, ammonium nitrate, and 270-day release fertilizers, respectively.

About 80% of this loss occurred during the summer months (during the application period). There was also a significant difference between rates of leaching, with averages of 13.2, 9.2, 7.1, and 1.9 mg of nitrate per litre of water leached for the liquid, 180-day release, ammonium nitrate, and 270-day release, respectively. The higher leaching rate for liquid fertilizers can be expected, as it was applied at a 50% higher rate. When calculating nitrate leaching as a percent of nitrogen applied, the liquid, 180-day release, ammonium nitrate, and 270-day release compounds, lost 7.7%, 10.3%, 4.5%, and l.l% of their applied nitrogen. All of these figures are lower than expected, as nitrogen use efficiencies for seedlings are typically around 50%. The effectiveness of slow-release fertilizers to reduce nitrogen loss through leaching is directly related to the release rate of the compound and the speed at which seedlings can utilize released nitrogen.

Artificial Pruning: Technical, Productive and Economic Considerations - a Review

Norocel-Valeriu Nicolescu
University Transilvania of Brasov, Faculty of Silviculture and Forest Engineering, Sirul Beethoven nr 1, 2200 Brasov, Romania
Tel: +(068) 41 86 00, FAX: +40 68 41 78 98, Email: nicolescu@yahoo.com

Keywords: Artificial pruning; Thinning; Certification

The pruning of the best stems in growing stands has been applied as a tending operation for centuries. According to Mayer-Wegelin (1952), interest in this operation dates from the 18th century when Carlowitz discussed it in his paper on wild trees (Silvicultura Oeconomica 1713).

In the evolution of artificial pruning, there has been a shift of silvicultural models from the traditional type (characterised by high stockings, light thinnings, and long rotations) towards a more dynamic one, involving the use of fast-growing species, widely-spaced plantations, heavier thinnings, and shorter rotations. Pruning is not considered a necessary intervention with traditional silviculture, because high stockings help control branch size and there can be a high rate of natural branch shedding. However, with the new dynamic silviculture, it is a fundamental economic and technological component to maximise the production of clear high-quality timber, while minimising the undesired effects (production of lower quality timber, characterised by low density and a high proportion of juvenile wood, as well as very large branches (knots).

Taking into account such evolution, this poster aims to provide an overview of different issues related to artificial pruning. Based on over 200 references published worldwide, it focuses on the most relevant characteristics of artificial pruning such as:
- Definition, types, objectives, and effects of pruning.
- Knots and their influences on timber qualities and end-uses.
- Pruning characteristics (e.g., species to prune; diameter of branches to cut; position of cuts; pruning height; pruning intensity and number of lifts (stages); pruning season; number of trees perha to prune; pruning tools; economics of pruning; pruning certification; and pruning and other silvicultural tools such as wide spacing, thinning, and fertilising).

Pruning is an expensive intervention and, as a consequence, is rarely practised on large scale. A model framework for artificial pruning is recommended as follows:
- Prune only the potential final crop trees (straight, vigorous, dominant and co-dominant, healthy and as evenly spaced as possible) for high-quality uses and from high-yielding and quality stands.
- Start pruning at an early age, when diameter at breast height is no more than 10-12 (max 15) cm.
- Cut only small branches (max diameter=3 cm).
- Use natural target pruning (protects both branch collar and branch bark ridge).
- Do not leave stubs.
- Use wound dressing only in special cases (e.g., widely damaging fungi).
- Prune up to a maximum of 6 m in 2-3 lifts.
- Do not remove more than one third of the live crown at any time (intervention).
- Always maintain a 50% live crown/bole ratio.
- Prune dead branches at any time of the year and living branches, with some exceptions, at the end of dormant season.
- When possible, use a combined pruning-thinning regime.
- Certify pruned stands as a label of quality and thus make higher prices for pruned timber possible.

However, when considering the need for pruning, it must be remembered that "If done carefully and correctly, pruning can increase the value of the trees. If done carelessly, it can do more harm than good" (Schlesinger 1988).

3.04.00 Operational planning and control; work study

A study on the productivity and work loads of natural forest harvesting in Turkey

H. Hulusi Acar and Tetsuhiko Yoshimura
Karadeniz Technical University,
Trabzon 61080, Turkey
Tel: +90-462-325-3223, Fax: +90-462-325-7499, E-mail: hlsacar@risc01.ktu.edu.tr
http://www.ktu.edu.tr/

Keywords: Natural forest harvesting; Productivity; Work loads

The objective of this research is to collect data on the productivity and work loads of natural forest harvesting in order to establish productive and environmentally sound forest operations with low work loads. Tower yarders of Urus MIII or Koller K300 have recently been introduced to forestry in Turkey. The clarification of the productivity and work loads is important because they are significant factors in mechanized forestry operations. Such data is also necessary to improve forestry operations so that they can be environmentally sound with high productivity and low work loads. This research was conducted in the northeast of Turkey in late June 1998. In this study, newly-introduced harvesting systems using tower yarders were compared to conventional systems using a stationary yarder of Gantner USW 60D or a skidder of MB trac Turbo 900 in terms of productivity and work loads. The productivity of each system was calculated based on the data of time study. The work loads of forestry workers were also measured using watch-type devices measuring heart rates. Furthermore, WBGT, an index of thermal conditions of work environment, was measured to clarify work conditions in natural forest harvesting.

The results showed that the productivity of the tower yarder system was a little less than the one of the others. However, tower yarder is easy to be set up and to be removed and therefore the productivity of this system is higher than the one of the other systems when setup and removal time are incorporated into productivity calculation. The productivity of the stationary yarder system was very high, however it must harvest trees from wider areas in terms of cost and benefit because it takes a lot of time, usually nearly one month, to set up or remove it. As a result, soil erosion, less forest cover and damages to the forest ecosystem are serious problems in Turkish forestry when using stationary yarders. We know that skidding system also often damages the forest ecosystem although this system is easy and productive on relatively flat terrain. Tower yarders are expected to improve such a situation in Turkish forestry by enabling us to thin trees from natural forests at an adequate level with lower impacts on the forest ecosystem. To introduce tower yarders, however, more forest roads are necessary and the construction of them may have negative impacts on the ecosystem. Therefore, it is necessary to construct forest roads minimizing environmental impacts on the ecosystem in order to introduce more tower yarders. The work loads of various kinds of work at various sites are classified based on the scale of Christensen. As a result, the work load of a chainsaw operator was found to be classified into heavy while the one of a yarder or skidder operator was lower than the work loads of the other workers and it was classified into light. The WBGT was high on the forest road while it was moderate in the forest. Thermal conditions were not critical because it was not in midsummer but in late June.

In this study, we clarified the productivity and work loads of natural forest harvesting in Turkey. We suggest that we should introduce more tower yarders to Turkish forestry and they should replace stationary yarders, which have been widely used in Turkey. More forest roads are necessary to use more tower yarders, but it is known that forest roads often damage the ecosystem. It is necessary that excavators should be used for road construction in order to avoid using bulldozers or dynamite and to make as narrow forest roads as possible or to make forest roads with as low impacts on the forest ecosystem as possible.

Harvesting System Optimiser: An Integrated Window-based System for Selection of Timber Harvesting System

Lan Zhangren
University of Helsinki, Department of Forest Resource Management,
Post Box # 24 (Unioninkatu 40 B), 00014 Helsinki, Finland
FAX: +358 9 1917755, Email: zhangren.lan@helsinki.fi

An integrated optimisation system with characteristics of the graphic user interface consultation has been built to select timber harvesting system in wood procurement chain. The system centres on the structure and function of building knowledge base system, and module-based architecture of system is a basis of problem-solving procedure under the control of friendly graphic user interface development environment. This integrated system is currently comprised of several modules built in a visual development environment: 1) A harvesting machine data-base system describes the harvesting machines' attributes and functionality. It can be retrieved in terms of specific description or users requirements; 2) Consultation module of harvesting system's operability under given conditions is based upon the topographic conditions, statistic data and information of forest stand, forest soil types and environmental requirement as well. It identifies a harvesting system adapted to a set of conditions in a given logging area; 3) Costs calculation model for individual machine or machine chain is built to generate the actual data which could be stored in data base for purposes of harvesting system simulation and optimisation; 4) Environmental evaluation module of timber harvesting operations gives an emphasis on minimising the effects of harvesting operations on forest area based on the environmental-oriented selection of harvesting system; and 5) Harvesting system simulation and optimisation module is based on the harvesting system behaviours and functionality on wood procurement chain, in which optimal harvesting system could be identified for the final decision making. The goal of integrated system is to select a sound harvesting system under which conditions users are specifying a set of real circumstances concerning timber harvesting operation mode, for instance, either ground-based system or cable logging system. An integrated optimisation system gives a user more flexible choice of decision making procedure, which is satisfied with the different situation from place to place or from country to country. This window-based program built on PC environment for general purpose harvesting system optimisation is suitable for users at different level.

3.05.00 Forest operations in the tropics

Ensuring Sustainable Supply of Wood: Impact of Some Harvesting Options on the Nutrient Stores in a *Nauclea diderrichii* Stand in the Ghanaian Rain Forest

Charles Adu-Anning, Dominic Blay Jr.
Forestry Research Institute of Ghana (FORIG),
University Post Office Box 63, Kumasi, Ghana
FAX: 233-51-60121, Email: forig@africaonline.com.gh

To counter the anticipated wood shortage in Ghana, extensive plantations of both exotic and indigenous tree species have been established in most parts of Ghana. One of the indigenous species, which has been found to be fast growing and therefore recommended to be grown in plantations, is *Nauclea diderrichii* (Opepe). This species has been found to be ideal for most of the domestic and industrial uses *Milicia exclesa* is noted for. The proposed, rotation is between 15-20 years and mainly by clear felling and removal of as much utilizeable materials age for harvesting is possible. However, such harvesting intensities in recent years, have been of concern to many researchers. That such harvesting intensities involve the removal of substantial quantities of available nutrients form sites and therefore lead to nutrient deficiencies within relatively short periods. Thus to determine the potential impacts of harvesting and utilization options on sustained productivity of *Nauclea*, the nitrogen, phosphorus, potassium, calcium and magnesium (N, P, K, Ca and Mg) stores in a *Nauclea diderrichii* (Opepe) plantation stand were estimated. These were used to determine the impacts of three harvesting methods (i.e. thinning, coppice with-standard, and clear-felling) combined with three levels of utilisation (i.e. stemwood only, bole only and bole together with branches). These were viewed against sustained site productivity of the *Nauclea diderrichii* stand.

To achieve the above objective, field studies were conducted in *Nauclea diderrichii* stand using modified Ovington et al unit area ratio method. The assessment was done in three temporary plots as fully stocked as possible. Dry matter production was determined as well as nutrient concentrations of the various tree parts. Litter and undergrowth quantities in the stand were determined, nutrients in the soil reserves, litter and undergrowth were analysed for N, P, K, Ca and Mg concentrations. All these were used to assess the quantities of these nutrients in the *Nauclea* stand.

Clear felling combined with any level of utilisation exerted the greatest impact on the nutrient stores. On the other hand, thinning below half of the stand density coupled with even complete utilisation of the above-ground biomass impacted a minimal stress on the nutrient reserves.

Rates of depletion were not specific but differed for individual nutrients, phosphorus drain from the stand was the most rapid followed by K, N, Mg and calcium being the slowest. Thus P and K are likely to severely limit the site productivity of *Nauclea diderrichii* stand if harvesting options like clear felling or coppice with-standard are adopted. There is no adequate data on these in Ghana. In order to adopt an efficient and sustainable management system that could delay the application of soil ameliorants, there is the need to forecast the order in which nutrients in the stand would drain and therefore become limiting.

The combination of harvesting and utilisation options as well as limiting nutrients to forecast the potential productivity of *Nauclea diderrichii* forest stand are discussed.

Keywords: Impact, harvesting, utilisation, limiting nutrients, *Nauclea diderrichii*, sustained Productivity.

The Human Aspect of Reduced Impact Logging under the Ground Skidding Logging System in Peninsular Malaysia

Bin Mohamad Borhan
Forest Research Institute Malaysia (FRIM), Regional Center for Forest Management,
Kepong, 52109 Kuala Lumpur, Malaysia

Manpower constitutes one of the major inputs in a production process along with other factor inputs such as machines, raw material and the man-machine interaction. Manpower's ability to work and produce efficiently at all stages of the operation is of paramount importance for the economy of the forest enterprise as a whole. Unfortunately few studies have been conducted in the tropical rain forest environment in the past on the manpower element as a factor in a timber enterprise production system; both as an individual as well as a social group. This glaring lack of knowledge and appreciation of the human element has been deemed the "missing link" in the attempt to successfully realize the Sustainable Forest Management (SFM) principle especially in those areas concerning (1) re-designing of work structure and procedures; (2) re-tooling of machines for better work performance (including reduced impact logging); (3) Prevention of hazardous work practices; and (4) identification of individual worker's well-being and training needs. The poster discusses findings from a study on the development of a reduced impact logging system in a timber enterprise in Peninsular Malaysia vis-à-vis the problems and roles of the forest workers with regards to reduced impact logging objectives and the challenges faced by the management and the forestry sector in general.

Reduced Impact Timber Harvesting in the Indonesian Selective Cutting and Planting System

Ir Elias
Bogor Agricultural University, Faculty of Forestry,
Kampus IPB Darmaga,
P.O. Box. 168, 16001 Bogor, Indonesia
FAX: +62-251-622202, 621256, Email: el-ros@bogor.wasantara.net.id

Timber harvesting being one form of utilization of the tropical natural forests in Indonesia is carried out by practicing a silvicultural system known as the Indonesian Selective Cutting and Planting System ("Tebang Pilih Tanam Indonesia/TPTI").

Conventional Timber Harvesting (CTH) being practiced until now is often considered to be the culprit of forest degradation. Concession holders usually carry out their timber harvesting operations in the simple way, mostly without sufficient detailed timber harvesting plans and proper work instructions for the timber harvesting operations, using improper technique and lacking control. Reduced Impact Timber Harvesting (RITH) on the other hand is based on: (1) Forest surveys prior to harvesting, for data required to design layout of felling compartments and inventory units and to plan the timber harvesting operations; (2) A tree location and topographic map as a basis for designing timber harvesting plan which serves as a guide for felling and skidding in timber harvesting operations; (3) Cutting of lianas before timber harvesting; (4) Regular training of workers, monitoring, supervision and block inspection; (5) Routine briefing on procedures and techniques (6) Adopt a base-pay and incentive-pay system based on quantity of production, quality of work and level of terrain difficulty.

The implementation of RITH in the TPTI system consists of some aspects as follows:

1. RITH Planning

RITH planning is a part of the overall forest management planning. It should be completed long before the loggers enter the site and must be developed comprehensively both strategicly and operationally to ensure that planning mechanisms protect all forest values at all times during timber harvesting.

2. RITH Technique Guidelines

RITH technique guidelines is one of the important factors to help guarantee successful implementation of RITH. RITH technique guidelines for the TPTI system should consist of: (1) RITH planning technique; (2) Controlled felling; (3) Felling technique of normal tree, leaning tree and tree with buttress; (4) Controlled skidding; (5) Skidtrail construction technique; (6) Winching technique;

(7) Skidding technique and (8) Prevention technique of post harvest environmental damage.

3. RITH Training

One of the best strategies for improving and socializing skills and work motivation of timber harvesting crews is through training in technical matters and environmental understanding and awareness.

4. RITH Payment System

To maintain high work motivation and discipline among timber harvesting crews, one useful strategy is to apply a payment system based on productivity and work quality influenced by physical field condition. This based-pay and premium-pay should be determined transparantly.

5. Organizational Structure and Job Description

Smooth implementation of RITH depends also on clear, detailed and tested job description and organizational structure provided to timber harvesting crews.

The implementation guidelines of RITH in the TPTI system are as follows:

1. Development of a tree location and contour map (scale 1:2,000 carried out two years before timber harvesting)

2. Cutting of liana (carried out during the forest inventory and topographical survey, two years before timber harvesting)

3. Development of a timber harvesting plan (to be done one year before timber harvesting operations)

4. Haul road construction and marking of skidtrail network, landings and tree felling direction in the field (to be done one year before timber harvesting)

5. Skidtrail construction, felling, winching and skidding (carried out during the timber harvesting year)

6. Prevention of further environmental damage after timber harvesting (carried out after timber harvesting).

Impact of Different Intensities of Logging on the Recovery Capacity of the Residual Stand

José Rafael Lozada Davila, Ernesto Arends
Universidad de Los Andes, Facultad de Ciencias Forestales y Ambientales, Da Chorros de Milla, 5101, Venezuela
Tel: 58-74-401581, FAX: 58-74-401580, Email: jolozada@forest.ula.ve

Keywords: logging, forest management, environmental impact, vegetable succession, Caparo.

This work is part of an investigation begun in 1987, at the Caparo Experimental Station, in order to evaluate the damages to and recovery of the residual stands generated from different intensities of logging. To achieve this objective three treatments were applied, according to the minimum diameter of cutting (mdc). It was applied an mdc of 20, 40 and 60 cm. In each treatment 3 replications were surveyed as well as two controls.

Mensurations were carried out before the intervention and in the later years, up to 1997. One result is that it is better to evaluate the impact of logging after about 5 years because some trees thought to be dead actually survived. Another result was that 22 to 48 % of the residual trees, about 6 to 23 % of the basal area, died from logging damage. Obviously the biggest damages happen in the treatments with more intensity of tree harvest.

In the parcels with low harvest levels, there were not significant changes in the Shannon Index (H'), the wealth of diversity increased and the floristic similarity (Index of Ellenberg) was lowered up to 80 percent. However, some species show important changes of IVI (Important Value Index) as they are reduced in presence. In the parcels with high harvest levels, there were significant losses of diversity (H'), although the wealth recovers to the ten years.

All trees species were assembled according to their ecological class and commercial value. In the most intense harvest levels, the pioneers dominated the recovery of the forest with a growth of 1.1 m^2/ha/year, while, in the low harvest levels, residual species proportions were similar to the pre-harvest conditions. It was also evidenced that the species with some commercial value are very scarce in the primary forest and their growth post-exploitation was very slow (0.1 m^2/ha/year).

Soil Compaction Effects of Timber Harvesting in the Amazon Basin

Ken McNabb, Robin Clawson, Graeme Lockaby, Bryce Stokes
Auburn University, School of Forestry, AL 36849-5418 Auburn, USA
Tel: 334-844-1044, FAX: 334-844-1084, Email: mcnabb@forestry.aubum.edu

One of the key elements of sustainable tropical forest management is the development of economically viable harvesting techniques that minimize environmental damage. Harvesting should be done so the immediate impacts do not damage the long-term ecosystem integrity. The objective of this study was to assess, using field plot techniques, some of the more relevant environmental impacts associated with conventional harvesting operations in the "terra firme" forests of the Brazilian Amazon. The location of the study was the Curua-Una Forest Reserve, a 72,000 ha tract in the east-central region of the Amazon Basin. A randomized complete block design was used to compare four harvesting intensities in three blocks. Each treatment plot was 80 m wide by 500 m long. Treatments were 0, 25, 50 and 75% removal of merchantable trees with diameters between 45 and 90 cm. Harvesting was done using chainsaw felling, and a rubber tired (50 cm width) Caterpillar cable skidder ("conventional methods") during the rainy season. Impact measurements were made in June, 3 months after harvest. Data were taken on tire rut width and depth as well as soil bulk densities in three disturbance classes: inside tire ruts, between the ruts, and 10 meters to the side of ruts ("minimally disturbed").

Harvesting removed an average of 184, 117, and 47 mü, from each of the 75, 50, and 25% commercial volume removal treatment plots, respectively. The volume of wood removed significantly impacted the amount of rutting with average rut crossectional areas of 1,357, 1160, and 531 cm^3 for the 75, 50, and 25% removal treatments, respectively. Soil bulk densities increased significantly on the harvested plots when compared to the control plots although bulk densities did not vary among harvesting intensities regardless of disturbance class. In the rut, between the rut, minimally disturbed, and check plot soil bulk densities averaged 1.25, 1.09, 0.99, and 1.02 mg/m^3 respectively.

These results are similar to those found in other regions of the world, where soil compaction occurs during the first 2-3 equipment passes and is insensitive to the number of passes thereafter.

Management and Decision Support System for Smallhold Tree Plantation Developers

Teodoro R. Villanueva, Loretto U. della Cruz, Renato A. Folledo
University of the Philippines, Institute of Renewable Natural Resources, College of Forestry and Natural Resources, Los Banos, Philippines
Email: Lucrecio L. Rebugio [llreb@laguna.net]

A decision support system in a form of a computer software was developed to assist smallhold *Gmelina* plantation developers in preparing a plan for their projects. The system analyzes site factors inputted by the user. It helps the developer prepare a plan which can be modified iteratively by the system. This allows the user to perform "what if" analyses and undertake simulation of plantation development under various conditions that may be specified by the farmer. These situations are dictated by the availability of labor and capital for fertilization and other cultural treatments.

Developed in dBase for Windows, the systems has two components: the database and the routines. The database contains knowledge about *Gmelina* plantations and technologies in their development. The routines include data entry, management plan preparation and inquiry and a cost tracking system which are driven mainly by process based growth and yield simulator.

Applications of the system showed it consistency in estimating plantation development scenarios. Results of different simulation of yields in various combinations of age, edaphic factors and treatments were not different from the observed actual yields in the different plantations.

The system is pilot tested in Bukidnon and installed in a government office there. It is operated by a systems administrator who shall assist farmers in using it and help the project in further refining it.

3.06.00 Forest operations under mountainous conditions

Comparison of Forest Skyline Systems for Harvesting in Turkey

Halis Hulusi Acar, Özgür Topalak
Blacksea Technical University, Faculty of Forestry, Department of Forest Engineering, 61080 Trabzon, Turkey
Tel: +90-462-325-3223, FAX: 00 90 462 3257499, Email: hlsacar@risc01.ktu.edu.tr

Turkey's forests cover 20.2 million ha, but only about 8.5 million ha of this area is productive. Unfortunately, these productive areas have been relegated to steep terrain, thereby creating forest management problems and more difficult logging operations. The construction of forest roads is more complicated and more expensive on these mountainous lands. Therefore, forest skylines are being used to help solve these technical and economic problems.

In Turkey, forest skylines are of three lengths: short, to 300 m; medium, 300m-600 m; or long, up to 1500-2000 m. The forest road density is approximately 8-10 m/ha. Because of this density, skylines are a very important factor in forest transportation, especially in the mountainous region of Artvin. Operational efficiency is achieved when skylines are strong, of reasonable distance, and quick and easy to set. Well-placed skylines will cause minimum harm to forest soil and the transported material. These mobile or yarder machines can transport forest products in two directions, and may be set up in different configurations at the harvest site.

The goal of our study was to review the use of these skylines over the past 10 years. Investigations were conducted at different test sites in the mountainous eastern Black Sea region in Turkey. The three systems - Koller K 300, URUS M III, and Gantner forest skylines - were examined for their technical and economical advantages during logging. We used the continuous-time measuring technique. The calculated values of operational costs were evaluated statistically according to a standard base distance. These methods have been approved by FAO.

Our results showed that hourly production was highest with the URUS M III system. In addition, this particular system of mobile skylines could be set up over longer distances, compared with the Koller K 300 system. However, the URUS M III skylines were more expensive to operate. In contrast, the Gantner forest skyline was more productive for distances over 600 m, although this system required more time for setting lines. Differences in productivity and cost among the tested systems depended on the production type of forest yield derived from the harvest compartment, the number of workers required, and the direction, distance, and slope of transport. From this study, we could also conclude that it is very important to first have a well-organized production environment in order to work more eight-hour days in a year with an insured and fully staffed team of equipment operators.

Testing an Experimental Rail-Type Machine (Tramcar II) for Operations on Steep Forested Slopes

Masaki Jinkawa
Forestry and Forest Products Research Institute, 1 Matsunosato, Kukisaki-machi, 305-8687 Ibaraki, Japan
Tel: +81-298-73-3211 (Ext504), FAX: +81-298-73-3796, Email: jin@ffpri.affrc.go.jp

In Japan, artificial forests, or plantations, account for 40% (107 ha) of all the forested area. Because such sites comprise many young trees, they must be properly tended and thinned to provide a steady supply of wood, while also maintaining adequate levels of soil and water conservation, and disaster prevention. Many of these forests are located on steep mountains. Therefore, forest operations usually are done manually, which can be unsafe and inefficient. The expansion of the forest-road network is a pressing need because it is indispensable for mechanization. However, road development is at only 40% of the target value, because the costs of construction and maintenance are very high.

Accordingly, we have developed the Tramcar II for operating on forest slopes. Using a rack-and-pinion driving mechanism that runs on a rail, the new machine can move up and down 45-degree inclines. The power truck utilizes a rail-support system to transport workers, forest machines, and equipment in the forest. Mounted with a grapple crane, the work truck can load wood for transport on the rail network. Results of a two-year, on-going field test show that worker efficiency can be improved by 25%, while maintenance and management costs are decreased by 1/3. Moreover, the load on the rail has been measured and proven safe.

The mechanical outline and specifications for this Tramcar II include:

1) Power truck:

Water-cooled, 3-cylinder diesel engine with a modified deep oil pan; Engine displacement: 1642 cc; Horsepower: 36.8ps/3000rpm; Hydraulic driving-gear system; Hydraulic, multi-bored disk brakes; Fail-safe system.

2) Work truck:

Grapple crane (4.56 ton-m); Outrigger; Tilting angle of base: 30 degrees; Winch.

3) Other features:

Four hydraulic driving wheels (2WD+2WD); Universal-coupling connecting rod; Two rails (main and sub); Rack-and-pinion drive.

On our test course, we examined the power truck for running performance, operation performance, stress to the rail and vehicle, etc. Running speed was 0 to 50m/min, the safety rating was a '3', and operating performance was excellent. The work truck was equipped with a grapple crane, leg-type outriggers, and a winch. Stress on the boom, arm, outrigger, work truck, and rail was measured by applying a load to the crane. Loading capacity was 300kg at a position of 7m. Moreover, we confirmed the scope of operations of the machine. Finally, we developed an automatic divergence device powered by a solar battery. This has made dispersed forest stands more easily accessible, thus greatly expanding the system's utility.

Keywords: forest operations system; rail-type machine; steep mountains; Tramcar II.

Re-engineering of Existing Road Networks - A Case Study from Southern Germany

Georg Sonntag
Forsthaus Stetten, Neuhewenstrasse 45, D-78234 Engen (Hegau), Germany
Tel: +49 7733 6337, FAX: +49 7733 1077

Throughout the world, the main task when opening a forest for harvesting is the conception and construction of, or the extension of, a road network into areas where it has not yet been completed. Because of intensive cultivation by forest enterprises in central Europe, road systems have become denser in recent decades.

The costs for constructing and maintaining forest roads represent a substantial part of the total budget for a typical forest enterprise in Germany. Because of scarce financial resources and insufficient income, it is important that existing road networks be examined for their technical and economic value, while considering the changes in future goals and demands. The increasing need for maintenance and construction puts a heavy cost-pressure on the forest industry.

The German forestry road network is relatively dense (sometimes too dense), according to international standards. Because of new harvesting methods (e.g., harvester-forwarder systems), the road distances could become even greater. Consequently, maintenance and costs might be reduced by decreasing the density of the road system. A case study was based on the activities of a large, privately owned forest enterprise in Germany. Here, the existing road network and future needs were analyzed to determine the possibilities for reducing road density, while accommodating their highly mechanized harvesting system. Data from a geographical information system (GIS) were used in proposing alternatives that would reduce density without limiting the enterprise's access to all portions of the forest. The goal was to create a databank of corresponding spatial positions, which could be used in problem-solving. A special method was developed to complete and check this data. The (relatively) best solution was defined as one that would minimize future road maintenance costs as well as those incurred during harvesting and transport.

Using this method, road density was reduced by 30%, without any loss in site access. Consequently, a new plan for executing this concept incorporates greater time-independent flexibility as well as calculations for the relative investments that are required. The result of this study provides a practical means for decreasing the high cost of a too-dense road network by eliminating excess roads. Doing so would also enhance the sustainability of natural-resource management and benefit the needs of society.

Numerical Iterative Method for Optimizing the Disposition of Soil Masses during Forest-road Construction

Milorad Zlatanovic, Bogdan Stefanovic
University of Nis, Faculty of Civil & Architecture Engineering, 14 Beogradska st., 18000 Nis, Yugoslavia
Tel: ++381 18 42 066, FAX: ++381 18 45 343, Email: Bogdan Stefanovic [lav@verat.net]

The job of transporting soil is inevitable during forest-road construction. How these soil masses are to be re-distributed at the site will affect mean transport distance, the number of machines engaged in the transport system, the period of transport, and total soil-transport costs. Among the methods for determining the best means for soil distribution, the optimal solution is obtained by a linear programming approach. This method provides several alternative optimal plans for moving masses of soil, depending on the objective function (minimizations of cost, mass movement, etc.). We used the Ford-Fulkerson algorithm, which is implemented with the Trans99 software package. An initial solution is generated by tabular calculations that are then iteratively improved until an optimum is reached. A case study was conducted at the construction site for the road Kamenica-Brezna, which is on the hillside of the mountain Goc in Central Serbia. The objective was to determine the optimum re-distribution of soil between seven cuts and five fills, at minimum cost for transport. The requirements for higher quality, and more economical and faster forest-road construction are key components when formulating a model that optimizes soil transport. We have demonstrated that this problem can now be solved efficiently by applying a linear programming approach. Because the cost of soil transport is such a large proportion of the total cost for construction, this analytical method is essential when trying to economically solve the problem of soil disposition.

3.07.00 Ergonomics 1+2

Forest workmanship in Turkey

Halis Hulusi Acar, Habip Erogul
Blacksea Technical University, Faculty of Forestry, Department of Forest Engineering, 61080 Trabzon, Turkey
Tel: +90-462-325-3223, FAX: 00 90 462 3257499, Email: hlsacar@risc01.ktu.edu.tr

Forest areas in Turkey are generally located on the mountainous region. Therefore, forest labour is affected by the shape and conditions of the field. In forestry, regeneration, reforestation, maintenance, production (cutting, skidding, transport), forest road constructions, their repair and maintenance, forest conservation and land sliding protection are required substantial labour.

These works are mostly done by local people living in near forest villages or forest village corporations. General characteristics of forest workmanship can be outlined as below; working in heavy conditions, work in high elevation, rough and vast areas, the necessity of accommodation in forest, because of that working place is far from the social environment, the obligation of working generally in day-time hours, taking care of the silvicultural treatments, the situation of being tentative workers in general, having high accident risk resulting from working in open air conditions, having lower labour pays than the other labour branches.

The forest employees according to their annual working periods can be categorised into three different groups as follows; permanent workers, seasonal workers and tentative workers. Forest workers in Turkey generally work during the spring, summer and autumn. Most of the forest workers are tentative and seasonal forest workers and the rest are permanent workers. Because of the workers' feeding, education, housing and walking problems, forest labour is not very attractive job for the people. Approximately, there are 40 thousand forest workers in Turkey. These workers have the tasks of logging, cutting, skidding and transporting the logs. The demand to the forest labour has been getting decrease because of forest workers' health problems, unsatisfied payment, high risks of getting injured and their hard working conditions. These unwanted conditions negatively affected forest workers’ productivity. The forest workers health should be checked-up periodically, mobile bureau should be ready in case of emergency where needed, first aid materials should be kept ready to use in order to increase forest workers' productivity. In our country, rheumatism, back, shoulder, arm and leg injuries, liver, lung and heart problems have been detected in many forest workers. The forest workers should be get paid more and social security should be provided to them in order to motivate and increase their productivity.

Keywords: Turkey, Eastern Black Sea Region, Steep Terrain, Forest Labour, Worker Health

Analysing the Postures and Efforst Expended in Timber Harvesting Operations on the Northern Coastland of Bahia State

Amaury Paulo de Souza, Nilton Cesar Fiedler, Luciano José Minetti
Universidade Federal de Vicosa, Departamento de Engenharia Florestal, 36571-000 Vicosa-MG., Brazil
Tel: +055 31 899 2478, Email: apsouza@mail.ufv.br

This study aimed to analyze the timber harvesting activities, which require inadequate efforts and postures for improvement of the worker's health, well-being, safety and comfort. The specific objectives were: a) to characterize the worker during timber harvest; b) to characterize ergonomically the work environment; c) to analyze the harvesting operations which require abnormal postures, load manual lifting, strength application and high physical work load; d) to propose some recommendations for the improvement of postures, the reduction of the efforts and the optimization of the physical work. The research was developed with forest workers in *Eucalyptus grandis* yield areas on the northern coastland of Bahia State. Data were collected by individual interviews, measurements and tests applied to the workers and loads as well as to the machines, tools and equipment used during work. The results indicated a high percentage of poorly trained and analphabetic workers performing heavy activities and presenting health problems. The individual protection equipments were not used by everyone and the accident index was high. The work environment showed thermal overload and high noise levels in all activities except the lumbering one. The machines presented ergonomical deficiencies. The posture analysis showed a need for intervention in all operations, which was urgent in delimbing, lumber arrangement, log hauling and pushing for arrangement in the truck during loading. Only the delimbing and branch disposition registered a weight handing below the pattern limits. The log bucking and positioning on waist during lumbering presented an inferior compressive load in the spine disc relatively to the limit compression load. All activities exhibited some articulation with the percent capable assistants inferior to 99% and the worse situations being during the assistance in felling and log throwing on the lumber rick which presented a percent inferior to 25% in all articulations. The physical work load was classified as: moderately heavy for chainsaw operators; light for chainsaw assistants; moderately weighty for the debarking assistants which supplied the receptor table; light for the assistant supplying the debarker and for that receiving the debarked log; and moderately weighty for the lumbering assistants.

Keywords: Timber harvesting, posture and physical work.

Increasing Productivity and Controlling of the Work Fatigue in Mechanized Forest Operations by Using Prescribed Active Pauses

Christos Th. Gallis
Perivlepto, 37 500, Velestino, Volos, Greece
Email: risto490@hotmail.com

Forest machine operators work very intensively during a work day, with a limited number of pauses, exposed to a variety of working conditions which affect their working capabilities and may cause work fatigue, health problems, and accidents. Fatigue causes decline in work performance, lower productivity, myoskeletal disorders, working errors, and accidents. The factors which affect work fatigue and deteriorate work performance may be grouped into three interactive categories: environmental factors (noise, vibration, temperature, humidity), human factors (age, sex, health, motivation, fitness,capabilities, trainings, emotional stability), and task factors (complexity, duration, skill, physical, mental or sencimotor tasks).

Work pauses are needed in maintaining working performance and efficiency required by work and in avoiding or decreasing fatigue effects. The effect of pauses on work performance is favorable more for shorter, about ten minutes, than for longer pauses.

A work/rest schedule for forest machine operators is proposed by providing prescribed active work pauses of ten (10) minutes duration after every fifty minutes of work. The ten minutes pauses will help the operators to recover from fatigue effects, to maintain work capacity and efficiency, to maintain

their adaptation to work task, and decrease exposure time to environmental factors. Active pauses (i.e.pauses with some gymnastics), on the other hand, will improve the restoration of overall work capacity and may have favorable effects on localized muscular fatigue. Also, ten minutes pauses may increase the net working time because operators may avoid taking spontaneous and disguised pauses.

Keywords: work fatigue, productivity, work pauses, forest operators, work/rest schedules

Questionnaires on Occupational Safety and Health of the Operators of Forestry Machines such as Processors, Harvesters, Tower Yarders, and so on

Yuki Imatomi
Forestry and Forest Products Research Institute, Shikoku Research Center, Asakura Nishi-machi 2-915, Kochi, Japan
FAX: +81-888-44-1130, Email: tomy@ffpri-skk.affrc.go.jp

The new forestry machines such as processors, harvesters, and tower yarders have been used in logging operations with the old model logging machines such as yarders and tractors in Japan. The new logging operations with these new forestry machines are contributing to not only logging efficiency improvement but also safe work and reduction of physical workload. But mental workload caused by intensive machine operations and static muscle tension caused by a fixed body posture are working environment problems in the operations of the new machines. In Nordic countries where highly developed mechanization work is executed, the new working systems such as shift systems or job rotation systems are used in order to reduce these problems. The aims of this study are to investigate the current status of logging operations with the new forestry machines and to obtain basic material to secure occupational safety and health of the operators. The author executed questionnaire survey about the work feeling (tension and monotonous feeling, etc.) and the consciousness symptom for the machine operators in the whole country.

The results of the investigation were as follows: The majority of operators were feeling the tiredness and the tension. About two-thirds of he operators were feeling the stress. The operators were complaining about the sense of incompatibility such as pains and stiffness by all the body parts except the elbow. The body part with a lot of the sense of incompatibility complaints was the lower side of the back, the neck, the shoulder, the wrist, and the upper part of the back. There were a lot of complaints such as tiredness of the eyes, anxiety, stiffness of the shoulders, and pain of waist. The factors that related to operators' consciousness symptom appeal were the rest time of a day, continuous working hours, and the operation days of a year.

How to develop forest machine enterprises - a holistic approach

Kaija Kanninen
The Finnish Forest Research Institute, Vantaa Research Centre, P.O. Box 18, FIN-01301 Vantaa, Finland
FAX: +358 9 8570 5361, Email: Kaija.Kanninen@metla.fi

For sustainable development of the global forest economy, not only economic and ecological views are needed, but social considerations also have to be taken into account. The assessment of sustainable development should encompass the quality of the products, the biological diversity after treatment, and also the health and psychological wellbeing of the workers. This is where the life force of a person comes out, and this is a pillar of social sustainability.

In sustainable forest economy, the main challenge during the next few years will be to preserve the vitality of the entrepreneurs. Today, forest machine entrepreneurs are among the biggest employers in the forest economy and are quite important for employment in the regions where settlement is dispersed. The functioning of the forest industry, based on modern computer technology, is also largely dependent on the vitality of the forest machine enterprises.

In the 1990s there have been numerous changes in the Finnish forest industry, deeply affecting forest machine enterprises and entrepreneurs. Research on the consequences of these changes and information on them have not solved the problems. The situation is the same in other fields. In order to find a solution, the Finnish Ministry of Labour initiated, in 1997, a National Workplace Development Programme. This is based on practical implementation of multidisciplinary research results. The aim is to improve productivity in small and medium-sized enterprises, and the quality of working life.

The Ministry of Labour Development Programme, headed by the Finnish Forest Research Institute, the Work Research Centre of the University of Tampere, and experts representing the Association of Machine Entrepreneurs, engaged 12 forest machine enterprises. These companies had a total turnover of almost FIM 30 million. They possessed 45 forest machines and employed about a hundred persons on a permanent basis. Development was focussed on the following themes:

* Improved relations between client and enterprise;
* Increased cooperation and networking between companies;
* Improved profitability of enterprises; and
* Promotion of the psychological wellbeing of the entrepreneurs.

The results, so far, are promising, and they will be used to extend activities within the research-based development to a larger group of entrepreneurs in the forest industry.

Problems of Forest Use in Conditions of Radioactive Contamination of Ukrainian Forests

V. P. Krasnov
Ukrainian Research Institute of Forestry & Melioration, Pushkinskaya str. 86, 310024 Kharkiv, Ukraine
FAX: (+ 0 380572) 43-25-20, Email: zahist@u-fri. kharkov.com

After the Chernobil accident, a considerable part of stands with intensive forest management appeared in the zone of radioactive contamination, which was irregular by intensity, by radionuclide composition and by forms of deposits. Diversity of soils and species composition of plants and animals involved into forest management was the source of a large number of radioecological problems. Many purposes forest use became impossible because of considerable contamination of certain raw materials and/or impossibility of safety conditions for forestry workers.

Up today radionuclides accumulation in tree species continues. If in 1991 the transition coefficient for 137Cs from soil to wood was equal to 1.0-4.3 in different forest sites, then in 1996 it was equal to 2.6-13.0. In consequence of it in the poor and relatively poor sites 6-30% of the total radionuclides contents in the biogeocenosis were accumulated in the tree species. It undoubtedly told on the possibility of tree species exploitation. Like this, in the moist subor the timber of *Pinus silvestris* L. was used for the sawed planks production in 1991 on the area with radioactive contamination density of 1110 kBc/m^2, and in 1995-884 kBc/m^2. As the part of fuel and thin logs is rather high, especially after thinning cutting, the problem of its utilization even at rather a low level of radionuclides contents in the soil (over 125 kBc/m^2) appeared. The transition coefficient from soil to needles and shoots is ten times more than from soil to timber. Therefore the storage of these parts of tree for conifer&vitamin meal production became impossible in most parts of Polessje forests. It causes the problem of these materials' utilization after main and intermediate felling. After traditional burning down of felling residuals, radionuclides concentrate considerably in the burning sites, where the special activity of 137Cs in soil increases more than 30 times. It leads to an increase of mosaic distribution of radioactive contamination and of possibility of further radionuclide transition into non-woody production - mushrooms, berries and herbs. It is necessary to take into account forest site and tree species composition in forest use planning, because of differences in radionuclide accumulation. In the optimal growth conditions in 1995 the index of 137Cs accumulation in timber was equal to 0.23 in *Pinus silvestris*; 0.19 in *Betula pendula*; 0.09 in *Populus tremula*; 0.09 in *Quercus robur*; 0.04 - in *Alnus glutinosa*. The most intensive radionuclides migration to tree species was observed in the most poor and moist sites. So, in 1996 the coefficient of 137Cs transmission to *Pinus silvestris* timber in the moist bor was equal to 13.0, in the moist subor - 5.5, in the moist sugruds - 0.8, in the fresh - 8.8, in the moist - 16.6, in the wet - 24.3. Most problematic is the use of wild berries, herbs and mushrooms. The maximal 137Cs transition coefficients in the moist subors are found for *Vaccinium myrtillus* (10.6), *V. uliginosum* (9.4), *V.vitis-ideae* (8.3). These indices vary for the same species in different forest sites. Like this, transition coefficient for *V. myrtillus* berries is 9.1 in the moist sugruds, 68.3 in the moist subors, 100.1 in the damp subors. It is calculated that one can store *V. myrtillus* on the poor and relatively poor soils when density of radioactive contamination is less than 74.0 kBc/m^2, on the relatively rich soils - at 555 kBc/m^2; berries of *V. uliginosum* in the moist subor - 74.0 kBc/m^2, in the moist bors and damp subors - 37.0 kBc/m^2. Raspberry, snowball and ashberry accumulate radionuclides less intensively. Special peculiarities of 137Cs accumulation are most visible in herbs which can be divided into 5 groups by transition coefficient: in very strong accumulators it exceeds 100 (fruit bodies of *Inonotus obliguus*, berries of *V. myrtilis*, spores of *Lycopodium clavatum*), in strong ones it is 50.1-100.0 (leaves of *V.vitisioleae*, springs of *Ledum palustre*, herb of *Chelidonium majus*, *Centaurium erythraea*, leaves of *V.myrtillus*, buds of *Pinus silvestris*.); in moderate it is 10.1-50.0 (herb of *Viola tricolor* and *Tancetum vulgare*, bark of *Frangula alnus*, leaves of *Arctostaphylos uva-ursi*), in slight it is 1.1-10.0 (herbs of *Convallaria majalis, Urtica dioica, Origanum vulgare, Thymus serpyllum, Digitalis grandiflora, Polygonum aviculare*, bark of *Q.robur*, racemes of *Helichrysum arenarium*) and in very slight ones it is less then 1.0

(berries of *Juniperus communis*, rhizomes of *Valeriana officinalis* and *Acorus calamus*).

137Cs accumulates rather intensive in the fruit bodies of edible mushrooms. Therefore in the area with soil radioactive contamination more than 37 kBc/m^2 storage of only slight accumulators is possible (*Armillariella mellea*). *Suillus luteus, S.variegatus, Leccinum scabrum* are strong accumulators even at low level of soil contamination. Analysis of radioactive contamination of forest resources allowed to recommend to forbid the forest management on the 40.8 thous. of ha out of 30-km zone of Chernobil power station, use of wood production is limited on the 101.5 thous. ha, use of non- wood production - on the 1190.5 thous. ha.

An Analysis of the Operator-Chain Saw System in Cutting Activites at a Brazilian Forest Company

Luciano José Minetti, Amaury Paulo Souza, Nilton Cesar Fiedler
Universidade Federal de Vicosa, Departamento de Engenharia Florestal, 36571-000 Vicosa-MG, Brazil
Tel: +055 31 899 2478, Email: lminetti@mail.ufv.br

This study was based on data from a paper and cellulose company in the State of Sao Paulo, Brazil. Its main objective was to analyze the operator - chain saw system in forest cutting activities. According to the obtained results, the following conclusions were drawn: The chain saw analyzed from the researcher's viewpoint on the one hand and the operators' on the other showed several ergonomic problems, so indicating the need for intervention into machine in order to improve the relation between the operator and his machine. From the operator's viewpoint, the ergonomic problems presented by chain saw were: all operators agreed in affirming that the used mensuration pole is prejudicial to operator, his performance and health. Relative to the variable exhaustion gases, 50% of the operators considered it as more aggressive to workers. A 21% percent of the operators considered the noise as the most harmful, whereas 12% claimed the vibration is troublesome to their work, and yet 10% considered the chain saw weight as excessive. The chain saw operators are subjected to tendon inflammation, lumbago, hearing loss and sight loss, which lead to suffering and to a lower working capacity in operators.

Heat stress research in forestry

Dianne Staal Wästerlund
Swedish University of Agricultural Sciences, Division of Forest Technology, Dept. of Silviculture, S-901 83 Umea, Sweden
Tel: +46-90 786 58 00, FAX: +46-90 786 62 78, Email: Dianne.Wasterlund@ssko.slu.se

Heat stress can be defined as the situation where the body experiences problems to dissipate its excess heat to the environment. Due to the heaviness of many activities in forestry, it is obvious that forest workers experience heat stress during warm periods of the year or in regions with warm climates. Yet heat stress has been largely neglected in ergonomic research in forestry so far. A literature review was done to determine what heat stress research has been done so far, what forestry can learn from this research and what directions in heat stress research would be most desirable for forestry.

Methods for determining heat stress are found in abundance. Yet according to evaluation studies, none of them is very reliable due to the complex and individual different reactions of the body exposed to heat stress. ISO has adopted two methods as standard methods for measuring and determining heat stress. A concealed conception of most measuring methods, including the ISO standards, is that the prime solution to limit heat stress risk is to adapt the environmental conditions. High accuracy on measurements of the environmental conditions are therefore required by heat stress methods while the physical work load needs only to be estimated. Estimations of the physical work load may however according to some researchers deviate 50% from the real work load. In forestry, possibilities to limit environmental heat are small. Heat stress risk in forestry can mainly be controlled by limiting the physical work load. It seems therefore obvious to demand high accuracy in physical work load measurements as well. Direct measurement of the oxygen in the field is however seldomly feasible while the most common field method for determination of the work load, measurement of the heart rate, is influenced by the environmental conditions. It is therefore highly desirable that studies are conducted on work load determination in hot conditions.

In sport activities, there is a high level of awareness on the effects of dehydration on performance. In forestry work, where physical demands have similar proportions as in sports, this level of awareness is much lower. Research has shown that a reduction of 2% of body weight or 1.5l of sweat for a person weighing 75 kg, implies a performance decrement of approximately 20%. During forest work in Vietnam where workers neither ate nor drank at the work place, workers had lost 3.2% of their body weight. Besides supply of water it is also necessary to raise awareness among workers to drink sufficiently. A study in Polish steel plant showed that 25-40% of the sweat loss was not replaced by the workers although water was freely available. How much water a forest worker needs to consume should be determined in relation to activity and environmental conditions.

Improving Transport Schedules: A Forest Research Contribution

Julio Eduardo Arce, Celso Carnieri, Vitor Afonso Hoeflich
Universidade Federal do Parana, Manejo Forestal del Curso de Ingenieria Forestal, R. Bom Jesus, 650, 80.035-010 Curitiba, Brazil
Tel: +55-41-232-9084, FAX: +55-41-253-2332, Email: jarce@floresta.ufpr.br

Keywords: dynamic programming; optimization; scheduling; transportation model.

A problematic aspect for forest production managers is to plan a forest company's resource use in a way that fulfills the manager's objectives and, simultaneously, satisfies legal, social, ethical, and market restrictions. In other words, forest managers are faced with trying to efficiently combine all the production factors.

Here, we have analyzed the schedules generated by a Transportation Scheduling System (TSS), and have focused on the rationalization of resources through reduced transportation costs. These schedules contains detailed information about departures and arrivals for each truck from the fleet at the garages, their production points and clients, and the eventual queuing times that depend on previous assignments.

The TSS system is composed of two modules (Fig. 1- not shown). The first module uses the Transportation Method Algorithm (TMA) for global minimization of transportation costs that correspond to the loaded trips. The purpose of the second module is to schedule activities for each truck in the fleet, via a Dynamic Programming-based algorithm, the Truck Scheduling Algorithm (TSA).

For trip assignments, we considered a continuous vector of hours so that the transportation schedules could allow the trucks to carry out partial trips, e.g., traveling to the loading point on one day, and traveling to the client on the next day. This was feasible because most of the fleet trucks worked continuously, alternating drivers from 0600 Monday to 1800 Saturday. Trucks that were not worked 24 hours per day were equally programmed. However, optimizing the transport schedules was limited because having to return to the garage made partial trips impossible.

Some pertinent aspects also are discussed with regard to implementation of the TSS. This heterogeneous situation originally was evidenced by the diverse financial, technical, and social conditions by which they characterized the truck owners, who, currently, are completely subcontracted. Initially, the direct beneficiaries were the truck owners, whose incomes were increased once the TSS reduced the day-to-day idleness of the trucks. When the increase in income for truck owners was forecast, however, the forest companies hiring the trucks viewed the TSS as an important tool for the freights-values negotiation, which oscillates between 3 and 9 R$/ton (US$ 1.00 = R$ 1.26, on January 1st, 1999).

Once completely established, the major benefit of the TSS will be its ability to minimize total transportation costs, reduce the idleness of some trucks, offer an important tool of negotiation aimed at reducing freight values, and, finally, contribute to a rational use of the resources that are annually spent on forest activities.

Extraction and Textile Application of Crude Dyes From Barks of *Dysoxylum altissimum* and *Pterospermum indicum*

Elvira C. Cabauatan-Fernandez
University of the Philippines Los Banos, Department of Forest Products and Paper Science, 4031 Laguna, Philippines
FAX: (63)-049-536-3206, Email: elcf@mudspring.uplb.edu.ph

Crude dyes were obtained from the barks of *Dysoxylum altissimum* and *Pterospermum indicum* by hot water extraction and freeze drying. The yields of extract from the above-mentioned species were 6.7% and 19.62%, respectively. These extracts still contain sugar compounds and tannins particularly *Pterospermum indicum*.

Different mordants such as ferrous sulfate, copper sulfate, oxalic acid and potasssium dichromate were used on silk and cotton yarns. Colorfastness to washing was assessed separately on the dyed silk and cotton with respect to change in color and staining on dyed materials. Likewise colorfastness to light was done to assess the resistance of the color of dyed yarns to the action of light.

Results showed that the crude dyes had various effects on the fibers in terms of color, shade and brightness using different mordants. *Dysoxylum* sp. and *Pterospermum* sp. dyes had stronger affinity to silk than to cotton. Dyeing experiments for both extracts showed good to excellent ratings in terms of washfastness and light fastness on dyed silk and cotton yarns. The physical appearance of the dyed sample also exhibited fair ratings in terms of its color, shade and brightness.

This study suggests that natural dyes are promising in view of their dyeing applicability to textile and a follow-up study should be conducted on dyes from the bark of those belonging to the lesser known tree species (LKTS) or if possible, those from fast growing tree species.

FAO's Non-Wood Forest Products Program (NWFP)

Wulf Killmann, Walter, Sven
FAO, Forestry Department, Wood and Non-Wood Products Utilization Branch, Viale delle Terme di Caracalla, 00100 Rome, Italy
FAX: +39-06-570-55618, Email: Wulf.Killmann@fao.org

Rural and urban people in Africa are heavily dependent on non-wood forest products (NWFP) for a wide range of needs including food, medicines, construction and shelter materials, fibres, dyes, resins, oils, aromatics and a variety of animal products like honey, beeswax and bushmeat. Many of these NWFP are important sources of income and employment at the local level, with some being traded at the international level.

It is often assumed that harvests of NWFP have less impact on forests than logging. However, sometimes this assumption is unfounded as harvesting of non-wood forest resources can affect wild plant and animal populations negatively. In order to ensure the sustainable exploitation and utilization of NWFP, more information is needed on harvesting and inventory methods as well as about forest dynamics (e.g. regeneration). In addition, socio-economic aspects affecting NWFP have to be taken into consideration.

In the framework of an EU-FAO Partnership Programme on "Data collection and analysis for sustainable forest management in ACP countries: linking national and international efforts" quantitative and qualitative information was gathered on the exploitation practices and production levels of major NWFP in (collaboration with) 52 African and Caribbean countries. The preliminary findings of this programme were discussed in five regional workshops held in East Africa (Kenya), Southern Africa (Zimbabwe), Central Africa (Gabon), West Africa (Côte d'Ivoire) and the Caribbean (Barbados).

These workshops revealed that practical methodologies for assessing socio-economic and biological factors affecting NWFP are not available and that an appropriate classification system for NWFP is much needed. In addition, a practical and widely applicable classification system of non-wood forest products (and of the forest resources, which may provide NWFP) is a basis for the assessment of the (biological) potential of NWFP exploitation.

The regional workshops also indicated the multitude of socio-economic and biological factors influencing the exploitation of NWFP. In order to gain a better understanding of these factors, pilot studies were realized in representative African and Caribbean countries (e.g. Uganda, Zimbabwe). In these countries, an assessment of the potential exploitation of selected (important) NWFP was carried out; important socio-economic and biological factors influencing the exploitation of NWFP were identified and analysed, and a proposal for sustainable management was elaborated.

Theory of the Timber Harvesting Based on Forest Function

Pjotr Paschalis
Faculty of Forestry Warsaw University, Dept. Forest Utilization and Engineering, Rakowiecka 26/30, 02- 528 Warsaw, Poland
Tel: +48 2849 7074, FAX: +48 2849 7074, Email: Paschalis@delta.sggw.waw.pl

The paper deals with problems concerning the timber harvesting based on identification of different forest functions. Firstly- The forest harvesting must be carried on , both as a direct utilization of timber and in the forms which are playing important values - the spiritual and esthetic and several other values. It means that all the benefits from the forests are irreplaceable for man together with material and other (spiritual) values. Secondly - Destruction caused by felling single trees, many trees,many ha of the forest etc. Which causes of definite forest ecosystem destruction could be minimized, and have all accessible methods really been used? Thirdly - To ensure the sustainable and multifunctional forest harvesting, proper methods of forest regulations must be used. The possibilities of solving all these problems could be seen only through properly applying a synthesis of theoretical and practical knowledge in compliance with several scientific disciplines, often far away from forestry sciences.

Restorative Planting of Degraded Sites In a Logged Hill Dipterocarp Forest Using New Approach And New Method

Raja R.S. Barizan, Shamsudin Ibrahim, S. Appanah , Chong Phang Fee, Othman Jusoh Wan Mohd Shukri Wan Ahmad & Samsudin Musa
Natural Forest Division, Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6302322, FAX: 603-6302321/6367753, Email: barizan@frim.gov.my

Keywords: logged hill forest, silviculture treatments, rehabilitation, enrichment planting, degraded sites, wild-boar attack

Currently, the harvesting technique used in the hill dipterocarp forests in Peninsular Malaysia is the crawler-tractor. This technique results in excessive opening of the forest canopy and causes much of soil disturbance due to construction of logging roads, landing sites, a maze of skid trails and tree fall gaps. Normally these degraded areas are highly to moderately compacted and have poor regeneration. To increase the productivity of logged-over dipterocarp forests and to ensure enough resource for the future crops, therefore, restorative of the degraded and poorly stocked areas using dipterocarp and other commercially indigenous species through enrichment planting is required. Current enrichment planting practice was associated with low survival, high maintenance cost, and poor performance of planted plant. Subsequent treatments were impeded by difficulty in accessibility to the site. Thus, a new semi-mechanized planting method is introduced and examined. A conducive planting condition for the early establishment is provided. The method emphasizes on using big healthy planting material, big planting holes, suitable species, and adequate light. The soil physical properties and soil fertility of the planting point were improved at the time of planting. Performance of the planted plants will be discussed. Preliminary results showed high survival. The new technique is expected to produce better growth and minima tending after planting as the planted plants can be left to establish on their own. A feasibility study on the time taken, manpower involved and type of machine used in the planting operation will be discussed. The initial problem due to wild-boar attacks was successfully overcome by introducing a deterrent guard.

Effects of Superposition of the Tractor Tire Tracks on the Level of Forest Soil Compaction

Amaury Paulo de Souza, Juliao Soares de Souza Lima, Carlos Cardoso Machado, Luciano Baiao Vieira, Luciano José Minetti
Universidade Federal de Vicosa, Departamento de Engenharia Florestal, 36571-000 Vicosa-MG., Brazil
Tel: +055 31 899 2478, Email: apsouza@mail.ufv.br

This work was carried out using forest tractors Feller-Buncher (411EX HIDRO-AX) and Skidder (CAT 525) in a *Eucalyptus* timber harvesting operation of charcoal producing company, located in Itamarandiba, State of Minas Gerais, Brazil. Its objective was to evaluate the level of soil compaction as a result of tractor tire tracks superposition in stands of *Eucalyptus*, according to the cutting module adopted by the company. The following physical properties of the soil were considered: bulk density; particle density; total porosity; water content; saturated hydraulic conductivity and soil resistance to penetration. The following conclusions were made: The average pressures applied to wheel surface were 90.6 and 73.9 KPa for Feller-Buncher and Skidder, respectively; saturated hydraulic conductivity had a greater change at 0-10 cm depth, among the soil's physical parameters; the cone index curves at the four depth levels showed an increasing change in soil resistance to penetration, due to traffic on the tracks. The effects of the superposition of tire tracks on the crop area became more evident at the depth of 0-10 cm, for all the physical parameters used; the total increment in bulkdensity of the soil before traffic and after log skidding was of 19.56%, at a level of 0-10 cm of depth; the effect of the traffic of the tractors on the soil was greater in the first travel and it was related to the Feller-Buncher operation. Its movement several times in the same place with the head loaded contributed to a greater mechanical compaction of the soil.

Effect of Forest Harvesting on Soil Physical Properties and Productivity: A Global Perspective

Ivor K. Edwards
Canada Department of Natural Resources, Canadian Forest Service, Northern Forestry Centre, 5320-122nd Street, T6H 3S5 Edmonton, Canada
Tel: (780) 435-7235, FAX: (780) 435-7359, Email: iedwards@nrcan.gc.ca

Keywords: soil disturbance, soil structure, bulk density, porosity, tree growth

The deleterious effect of forest harvesting on long term site productivity has been documented in several countries. Decreased productivity has been

attributed to lowered soil fertility caused by removal of harvested biomass components, leaching, erosion, and chemical and biological transformation phenomena. Site productivity decline also results from soil structural degradation that occurs when harvesting takes place under unsuitable conditions. Repeated traffic by forestry equipment during logging, causes soil disturbance and, depending on texture, wetness, type of equipment, and traffic intensity, may result in displacement, compaction, rutting, and puddling. Under partially saturated conditions, soil strength decreases as soil water potential decreases (soil becomes wetter) and fine textured soils are more susceptible to compaction because they dry more slowly. Compaction results in increased bulk density, and capillary pore space (micropores) but there is a decrease in non-capillary pore space (macropores), infiltration rate, and permeability as soil particles are forced closer to each other. The resulting impairment in soil-air-water balance and the physical impedance presented to roots reduce their elongation and hence plant growth, and inhibit production of suckers in aspen (*Populus tremuloides* Michx.). Tree species differ in their tolerance of changes in bulk density and macroporosity, and management in each jurisdiction should define the level of soil wetness that is commensurate with significant compaction, given the logging equipment that is being used. Critical soil water potential in the range of field capacity can be measured with instrumentation, or can be estimated by observing the ease of breakage of a molded clod that is squeezed between the fingers.

Deterioration in soil structure may last a few months or several decades, depending on soil texture and the severity of disturbance and it is incumbent on forest managers in all climatic regimes to be proactive in developing a rating of compaction risk for their soils. Cyclical phenomena such as wetting and drying, and freezing and thawing (in north temperate and boreal climatic regimes), act as ameliorative processes on compacted soils, but their effectiveness depends on the presence of expandable-type clay minerals, and the soil moisture content when freezing occurs. Amelioration through plowing, disking, and bedding have been used successfully but subsoil tillage operations have not always been effective, despite the high cost of specialized equipment that is necessary.

Strategies to minimize soil disturbance during harvesting and restrict disturbance to acceptable levels include a) developing a rating of disturbance risk for managed areas and mapping the soils accordingly, b) traffic avoidance until soil water potential is above the critical point for significant compaction, c) use of larger and wider rubber tires at reduced inflation pressures, d) use of rubber-tired or tracked equipment capable of articulation and extension, e) use of a traffic mat comprising tree branches, foliage, and harvest residues, f) use of designated skidtrails (machine corridors) commensurate with an acceptable level of disturbance, and g) in boreal climates, harvesting aspen and other poplar species in winter only, to take advantage of greater soil strength offered by frozen soil.

Research of Forwarder Performances on Hard and Soft Soil

Dubravko Horvat, Tomislav Porsinsky
University of Zagreb, Faculty of Forestry,
Svetosimunska 25, HR 10 000 Zagreb, Croatia
Tel: +385 1 230 22 88, FAX: +385 1 218 616, Email: dubravko.horvat@hrast.sumfak.hr

Keywords: wood extraction, forwarder, soft soil, hard soil, penetration characteristic, rut formation, wheel slip, productivity

This paper deals with the investigation of the impact of forwarders on soil, their tractive performance and productivity on hard and soft soil. Heavy, six-wheel forwarders with a capacity of 14 tons are the most frequently used vehicles for wood extracting after reproductive and final cutting in low-land oak forests in Croatia. Since this transportation is mostly carried out during winter with unfavorable soil conditions, the impact of the forwarder on the soil and its productivity represents an essential technological parameter.

The measurements were carried out in two ways:

1) The investigation of the impact of forwarders on soil was performed under controlled conditions on 2 testing skid trails: soft and hard. At the same time granulometric composition and soil moisture were determined and the measuring equipment in the laboratory vehicle was used to measure:
- soil penetration resistance before and after the pass of the vehicle with cone penetrometer
- rut formation
- wheel slip curve (gross tractive coefficient vs. slip)

2) Productivity investigation was carried out by work study methods during the transportation of wood from an oak stand without influencing the forwarder driver. The soil was divided in two categories: hard and soft. 207 transportation samples were recorded on hard soil and 163 on soft

soil. The differences of mean load volume, traveling time and productivity depending on soil conditions were defined.

Sediment Yield of Hill Forest Watersheds in Peninsular Malaysia

F. S. Lai
University Putra Malaysia, Department of Forest Management, 43400 UPM, Serdang Selangor, Malaysia
Email: lfsee@forr.upm.edu.my

This paper reports on sediment yield of several hill forest watersheds assessed for logging impact. The discussion includes suspended and bedload transported from four steep gradient streams draining the headwaters of the Main Range in Selangor. Although the Batangsi, Chongkak, Lawing and Pangsun watersheds were monitored at different times, interesting characteristics in sediment yield were detected. Sg. Batangsi was monitored between 1987 to 1989 when logging was on-going, while in Sg. Chongkak, logging ceased. Suspended loads from Batangsi were then about fifty times higher than natural watersheds. The Sg. Lawing, where about 40% of the lower basin was logged in 1993, produced loads about twenty times higher prior to timber harvest. While exposed areas are primarily responsible for much of the sediment transported, hydrometeorological events also determine, to a large extent, the sediment loads evacuated. The undisturbed Sg. Pangsun, intensively gauged in 1997 through 1998, for example produced rathed low suspended load because of a period of severe dry spell.

Soil Compaction by a Small Sized Processor, Forwarder, and Skidder inTimber Harvesting

Juang R. Matangaran, Masahiro Iwaoka, Hideo Sakai, Hiroshi Kobayashi
University of Tokyo, Graduate School of Agricultural and Life Sciences, 1-1-1 Yayoi Bunkyo-ku, 113-8657 Tokyo, Japan
FAX: +81-3-5800-6994, Email: juang@fr.a.u-tokyo.ac.jp

Keywords: Soil compaction; Bulk density; Processor; Forwarder; Skidder

Various kinds of forestry vehicles are used for logging operations in forests. Soil compaction is a concern because of the increased use of heavy equipment. Soil compaction reduces macroscopic pore space in soil, aeration, water movement, water holding capacity, and it prevents root penetration. We investigated the soil compaction of skid roads by a small sized processor and a forwarder which were developed especially for thinning operation, and also the recovery of bulk density and organic matter in an area where logging operation had ceased several years earlier.

Investigation areas were at a forest in Matsuida, Gunma Prefecture, and Tokyo University Forest in Hokkaido, Japan. Cone penetrometer was used to measure the soil hardness. In Matsuida, soil hardness was measured from the surface until 50 cm depth of the soil at the skidding trail and center of the skidding road, and undisturbed area. The forest consisted of artificial forest of Japanese Cedar and thinning was operated in 1996 by a processor and a forwarder. At the Tokyo University Forest in Hokkaido, soil samples were taken from sites where logging operations had terminated 1, 5, 8, and 12 years prior to sampling. Bulk density and organic matter were analyzed for soil at the surface and at 20cm depth in each main and branch skidding road, landing area, and undisturbed area. The forest was covered with natural forest and selective cutting was performed with a crawler type tractor.

In the Matsuida forested area, hardness of soil at skid trail and center caused by only a processor was not different from the undisturbed area. The soil became more compacted at the skidding trail of entrance section by the traffic of forwarder, especially at the surface of skidding trail. The existing condition of soil hardness in the investigated area was originally hard. The skidding distance was kept shorter by the density of the forest road. The percentage of opening up forested area was only about 3.25%. Even though soil hardness at the permanent skidding road was higher than that of the undisturbed area, damage did not increase seriously at the processor site. The small percentage of the disturbed area in thinning operation will not cause serious problems of soil compaction in an area such as Matsuida forest.

The organic matter at the surface down to 5 cm tended to increase in several years after logging operations. The surface of the soil at the branch skidding roads which were not intensively disturbed had apparently recovered to the original conditions of such as in the undisturbed area. Several years after logging operations, bulk density showed some recovery as indicated by a decrease in bulk density. The bulk density of the surface of the branch road showed some recovery 5 years after logging, though to the original condition represented by the bulk density of the undisturbed area. At the main skidding road, the bulk density did not recover during 8 years after termination of logging but the density decreased 12 years after logging operations ended. At the landing area, the bulk density did not

recover to the same conditions of the undisturbed area even 12 years after logging.

EXPLORE: Expert Systems for Predicting the Effect of Logging Roads on Environment

Ahmad Che Abdul Salam, Baharuddin Haji Kasran
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Email: iraforce@tm.net.my

Logging roads are crucial for transportation and forest management and a major cause of negative impact toward sustainable forest management. This paper presents an expert systems for predict effect of logging roads on environment based on knowledge acquired from the experience expert. The rule-bases of the system is developed using wxCLIPS 1.64, an Expert System Shell which is designed by Artificial Intelligence Application Institute, University of Edinburgh, The prototype of EXPLORE is to provide users with as much related information as possible to provides an understanding of effect of logging roads on environment.

Keywords: Expert System, Prediction, Logging roads, Impact.

Roots Under the Impact of Logging and Hauling Machinery. Application of New Field Techniques.

Radomír Ulrich, Nadezhdina,N., Cermak, J., Neruda,J.

Keywords: Heavy machinery, Soil compaction, Tree roots, Mechanical damage, Spruce

Aim of the research is to estimate objectively the impact of mechanical perturbations of soils and changes in water capacity along skidding trails and roads in forest stands caused by movement of heavy logging and hauling machinery on tree roots, especially their health as reflected by water absorbing functions. Present measuring electronic techniques available on the field of tree eco-physiology and structure allow to detect the impact immediately, to quantify its harmful effects on the individual root and the whole tree level and to specify, which are the most important features of the injury. Heavy forest machinery with defined tires and specific load moves along skidding trails during experimental load. Pressure caused by the machinery in different soil depths is measured by flat plastic sensors connected by flexible tubes to tensiometric devices, which are connected to dataloggers. The important changes in the soil water capacity are measured in addition. Studies include the most widespread coniferous species, particularly Norway spruce (*Picea abies* (L.) Karst.) and forest stands growing on different soils. Sap flow is measured in different depths along radii of selected coarse roots and stem basis by the heat field deformation method before, during and after the experimental load (just after the load and repeatedly after longer periods of time to check for eventual root regeneration). By comparing response of sap flows of experimental and control trees we can specify the extent of functional damage. Repeated measurements show how long time the effect of root perturbation persists. Root systems of trees are finally excavated by the harmless air-spade (ultrasonic air stream) technique and photographed in details to check for a structural extent of eventual damage. Ground penetrating radar technology can be optionally applied for this purpose. On the basis of such studies we can recommend the maximum load along a skidding trail in a particular soil and environmental conditions (number of movement of heavy machinery under a specific load), still not causing erosion and damage to tree root systems.

Logistics of Ash Recycling in Boreal Conditions

Kari Väätäinen, Lauri Sikanen & Antti Asikainen
University of Joensuu, Faculty of Forestry, P.O.Box 111, FIN-80101 Joensuu, Finland
Tel: +358 13 251 2717, FAX: +358 13 251 3590, Email: lauri.sikanen@forest.joensuu.fi

Wood processing in pulp mills cause large amounts of wood wastes, which can be combusted in energy plants. This combusting causes considerable amounts of ash, which contains nutrients useful for trees. Instead of dumping the ash it can be used as a long term fertiliser to forests. Spreading of normal ash to forests has drawbacks such as loose structure, which means ineffective logistics and dust problem. Normal ash is also easily washed away by spring floods and rains. In order to solve aforementioned problems, the granulating system has been developed. This study concentrates on logistic systems from millyard to forest. Granulated ash is spread either by a helicopter or by a forwarder-mounted centrifugal spreader. Preliminary tests of forest spreading of granulated ash have been started in Eastern Finland. Problems faced so far are i) helicopter spreading is remarkably more expensive than forwarder spreading, ii) helicopter spreading is very much weather dependent whereas forwarder spreading requires thinning cutting made

beforehand, iii) moist soils can not carry forwarder except when frozen.

System design includes organising of millyard-forest transportation and the spreading of ash in forest as well as identifying of potential spreading areas as a part of the normal timber procurement process. Time studies were done for forwarder and helicopter and other collaborative apparatus like trucks and loaders. Logistic systems will be evaluated with discrete event simulation technique.

The most competitive and cost effective logistic system with annual production of 6 000 tonnes of ash included 1) Large ash storage on the millyard far enough from the pulp mill in order to avoid the harm caused by ash in the pulping process. 2) Transportation from the mill to forest by trucks made for sand transporting. 3) Small operative ash buffer in the forest. 4) Spreading by forwarder mounted centrifugal spreader. Especially in winter ash cannot be stored in open air in the forest more than a couple of weeks without quality problems.

Unit costs of transportation and spreading with the most competitive millyard logistics and transportation alternative were USD 14.8/t with forwarder spreading (average spreading distance, ASD 0.5 km, distance from the forest storage to the spreading area) and USD 55.4/t with helicopter spreading (ASD 0.8 km). When the unit costs of oneha of spreading (transportation excluded) is considered with the recommended spreading amount of 3000 kg/ha, unit costs with forwarder were USD 26/ha and with helicopter USD 128/ha. (ASD 0.5 km). Because of the considerably lower unit costs, the forwarder mounted centrifugal spreader has to be considered as a primary spreading method. In boreal conditions storages in the logistic chain have to be placed at the beginning of the chain and transportation and spreading should be organised as a "hot chain".

Effects of Slash Disposal Methods on the Physical and Chemical Properties of Soil on Harvested Sites

Lihai Wang, Sun Molong
Northeast Forestry University, Centre for Forest Operations & Environment, Post Box # 245, 150040 Harbin, China
Email: wanglihai@ihw.com.cn

According to the Stipulations of Forest Harvesting and Regeneration issued by the Forestry Ministry of China in 1987, there are three methods of harvesting slash disposal, piling, burning and spreading. The burning method was restricted in the dry season in recent years due to forest fire. Field survey for effects of slash disposal methods on soil properties was carried out in Dailing Forest Experiment Bureau, Heilongjiang Province, China. The test sites are located in Dongfanghong Forestry Farm, 128°47'32" E and 47°13'10" N. Forest stands before harvesting are mixed stands of conifer and broadleaf trees, 70% to 30% in proportion. Average slope on test sites is 16-22°. Forest soil is dark brown soil. Clear cutting and selective cutting systems with ground crawler skidding were employed in the harvesting. For each small block of test site, there is another small block with the mostly same conditions (time, space, and operation) taken as the reference block. The small test block for burning and spreading methods was 100 (100m^2 which contents 9 small sample squares evenly distributed. And for piling method, the small test block was 300 (300m^2 which contents 25 small sample squares unevenly distributed. The soil samples taken for piling and spreading method are from the year of 5, 10, 15 and 20 after harvesting and slash disposal operations. And those for burning method are only from the year of 1986, 1990 and 1996 due to the slash on a few of operation sites disposed by burning.

In order to evaluate the soil physical property changes, bulk density, saturated water retention capacity and total porosity of soil were measured. The results of laboratory analysis showed that, compared with its own reference site, (1) the bulk density on spreading, piling and burning site is changed with a rate of 1.3% of decreasing, 3.2% of decreasing and 5.2% of increasing respectively; (2) the saturated water retention capacity and the total porosity of soil on these three test sites were also changed with changing rates mostly below 10%, and changing trend just opposite to bulk density.

The parameters of soil chemical properties, pH, organic matter, total N, total P, total K, hydrolytic N, available P and available K, were taken as the evaluation criteria and they were measured. The chemical criteria above on spreading site were changed within 7%, compared with those on reference site There is no significant difference between pH values of soil on piling site, but not the burning site (increasing 9%), and on reference site. The organic matter content of soil on piling and burning site is significantly higher, 24.6% and 13.2% respectively, than that on reference site. The contents of nutrient elements of soil on piling site are also higher than those on reference site with the increasing rate mostly over 10%. But these on burning site are significantly lower than those on its reference site, mostly changed up to 30% or even lower.

Conclusions of this study were derived from the results above. (1) Both piling and burning methods do not affect the soil physical properties significantly. (2) Piling method is quite helpful for the site to maintain the productive soil. (3) Burning method is useful for soil acidification improvement, but it is easy to lose nutrient elements. (4) Spreading method does not change much the soil properties, but high cost for planting after harvesting.

Environmental Impact Caused by Forest Operations

Takeshi Yamada, Sasaki S, Umeda S, Sasaki, T, Endo,T
Forestry and Forest Products Research Institute, Forestry Technology Division, Silvicultural Technology Laboratory, P.O. Box 16, 305-8687 Tsukuba Norin Kenkyu Danchi-nai, Ibaraki, Japan
Tel: +81 298 73 3211, FAX: +81-298-73-3796, Email: kenchan@ffpri.affrc.go.jp

Keywords: environmental impact, soil disturbance, compaction, root damage, ground pressure

Environmental impact caused by forest operation makes land productivity less. Especially forest vehicles cause forest floor disturbance including soil degradation and root damage on residual trees. It must be reduced for sustainable forest management. It is necessary to obtain knowledge of environmental impact to reduce it.

Two studies on environmental impact had been done. The first is an investigation of soil properties on a harvested site in tropical rain forest in Malaysia.

In Malaysia, ordinary logs are primarily collected by bulldozers and are secondarily transported by large sized forwarders. Bulldozers enter into forests over long distances; therefore much forest floor was occupied with bulldozer trails. Bulldozers repair the surface of logging trails so many times that surface soil is hardly removed. The logging trails were classified in 2 categories: main logging trail and sub logging trail by travel times of bulldozers and whether surface soil had been scraped or not.

Soil properties on main logging trails, sub logging trails and the natural forest floor as control were investigated. The result shows that soil on main logging trail is very dense because of many travels and surface soil scraping. Soil on sub logging trail has medium density between main logging trail and natural forest floor. It is decided that surface soil on main logging trails had been lost, and that surface soil on sub-logging trails remains, through the measurement of organic mater contents of surface soil comparing with natural forest floor.

The second study is the trial to measure the tension on root caused by the ground pressure of forest vehicles. It is difficult to observe the process of root damage directly because root system exists underground. And it is difficult to do reproducible experiment because roots are fragile and of varying shape. Therefore dummy roots made from wire rope were used in experiment of root damage by ground pressure of the forest vehicles.

Before the experiment, the diameter of the real cypress root equivalent to dummy root was guessed through the measurement of pulling resistance of cypress root and dummy root. A regression equation between diameter and pulling breakage strength was obtained by measuring pulling breakage strength of various diameters of real cypress root. Ground pressure and tension on dummy roots were measured while a vehicle travels on buried dummy roots 50 times. Though the ground pressure decreases after the vehicle passes, tension force on dummy roots decreases slowly after the vehicle passes. Therefore tension force on the dummy roots was integrated. The result shows that maximum value of integrated tension force was superior to the breakage strength of real cypress root equivalent to the choking point of the dummy root. It is guessed that real cypress root would be broken by short interval travels of forest vehicles.

Observation of Soil Erosion in a Logged-over Tropical Forest in Pasoh Forest Reserve, Negeri Sembilan, Malaysia

Email: mkamil@fsas.upm.edu.my

The study was conducted in the area of a logged-over tropical forest in Pasoh Forest Reserve, Kuala Pilah, Negeri Sembilan, Malaysia. The attempt of this study was to investigate and observe soil erosional characteristics of a logged-over tropical forest. Soil erosion was monitored by using erosion pins at five unbounded 10m x 10m research grids in a 100m x 100m research plot. The occurrence of soil erosion and soil deposition were observed. Among the research grids, the maximum soil erosion was 14.6mm and the maximum soil deposition was 7.2mm. The form of soil erosion that occurred consisted of sheet erosion and splash erosion. Generally, the pattern of soil erosion varied significantly between locations within the plot.

However, the pattern of erosion did not show any significant difference with time of sampling.

An Information System for the Soil Protecting Use of Forestry Machinery

Martin Ziesak
Lehrstuhl für Forstliche Arbeitswissenschaft und Angewandte Informatik, Am Hochanger 13
Tel: +49-(0) 161-71 4659, FAX: +49-(0)8161-71 4658,
Email: ziesak@forst.uni-muenchen.de

To avoid damage of the forest soil caused by forest machinery when driving on the forest ground, an information system is introduced to enable soil protecting machine operations. The key for this tool is the knowlege, that there is for every siteclass and for every soil water content a limiting maximum soil pressure, which must not be exceeded to avoid damage. The specific soil pressure depends on machinery parameters of the equipment used and it's type of tyres.

The siteclass, and geology where applicable, are widely available through site classification maps

The information system uses a database, which is filled with information concerning these stratums: data on (forestry) machines, tyres and site information.

Thus for a given site class and the equipment to be used at that site the infomation system is able to calculate the soil water content, which must not be exceeded when a soil protecting operation takes place.

With this prediction-which is specific for a forest stand, the planned operation and the equipment configuration to be used - for the first time a precise instrument exists, which makes a truely soil protecting machine operation possible.

Structural analysis and crown modeling of tree population relics in coastal lomas (Mejia, South Peru)

G. Calamini, Salbitano F.
Institute of Silviculture, Via S. Bonaventura, 13, I-50145 Firenze, Italy
Tel: +39.055.30231246, FAX: +39.055.307263, Email: salbitano@cesit1.unifi.it

In central and southern Peru the coastal vegetation is semi-arid, or steppe like, with the presence of scattered trees. This so-called lomas (hills) vegetation can be divided into several physiognomic types on the basis of the dominant species, i.e. from herbaceous to shrubby and tree lomas. The area has a very low annual average rainfall of 20mm. The vegetation depends on fog and mist interception for its water supply, and moisture intercepted by leaves and branches can contribute up to the 80% of tree transpiration. The region is also strongly affected by man's historical activities. In the Department of Arequipa, a few of the endangered ecosystem relics include tree lomas. Up to present, grazing is rather intense in the region.

The specific objectives of the research are to (1) study the magnitude and dynamics of site degradation factors, (2) describe the spatial structure of tree populations, and (3) characterize the morphological features of relic trees for crown parameters related to fog interception and throughfall. The study was carried out in the Lomas of Mejia, Valdividida district (La Curva). The lower limit of the fog is between 200-300 m a.s.l., while the upper limit coincides with the base of the thermal inversion between 700 and 1000 m. Eight plots in a transect were selected in two distinct valleys with differing grazing pressure, average elevation, and slope exposure. In each plot the presence/abundance of shrubs and herbaceous species, structure of trees, DBH, height, crown intersection and projected areas, number of cut shoots, number of clustered buds and sprouts, and the type and positioning of tree damage were recorded. Fifteen trees where sampled at altitudes ranging from 450 to 750 m a.s.l to characterize morphological parameters, including crown shape and size, and branch volume and pattern. Throughfall distribution was investigated by placing rain gauges under the crown projection of trees. The spatial distribution of throughfall was analyzed by means of the Blackman's Dispersion Index. Evaluation of tree damage was carried out by counting cut scars, fire signs, and bud/shoot proliferation nuclei. The polycormic structure of trees was noted as well as reaction to past logging. Crown shape and volume, branching pattern and density were processed with Autocad software. Discriminant and multiple regression analyses highlighted relationships within state factors, morphological parameters and throughfall.

Caesalpinea spinosa trees form single-layered and even-aged stands. The crown cover index of these trees was 10.4%, and the average basal area was 1.3 m^2/ha. Signs of utilization were seen on 56% of trees. Regeneration of trees is absent. Tree density is higher on slopes facing the main fog stream. Leaves and seeds are mostly located in the leeward part of the crowns, very likely in relation to the sulphuric acid pollution produced by a copper refinery 50 km south of Mehia. Crowns project toward the prevailing wind direction and have high efficiency for moisture capture. Rather high total and daily throughfall amounts were measured in relation to the crown volumes and tree branching patterns. Tree diameter and crown volume appear to correlate well with water capturing ability. Despite the low total leaf area and leaf location opposite to the prevailing wind direction, high capturing efficiency of the branching patterns was verified. Nevertheless, the estimation of the water available for trees from these results is difficult due to the need to account for infiltration and runoff associated with hillslopes and physical modification of soils.

Economic and ecological sustainability of neotropical rain forest management: results from one decade in Central America

José J. Campos Arce, Marlen Camacho, Bryan Finegan and Rosalba Ortiz
Tropical Agricultural Research and Higher Education Centre (CATIE), 7170 Turrialba, Costa Rica
Tel: (506) 5560401,Email: jcampos@catie.ac.cr

The new paradigms governing sustainable forest management in the neotropics are examined, particularly those related to keeping an appropriate balance between the continuous flow of economic benefits derived from forest management and the maintenance of the ecosystem integrity. The paper specifically assesses the sustainability of managing natural rain forests in Central America, based on one decade of research results regarding the effect of forest harvesting operations and post-harvesting treatments on the economic feasibility, forest growth and plant biodiversity. This study provides a close analysis of the possibilities of natural forest management in the neotropics and how far we are from achieving sustainability in these types of forests.

It was found that at least 30 ha of forest and 10-15 m^3 ha^{-1} of commercial timber should be harvested in order to make natural forest management economically attractive in conditions similar to those found in the region where this study was carried out. Post-harvesting treatments significantly increased growth, especially for commercial species; these operations, however, affected negatively the economic feasibility of the whole management scheme. Some kind of financial compensation, such as the innovative payment of environmental services prevailing in Costa Rica, would be required to make post-harvesting treatments economically feasible. Tree species that colonized disturbed sites were favored in areas directly affected by forest operations.

Simulations tested using the SIRENA II model for scenarios combining different forest harvesting intensities, cutting cycles and post-harvesting treatments, suggest better possibilities for achieving sustainability in managing natural rain forests when: a moderate harvesting is implemented (approx. 60% of the commercial volume); post-harvesting treatments are prescribed in order to maintain an appropriate composition of commercial species; and a cutting cycle of at least 20 years is selected. Under these conditions, it would be possible to harvest a sustained yield of 15-20 m^3 ha^1 of commercial volume.

These results could serve as a reference for future actions to improve forest policies that aim at promoting sustainable forest management as a conservation tool in neotropical countries, such as the ongoing processes of development and validation of criteria and indicators for the sustainable management of natural forest in some Central American countries.

Effect of different spacing on storm-resistance and volume of young *Eucalyptus urophylla*

Shaoxiong Chen
China Eucalypt Research Center, Renmin Road Mid. 30, 524022 Zhanjiang, Guangdong, China
FAX: 86 759 3380674, Email: cerclb@pub.zhanjiang.gd.cn

Key words *Eucalyptus urophylla*, spacing, volume, storm-resistance

Most of the eucalypt species are planted around coastal districts in southern China for pulp and paper. Eucalypt plantations especially young plantations are strongly damaged by the storms which happened 3-4 times in these regions each year. Storm is the main obstacle for the development of eucalypt plantation in south China. An *Eucalyptus urophylla* spacing trial which included 5 planting densities of 3m/1m, 4.5m/1m, 3m/2m, 4.5m/1.5 m and 3m/3m was established in Leizhou Peninsula, Guangdong Province where 20%-50% of young eucalypt plantation were damaged by the storms every year. The design was a randomized complete block. The area of each block was 0.169 hm^2. All areas were ploughed with the Shearer Majestic disc plough followed by a single run with the Shearer offset discs. Study on the effect of 5 different spacing on storm-resistance and volume of young *Eucalyptus urophylla* plantation showed that: (1) The more the planting density, the stronger the storm-resistance in 5 spacing of the trial. The percentages of damaged trees of 5 planting densities from 3m/1m to 3m/3m were 9%, 12.5%, 16.6%, 19.2% and 27.9% respectively at one year. (2) The more of planting density, the bigger is the stand volume. The volume of 5 planting densities from 3m/1m to 3m/3m were 139.8 hm^2, 136.5 hm^2, 108.1 hm^2, 101.4 hm^2 and 81 hm^2 respectively at the age of 3.5 years. Planting density may be increased up to 2500-3000 trees/ha instead of 1667 trees/ha which is the popular spacing in forest practice in south China. (3) The spacing of 3m/3m is the worst one.

Harvesting plan - a case study in producing a good quality map for harvesting in tropical hill forest.

Muhammad A. R. Farid, Salleh M., Amir Adul Nasir S., Mohd. Adnan A.
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6342633, FAX: 603-6367753, Email: farid@frim.gov.my

Malaysia had formulated and operationalised the Malaysian Criteria and Indicators for Sustainable Forest Management (MC&I) using the (International Tropical Timber Organization) ITTO guidelines for the Sustainable Management of Natural Tropical Forests and ITTO Criteria for the Measurement of Sustainable Tropical Forest Management. Malaysia has further developed a set of MC&I for purposes of forest management certification at the Forest Management Unit (FMU) level.

A total of 71 activities and 164 management specifications covering six criteria and 28 indicators have been formulated. Following the formulation of MC&I, a number of assessment, both internal and through independent external assessors, have been conducted to assess the implementation of all prescribed activities at the FMU level. The first internal assessment for Peninsular Malaysia conducted in 1996 produced some valuable feedback for the improvement and refinement of the MC&I.

Well-documented forest management has been developed in Malaysia over a very long period, within the Permanent Forest Estate (PFE). A good system of Totally Protected Areas and Virgin Jungle Reserves was being extended further. The main concerns had been over the effectiveness of implementation and logging contracts, and involvement of local people.

With respect to the concerns above, further assessment on current forest management practices especially implementation of a forest harvesting plan was undertaken by the Forest Research Institute Malaysia (FRIM) in collaboration with the Kumpulan Pengurusan Kayu Kayan Terengganu Sdn. Bhd. (KPKKT). The findings from this study may result in the possible revision and improvement of the MC&I. The study was done in Block Beta of Compartment 51, Jengai Forest Reserve, Terengganu. The area for this study covers 42 ha.

This paper explains the procedure and some of the costs involves in producing a good quality map for the purpose of harvesting to extract commercial trees. The boundary and streams within the block was first surveyed to produce a base map of scale 1:1000. In the MC&I the scale for the map stated was 1:5000. So, causes for the scale 1:1000 chosen are stated too. The location of the Base Line was decided on the map and then the base line was demarcated together with the 30 meters apart strip lines on the ground. The strip lines were used to gather data for topography and trees marked for felling (tree mapping). The height of every 30 meters (horizontal distance) on the strip lines are recorded from the inclination readings obtained by using either clinometer, Impulse or Criterion.

The Impulse equipment was used for the boundary survey and the Criterion Laser 400 equipment was used for the stream survey. Errors encountered during boundary, streams and strip lines surveys are explained in this paper and mitigation measures stated to minimize errors in the future. The initial stage of producing the base map was totally done manually. Hence the time consumed are noted for improvement if computer software are used to produce the map. The possibility of using better equipment for producing a good harvesting plan are discussed further. These include equipment such as Trimble Pro-XR, Geoexplorer and software such as Roadeng, Forest Low Density Road System (FLDRS) and Earthwork.

Last but not least this paper explains the perception of the present logging contractors on the MC&I and steps taken to convince them of the usefulness of advanced technologies for the use in the forestry sector especially for harvesting.

Long-term financing as a determining factor to investments in reforestation: the case of *Pinus* spp. in Paraná State

Vitor Afonso Hoeflich, Arnaldo José de Conto, Erich Gomes Schaitza
Universidade Federal do Paraná Embrapa Florestas, Brazil
Tel: 041-3425332, FAX: 041-244-1545, Email: hoeflich@cnpf.embrapa.br

Brazilian annual consumption of roundwood is around 350 million m^3. Forestry sector annual product is around US$17 billion or 2.2% of Brazilian GNP and it generates 700 thousand direct and 2 million indirect jobs. Exports reached US$4.1 billion in 96 and US$3.3 billion in 97. The industrialization of urban areas and the mechanization of agriculture where causes of deforestation in South and Southeast Brazil. In the 70's, Brazilian government implemented some tax incentive measures to foster reforestation with fast growing species. In South Brazil, most of incentives became Pine plantations, which supplied pulp and paper industries. This successful policy, together with investment in research and genetic improvement of pines, led to a tremendous growth of the pine-based industry in South Brazil. The 80's and 90's were marked by a strong economic crisis in the country with an inflationary process and bankruptcy of public budgets. Tax incentives were interrupted and since that time forest sector does not have any public policy, which can promote reforestation. Forecasts of production based on modeling the production of stands planted and on a near stable demand of pine roundwood shows that a shortage of pine wood will occur by the year 2013. To avoid that, an annual reforestation program of 12,000ha must be established.

Considering that all tax incentives were extinguished and that existing plantations were poorly managed, there is a strong need of establishment of a set of policies aimed at promoting industrial reforestation, research and defining a program directed to small land owners.

Growth and modernization of Paraná's Forest Sector depend upon a financing policy which takes into account local specific conditions of production, profitability, yield, costs and technological level.

This work was developed through the analysis of the productive system of pine in South Brazil, with emphasis in Paraná State. The methodology allows the definition of main elements of the productive system and the quantification of their economic efficiency. Main bottlenecks of the productive system and basic conditions of its development are also identified.

Two methods of selection cutting systems for sustainable management of natural hiba (*Thujopsis dolabrata* var. hondai) forest

Yoshihiko Itoya, Takayuki Ota
Tohoku Research Center, Forest Regeneration Lab. Forestry and Forest Products Research Institute, 72 Nabeyashiki, 020-0133 Morioka City, Japan
Tel: +81-19-648-3942, FAX: +81-19-641-6747, Email: itoya@ffpri-thk.affrc.go.jp

Two plots were made in Kansuizawa experiment forest in 1927 to develop the selection cutting system for sustainable management of natural hiba (*Thujopsis dolabrata* var. *hondai*) forest. Strip clear-cutting system (the width of every strip was 15 m) was applied to one plot (plot A) and 28 percent in volume was logged. To the other plot (plot B), single tree selection cutting system was applied and 36 percent in volume was logged. The dbh and height of trees were measured in 1997, 70 years after selection cuttings, and stand structure of each plot was compared with that of 70 years ago. In plot A, population of *T. dolabrata* in middle class (22 cm <= dbh < 52 cm) decreased though population of *T. dolabrata* in small class (6 cm <= dbh< 22 cm) increased greatly and that in large class (dbh >= 52 cm) showed a slight increase. It is considered that the growth of young seedlings of *T. dolabrata* was urged by strip clear cutting and the growth of *T. dolabrata* in sub tree layer in reserved belt area was restricted by the coverage of tree layer. The annual growth rate of *T. dolabrata* in small class, middle class and large class in 70 years was 0.2,0.1, 0.2 m^3/ha/yr, respectively. In plot B, the increase in population of small class was not so clear compared with that in plot A. The stand structure of plot B showed little difference from that in 70 years ago. The annual growth rate of *T. dolabrata* in small class, middle class and large class was 0.8, 2.0, 0.6 m^3/yr/ha, respectively. In these 70 years, these two plots had been logged four times. And from the second time of logging, single tree selection cutting system was applied to plot A, especially to the reserved belt area. The total harvest volume in 70 years is 270 m^3/yr/ha in plot A and 363 m^3/yr/ha in plot B. Judging from these results, we concluded that single tree selection cutting system should be applied to natural *T. dolabrata* forests in selection forest type to earn more harvest. And in the *T. dolabrata* forest in uniform forest type where the populations of young seedlings are small, clear-cutting system should be used in order to urge the regeneration of *T. dolabrata.*

A Sustainable Forest Management in Devastating Land by Typhoon

Masaru Ken Iwamoto, Ryo Noda
Nishi-nippon Institute of Technology, Dep. of Civil Engineering, 800-0394 Fukuoka, Japan

Japan forests in the northern Kyushu were severely damaged by typhoons 9117 and 9118 (Vmax = 61 m/s) in 1991. Especially in Sugi forest (*Criptomeria japonica* D. Don), the trees were completely destroyed in the various types of wind damage, such as the stem breaking, overturning, bending and branch breaking etc. Even in the residual forests, the growth level and wood quality were clearly reduced by the internal damages with cambium zone. In addition, the secondary disasters (landslide and floodwood) began to occur since then. From the results of actual condition research and experimental analysis for silviculture and strength of wood material, several counter plans for waste management, reforestation plans and hazard assessment were done and the following matters were suggested;

1. Damaged trees will be used for the pulpwood and logs with low quality.
2. Slightly damaged trees will be still remained as a long rotation trees because of the rehabilitation of wood quality.
3. Environmental forest management is superior to the economic efficiency in Japan because of the climate and topographical conditions.
4. Mixed and multi-storied forest should be planned to promote the functions of ecosystem and soil and water conservation.
5. Coniferous trees should be planted at the suitable site condition, for example on a slope between mountain ridge and valley.
6. Native trees, such as broad-leaves ones, should be planted on a ridge and along valley because of their dominant characters.
7. Hazard assessment, such as prediction for criteria of rainfall intensity with landslide and how to reduce and evacuate from disaster, is the significant project to maintain the mountain and keep a human life and their properties in Japan.

Revenue Losses Arising from Inadequate Market Information: A Case Study of the Local Extractors and the Forest Department-Kakamega Forest in Kenya

Lubanga Makanji
Tsukuba University, Laboratory for Appropriate Technology for Rural Development. Agriculture and Forestry Division, Tennondai 1-1-1, 305-0006 Tsukuba City, Japan
FAX: 81-298-53-4761 (office), Email: lmakanji@hotmail.com

Kakamega Forest is refereed to as the eastern-most tropical rain forest in Africa. It covers an area of about 23,000 ha. About 16,000 households, for their various needs, rely on it. As the people extract products legally or otherwise, some of the products enter the market. Mainly, wood products, namely, timber, poles, posts, charcoal and firewood are marketed. Other non-timber products are also marketed but this paper will only review the case of wood based products. These products then undergo what is called marketing. This can simply be refereed to as the process that involves production and all the practices that the product undergoes, till it reaches the final buyer or consumer. The marketing process requires that there is information. This is what is called marketing information. Marketing information must posses certain characteristics if it is to be useful for decision making. That is, it must be accurate, current, sufficient, available and relevant. Any market that operates without proper information is therefore likely to be imperfect. For the case of Kakamega forest, there is a general inadequacy of information in all the characteristics.

The local extractors do not have the right information on which to base their decisions. Middlemen collect information from the markets or create it when there is need, "analyze" it and then use it for their own benefit. Pricing, which is very important in any production and marketing practice is the preserve of middlemen. They set the base price on which the local people then base their producer price. Issues concerning far off markets are beyond the reach of the extractors. They thus rely on middlemen to provide some information. In so doing they are exploited by the middlemen. Middlemen may set prices that are low and later on, sell at higher prices. They are also capable of buying on credit to the disadvantage of the extractor as they create a situation where the extractor is not sure of whether the middleman will pay or not. The government or forest department, on the other hand, by not collecting and providing information looses a lot of revenue. The local people are engaged in extraction for sale under the guise of home consumption. As the products leave the forest and get in to the homesteads, and eventually on to the market, the government looses revenue. This is because home consumption products are obtained free of charge. The government can not benefit from license fees that are applicable to commercial dealers nor from royalty fees. At a higher level, if the products get in to the formal market, the government or forest department loss value added tax. The losses can be worked out and given a monetary value. Preliminary studies show that the revenue looses may be much higher than the revenue that the forest department officially collects.

Crown Condition and Increment

Gottfried Steyrer
Federal Forest Research Centre, Seckendorff-Gudentweg 8, A-1131 Vienna, Austria
Email: Gottfried.Steyrer@fbva.bmlf.gv.at

Due to well-known drawbacks, crown condition is only conditionally suited as indicator for the condition of forests. However, because of increasing doubts about its suitability, it became necessary to search for another indicator. Various increment parameters seem to be more useful, mainly owing to the higher objectivity of measured data. In 1992/93 it was for the first time possible to analyse increment data and timely corresponding crown condition data from the Forest Damage Monitoring System of Austria (Waldschaden-Beobachtungssystem, WBS). Increments were found to decrease considerably with increasing defoliation, notably in the case of needle losses of more than 25%. Especially the two parameters basal area increment and basal area increment related to crown diameter have clearly shown increment losses.

Growth of the Trees in the Mixed Stands of Black Pine (*Pinus nigra* Arn) and Beech (*Fagus moesiaca* M) Depending on the Type of the Mixture

Pande Trajkov, Petrus Ristevski
Faculty of Forestry - Skopje, Bul. "Aleksandar Makedonski", Bb, 91000 Skopje, Macedonia FYRO
Tel: 389-91-135-033, FAX: 389-91-234-560, Email: ptrajkov@ukim.edu.mk

The practice of raising monocultures is being abandoned in modern forest management, in favor of mixed-species forest. This trend is of particular interest for management of forest of heliophyte species, such as *Pinus nigra.* Raising mixed stands composed of heliophyte and sciophyte species can increase productivity, stabilize the forest ecosystem and eventually these stands might evolve in permanent mixed forest stands of coniferous and deciduous species.

This is the fairly new trend and there is lack of long-term data and information, so many questions remain unresolved on the development structure of mixed forest stands. As a result of this, the management of mixed forest stands utilizes no long term concept or concepts valid for single-species stands (monocultures) are being used. This results in inprecise evaluation and assessment.

In order to reach the basic concept for the development model in such forest, apart from investigation of their structure and productivity at various ages, a very important can be achieved by stem analysis. This would generate retrospective data on the growth of single trees.

In the complex investigations in order to determine the dependence of productivity of participation in species, of mixed stands of black pine and beech we have established experimental plots in stands of three different ages with different participation of both species. The stands are at of 80,100 and 120 years. Our purpose is to observe the development of the stands in a long-term period. A medium basal area model tree of black pine and beech from the vicinity of each experimental plot were cut off and analyzed, which is the subject of this paper.

Biodiversity and Stability of a Mountain Beech Stand where Cleanings of Different Intensities were Performed

Stefan Vlonga, Valentin Bolea, Mihaela Mandai
Mihaela Mandai
Forest Research and Management Institute, Romania

The research focused on the influence of cleanings of various intensities on stand biodiversity and stability. The fieldwork was carried out in a 30-years old beech stand where extraction racks had opened in 1991. In 1992, an experimental block with three variants of cleanings (high, moderate, as well as non-intervention variant) was established. Two cleanings (a high intensity in 1992 and a moderate intensity intervention in 1996) were carried out in the high intensity intervention variant, while only a moderate intensity intervention was carried out in 1994 in the moderate intensity variant. The inventory of shrubs, seedlings and ground vegetation was carried out in 1998.

After cleanings, the stand composition has improved (the beech proportion increased with about 20 per cent, while hornbeam proportion decreased with about the same value)

The intensity of cleaning in the high intensity plot was 80% per number of trees (N), 48% per basal area (G) and 37% per volume (V). In the moderate intensity plot the cleaning intensity was 43% per N, 20% per G and 14% per V.

The light intensity within the stand represents 4% of that on open land in the high intensity plot, 2% in the moderate intensity plot and 1% in the non-intervention plot. The monochromatic light penetrates the stand canopy in uneven proportion, so that the proportion of red and infrared waves is higher than that of blue waves.

The slenderness index of trees is 125 in the high intensity plot, 148 in the moderate intensity plot and 158 in the non-intervention plot. These values show that trees are vulnerable to snow and wind damages, especially in the latter two variants.

The tree distribution on diameter classes in the non-intervention plot is an irregular (uneven) one. As the cleaning intensity increase, the distribution approaches a regular, even (Gauss-type) one.

The highest number of shrubs (0.6 samples/m^2) was recorded in the high intensity plot, followed by the moderate intensity plot (0.2 samples/m^2). In non-intervention plot 0.1 samples/m^2 were recorded.

Although the stand is young (30 years old), trees are already mature so that 0.4 seedlings/m^2 were recorded. The highest seedling (1-3 years old and 5-15 cm tall) density was found in the plots where cleanings were performed.

The density and amount of ground vegetation species, as well as the surface occupied by these species, were highest in the high intensity plot (24.4 samples/m^2), with 26 species spreading over 35% of the surface The lowest values were recorded in the non-intervention plot: 6.4 samples/m^2, respectively 9 species spreading on 15% of the analyzed surface.

Tree stability was not affected by cleanings. On the contrary, such detrimental effect was recorded in the non-intervention plot, where about 20% of the trees of 2-4 cm diameter were bent over, as well as in moderate intensity plot, where about 10% of the trees were bent over. In conclusion, the plant diversity and tree stability are higher in cleaning stands than in the non-cleaning ones.

4.01.00 Using growth models for better forest management in the tropics

A Process-based Model to Assess Forest Management Strategies in Tropical Rain Forests

Peter Köhler, Andreas Huth, Thomas Ditzer
University of Kassel, Center for Environmental Systems Research, Kurt-Wolters-Str. 3, 34109 Kassel, Germany
Tel: +49.561.804.3175, FAX: +49.561.804.3176, Email: koehler@usf.uni-kassel.de

Until now, attempts to model and simulate tropical rain forest are very few. The approach we present here is highly focussed on available field data, their analysis and the state-of-the-art knowledge on rain forest tree growth. Our model FORMIND is an individual-oriented and process-based rain forest growth model with special emphasis on dry matter dynamics. To predict tree growth, we model photosynthesis and overcome the problem of estimating respiration - where normally data are not available - by integrating diameter increment data from field observations in the model. Together with precise tree geometry information (incl. relation between diameter, height, leaf area, crown extension, aboveground biomass) single tree growth can be determined very accurately. Modules for light competition on patches of 20m x 20m in size, mortality (incl. falling trees creating gaps) and establishment enable FORMIND to simulate forest stands up to a size of several tens of hectares. Tree species are aggregated based on a generalized approach to derive typically 5-10 plant functional types with respect to their light demand (shade tolerance) and their potential maximum height. Because of the general formulation of basic processes, sites in different world regions can be simulated. Including typical environmental factors like dry seasons of various lengths, rain forest stands in South-East Asia and South America were simulated with a satisfying precision.

As one of the most urgent model applications, the impacts of different management scenarios on tropical rain forest are discussed in detail. Due to a lack of field data it is still not clearly known how management of tropical forests influences tree mortality, forest regeneration potential and its time scale. We therefore simulate the huge variety of possible impacts of different logging strategies and compare simulation results with field observations to identify those impacts, which might be of major importance for forest growth. This analysis has a special focus on establishment processes and how their changes due to logging impacts are responsible for future forest development.

The results show that even with an optimistic constant seedling input logging intensity and the length of logging cycles have to be on levels which are not observed in practice at the moment. If highly likely impacts of logging on seedling input and survival rate are taken into consideration it becomes very clear how far common logging practices are away from sustainability.

The Influence of Age on Forest Site Productivity: A Case Study with Suppressed Black Spruce Trees

Daniel Mailly, Jean-Pierre Carpentier
Ministere des ressources naturelles (Québèc), Direction de la recherche forestière, 2700, rue Einstein, G1P 3W8 Ste-Foy, QC, Canada
Tel: 1 418 643-7994 ext. 369, FAX: 1 418-643-2165, Email: daniel.mailly@mrn.gouv.qc.ca

Keywords: site index; productivity; stand age

In forestry work the age of a tree, as indicated by the number of annual growth rings at the base or at breast height, is generally the only age considered. Studies related to the phenomenon of tree suppression in juvenile age of black spruce trees (*Picea mariana*) have raised doubts as to whether the total age of a tree is the best indication of its true physiological or economical age on a given site. Tree suppression usually occurs when black spruce advance regeneration suffers from competing, taller trees. Tree growth is then severely limited, and these trees have distinct, slow growing annual rings. This slow accumulation of diameter growth during the juvenile years leads to a sigmoidal pattern of diameter increment over age. By considering this, our aim was to develop a method that removes the influence of the initial suppression years, and provides an estimate of the "economical" age of a tree.

To achieve this goal, we sampled three black spruce sites (6 plots per site) growing in north-east Québèc, Canada. On each site, all merchantable trees were tallied and tree height as well as tree diameter at 1 m were recorded. In addition, an increment core was taken at 1 m for patterns of diameter growth accumulation. Traditional site index determinations were calculated using the 4 biggest trees per hectare using total age at 1 m. With these data, a method was developed using a logistic nonlinear regression model of cumulative annual ring widths regressed against age in order to determine the "economical" age of a tree. This was done by extrapolating the linear portion of the logistic curve down until the tree diameter equals zero, assuming that the pattern of cumulative annual ring widths with age of non-suppressed trees is generally linear.

By using the "economical" age as a replacement for total age, site index estimates were shown to increase by as much as 1-2 m (site index based on age50 at 1 m). Since tree age is an important factor in determining site productivity of black spruce stands, the use of the "economical" age is recommended since it yields more realistic and less conservative site productivity indices. The use of the "economical" age as a replacement for total age had, however, slightly less impact on plot merchantable volume determinations since plot volume is not only dependent on age but also on other plot variables such as density and mean quadratic diameter.

Nutrient Cycling in Tropical Tree Species on Semi-arid Region.

M. V. Rao, T. Syamala
Bharathidasan University, Dept. of Plant Science, 620 024 Tiruchirappalli, India
FAX: 091-0431-660245, Email: mvrao@bdu.ernet.in

The processes of soil nutrient uptake by vegetation, litter nutrient return to the soil and nutrient release during litter decomposition maintain the nutrient flux between biotic and abiotic systems. The rate of nutrient cycling determines the sustenance of vegetation on the soil. The present study reports nutrient cycles (N,P,K, Ca and Mg) of *Acacia auriculiformis*, *Acacia holocericea*, *Casurina quisetifolia*, *Eucalyptus tereticornis* and *Leuceana leucocephala*, plantation on semi arid region. Leguminous species such as *A. auriculiformis*, *A. holocericea* and *L. leucocephala* had the higher concentration of nutrients than non legumes such as *Casurina equisetifolia*, and *Eucalyptus tereticornis*. The ranking of species with regard to nutrient storage was as *E. tereticornis*> *Leucena leucephala*> *Acacia auriculiformis* > *Acacia holocericea* > *Casurina equisetifolia*. The turnover time of nutrients in the vegetation of *A. auriculiformis*, *A. holocericea*, *C. equisetifolia*, *E. tereticornis* and *L. eucephala* were comparatively much lower. The loss of N, P, K, Ca and Mg during decomposition were significant during initial months. The turnover time (based on litter decomposition) of anions like N and P were longer than cations like K, Ca and Mg. The five species aligned with regard to efficiency on nutrient cycling of *E. tereticornis* > *A. holocericea* > *A. auriculiformis* > *L. leucocephala* > *C. equisetifolia*. The architecture, N economy and a higher utilization efficiency of nutrients allowed *E. tereticornis* to emerge as the best among the five species.

4.01.04 Using models for forest growth and stand dynamics to evaluate sustainability

Sinergetic Theory of the Forest Stands Growth, Structure and Stability.

Alexander S Alekseev
Forest Technical Academy, Dept. ForestMensuration and Management, Institutsky per.,5, 194021 Sankt-Petersburg, Russia
Tel: +7-812-555 87 98, FAX: +7-812-550 08 15, Email: Alekseev@AA2996.spb.edu

The theory allowing to describe and explain the process of formation of the size structure of various forest stands is elaborated on the basis of synergetic approach. The structure in question generally is formed under influence of two sharply different kind of the processes, first is the process of strictly deterministic trees size growth, second is the process of non-regular, due to a lot of external (ecological) and internal (genetic and physiological) factors, trees size differentiation. For the explanation of the mechanisms of forest stands structure formation both this processes must be taken into account and analyzed simultaneously. Such a possibility is offered namely by synergetic approach. The analysis of the growing and at the same time differentiating forest stand was done using the Fokker-Plank equation. As a result of analysis the forest stand size structure under stationary condition may be described by following equation:

$$n(x) = n0 \exp(-V(x)/B)$$

where x is individual size, n(x) is a share of trees with size x, n0 is a constant

$$d/dx(V(x)) = -A(x)$$

A(x) is an expression describing deterministic growth rate of forest stand, B is a parameter describing the intensity of random non-regular differentiation of trees within the stand. The type of forest stand structure is determined first of all by the type of trees size growth. Different size structures are studied by using growth functions most common in quantitative ecology, such as linear, Hompertz, J-shape, S-shape and several modifications of the logistic curve. This analysis is resulted in 7 types of forest stand size structures covering all principal cases known from literature. A correspondence between growth and statistical characteristic is established for some of the most common types of the size structures. The synergetic approach to forest stands growth and structure allows introduce and investigate the stability features of the forest stands equilibrium state. Stability attribute of the forest tree stand is understood as an ability for restoration after some disturbances, it is described by the time needed for returning to initial state. Special macroscopic characteristic functions of forest stands are introduced for holistic description of the size structure, such as entropy, free and average growth energy. Their mutual relation is established. This part of the analysis offers a new facility for evaluations of forest stands growth dynamics and sustainability. The developed theory was checked using the data on distribution of the trees over thickness classes for Scots pine and Norway spruce tree stands of different ages and forest types from Sankt-Petersburg Forest Technical Academy experimental and training forest enterprise.

Growth Trends in Pedunculate Oak Stands in Croatia

Miroslav Benko, Novotny, V., Vuletic
Forest Research Institute, Jastrebarsko Trnjanska 35, HR-10 000 , Croatia
Tel: +385-1-615-0742, FAX: +385-1-611-3372, Email: benkom@jaska.sumins.hr

In Croatia, the growing stock of Pedunculate oak (*Quercus robur*, L.), is the second largest with contribution of 14% and also takes first place in total market value of timber.

In researching ecological-managerial forest types in Croatia, for the past 40 years, the Forest Research Institute Jastrebarsko has established approximately 3000 sample plots in 500 dry (II-G-10) and humid (II-G-20) Pedunculate oak stands. The EMFT II-G-10 is represent with associations of Pedunculate oak and common hornbeam (*Carpino betuli - Quercetum roboris*), while the EMFT II-G-20 are associations of Pedunculate oak and great green weed (*Genisto elatae - Quercetum roboris*).

In compiling all parameters for evaluating the population structure of each sample plot, 1-3 mean stand trees were felled, dependent on the age of the plot and the number of trees. The data was recorded in the EGTRH database and in the CANASTA sub-database, and the stem analyses were carried out.

The ecological-managerial forest type is considered to be a specific area of the forest and a forest land that has similar ecological and managerial factors that normal forest management depending upon. The ecological - managerial forest type can be determined by its geological structure, phytocenosis, soil type, climate, sylviculture characteristics, production capabilities and stand value. For each ecological-managerial forest type and forest land, the most favorable stand form, rotation, felling maturity, normal production and its value are determined.

In examining the measured data and in calculating the width, height and volume increment of the analyzed trees stem, one can obtain an understanding of the growth trend of the Pedunculate oak trees as a representative of its stands.

After 20-30 years on these plots (however, fewer in number than previously), a number of trees were felled and analyzed. The obtained results were compared with the first measured results. This was done so as to compare them with the estimated growth trends therewith.

Quantic Hypothesis of Growth and Development

Karlo Bezak
Forest Research Institute Jastrebarsko, Trnjanska 35, 10000 Zagreb, Croatia
Email: Ninoslav Novak [nnovak@znanost.hr]

The wood is the most complex natural macrosystem and its growing is the basic property of nature. The periods of growing and developing of wood, the oscillations of increasing by growing are not completely congruent with axiom in the biotechnical science. Axiom with one culmination of increasing by growing and two points of inflexion suggests unperiodical motions in nature. The cause of unperiodical motions is a strong force of the resistance that prevents the system to attain to balance position. The essence of the modern biotechnical science is its foundation on the quantum mechanical principles and without them is impossible to explain periodical phenonema in nature. Cognition of quantum mechanical laws, necessity of knowing behavior in microsystem is necessary for explaining macrosystem behavior. For quantum mechanical observing of the growth and development woods system is necessary to understand and to know the wood. It is needful to study its biological essence on its basic phenonema in order to understand its micro and macro system. The basic characteristic of material is wave property and this is a fact. The wave notion about material leads naturally to general procedure quantifying. Explaining the phenonema in the wood that couldn't be explained in classical manner the another sets quantic hypothesis using classic differential equation of the suppressed sinusoid oscillations law. Here using universal quantic relations and intuition, the author sets wave equation of growth and development woods:

Diameter growth – $D'' = Ae^{-kt} \sin(w_0 a t - j)$

with reference to

$$Height\ growth - H'' = Ae^{-kt} \sin(w_0 a t - j) + A_1 e^{-kt} \sin(w_1 a t - j_1)$$

In equations some symbols are:
D" – derivating of derivations of diameter growth; H" – derivating of derivations of height growth; A, A_1 – amplitudes of growth; e – natural logarithm; k – resistance coefficient; t – time; w_0, w - elasticity coefficient; a - fine structure constancy; j , j_0 - phase.

Elasticity coefficient respectively frequency of motion w in wave equations speaks to us about the speed periodical phenonema in nature and constant of fine structure, a is its multiple. Constant fine structure α introduces us in the world of quantic phenonema in nature. Supposition is that fragment wave description satisfies the separate relativity principles, that means the connection between wave vector and frequency wave, impulse and energy fragment must be the same in every inertial system. With quantic hypothesis meaning the hypoothesis about discretion physical magnitudes with the hypothesis that the wood cellules are oscillators making ansamble, the author demonstrates growth continuance and enters in trace to universal law of growing.

Let us suppose that macrosystem, as well, as microsystem have wave properties then for the wood may be set wave equations, and so by then may be foreseen phenonema being observed experimentally. Setting up of such wave equation and foreseeing of experimental results enable the basic tasks of the quantic theory field. The waves in hyphotesis are described by quanticmechanical fields and in certain point of view they are quanticmehanical generalising of the classic wave function. Quantic theory of field is actually a theory of many fragments making a unique method suitable for condition describing by voluntary number of fragments of determineal sort.

The wave equations of growth and development woods everywhere disappear identically, meaning that they are producing a complex vector space. Graphic resolving of the wave equations make a complex vector space of growth and development woods. Its vectors are determined complex functions of space and time. Increment and prognosis of developing diameter growth and height growth of the structure may be established by great punctuality using wave equations.

Dendrochronology of the trunk growth or its component barts may be detected and quantified by resolving wave equations of growth. By using wave equations of growth and development woods the construction of standard quality tablet is simple.

Quantic hyphotesis of growth and development woods reflects the deepest nature laws, by the way, they are great advancing to the right fundamental theory of growth.

Keywords: growth and development of woods, micro & macro system, quantic theory, complex vector space

Calibration of the Prognosis BC Regeneration and Small Tree Models

C. Boisvenue, A. Zumrawi, P.L. Marshall, and C. Lencar
University of British Columbia, Faculty of Forestry, Canada
Email: Abdel-Azim Zumrawi
[zumrawi@interchange.ubc.ca]

Models for predicting natural regeneration and small tree dynamics are essential components of any growth simulator used in projecting partially-cut stands. PrognosisBC is an adaptation of the Northern Idaho (NI) version of the Forest Vegetation Simulator (FVS), to the Southern Interior of British Columbia. In this poster, we will summarize the sampling methodology, data collection, and calibration approaches used to calibrate the regeneration and the small tree height increment models in PrognosisBC, for the Interior Cedar Hemlock, warm, moist sub-zone (ICHmw2). The ICHmw2 is one of the most extensive and productive sub-zones in the southern interior of BC. Fifty-eight stands were selected. Eighty percent of the plots were in stands that were disturbed (partially cut) in the last 20 years, 10% in undisturbed stands and 10% in stands that were clear cut. An attempt was made to cover a wide range of elevation, aspect and slope, within the geographic range of the sub-zone. A total of 186 temporary sample plots were measured. Plot centers were systematically located in selected blocks. At each sampling point, a fixed-area main plot of 0.04 ha was established and two smaller nested sub-plots of 0.005 and 0.00135 ha, were used to collect small tree 5-year height increment and regeneration data, respectively. In addition, four satellite regeneration plots were established at the edge of the main plots in the four cardinal directions. The regeneration plot size was determined for consistency with the original design used to develop FVS, to reduce differential design errors. Initial summaries of the regeneration data confirmed the inadequacy of the regeneration model in FVS for the southern interior of BC. Similar problems were identified in other studies using regeneration survey data. Preliminary results from the 5-year height growth of trees < 7.5 cm dbh showed that the small tree height increment model in PrognosisBC, significantly overestimated growth. A significant trend over stand density was observed. Further analysis will be conducted to calibrate the model components that predict probability of stocking and the occurrence of advance and subsequent regeneration. A small tree 5-year height increment modifier will also be developed. Final results, conclusions and recommendations, will be available prior to the meeting.

The Development of Young Beech Stands and Environmental Effects

Serdar Carus
University of Istanbul, Branch of Main Science of Forest Yield Study and Biometry,
80895 Bahceky, Istanbul, Turkey
FAX: +90 212 226 11 13, Email: scarus@istanbul.edu.tr

Oriental beech (*Fagus orientalis* Lipsky.) forests consist of %8 Turkey' s forest area. Beech wood very important for forestry industry (furniture, parquet etc.). In this study, it was investigated the relationships between site quality and some marks of site (main rock, distance from edge, slope, exposure, lime content of main rock, elevation, distance from the sea) of even-aged oriental beech forests on West and Middle Black Sea region in Turkey. For this purpose, temporary plots were chosen different of site. Oriental beech forests located on very different main rock in research area. It was seen that best growth of these forests on andesite main rocks and also worst growth of this forests on quartz main rocks. Slope is estimated as an important works of site on growing of oriental beech forests. Exposure and main rock (magmatics, sedimentary and metamorphoced rocks) explain variation of site in %51 ratio (R2= 0.509).

The models were developed predict periodic (5-10 year) increments which are diameter at breast height, height, basal area, volume. Tree, stand and site factor information was recorded at 116 randomly located sample sites. Corresponding diameter growth for the past 5-10 years was measured from increment cores of the individual trees. Correlation between the latter and independent environmental variables was tested by regression analysis. Least squares regression techniques were used to obtain estimates of the required parameters. Information needed to predict volume and other volume elements increment of individual trees on a given site includes diameter of each tree, stand density (basal area per hectare), elevation, latitude and percent slope. Slightly better predictions can be made when site index information is available for a given species on a particular site.

Simulation of Increment and Growth in Even-aged Oriental Beech Stands

Serdar Carus
University of Istanbul, Branch of Main Science of Forest Yield Study and Biometry, 80895 Bahceky, Istanbul, Turkey
FAX: +90 212 226 11 13, Email: scarus@istanbul.edu.tr

A model was developed to simulate the increment and growth of even-aged *Fagus orientalis* Lipsky.(oriental beech), forests in this research. In this study, even-aged, oriental beech natural stands of normal canopy closure in Turkey were examined. For this purpose, a lot of measurements were carried out in 116 temporary sample plots selected from West and Middle Black Sea region.

In this research, increment and growth relations of beech for single tree and stand according to age and site conditions were investigated separately. Volume and other elements in single tree were related to age and site quality degree. Then, optimal stand density, which can maximize the stand volume and increment for every ages and site index was researched.

SARACOGLU's (1988), method which is different from known methods was used to determine the site index in temporary plots. Arithmetic mean height of stand which is affected smallest by technical treatment and arithmetic mean diameter of stand in plots were used as a measurement of stand productivity in determining of site index.

After the trying of different models according to least squares method, data of single tree and stand were balanced. Computations were realized by using of SPSS version 5.0.1, and some statistical programs written in QBASIC programming software.

Beech shade-tolerant characteristic, number of trees diameter classes distribution aren't figure normal distribution which is right skew shape. Stand of basal area and volume diameter classes distribution are alike diameter distribution. The alteration of the diameter, volume and basal area diameter classes distribution by site quality and age, present by the actual structures of even-aged oriental beech stand, related to the models constructed by basing on the distributions of Gamma, Beta, Weibull and Normal. A linear model has been constructed for each distribution, and the coefficients in the model have been computed with the help of regression analysis. Gamma model seems to be more suitable than the distribution models.

A model was developed to simulate the increment and growth of even-aged beech, forests in this research. Model was growth diameter distribution and stands during one period (10 years), to determine the volume increment, stand volume, basal area, mean height and basal area increment beginning and end of period. In this simulation model, stand density, which can maximize the volume increment with respect to stand age, and site quality degree was investigated. This model was tried for every ages and site index.

The relations found in the investigations of increment and growth of stands have been used to determine the optimum stand structures even-aged oriental beech, by means of the iteration method. The method was applied so as to maximize the stand volume annual increment, by the computer program named AYNI_KAYIN, which he developed in the QBASIC programming software. The program determines the optimum stand structures, according to the desired age and site quality degrees. The basal area of the optimum stand structures was limited between 20 to 80 m^2/ha. Diameter distribution was limited dmax (maximum diameter), according to the age and site quality degrees. The stand volume increment has been thought of as a function of the density degrees (SD) in the approximation.

By the inspection of the optimum stand structures, it has been recognized that the stand volume increment would increase as long as the density degree (SD) would increase. Volume increment indicated relationships site index, basal area and age. Stand volume increment young (50-70 age) maximum rise up, forward ages together happens decrease.

In this program (AYNI_KAYIN) for periodic mortality to take not predictor is not obtainable from any sampling scheme which results in a list of diameters. dmax is average value, really more than dmax is going to be and in the stands different diameter distributions is going to indicate.

The purpose of production forests for timber is to product the timber raw material in maximum quality and quantity can be generated by site in perpetuity. For this reason, optimal structure of forests must be known and stand structures must be transformed to optimal structure. Results of these tries, it was seen that volume and volume elements of beech forests had to be known to manage them. Yield knowledge on beech will allow the utility of these forests in full capacity. Also, after the research, knowledge, which is needed to compare optimal and actual growth, was ensured.

The Alteration of Stand Height Curve by Site Quality and Age in Even-aged Oriental Beech Stands

Serdar Carus
University of Istanbul, Branch of Main Science of Forest Yield Study and Biometry, 80895 Bahcek, Istanbul, Turkey
FAX: +90 212 226 11 13, Email: scarus@istanbul.edu.tr

When stand volume is calculated from measurement of diameter of all trees on an area and estimates of height based on a sample of those trees, a common procedure is to relate height to diameter and then to obtain volume per tree by entering a standard volume table with the measured tree diameter and the estimated height given by the height-diameter curve.

The stand height curve is steep for young crops on good sites and near flat and linear for old crops and those on poor site.

In this study, it has been aimed to investigate the natural relationships which the actual structures of even- aged oriental beech (*Fagus orientalis* Lipsky.) stands denote according to site quality and age in the West and Middle Black Sea region.

Temporary plots taken in the pure, even-aged, untouched normal stocked and naturally grown stands of beech. Temporary plots, were scattered according to age class, site quality in the research area to define different beech stands. After the normality control, 116 plots were accepted to research.

A number of stand height curves age- site quality-diameter equations were compared for oriental beech. Most gave similar results within the range of the data. Some appeared undesirable because of unreasonable curve shapes when extrapolated. For remeasured plots, use of a single age- site quality-diameter equation for each plot rather than individual height- diameter curves for each measurement will give more accurate and more consistent estimates of volume, periodic increment and site index. A number of suitable equation forms are suggested. Besides, the stand height curves have also been graphically showed according to site quality and stand age.

Growth and Yield in Sustainable Forest Management

T. Y. Chin, T.K. Yong
Jalan Sultan Salahuddin, Forestry Department Peninsular Malaysia, 50660 Kuala Lumpur, Malaysia
Tel: +603-298-8244, FAX: +603-292-5657

The mounting global pressure on tropical forest resources and the realization of the need to manage these resources sustainably has propelled accurate determination of growth and yield to the forefront of tropical forest management. This is not surprising as growth and yield is the lifeblood of sustainable forest management and accurate growth estimation is needed to determine the level of sustainable harvest in accordance with the forest management systems applied.

Since the 1970s, the Forestry Department Peninsular Malaysia has embarked on an integrated growth and yield program with the primary aim of studying and monitoring the growth and development of logged-over natural forests. To date a total of 12 study areas and 95 permanent sample plots have been established throughout the peninsula, resulting in the gathering and collection of valuable and informative data on these forest stands.

Stand Dynamics and their Simulation for *Pinus brutia* Ten Forests

Nesat Erkan
Southwest Anatolia Forest Research Institute, Post Box # 264, 07002 Antalya, Turkey
FAX: +90-242-345 04 42, Email: nesaterkan@yahoo.com

Forest stands are mainly simulated in two ways. One of them is based on the distribution of stand parameters i.e diameter, height and stocking. The second is based on the individual tree growth. In the second method individual tree growth in different conditions (such as site quality, neighborhood relations and age) is predicted by sampling. Stands can be simulated after individual tree growth relationships have been established. In this study the simulation was based on the individual tree growth. Firstly an initial stand was formed at the age of 15. Coordinates of trees in the stand were produced at random. Diameter at breast height (dbh) of trees were produced from the diameter distribution and applying parameters obtained from natural stands. Height of trees in the initial stand was estimated from the height equation.

After the initial stand was simulated, trees were grown up to the age of 120 using the individual tree growth functions. To explain the variation of individual tree growth a distance-dependent competition index (BEN) was developed and used as an independent variable in growth function with the other effective factors. This index can explain 52% of individual tree diameter increment variation. Individual tree growth was based on the dbh increment which was predicted as a function of age, BEN, site index (SI), and dbh. Heights (H) were estimated from the height function which contains dbh, age and SI as independent variables.

Uncertainty Analyses of a Process Model when Vague Parameters are Estimated with Different Methods

Shoufan Fang
University of Illinois, Department of Natural Resources & Environmental Science, Il 61801 Urbana, USA

For many process models there are often model parameters for which there is no real data or common knowledge on what these parameters should be. Often traditional statistical techniques can not be used to estimate these parameters. Presented here are some results of a study where the Maximum-Entropy Principle and the Bayesian method with weighted bootstrap sampling were used to estimate unobservable parameters of a pipe model calibrated for red pine (*Pinus resinosa* Ait.). An uncertainty analysis based on the estimated parameters was conducted. Three parameters of this model have been estimated to demonstrate the estimation methods and uncertainty analysis with different amounts of information. The mean values of the estimated posterior distributions based on the two methods applied in this study were very close to those of their corresponding prior distributions. The posteriors estimated by the Bayesian method had less variation than did their corresponding priors. The relationship between uncertainty in posterior distributions of parameters and uncertainty in projections made with the model was assessed.

Studies on Stand and Tree Growth Models in Natural Forest Region in China

Du Ji-shan
Chinese Academy of Forestry, Post Box # 9, 100091 Beijing, China
FAX: +8610-62888315, Email: dujishan@info.forestry.ac.cn

In order to update and predict forest resources on the level of forest bureau and forest farm in natural forest region in China, stand growth models are developed based on permanent plots of forest management inventory in 1997, taking Wangqing forest bureau in Jilin province in China as an example. The stand growth models can be used to update forest resources data in natural forest region. Natural individual tree models are also studied. The main conclusions are as follows:

(1) Combined with integrated stand model, subcompartment forest resource data updating models are developed, which can be used to update

subcompartment in forest bureau and forest farm in natural forest region without human disturbance. The updating factors of subcompartment include mean height growth, site class index, estimation of mean height, basal area per hectare, stand density index, mean diameter, number of stems per hectare, form-height, growth stocking volume, degree of closeness, and volume of open-grown trees.

(2) Given current of situation of a certain subcompartment, the stand measurement factor values of the subcompartment without human disturbance and its composing tree species at any time may be updated and predicted dynamically by the stand growth models. The tested results are good.

(3) By composing tree species of a stand, taking site class index stand density index, and prediction interval as independent variables for updating the data of natural growth subcompartment, the stand growth models are more suitable for updating the data in the natural mixed-species and uneven-aged subcompartment.

(4) With regard to prediction results and practical usage, individual tree models are not suitable for updating the data in permanent plots and in subcompartments. Subcompartment forest resource data should be updated by stand growth models.

Gmelina arborea and *Swietenia macrophylla*: Species-Site Compatibility Assessment Without Establishing Field Trials

Celso B. Lantican, Celso P. Diaz, Leuvina M. Tandug, Manolito U. Sy and Paulino A. Umali
Forestry Campus College, Makiling Heights, 4031 Laguna, Philippines
Tel: (63-49) 536-0596, FAX: (63-49) 536-3615, Email: cblant@laguna.net

Sample plots were established in randomly selected 3-10 year old plantations of *Gmelina arborea* (yemane) and *Swietenia macrophylla* (mahogany) in different parts of the Philippines. To systematize sampling, the country was divided into 10 zones of equal width from the northernmost to the southernmost part of the country. The plantations sampled were selected at random from each zone. For *G. arborea* a total of 223 sites were sampled. For mahogany the total is 163.

From each sample site data on tree height and diameter, spacing, elevation, slope, aspect, soil properties of the A- and B-horizons, rainfall, temperature, wind speed, and relative humidity were obtained. Climatic data, averaged over a period of 10 years (1988-97) were obtained from the nearest weather stations of the Philippine Weather Bureau.

Data were analyzed using the methods of analysis of covariance, multiple regression analysis, multiple partial correlation analysis, and discriminant analysis. Tables and graphs were prepared as necessary to help in the interpretation of the results. Tree measurements and most of the environmental parameters were found to vary significantly from the northern to the southern part of the country. This jibes with the findings that site conditions that affect tree growth show significant variations from one zone to another. Adjustments for differences in tree age and spacing were made in all analyses involving tree height and diameter using multiple regression analysis. Site classification functions were derived for each species by discriminant analysis using data that have been adjusted to account for differences in age and spacing among sites. The functions, which used environmental parameters as predictors, were tested and found highly acceptable for classifying sites as good, average or poor for mahogany. With the aid of the classification functions it is possible to classify a site designated for planting as good, average or poor for *G. arborea* or *S. macrophylla*. For *G. arborea*, the variables found to have significant discriminating effects were zone number, elevation, temperature, depth and potassium content of the A-horizon, and pH of the B-horizon. For *S. macrophylla*, the variables with significant effects were zone number, wind speed, soil depth (A-horizon), relative humidity, temperature, and rainfall.

Needle nutrient ratios affects Scots pine seedling survival and height growth in Finnish Lapland

Kari Mäkitalo and V. Alenius
Rovaniemi Research Station, Eteläranta 55 , FIN-96300, Finland
Tel: +358-16-336411, FAX: +358-16-3364640, Email: kari.makitalo@metla.fi

Scots pine (*Pinus sylvestris* L.) has been widely used in the artificial reforestation of both the dryish native pine sites and more moist and fertile native Norway spruce (*Picea abies* L. Karst.) sites in Finnish Lapland since 1950s. The reason for choosing pine has been it’s better productivity compared to that of spruce or pubescent birch (*Betula pubescens* Roth.), and the promising results achieved in reforestation in the 1930s. However, severe *Gremmeniella abietina* [(Lagerb.) Morelet] and *Phacidium infestans* (P. Karst.) epidemics and dieback have occasionally occured in pine plantations during the last three decades especially on spruce sites. Unfavourable physical soil conditions, e.g., excess water and low temperatures, have been suggested to be one of the main causes of this dieback. Thus, intensive site preparation methods such as ploughing has been widely used to improve the growing conditions.

Our aim was to model the survival and height growth of Scots pine seedlings. We followed the performance of Scots pine during 16 growing seasons using a split-split-plot design in randomized blocks. Four of the eight clear-cut forest sites were dryish pine-dominated sites and four were moist, formely Norway spruce-dominated sites. The site preparation methods were prescribed burning, patch scarification, disk trenching, and ploughing. The reforestation methods were sowing and planting with containerized seedlings and bare-rooted transplants. A total of 72 000 reforestation spots were sown or planted in 1975-77 on the 288 plots using the reforestation density of 2500 spots ha^{-1}.

We used the mixed model technique to evaluate explanation models for survival percentages and mean height growth. In the model, the site preparation and regeneration method were fixed treatments, and the plot and regeneration year random effects. With the mixed modelling approach the dependent variables were explained by soil stoniness, topography, inclination, mineral soil nutrients, needle nutrient content, and the experimental design. The estimation method was based on maximum likelihood, in which the variance components adjust the parameter estimates of the fixed effects.

After 16 growing seasons, average survival was 41% and mean height 247 cm. The survival was the higher, the closer the site was to a typical native pine site. *P. infestans* and *G. abietina* were the most common causes of damage. Neither site preparation nor reforestation method showed significant effect on survival. However, both of them influenced significantly on mean height. The mineral soil nutrients showed no significant influence on survival or mean height. The needle nutrient ratios, e.g. N/(Ca+K+Mg+P), affected negatively and highly significantly on both survival and mean height. In addition, the interaction between topography and inclination showed a positive significant effect on survival. Our results indicate that unbalanced needle nutrient ratios are related to the survival of Scots pine seedlings. The results coincide with the earlier published laboratory studies which show that host nutrient imbalances affect, to *G. abietina* the resistance of Scots pine.

Investigation of the Sustainability of some Management Practices of the Rainforests of Ghana Using Individual Tree-Based Simulation Models

Kwaku Appiagyei Nkyi
University of Science and Technology, Department of Silviculture and Forest Management, Institute of Renewable Natural Resources, Kumasi, Ghana, West Africa
Tel: 00 233 51 60381, Email: bot152@abdn.ac.uk

The sustainability of tropical rainforest management is currently the subject of strong concern and interest. GHAFORGROM, a semi-stochastic simulation model is used to predict the growth and yield of the natural tropical high forests of Ghana, using individual trees as the basic unit of growth entities. GHAFORGROM has been used to evaluate the biological sustainability of some management practices currently being used for the rainforests of Ghana. Simulation studies employ felling cycle analysis and yield estimation to demonstrate the sustainability of logging. The studies indicate that for a specified logging rule, selection harvesting could sustain a viable timber harvest of about 0.2133 m^2 ha^{-1} yr^{-1} or 3.4 m^3 ha^{-1} yr^{-1} for a 40-year felling cycle for trees of dbh > 10.0 cm. For trees of dbh > 10.0 cm, 40-year felling cycle is the minimum number of years to ensure sustainability using a specified logging rule. It takes about 80 years for the basal area or volume of trees of dbh greater than specified felling diameter limits for timber classes 1 and 2 species to regain their initial value. Similarly, it takes about 110 years for the basal area or volume of trees of dbh greater than the specified felling diameter limits for timber class 1species to regain their initial value.

Lignum: Towards a (Forest) Scientist's Workbench Using Scientific Visualization.

Jari Perttunen, M. Lehtonen and R. Sievänen
The Finnish Forest Research Institute, Vantaa Research Centre, P.O. Box 18, FIN-01301 Vantaa, Finland
Tel: +358-9-85705362, FAX: +358-9-85705361, Email: jari.perttunen@metla.fi

When three dimensional tree models become more and more popular one of the questions that rises naturally is how to present the results produced by the model to the scientist. Plotting some characteristics, e.g., the taper curve, on a data sheet is always an option but these often two dimensional ways of presenting data fall short with the three dimensional models like Lignum.

Lignum is a three-dimensional tree model and the natural way of presenting its simulation results to use scientific visualization. This is often the fastest way to understand, analyze and communicate the results. Currently a simple "scientist's workbench" has been developed using industrial standard OpenGL programming library to visualize the simulations of Lignum. Using this workbench scientists can take different views of a tree depending on his or her interests. It is possible to view the general appearance of the tree, examine its architecture or scrutinize the internal structure of it, to study, e.g., the formation of heartwood. Naturally the scientist can interact with the tree or a group of trees by taking different viewpoints in the program.

The scientific visualization of trees generated by Lignum can be taken a step further. Virtual reality (VR) represents computer technology where it is possible experience artificial computer generated environments. The environment is generated by a computer and is presented with an ordinary (stereo) computer display, with special devices like display helmets or in a special virtual room where the images are reflected on the walls, ceiling and the floor. The user can interact directly with the artificial environment with medium that transmits movements allowing feeling things, to touch things and to hear them very much like in the physical world. Regarding Lignum the idea of virtual rooms is worth pursuing with, e.g., CAVE like systems that are becoming popular. A tree generated by Lignum is shown in a CAVE system.

Another (research) problem in the scientific visualization of model trees is how to present large complicated data sets effectively. One approach to solve this problem is to use level of detail (LOD) techniques where alternate representations of an object or a scene with varying levels of complexity can be specified. For example several graphical models with different accuracy can be specified to visualize the foliage. Depending how far or close the scientist is from the tree the appropriate model can be chosen to give realistic image of the foliage. Some examples of LOD techniques in the conjunction with Lignum are shown.

Management of Deciduous Forest in Central Cambodia - A Case Study in Sandan District

Nophea Kim Phat, Syphan Ouk and Yuji Uozumi
Gifu University, Laboratory in Shinshu University, 8304, Minamiminowa, Kamiina, 399-4598 Nagano, Japan
Tel: 81(265)771514, FAX: 81(265)771515, Email: fplan01@gimpc.shinshu-u.ac.jp

It is believed that one of the key points to ensure the sustainable management of the forests is to understand their population dynamics. The aim of this paper is to provide useful information on the population dynamics of Cambodia's deciduous forest, as a basis for management decision making. Cambodia was one of the most heavily forested countries in the world, but a large proportion of forest has been destroyed as a result of wars and political instability over the past 30 years. Forest management in Cambodia has been difficult because until recently, there has been very little scientific research to provide the required information. The management purpose for deciduous forest is to harvest fuelwood and poles for local use. It is managed on a 12-15 years selective felling cycle. By 1997, deciduous forests covered about 4 million ha or 38% of the total forest area in Cambodia. Under the national forest inventory project, Sandan district, in central Cambodia, was chosen to conduct a forest inventory. With a population of 40,000 people, Sandan has a total land area of 280,000 ha, 92% of which is fully forested. Deciduous forest covers 24,900 ha or 8% of the total forest area. Approximately 131 inventory clusters were laid out on the map, but, due to security problems, only 63 clusters were successfully established in the field. Of this figure, 4 clusters were established in deciduous forest, containing 36 plots or 4.32 ha of forest. Statistical analysis showed that the average density was 596 trees/ha, of which trees with a diameter of 5-9 cm comprised 53%; trees 10-29 cm, 33%; and greater than 30 cm accounted for 14%. In terms of species, 11% of total trees were from the family *Lyrthraceae*; followed by 7% of *Myrtaceae*; 4% of *Dipterocarpaceae*; and 36% of unknown and minor families. The average volume per hectare was 107 m^3, of which the volume trees within DBH greater than 30 cm was 102 m^3. On a felling cycle of 15 years, the mean annual allowable harvest volume is 7 m^3 /ha. There is a need to firmly protect the forests from repeated encroachments by outsiders so that the young trees can naturally regenerate and reach the harvesting size over a period of 12-15 years felling cycle. A further vegetation research is also needed since the proportion of unknown trees is still remained high. All these trees will produce additional wood for the present and future needs. In addition, political will and the cooperation of all parties involved are required to ensure long-term sustainable management of the forests.

Acknowledged Seed Stand (Bald Cypress) *Taxodium distichum* Rich. in Croatia

K. Postenjak, M. Gradecki
Forest Research Institute, Jastrebarsko, Cvjetno naselje 41, 14050 Jastrebarsko, Croatia
FAX: +385 1 628 1 493, Email: Marijag@sumins.hr

In 1933 a culture of Bald Cypress (*Taxodium distichum* Rich.) was raised in the Mirna river valley (in region III and zone Ja in the seed unit "Da") by the planting of plants with seeds from an unknown provenance. In 1960, after phenotypical assessment and determination of site class, they were entered into the Register of acknowledged seed stands in the Republic of Croatia. During the first 30 years the culture of Bald Cypress was not managed, which had a significantly negative consequences on growth and increment of this stand. The first thinning was carried out in 1959, when 61 trees were felled (i=12.87% of the number of trees). The second thinning was performed in 1961, when 63 trees were felled (i=14.32% of the number of trees). The thinning effectively influenced increment in the stand. Since that time no thinning has been carried out. At the age of 30 years the culture had 1100 trees/ha, a basal area of 44.30 m^2/ha, growing stock 265.50 m^3/ha, annual increment of growing stock 29.65 m^3/ha, which at the age of 65 years the culture had 593 trees/ha, basal area of 96.85 m^2/ha, growing stock of 1458.12 m^3/ha, and annual increment of growing stock 35.77 m^3/ha. Mean basal area tree in the 65th year had diameter breast height of 45.31 cm, height 29.6 m, stem length 11.3 m, crown length 18.3 m, crown width 6.95 m, crown volume 231.29 m^3, crown shape (crown width/crown length) 0.3798, crown development (crown length/height) 0.6182 and site index (crown width/diameter) 15.3388. The presence of 6.33% negative trees was determined in the stand. Although, during its growth this stand was mainly left unattended, i.e. no management was undertaken (neither were silvicultural works carried out, tending, clearing and thinning), the measured parameters undoubtedly indicate the significance of the Bald Cypress as a fast growing, allochthonous species. Its site in zone III J suggests that it could, and should, be utilised in this zone and in zone II G, in sites with stagnant or limited running water, such as swampy areas in the vicinity of our large rivers and their estuaries (particularly with regard to the Neretva river and the marshlands of the Drava, Danube and Sava rivers) which are suitable for the recultivation with the above fast growing species, whose wood is valued because of its extremely good quality and versatility.

A Study on *Buxus* Growth in Hyrcanian Forests (Iran)

Teymoor Rostami Shahraji
Gilan University, Dept. Forestry, Post Box # 41335-3179, Rasht, Iran
FAX: +131 37022, Email: trostami@agri.gu.ac.ir

Box tree (*Buxus hyrcana*, Pojark) grows in southern part of the Caspian sea from -20 to 1200 meters altitude. It is scattered in small and large area extending from Astara to east of Kordkoey (45 to 54 Longitude). The objective of this study is to indicated the Box tree growth and performance in different forest conditions. The tree height, dbh and under story vegetation were measured in separate plot at each study area. The obtained results were indicated that apart from geographical differences the edaphic factors affected Box tree growth. Soil texture analysis indicated that the loam soil texture is the most desirable for Box tree. However Box tree highly shade-tolerant but more light enhances to its natural regeneration. The vegetation study indicated two types of plant communities in three study areas.

Birch as an Admixture in a Young Pine Stand

Timo Saksa, Valkonen, Sauli
Finnish Forest Research Institute, Suonenjoki Research Station, FIN-77600 Suonenjoki, Finland
Tel: +358175138300, FAX: +358 17 513 068, Email: saksa.timo@metla.fi

Keywords: pine, birch, sapling, mixed stand, competition

In the Nordic countries, the principal management objective for Scots pine (*Pinus sylvestris* L.) stands is to produce high quality timber. The key quality factor is branchiness, which is mainly controlled by site fertility and stand density. The current stocking levels used in Finland, about 2000 seedlings ha^{-1} at planting, seem far too low for a satisfactory quality development in young pine stands. Stocking levels from 4,000 to 8,000 stems ha^{-1} would be required to ensure optimum quality. This can be achieved in direct seeding. However, the problem is greatest on fertile sites where direct seeding is not a feasible alternative to planting because of intensive weed competition. Increased planting density is not considered an economically feasible solution to the problem either.

The number of pine or spruce (*Picea abies* K.) seedlings emerging from natural seed sources is generally quite small on these fertile sites. Additionally, they can not keep up with planted pine seedlings in height growth. The most promising solution available at the moment seems to be the utilisation of naturally regenerated birch seedlings (*Betula verrucosa* Ehrh., *Betula pubescens* Ehrh.) as an admixture in young pine stands. The admixture of birch should be retained until the pines exceed 7 - 8 meters in dominant height in order to enhance the wood quality of pines. However, pine and birch show substantial differences in their height growth rhythms, causing problems for the regulation of stand dynamics and the competition pattern between the species. Planted pines and naturally emerged birches often differ in age, which further complicates the possibilities to use birch as an admixture.

The aim of this study was (A) to compare the height development of planted pines and naturally emerged birches within stands, (B) to describe the competition between pine and birch using the distance dependent competition model approach (C) to evaluate the possibilities to enhance the external quality of pines with a birch admixture in practical forestry. The average number of naturally emerged birches and its variation in young stands planted for pine were studied in a field survey data in Southern Finland. A data set from temporary sample plots with mapped trees was used to study the height development and external quality of birch and pine saplings. Individual tree height and diameter increment and branchiness were predicted using distance and size dependent models. A set of permanent plots with varying competition situations has been established in order to monitor the dynamic competition patterns of the species.

Site Factors Effecting on Growth of Oak Coppices in Turkey

Nedim Saracoglu, Birsen and Ali Durkaya
Zonguldak Karaelmas University, Bartm Forestry Faculty, Turkey
FAX: 90 378 2277421

Turkish forest area occupies about 26,6% (20,7 million ha) of entire land area. Of which 48% is productive. Productive high forests cover about 39.4% of total forest area and 10.5% of total land area. Estimated total annual wood increment in Turkish forests is about 34 million m^3. Annual total wood production including private is about 28 million m^3, of which 63% is consumed as fire wood.

Coniferous species make up about 54% and broad-leaved species 46% of designated forest area. Among coniferous pine, fir, spruce and cedar and among hardwoods oak, beech, chestnut, hornbeam and alder constitute the major tree species. Among broad-leaves species oak with 34 subspecies has 6 million ha forest area. Therefore Turkey is known as an oak paradise. In terms of biological diversity, Turkey is one of the richest countries in the world too.

This research was carried out in Bartin region at north-west of Turkey in order to determine the site factors effecting on growth of oak species. 31 sample plots were laid out in this region. One year old and six years old heights were measured on three dominant shoots in each sample plot. Physiographic characteristics of sample plots were determined. Soil samples were taken from digger soil profiles. By soil analysis in laboratory, data related to soil properties will be obtained for sand, clay, dust, N, Ca, K, Mg, Na, CEC.

Simple and multiple regression analysis were used to evaluate the data. In regression analysis, the six years old shoot heights were used as dependent variables and the effects of different site factors on it. The main results of this research are as follows: For the upper layer (0-10cm) and lower layer (30-40cm) of soil sand, dust and clay factors are more effective on growth of shoots than others.

An Inquiry For Estimation Of Stand Density At Biological Optimum

Sanniyasi Shanmugasundaran
1/41, Thanam Nagar Nagar, Mugalivakkam, Chennai, India

Stand density is a significant variable in determining the productivity of forest crops. Biologists, particularly foresters find estimation of optimum density of crop an evasive issue. Nevertheless the relationship of a rectangular hyperbola between density and crop-diameter has been used to search for the existence of any natural law which determines biological optimum density. Finally an indication of the existence of such a biological law has been discovered and reported herein. The law suggests that the aphotosynthetic living surface, in other words the cambial area of a stand reaches the biological maximum, which equals the land area occupied by the crop. The under-bark bole surface area is a good proxy to the cambial area. Area of bole surface is easily measurable in the field.

Cyclic and Morphological Aspects of Relationships between Growth and Cone Production in Stone Pines of Eurasia

Vladislav Vorobjev, Dmitry Savchuk, Nina Vorobjeva and Zhao Guang-yi
Russian Academy of Sciences, Siberian Branch, Institute of Forest, the Filial, Academichesky prospekt 2, 634021 Tomsk, Russia
Tel: +7 3822 258855, FAX: +7 3822 258855, Email: root@ienc.tomsk.su

The dynamics of the reproductive activity (cone production) and radial growth (tree-ring width) were studied in 3 species of stone pines (*Pinus sibirica*, *P. cembra* and *P. koraiensis*) in several localities of West Siberia, Khabarovsk Region, Northeast China, and Altai and Carpathian Mountains. To investigate radial growth dynamics, we use the standard procedures (Stokes and Smiley, 1996). To examine the entire cone production dynamics, we use the original methods of identification of the seed cone scars and traces on the bark and cross-sections of annual shoots of cone-bearing branches (Vorobjev et al., 1994). Methodic difficulties for the identification of the scars and traces in *P. koraiensis* were determined by its too long summer shoot and scaling the bark of shoots over 20-25 years old. The following reproductive time series were built for up to 100 years before the present: the number of initiated seed cones per one shoot, the number of 1-year (pollinated) seed cones per one shoot, and the number of 2-year (normally mature) seed cones (cone crop) per one shoot. We also built growth time series (ring width). Both the reproductive and growth series were converted into index ones and averaged to obtain local chronologies (Graybill, 1983). The number of xylem and cambial cells were calculated and their sizes were measured on tree female shoots which produced and did not produce the 1-year and 2-year cones. The structure of cyclicity of the radial growth and reproductive activity in 3 stone pines in-cludes 2.8-3.6, 3.3-3.7, 4.2-4.7, 4-5, 5.1-5.6, 6.5-7.2, 7.5-8.4, 10-11.5, 12-14, 16-18, 20-25, 26-29, 32-34, and 58-68-year cycles. Each pine has itself cycles of the cycle set. The uncoincidences of the curves are explained by regional and local conditions (first of all, climate). The fundamental differences between growth and reproductive processes are found in little cycles (up to 5-10 years). Smoothing the curves of radial growth and reproductive activity indicates on negative correlation between them. The aborted initiated, unpollinated and immature cones disturb the cyclicity of cone crop in all pines. In *P. koraiensis* the heavy crops, great cones, thin latewood in summer shoot are causes that the tops of the cone-bearing branches are broke off. New branches instead of broken ones do not produce cones for 2-4 years. This process also disturbs the crop cyclicity. The cyclicity of reproductive activity of the first-order branches determines that of a tree. Annual fluctuations of the number of the initiated cones have less amplitude than those of the number of mature ones. In the growing female shoot axis the size of cambial zone decreases by 15-20% during flowering before and increases by 20-28% during flowering after development of the 1-year cones. Xylem dimension increases by 45-50% for the same period of time. Influence of the 2-year cones at the status of cambial zone is the same as 1-year ones. The differences are only in varying degrees of size changes. The size of xylem decreases by about 15-20% in time of linear growth of the shoots and development of the 2-year cones when the 1-year cones are absent. The xylem size increases by 30-40% at the same time when the 1-year cones are present. Thus the size of the xylem and a degree of growth changes depend on reproductive load. The size of the cambial cells increases also. So development of the 1-year cones is favoured to rise the cambial cell division activity and xylem cell differentiation. The number of the xylem cells and the size of the cambial cell reduce during growing season under conditions of 2-year cone nutrition. These changes and differences above allow to propose that the decrease of the cambial cell differentiation activity is a cause of the xylem growth diminution.

Height Growth Pattern of Dominant White Spruce in Relation to Natural Regions in Alberta

G. Geoff Wang, Shongming Huang
University of Winnipeg, Department of Biology, R3B 2E9 Winnipeg, Canada
Tel: 204-786-9407, FAX: 204-774-4134, Email: wang@uwinnipeg.ca

Based on provincial stem analysis data of 1018 felled dominant and codominant trees, the height growth pattern of white spruce (*Picea glauca*) were compared among the five major natural regions (1-Central Mixedwood, 2 - Dry mixedwood, 3 - Wetland Mixedwood, 10 - Upper Foothills, and 11 - Lower Foothills) in Alberta. The comparison used the ratio of height at 70 and 30 years of breast height age (Z ratio) as a quantitative measure of height growth pattern (i.e., the response variable), site index (height at breast height age of 50 years) as the covariate, and natural region as the factor. The result indicated that (1) the height growth pattern in Wetland Mixedwood was significantly different from other natural regions and (2) no significant differences in height growth pattern were found among other four natural regions. Two reference-age invariant polymorphic height and site index curves were developed for the Wetland Mixedwood region and the rest four natural regions, respectively. Comparisons between the two curves indicated that, for the same site index, trees in the Wetland Mixedwood region grow slower (when site index 15 m) or faster when site index <10 m) after site index age depending on site quality. It was recommended that these natural region-based curves should be used for predicting white spruce site index or height at any age in Alberta.

4.01.04 Modeling regeneration and the development of young forests

Effects of Global Change on Forest Disturbance and Regeneration: A Gap Model Study in the Netherlands.

Peter J. van der Meer
Institute for Forestry and Nature Research
Tel: 0317 - 477891, FAX: 0317-424988, Email: p.j.vandermeer@ibn.dlo.nl

Numerous different patch or gap models have been used to estimate the effect of global warming on forest ecosystem functioning (e.g. Shugart & Smith 1996). In gap models (Jabowa-Forêt type) forest processes (like establishment, growth, and mortality) are simulated on a relatively small patch ("gap"). In general the gap size is determined by the area which is occupied by a mature tree. Key processes in most models are growth, recruitment and mortality of individual trees.

Modeling of growth in most gap models is well advanced. In the new generation gap models, growth is described by physiological processes at tree level, as opposed to a more descriptive approach of plant growth in the old generation gap models. However, recruitment and mortality are not that easily described and thus modelled. Seed dispersal patterns and early seedling growth and survival are greatly affected by stochastic processes and therefore hard to predict. Tree mortality is poorly understood and stochastic events like storms, insect outbreaks etc. play an important role. As seedling establishment is a fundamental step in forest regeneration and succession, the processes in gap models simulating tree mortality, canopy gap formation, and seedling recruitment will have to be improved.

In this study functional relations in recruitment, (seedling) growth, and mortality are further refined to improve an existing gap model. This improved gap model will be used to investigate whether and how different climate change scenarios affect patterns of tree mortality (gap formation) and recruitment (establishment & seedling survival to 2m tall) for three forest-types in the Netherlands. Consequences for long term forest development will be discussed.

4.01.08 Environmental effects on forest growth and stand dynamics

Evaluating Growth and Stand Dynamics under Climate Change and New Management Strategies. Model Studies with the Forest Succession Model 4C

Franz-W. Badeck, Harald Bugmann, Petra Lasch, Marcus Lindner, Jörg Schaber & Felicitas Suckow
Potsdam Institute for Climate Impact Research, Post Box # 601203, D-14412 Potsdam, Germany
FAX: (49) 331 288 2695, Email: badeck@pik-potsdam.de

We use a new forest gap model 4C (*Fores*t *E*cosystems in a Changing *E*nvironment) to evaluate growth responses and stand dynamics under climate change conditions. The current generation of forest gap models can be classified into two broad categories: On the one hand, there are fairly simple models that largely ignore ecosystem functions like biogeochemical cycles and concentrate on structural effects. On the other hand, there are quite complex, "mechanistic" models that attempt to link structural and functional aspects of forests within a single framework, but those models can deal with few tree species only or are restricted to short-term investigations. We propose a new approach to simulating long-term forest development that is based on ecological and evolutionary theory about the functioning of plant communities. The resulting model is considerably more "mechanistic" than classic models, but less complex and thus computationally less demanding than the existing "mechanistic" models.

4C does not only describe the succession dynamics in natural forests but has been complemented by modules which allow for simulation of management practices and initialization of stands from inventory data. Currently the model is parameterized for temperate forests in Europe.

Results from simulation experiments under scenarios of climatic change and future CO_2 levels will be presented. The development of current forest vegetation on regional scales will be investigated. In many European countries new forest management strategies are discussed. Specific objectives are species composition more close to natural forest vegetation, minimization of risks due to climate change, cheaper regeneration practices, and enhancement of recreational and ecological services of forests. Forest management strategies based on different weights assigned to yield, risk minimization and non economic services will be studied. The discussion focusses on the impact of climate change on multi-functional forestry in Central Europe. Possible response strategies are elaborated.

European Forest Ecosystems: Building the Future on the Legacy of the Past.

E. P. Farrell, E. Führer, D. Ryan, F. Andersson, R. Hüttl, P. Piussi
University College Dublin, Department of Environmental Resource Management, Dublin 4, Ireland
Tel: +353 1 706 7716, FAX: +353 1 706 1102, Email: ted.farrell@ucd.ie

The viability of the many civilisations of Europe has depended, to a very large extent, on an adequate supply of wood. In the Ancient World, this supply was secured through the exploitation of forest reserves, the conquest of new territories and, when these opportunities no longer presented themselves, through the conservation of diminishing resources. Ultimately, civilisations collapsed because of the shortage of wood. Although some silvicultural techniques were known in the pre-Christian era, the scientific management of forests was not widely practised until the late eighteenth century. It is argued that the controlled exploitation of "nature", on sustained yield principles, only became possible when men came to view the forest, not as a nuisance, an Arcadia or a pagan horror, but as a centre of wood production, a biological factory.

The emergence of scientific forestry, however, did not put an end to the exploitation of forest resources. Unregulated felling and traditional practices such as litter raking exerted an insidious, negative influence on the fertility of the soil. The impact of human exploitation has often been underestimated by scientists, in recent decades, in particular, in the context of forest decline.

While sustainable management, seen as sustained yield of wood supply, has been practised in forestry for centuries modern ideas of sustainability are broader in scope, embracing all the goods and services of the forest. Increasingly, forests are being managed as multifunctional ecosystems, often for amenity purposes.

Forest ecosystem research, which developed from a range of traditional, highly focused disciplines, requires, if it is to make a meaningful contribution to forest management, long-term interdisciplinary studies. It provides the basis for ecologically intelligent management decisions and as such, is central to the development of sustainable forestry management. Central to the successful implementation of research findings is their efficient transfer from the researcher to the manager. If the research community identifies such an interchange as an important part of their duties, it will be a decisive step towards the better use of forests in Europe.

It is only by deepening our knowledge of the past, accepting the challenge of the present and acknowledging that, as researchers, we have also a responsibility to communicate with users, that we can foster the growth in wisdom which is fundamental to the wise use of Europe's forests in the next millennium.

International Ecological Collaboration in Russian Far East

Leonid Kondrashov
71, Volochaevskaya Street, 680030 Khabarovsk, Russia
Tel: (4212) 21 79 52, FAX: (4212) 21 67 98, Email: postmaster@leokon.khabarovsk.su

Current scale and the acuity of the ecological problems determine the necessity of their solution by joint efforts not only of individual scientists but institutions, countries and international community en masse. The banding of endeavors and resources provides the opportunity to soften, solve and forecast ecological problems with a greater effectiveness. Russian Far East, due to its huge nature resource potential, degree and possibilities to influence the climate change and other ecological problems of global-regional interconnection increasingly attracts the attention of international scientific community first of all as the source of getting information in the extreme conditions, test range to drill the methods, experiment ground, monitoring and check and exploitation of the advanced equipment. Today, on the territory of the region there are not less than 50 international ecological programs with sufficiently large financing are fulfilled. The analysis of main research directions shows a mammoth scale of works implemented by the international scientific community inside Russia. Practically, the projects are formed and actively developed on ecosystems disturbances generated by natural and anthropogenic causes; trace gasses fluxes; aerosol emissions and their transportation; carbon modeling: hydrology; permafrost; the history of climate and land cover disturbances; remote registration of the events and their modeling, etc. However, the leading field of collaboration is the forest complex. The Far east has 3% of world's forests. These forests represent a mammoth potential for carbon sequestration plus a possibility to maintain terrestrial ecosystems stability of the neighboring countries of the Pacific region. In spite of the fact, that in overwhelming number of research directions Russian science has a significant backlog, it is presented in many international programs insufficiently, not fully presented in international turnover the available Russian scientific data already published in the domestic literature. The program and projects diversification gives the foundation to talk about the necessity of rapid work coordination development, their management improvement, compatibility of results elevation using a wide range of discussions and publications. Russian party coordinative efforts are bringing recently some results: such important research directions as 90 and 135 meridians are admitted worth to arrange works and International Steering Committee of International Geosphere Biosphere Program is discussed for these purposes with a wide representation of Russian specialists. And regional interested institutions could be used as infrastructure bases for international projects realization with the assistance of local scientists. The prospects of further international ecological collaboration development are increasingly depending not only on the goodwill of the representatives of the scientific community, but also on the ability of many cooperative parties to work jointly and solve arising problems.

Carbon Sequestration in Forest Ecosystems: Presentation of a General Evaluation Tool and Generic Case Studies Using the Model CO2FIX

G. M. J. Mohren, O. Masera & G.J. Nabuurs
DLO-Institute for Forestry and Nature Research (IBN-DLO), Post Box # 23, NL-6700 AA Wageningen, Netherlands
FAX: +31.317.424988, Email: g.m.j.mohren@ibn.dlo.nl

Carbon sequestration rates in forest ecosystems can be derived from biomass growth rates, combined with understanding of soil organic matter dynamics, and an analysis of the amount of carbon in woody products removed during timber harvest. In this paper, an overview of the main aspects influencing forest ecosystem carbon balances will be given, and a general model (CO2FIX) will be presented together with model results for a range of case studies in forest ecosystems world-wide. This model is being developed as part of an EU-funded INCO-DC project, in which an Internet-based user platform applies the model to selected case studies, especially in the tropics and sub-tropics (EU-CASFOR). The model, which is available on the project's Internet site, can be used to estimate the carbon sequestration potential of aforestation and reforestation projects, and can be used to quantify the effect of different types of forest management and forest use for the overall carbon budget. The model includes submodels for forest growth, forest management, utilisation of harvested products, and soil organic matter dynamics. It will be shown how the model complies with IPCC guidelines, and what the consequences are of the various definitions of aforestation, deforestation and reforestation as indicated in the Kyoto-protocol. Also, consequences of various types of forest management such as selective, low-impact logging and other sustainable forest management systems in tropical forests will be quantified with respect to their consequences for the overall carbon budgets will be outlined in a case study of Mexico and Costa Rica.

Interim Protocol for Sampling and Measuring Changes in Soil Organic Matter and Physical Properties Following Harvesting of Native Forests

M. Abdur Rab, John Raison and Jürgen Bauhus
Centre for Land Protection Research, Department of Natural Resources and Environment, Ballarto Road (PO Box 48), 3199 Frankston, Victoria, Australia
Email: A.Rab@nre.vic.gov.au

Forest roading, harvesting and regeneration operations can have a substantial impact on forest soils, including soil compaction, soil profile disturbance, soil erosion and changes in nutritional capacity. Soil compaction and soil profile disturbance change bulk density, porosity, soil strength, infiltration and saturated hydraulic conductivity. These effects in turn, can have a substantial impact on forest growth and floristic composition and in forest hydrology. For example, it may take more 25 years for soils to recover from compaction. Formal monitoring and evaluation of forest soil changes is expected in the near future as a basis for sustainability accreditation under Montreal process, ISO and/or consumer driven initiatives. Monitoring by planners, supervisors and contractors provides a basis for the continuous improvement in forest operations that will be required to attain sustainability accreditation. The purpose of this study was to provide forest practitioners with a simple system for monitoring and improvement of their on-ground roading, harvesting and regeneration operations. Sampling methods and systems for stratifying soil disturbance were critically reviewed and a draft protocol for assessing change in soil properties, particularly

Montreal process soil indicators was developed. Calculation and statistical methods are provided to make quantitative statements of the accuracy of the estimates of various soil disturbance classes and Montreal process soil indicators 4.1d and 4.1e. The protocol was tested on 30 harvesting coupes in southeastern Australia. The interpretation and evaluation of the indicators will differ for different soil and forest types. As an example, a method for evaluating soil indicators is presented for Victorian mountain ash (*Eucalyptus regnans*) forest.

Modeling Environmental Effects on Forest Growth

Laszlo B. Szendrodi
West Hungarian University, Faculty of Forestry, PO Box 132, 9401 Sopron, Hungary
Tel: +32+2-296-5502, FAX: +32-2-296-4289, Email: Laszlo.Szendrodi@dg12.cec.be

Growth of the trees regulated by several internal (age; genetic bases; health conditions; etc.) and external (temperature; soil conditions; hydrological conditions; light, water and nutrients available; etc.) factors regularly as well as by disturbances (competitions, wild fire, grazing, frost, windstorm, epidemic events, environmental pollutants, etc.) sometimes. These factors and/or events are usually changing by space and time. Process models and empirical models were developed to describe growth of individual trees. Although these models are also very complex, modeling of growth relations for forest stand with distance dependent/independent single tree or stand models are much more sophisticated. Structures of process models would be appropriate to model environmental effects on growth of trees and stands. Unfortunately, stand models based on process modeling have not satisfactorily developed for practical use till now. Not only the models but also methodologies of modeling are essentially important for further developments.

The most important goals of the estimation would determine the structure of the model. Estimation of growth relations of a tree species for a certain site requires quite different empirical models than estimation of growth relations for the whole distribution area of the same species. Large area always contents more independent variables, which are changing by time, also. The site (characterised by similar soil, hydrological and climate conditions) is usually an adequate unit for structuring the model. Only a module system of sub-models is an appropriate tool for modeling growth of trees and/or stands under various conditions and different environmental effects. The model must content all the important factors as independent variables while the dependent variable is the biomass production of the single trees. Relations among independent variables practically are multiplication. Linear approaches are usually not applicable, because asymptotic limitations of the growth appear. That way asymptotic, "n" dimensional mathematical equations as "n" dimensional growing surface can describe the growth of the single trees under changing environmental conditions and effects. The structure of this growing surface in general:

$$B = A\ f1\ (x)\ f2\ (y)\ f3\ (z)\ \text{etc.}$$

where B is biomass production of single trees as dependent variable; A is an asymptotic value for growth of the species on the site; f1, f2, f3, etc. are non linear equations; x, y, z, etc. are independent variables.

Independent variables and equations are sub-models, and can be changed by different needs in the general model. Calibrations of the parameters require adequate databases.

4.01.00 / 4.02.00 / 1.07.00 Using growth models for better forest management in the tropics

Rapid Methods for Estimating the Age and Growth Rate of Rattan Stems in Lao PDR

Tom Evans, Khamphone Sengdala, Oulathong V. Viengkham, Banxa Thammavong
Darwin Initiative Project on Rattan Diversity and Sustainable Management, Box 8916, Vientiane, Lao PDR
FAX: 00 856 21 732282, Email: tom.evans@plants.ox.ac.uk

Measuring rattan growth rates is valuable because it allows one to estimate the potential sustainable yield from natural populations. However, estimating growth rates from permanent sample plots is labour intensive, takes several years to produce robust results and is always vulnerable to theft of the study plants or discontinuities in funding or personnel. It is not feasible to establish enough permanent plots to cover the wide range of species and habitat types for which data are required. This study examines two potential methods of aging stems directly to allow calculation of growth rates in the space of weeks rather than years. One involves analysis of the frequency and spacing of flowering events, which are believed to be annual and strongly seasonal in the strongly bi-seasonal Lao climate. The average spacing of such events probably indicates the average annual growth of reproductively mature stems. The second involves analysis of the variation in internode characteristics (especially length and diameter) in relation to the season in which they are produced. Some cyclical variation can be detected in these characteristics at the level of small populations - these cycles may relate to annual cycles of growth, and thus indicate annual growth rates. Data collection for this study is underway at several sites in Lao to calibrate these rapid methods against traditional long-term permanent plot methods. The dates of appearance of internodes and inflorescences will be recorded to confirm whether or not cycles really are annual.

La structure diamétrique de *Celtis zenkeri*: un indicateur du type de forêt dans laquelle l'espèce est rencontrée. Conséquence pour l'aménagement

Eric Forni
CIRAD-Forêt, BP 2572 Yaound, Cameroun, France
FAX: 237 20 29 69, Email: forni@camnet.cm

Cette étude est effectuée à partir des données de l'inventaire d'aménagement du projet Aménagement Pilote Intégré (API) de Dimako dans l'Est du Cameroun. Cet inventaire est de type systématique à 1% et couvre une superficie de 500 000 ha.

On décrit la structure diamétrique de *Celtis zenkeri* dans la zone inventoriée. Des variations importantes sont observées, la structure diamétrique de cette espèce pouvant passer progressivement d'une courbe en « J » inversé à une courbe en cloche en fonction de l'endroit où elle est observée.

Ces variations sont analysées en relation avec les types de forêts dans lesquelles *Celtis zenkeri* est rencontrée, son tempérament et l'histoire ancienne (passé paléoclimatique) et récente (action anthropique) de ces forêts.

Les conséquences de cette variabilité sont analysées dans l'optique de l'aménagement durable des massifs forestiers du sud-est du Cameroun.

Growth Rates and Dynamics of a Tropical Primary and Secondary Forest in the Amazonian Region, Brazil

Guilherme Luís Augusto Gomide, José Natalino Macedo da Silva
Paraná Federal University, Doctoral Programme, Curitiba, Brazil
Tel: +55 41 254-1128, Email: ggomide@cce.ufpr.br

The variations of the species composition, horizontal structure and dynamics (recruitment, growth and mortality) of an unlogged (primary) forest and of one that had been clear felled (secondary forest) were studied over a period of 11 years, through continuous inventory. The area is located at the "Felipe" hill, and belongs to Jari Celulose S.A., in the State of Amapa.

A total of 169 species were found in the first inventory of the unlogged forest (1985) and 184 in the second one. Over the period of recording, the primary forest showed a 3% increase in absolute abundance and no significant variation regarding the species with the greatest abundances and frequencies. The forest showed a diameter distribution with J-reversed shape, for the whole forest as well as for the commercial groups of species. Between 1985 and 1996, the basal area of the forest almost did not vary, going from 35,61 to 35,54 m^2/ha. The volume revealed a 1,6% decrease between 1985 and 1996. The commercial and potentially commercial groups of species showed greater values of basal area and volume, when compared to the non-commercial ones. On the other hand, the non-commercial groups of species presented quite a greater value of abundance.

The secondary forest had 176 species in 1985 and 174 in 1995. During the observation period, the abundance of the forest increased in 217%. Over the period, the pioneer species of the *Cecropia* genus, dominated the area in abundance, frequency and dominance. At the end, a decrease in the number of plants of these species in the classes of seedlings and saplings was observed. As in the unlogged forest, the secondary one showed and J-reversed shaped diameter distribution, although with a less steep fall in the number of plants per DBH class. The forest presented a great variation in basal area and volume, the figures being, respectively, 760% and 710%. On the contrary of the primary forest, the non-commercial group of species dominated in basal area, volume and abundance in the secondary stands.

The periodic annual increment (PAI) of diameter, in the unlogged forest, was 0,14 cm/year and for the commercialization groups I, II, and III, the PAIs were 9,20; 0,14; and 0,12 cm/year, respectively. The greatest growth rates (PAI) were observed in the greater diameter classes. The growth rates in basal area and volume for the 1985-1996 period, considering all the species of the primary forest, were 0,086 m^2/ha/year and -0,39 m^3/ha/year, respectively. The secondary forest showed a diameter PAI of 0,60 cm/year, and for the commercialization groups I, II, and III the PAIs were 0,46; 0,44; and 0,63 cm/year, respectively. The growth rates in basal area and volume for the 1985-1996 period, considering all the species of the secondary forest, were 2,33 m^2/ha/year and 3,53 m^3/ha/year, respectively.

Considering the whole observation period (1985-1996), the primary forest presented a positive balance, the number of dead trees being approximately 16 ha/year and the number of recruited ones being 13 ha/year. The group of commercial species was the only one that showed negative balance (0,29%), but the groups of potentially and non-commercial ones revealed positive balance of 0,41 and 0,33%, respectively. Analyzing the entire period, the secondary forest showed a positive balance, with a mortality of 111 trees/ha/year and a recruitment of 264 trees/ha/year.

Selected Indigenous Tree Species and Design of Simulation Models for the Multi-Storied Forest Management Project in Peninsular Malaysia Naoto

Naoto Matsumura, Ismail b. Katim, Samsudin b. Salleh, Che Aziz b. Ali, Yoichiro Akioka, Yuzuru Kimura, Kaori Ito
Shikoku Research
Tel: +81 888-44-1121, FAX: (+81) 888-44-1130, Email: nma@ffpri-skk.affrc.go.jp

Keywords: Growth model; yield table; *Acacia mangium; Dipterocarpus*

Since 1992, a joint-project implemented by the Governments of Japan and Malaysia has been carried out in the State of Perak, Peninsular Malaysia. One of the objectives of this project was to examine the artificial conversion of a man-made forest and a selectively felled logged-over secondary forest to a multi-storied forest, considering the effect of industrial planting activities and environmental factors in the country.

As target forest types, hill forest, lowland secondary forest and lowland forest of *Acacia mangium* and rubber plantation were selected. For species selection, twenty-three species were recommended by the project based on the analysis of survival rate, diameter and height growth. For each forest type, following indigenous tree species were selected by multiple growth comparison;

1) Hill forest: *S. leprosula, S. macroptera, D. baudii, S. parvifolia*
2) Lowland secondary forest: *S. talura, S. ovalis, S. leprosula, S. glauca*
3) Lowland forest of *Acacia mangium* and rubber plantation, *S. leprosula, S. parvifolia, S. ovalis*

For planting direction, there were few differences in EW and SN on survival rate, height and diameter growth. About planting types, some significant differences were observed. The narrow planting type (A-type) was better than the wider ones (D-type, E-type) in survival rate. But the diameter growth was better in wider ones. By thinking of planting risks at initial stage and yield operation of crop trees, the C-type (4 rows of upper layer by 4 rows of under layer), D-type (8x8), or the medium type (6x8) were suitable and preferable.

Using simulation models for selected forest types and species, case studies were carried out under some managerial strategies and economic viewpoints of IRR (Internal Rate of Return). As a conclusion, if a high return of investment is only required, a short rotation period of mangium is recommended. However, the disadvantages of monoculture were evident in many cases in practice. By computer simulation, it was demonstrated that the reduction of the initial establishment costs and logging costs would be equivalent to twice the log price.

Growth Dynamic of *Anadenanthera colubrina* VAR. *cebil* and *Tabebuia impetiginosa*. From a Natural Forest of Pantanal Mato-Grossense, Brazil

Patricia Povoa de Mattos, Rudi Arno Seitz
Empresa brasileira de pequisa agropecuaria, C.P. 319, 83411-0001 Colombo, Brazil
Tel: (55-41) 766 1313, FAX: (55-41) 766 1276, Email: povoa@cnpf.embrapa.br

The information on the influence of environmental factors upon growth rate of trees is very important for the development of forestry management programs. The use of growth ring information is being enhanced and this is of great importance for tropical natural forests, where there is a great demand of wood, but usually no registered data are available to structure a management program. The Pantanal of Nhecolandia, sub-region of Pantanal Mato-grossense may be viewed as one of this regions, as its natural forests are being systematically used to extract wood, or deforested to introduce cultivated pastures, but the dynamic of the tree species are still unknown. Climatic and soil factors characteristics of Nhecolandia induce the formation of annual growth rings. The aim of this work was to determine the radial increments of *Anadenanthera colubrina* var. *cebil* and *Tabebuia impetiginosa* by growth ring analysis. The samples of disks of the stem of the trees were collected, in July 1996, in Nhumirim Farm, EMBRAPA Pantanal, located in Nhecolandia sub-region, Pantanal. Disks from eight trees of *Anadenanthera colubrina* var. *cebil* and six of *Tabebuia impetiginosa* were collected at 0.3, 1.3; 2.5; 5.0; and 7.5 m height. The trees were selected, by good canopy formation. The growth rings were counted and measured on eight radii of each disk. The trees of *Anadenanthera colubrina* var. *cebil* were 14-30 years old, with diameter increment at 1.3m height varying from 5.4-8.0mm/year and, *Tabebuia impetiginosa*, 15-30 years old, with diameter increment at 1.3m height varying from 4,8 a 11,6mm. The average time for *Anadenanthera colubrina* var. *cebil* and *Tabebuia impetiginosa* to reach 40cm of diameter was estimated in, at least, 55 years.

The Growth Performance of 15-Years Old Teak By Stump Planting

Hashim Md Noor, Lok Eng Hai and Ong Tai Hock
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603-9432514, Email: kamardin@forr.upm.edu.my

Forest plantations are important in ensuring continuous supply of timber products. In view of this, several high quality timber species such as teak (*Tectona grandis*) are already being tried and planted in a large scale in Malaysia. Such plantation grown timber teak, with promising growth rates can be harvested within a short rotation of 15-20 years. One of the satisfactory planting method is using stumps because of promising growth rates, high survival and other suited economic factors required by the species. Hence, this paper discusses the growth performance of 15 years old teak planted using different stump sizes at Mata Ayer Forest Reserve, Perlis, Malaysia.

Net Primary Productivity of Tropical Tree Species on Semiarid Region

T. Syamala, M.V. Rao
Bhararthidasan University, Dept. Plant Science, 620 024 Tiruchirappalli, India
FAX: 091-0431-660245, Email: mvrao@bdu.ernet.in

The basic problem in forestry in India is the widening gap between supply and demand of wood on account of over population and lower productivity of the planting stock. Hence the goals of forestry involves taking short and long range practical steps which would be pro-nature, pro-poor, pro-women and pro-job generation decision. One type of forestry that emanates from such goals is restoration forestry. This brings about amelioration of degraded forest areas and enhance the productive capacity. The present study reports the net primary productivity of tropical tree species such as *Acacia auriculiformis*, *A. holocericea* , *Casurina equisetifolia*, *Eucalyptus tereticornis*, and *Leuceana leucocephola*, on semi arid region. The total biomass of *A. auriculiformis*, *A. holocericea*, *C. equisetifolia*, *E. tereticornis* and *L. leucocephola* were 16812, 19055,3711, 35460 and 21363. kg per ha. respectively. The ratio of aboveground biomass to belowground biomass was 4.3, 6.8 , .8, 4.5. and 2.6 for *A. auriculiformis*, *A. holocericea*, *C. equisetifolia*, *E. tereticornis* and *L. leucocephala* plantations respectively. The mean annual net productivity (MANP) of *A. auriculiformis*, *A. holocericea* , *C. equisetifolia*, *E. tereticornis* and *L. leucocephala* were 2.4, 3.2, 0.5, 5.1, and 3.1 t/ha/yr. respectively. Biomass accumulation ratio for *A. auriculiformis*, *A. holocericea* , *C. equisetifolia*, *E. tereticornis* and *L. leucocephala* were 2.98, 2.22, 0.88, 3.29, and 3.55, respectively. The total annual litterfall was 2.7, 4.5, 3.1, 5.1, and 2.6,t ha/yr. for *A. auriculiformis*, *A. holocericea* , *C. equisetifolia*, *E. tereticornis*, and *L. leucocephala* respectively. Turnover of litter in *A. auriculiformis*, *A. holocericea*, *C. equisetifolia*, *E.tereticornis* and *L. leucocephala* were 0.7 2, 0.43, 0.73, 0.73 and 0.82 respectively. The turnover time for five species were 1.38, 2.33, 1.40, 1.32 and 1.22 years. The superiority of *E.tereticornis* over others species in total biomass and MANP might be due to its capacity to resist drought, to thrice in low nutrient soils and to grow fast.

4.02.00 Forest resources inventory and monitoring

Shrubs an Alternate Source of Energy / Biomass for Himalayas - An Inventory

Rajesh Uppal, PK Khosla
COA, HP Agricultural University, Department of Agroforestry and Environment, 176 062 Palampur, India
Tel: 91-1894-33961, FAX: 91-1894-30511, Email: atul@hpkv.hp.nic.in

Keywords: Energy; Sustainable development; Denudation; Genetic Resources, Floristic

Energy and environment are on the top most priorities for the sustainable development. As far as the rural scenario of Indian sub-continent is concerned, the two are immediately inter-linked, because of environmental degradation which is to a large extent the result of utilization of biomass for domestic energy consumption. In-fact over 50% of the fuel is consumed in India for cooking. Wood is the principal source of fuel accounting for 68.5% of the country requirement. The demand of wood for fuel and as a raw material in industry has been responsible for the large-scale deforestation that a country has witnessed.

The various factors contributing towards large-scale denudation of hills in the Himalayas are the over exploitation of fuel, fodder, and packing material from forest. Average per capita consumption of fuel wood in Himachal Himalayas is 0.6% per year, amounting to a total of 2.3 M tons per annum as against the prescribed yield of 0.7 M tons from the forests covered by working plan.

The Himalayas are endowed with rich diversity of genetic resources from subtropical to alpine vegetation comprising of mixed broad-leaved forests to coniferous stands and alpine scrubs to seasonal herbaceous flora. The floristic of the region embodies wide repository of economic plants irrespective of their habitat, weather herbs shrubs and trees, the harvesting of timber had been a major source of revenue from forests but the shrubs played an important role in rural economy by providing fodder, fuel, fiber and small timber, medicinal and aromatic sources, etc. Unfortunately, irrespective of their multiple uses, which are available with ease from the forest floor to hill people, these have not drawn the attention of foresters and scientists. This nature's reservoir, capable of self regenerating by coppicing have never been studied as systematic component of any ecosystem both from the ecological and economic stand point of view.

An attempt has been made to develop an inventory of the shrubby flora of Himalayas. In all 128 species have been described with respect to the habit, habitat and ecological niche and the indigenous uses, its potential for integration in the land use etc. Using the herbarium and the local interaction with the people did updating of this d-base. The shrubs due to their hardiness to frost and draught, resistant to pest and diseases are more adaptable to their habitat. There is a huge number of shrubs in sub-Himalayan tract which are not only helpful as soil binder but can provide a plentiful of fuel wood and fodder to the local people hence ameliorate the economic status. These shrubs are also valued for their medicinal properties, therefore it is a prerequisite to make these shrubs an integral part of the program of eco-development and management of watersheds. However the basic priorities in the planting of the shrubs should remain a step towards restoring green cover and subsequently to create favorable conditions for the growth of trees by improving the site. The useful shrubs also have an impact on agro-ecosystem, as these shrubs strengthen the field bunds, check runoff rate, maintains soil fertility, conserve soil, thereby augment economy.

4.02.01 Forestry products collection and sustainable forest management

An Overview of the National Forest Resources Study of Nigeria

Shadrach Olufemi Akindele
Federal University of Technology, Department of Forestry & Wood Technology, P.M.B. 704, Akure, Nigeria
Tel: (234) 34 243 492 (Ext. 2158), Email: femi_akindele@yahoo.com

A study for the assessment of timber resources in Nigeria was commissioned by the Federal Government of Nigeria in 1996 through the Federal Department of Forestry. The overall objective of the study was to provide reliable data on the state of the resources with a view to enhancing industrial forest development and facilitating management of the remaining forest resources in an efficient and environmentally sound way. The study covered three major forest types, namely mangrove forest, freshwater swamp forest and lowland rainforest. The study area consists of 635 forest reserves, covering a total area of 4.8 million ha. The ratio of forest reserves area to total land area is 7.65%. For the field inventory, systematic cluster sampling technique was used for the high forests while stratified random sampling technique was used for the plantations. A sampling intensity of approximately 0.01% was used for both high forest and plantation areas. In the lowland rain forest area, timber-size trees (dbh>=60cm) account for 12.6%, 14.3% and 5.7% of the stem densities in undisturbed, disturbed and highly disturbed areas, respectively. In terms of volume production, these trees account for 62.8%, 61.2% and 41.9% of the volume per ha in the respective areas. Other forest types (freshwater swamp forest and mangrove forest) account for less volume per unit area. The gross volume within forest reserves is higher than that of the adjoining areas. The volume estimates of all tree species (minimum dbh = 20cm) are 140.6 million m^3 and 120.7 million m^3, respectively. Within forest reserves, existing forest plantations cover an area of 184,611 ha, representing only 3.8% of the total area of forest reserves. The three most prominent plantation species in the study area are *Gmelina arborea*, *Tectona grandis* and *Eucalyptus* species, occupying 59.3%, 25.1% and 2.8% of the total plantation area, respectively. In terms of gross volume production, the total yield of *Gmelina arborea* in the study area is about 57million m^3, representing 72.8% of the total volume production from plantations within the study area. When compared with previous studies and projections, results of this study indicate that the forest estate in Nigeria has suffered serious degradation in recent years. The major factors responsible for this trend were enumerated in the study.

Standardization of Propagation Technology of *Viola* Species Containing AIDS Curing Agent

Atul, Neeta Raj Sharma
COA, Himachal Pradesh Agricultural University, Indigenous Agroforestry Technologies for Sustainable Himachal Himalayan Development, 176 062 Palampur, India
Tel: 91-1894-33961, FAX: 91-1894-30511, Email: atul@hpkv.hp.nic.in; atul1028@email.com

Keywords: Standardization, Propagation, *Viola* species, GA3, Flowering.

The use of forest plants as sources of medicines and human sustenance has been in vogue since antiquity. Plant based drugs have created a sweeping resurgence in the west in their favor and the demand for these has reached a scale never witnessed before. The excessive exploitation from the nature has resulted in shrinkage of these plant species while a few others are facing threat of extension and *Viola* species is one of them. The population of *Viola* species is threatened due to the indiscriminate plucking and uprooting of the plant material from natural habitat. The export quantity of this herb has declined considerably (from 2,800 to 710 quintals) during the past few years. Therefore, organized cultivation i.e., selection, propagation of the best strain of *Viola* sp. and scientific collection of its products is the need of the hour, which will help, in its sustainable production and conservation.

Viola species, a glabrous herb with deep violet, sweet scented flower and stout stolons, slender root stock which is likely to be threatened, is found in Himalayas upto an altitude of 1500m to 1800m. Flowers of this herb have been reported to be rich in active ingredients violin (0.003%), rutin (> 5%), rutoside (0.4%), total flavonoids (1.1%), tannin, anthocyanins (4.0%), mucilage (18.0%) and ash (8.5%). Rutin is an important pharmaceutical product. Recently, some preparations incorporating rutin have claimed improvement in-patients testing positive for HIV and showing the symptoms of AIDS and AIDS related syndromes. According to recent reports, *Viola* is also useful in curing eye inflammation and oesophagus cancer. Keeping these facts in view, the present study was undertaken.

The germplasm of *Viola* species was collected from different localities of Himachal Himalayas and selection of the best strain was done on the basis of their potential for the emergence of new plant-lets, which were than further used for cultivation studies *in vivo* and *in vitro*. The effect of various doses of FYM (30 t/ha, 60 t/ha & 120 t/ha) and planting densities (30x15 cm^2, 30x30 cm^2 and 30x45 cm^2) alone, was studied in field conditions. In order to enhance the flowering under the nursery, poly-house and mist conditions a growth hormone GA3 was also tested.

GA3 (1000 ppm) was found to be the most effective concentration for breaking the seed dormancy, when previously chilled seeds (40C) for one month, were treated with various concentrations of GA3 and kept in BOD at 300C in medium light intensity. On fresh weight basis of the flowers yield per 1000 plant, the spray of 100ppm of GA3 was found to be the most effective in poly-house condition i.e., 725g as compared to 410g in untreated population. Whereas, in the nursery condition the yield was 610g and 376g respectively. In field condition, FYM dose of 120 t/ha and planting density of 30x15 cm^2 gave the maximum flower yield of 154.2 kg/ha and 26.95 kg/ha on the fresh weight and dry weight basis respectively. In *in vitro* propagation, the best multiple shooting (80%) was observed when root cuttings were kept on Murashige & Skoog medium containing 6-benzylaminopurine (BAP) (2mg/l). This has helped in standardizing the protocol for mass multiplication of the strain for the future.

Rubber Forest Plantation For Wood Production

Mohamad Abu Bakar, Thai See Kiam, Wan Yusoff Wan Ahmad and Ridzuan Salleh
Forestry Department Peninsular Malaysia, Jalan Sultan Salahuddin, 50660 Kuala Lumpur, Malaysia
Tel: +603-298-8244, FAX: +603-292-5657

Pilot Rubber (*Hevea spp*.) Forest Plantation Project was started in 1990 with the objectives to study and evaluate the planting of *Hevea spp*. for timber as the major product. To date about 1,667 ha of rubber forest plantation have been established by the Forestry Department of Peninsular Malaysia with technical assistance from the Malaysian Rubber Board in five states namely Negeri Sembilan, Selangor, Pahang, Terengganu and Kelantan. The clones identified suitable for hevea wood-latex plantation are from the RRIM 900 series, RRIM 2000 series and PB 200 and PB 300 series. They were selected on the basis of high log volume (clear bole height) and good characteristics such as vigour, good clear bole height, and wind tolerance and disease resistance. This paper will give some preliminary results on the initial growth performance of some potential rubber clones and highlighted experiences gained in the implementation of the project.

Wood Alternative Source in Sustained Forest Management Problem and Prospect

Jamal Balfas
Pematang Siantar Forestry Research Institute, Kampus Kehutanan Terpadu Aek Nauli Sumater Km.10,5a Utara Sibaganding, 21174 Parapat, Indonesia

Indonesian wood industries are now facing log shortage of approximately 25 million m^3 annually. The deficit is predicted to be more serious in the following years, hence, giving more pressure on natural tropical forests as well as forcing many people to search other woody source beyond the forest concession. The only realistic and instant measure to enlarge the use of woody wastes extracted is to intensify and enlarge the use of woody wasters extracted from replanting activities of the nature plantations.

This study investigated the current and future national plantation potential in wood production and problems associated with utilization of such materials. The most promising woody source plantations available in the country are rubber, coconut and palms oil, which respectively covered 3.6, 3.7 and 2.7 million ha. These plantations produce coconut and palm oil wood every year, which collectively exceeded the volume required to work out the national timber deficit. The figures may further increase in accord with the enlargement of the corresponding plantations, ensuring long-term sustainable supply. The most important factors limiting the use of plantation woody materials is inadequate infrastructure, technical processing expertise and plantation ownership.

A Study of Quality and Yield of Timber from *Pinus sylvestris* Harvested at Altitudes from 500 to 930 Meters Above Sea Level in Central Southern Norway

Rolf Birkeland
Agricultural University of Norway, Department of Forest Sciences, PO Box 5044, N-1432 AAS, Norway
FAX: +47 64948890, Email: rolf.birkeland @ isf.nlh.no

12 pine trees from each of 8 different stands at altitudes from 500 to 930 meter (very close to upper growth limit of the species in the area) above sea level in a large area in Central Southern Norway were harvested in 1997. The stems were cut to saw log lengths and graded according to current practice by official log graders. Four quality classes as defined in the Norwegian log grading system were used - three of which are saw log grades and the fourth is a pulpwood grade. All logs of all four grades and of dimensions fit for sawing were then sawn into 25mm boards. Technical properties like density, annual ring increments, spiral grain, MOE, bending strength, heartwood percentage etc. were measured and described in relation to relevant stand factors like altitude and age. The timber was measured and graded according to the grading rules laid down in the Nordic Timber grading rules. The suitability of the boards as raw material for components for furniture and joinery products was also studied.

The log grading system used does not give a concise prediction of timber quality obtainable. Timber quality obtainable increased with log diameter. The timber quality graded according to the Nordic timber rules decreased with increasing altitudes. Density, MOE and bending strength decreased with increasing altitudes. The study of heartwood formation showed an increasing number of annual rings of sapwood with increasing tree age.

The correlations between growth factors (altitude etc.), log grades and product qualities are to be used as a basis for a possible revision of the log grading rules for pine logs.

Les perspectives de l'offre et de la demande de bois rond industriel en Tunisie - l'horizon 2015

Hamed Daly Hassen
INRGREF, Institute National de Recherches en Génie Rural, Eaux et Forêts, B.P. 10, 2080 Ariana, Tunisia
Tel: 216 1 230 039, FAX: 216 1 717 951, Email: dalyhassen.hamed@iresa.agrinet.tn

Afin de comparer l'offre et la demande de bois industriel à long terme, des modèles d'évolution de la récolte de bois bruts et des besoins en produits dérivés de bois sont élaborés pour la période 1995-2015. Les modèles d'offre tiennent compte du stock de bois, des accroissements et du taux de prélevement pour les differentes classes d'âge. Ces données figurent dans les résultats de l'Inventaire Forestier et Pastoral Tunisien (PAFT) récemment crée. Toutefois, la réalisation d'une seule série d'inventaire, le manque de précision proposée de l'âge des peuplements et l'absence de tables de production pour les différentes espèces forestières nous a amené à effectuer certaines hypothèses. Pour estimer la demande future de bois, des modèles d'évolution des besoins sont élaborés pour les produits dérivés tels que les sciages, les contreplaqués, les panneaux de particules, le papier journal, le papier d'impression et d'écriture et les papiers et cartons d'emballage. Il s'agit d'équations de régression de type linéaire ou logarithmique entre la consommation apparente par habitant de ces produits d'une part, et leurs prix, les prix des produits de substitution, le niveau de vie d'autre part. Les modèles obtenus révèlent une forte élasticité de la consommation des produits dérivés de bois au niveau de vie de la population. La comparaison entre l'offre et la demande montre une aggravation du déficit en bois d'oeuvre et en bois d'industrie au cours de la période 1995-2015. Ainsi, il convient d'améliorer le mode d'exploitation de bois et d'identifier les aménagements réalisables afin d'adapter l'offre aux besoins de bois industriel. Par ailleurs, l'engagement de la Tunisie dans la libéralisation du commerce extérieur nécessite la production de bois bruts, de sciages et de panneaux compétitifs pour confronter la concurrence internationale.

Quel rôle jouent les aspects scientiques et techniques dans la gestion durable des forêts tropicales?

Bernard Dupuy, Henri-Felix Maître
CIRAD-Forêt, Campus international de Baillarguet. BP 5035, 34032 Montpellier Cedex 1, France
FAX: (33) 4 67 59 37 33, Email: dupuy@hpbaill.cirad.fr

En termes scientifiques et techniques, la durabilité des actions forestières se heurte à plusieurs difficultés qui trouvent leur origine dans le comportement des acteurs: la dimension éthique dont dépend la définition de la durabilité, l'approche analytique réductrice propre au champ technique; et la prise en compte simultanément de différentes échelles de temps et d'éspace. Ceci entraîne concrètement de très grandes difficultés méthodologiques et métrologiques en particulier pour l'évaluation des pratiques sylvicoles. Il ne s'agit plus d'évaluer seulement, les effets mais aussi les conséquences qu'elles sont susceptibles d'entraîner à long terme sur d'autres objets ou systèmes (agronomiques, climatiques, hydriques...).

La gestion viable des forêts tropicales doit répondre aujourd'hui à plusieurs défis: garantir le fonctionnement des grands cycles écologiques, produire des ressources, fournir des emplois, et surtout participer au développement tant local que national ou régional. D'importants efforts techniques ont été réalisés au cours des dernières années. Pourtant, presque partout, la mise au point des plans d'aménagement n'a pas été suivie de mise en application. Les connaissances techniques disponibles sont importantes, même si elles sont encore à consolider. En effet, le bilan en matière de sylviculture est plutôt positif et de nombreuses études et projets ont permis de fournir la base nécessaire pour une sylviculture efficace dans les forêts naturelles tropicales. Il apparaît ainsi que trois impératifs techniques doivent être respectés: s'assurer que le taux de prélèvement de bois d'oeuvre coïncide avec le potentiel de production; faire en sorte que les modalités de prélèvement soient planifiées correctement et à temps; stimuler la croissance des essences de valeur tout en assurant la régénération naturelle et le maintien de la biodiversité.

Le concept d'aménagement forestier en Afrique et en Amérique tropicales est, certes, plus récent qu'en Asie mais aucun plan d'aménagement n'a encore atteint le stade de mise en oeuvre intégrale. En fait, ce n'est que récemment qu'a été ressentie la nécessité de gérer correctement la ressource par la forte pression exercée sur la forêt non seulement par le ranching ou par l'agriculture, mais aussi par la prise de conscience internationale.

Le dénominateur commun de la plupart des programmes d'aménagement interrompus dans ces régions, est qu'ils échouent rarement par infaisabilité technique! A titre d'exemple, l'expérience issue d'Asie montre que l'aménagement des forêts tropicales pour une production ligneuse durable, est techniquement possible, bien que les systèmes malais et indonésiens aient été plus ou moins respectés faute de réelle application et de contrôle. L'interruption des programmes initiés en Amérique latine est due à des problèmes socio-économiques ou politiques (maîtrise du foncier, commercialisation des produit ligneux...). En Afrique, ce seraient plutôt les déficiences dont souffrent les administrations forestières et les organismes en jeu qui font que la mise en application soit difficile.

La dégradation des ressources issues de l'écosystème forestier est directement liée à leur utilisation abusive ou excessive qui s'explique par une série de facteurs (ou écueils) souvent concomitants de nature: politique, économique, institutionnelle, réglementaire, démographique, conceptuelle et finalement technique; et ceci, du fait de l'ignorance de la nature précise des ressources et des modalités adaptées de récolte de celles-ci, aussi de l'inconstance et de l'impéritie pour leur maintien et leur reconstitution. L'ensemble peut être regroupé suivant deux facteurs: d'une part le facteur temps qui, faute d'être pris en compte, est à l'origine de nombreux échecs et d'autre part le facteur diversité des écosystèmes forestiers dont la complexité est source d'enjeux disparates et antagonistes, et alourdit les difficultés d'étude, d'approche et d'exécution.

Construction of Biomass Tables of *Quercus* in Zonguldak Forest Region Administration

Birsen Durkaya, Ali Durkaya, Nedim Saracoglu
Zonguldak Karaelmas University, Bartin Forestry Faculty, Turkey
FAX: 90 378 2277421

The general area of Turkey is 77 056 192 ha. The forest area that forms 26.6% of the soil in country is not completely productive forests and forested area that is high productive, covers approximately 39,4% of total forested areas. The rest of forested areas are low stocked or else composed of completely unproductive, spoiled marquis and bushes.

It is well known that there has been a shortage of forest wood production in Turkey. In the case of not finding efficient solutions, present state will continue increasingly. Oak plantations can create reliable resources to reduce this shortage. Oak forests have 380 118 ha areas as high quality forests and 4 220 875 ha areas as coppice forests and total 4 600 993 ha forest areas that forms 22,78% of Turkey's forest area.

The object of this study is to estimate the biomass per a single tree and ha for *Quercus spp*. (*Quercus robur* L., *Quercus hartwissiana* Stev., *Quercus petrea* Mattascka Lieb.) Fresh and dry weight tables are constructed by means of the material collected from 32 sample trees chosen in 32 trial areas in the Zonguldak Forest Region Administration.

The size of the established sample plots was 0,04ha (20 m x 20m) in stands of various maturity stages and density classes. In those fields all trees were measured for their height, dbh and average crown diameter. A tree with an average basal area has been selected as the sample tree in each trial plot. Again for each 32 sample tree, followings were measured: dbh, height, crown (height, diameter, volume), number of branches. Then all branches of trees were cut to be used in other measurements.

The main stems were cut from bottom to top for selections with 2,05m thickness. Sample disks with 5 cm thickness were taken from the middle of all stem section. Green mass of the branches: live and dead, were taken and recorded. Sample of stem disks, samples of live branches, samples of twigs and leaves were collected.

Following equations are used to estimate fresh and oven-dry weights of single tree components and perha . The equations of fresh weights of tree components are:

Stem Log FW= -0,692+2,369 Log (d1.3)$_I$ r= 0,96 s=0,09
Branch Log FW=0,622+0,059 Log (d1.3)$_I$ r=0,89 s=0,17
Leaves Log FW=0,269+0,034 Log (d1.3)$_I$ r=0,90 s=0,09
Crown Log FW=0,755+0,055 Log (d1.3)$_I$ r=0,90 s=0,16
Whole tree Log FW=-0,552+2,362 Log (d1.3)$_I$ r=0,97 s=0,07

The equations of fresh weights of tree components perha s are:

Stem Log FW = 30935 + 0,993 Log (d1.3)i r=0,56 s=0,19
Branch FW= 13469,8+3269,55 (d1.3)i r=0,67 s=20542,5
Leaves FW=28962,41-16202,8 Log (d1.3)i r=0,38 s=5087,5
Crown FW=-11130,9+3481,2 (d1.3)i r=0,66 s=22920,2
Whole tree LogFW=30959+1,071Log (d1.3)i r=0,63 s=0,17

The equations of dry weights of tree components are:

Stem DW= -207,805+19,033(d1.3)i r=0,95 s=36,9
Branch DW=-71,415+5,555(d1.3)i r=0,86 s=19,16
Leaves DW=-20,948+1,823(d1.3)i r=0,86 s=6,29
Crown DW=-94,388+7,532(d1.3)i r=0,88 s=23,09
Whole tree DW=-302,193+26,566(d1.3)i r=0,95 s=48,99

The equations of dry weights of tree components perha are:

Stem LogDW= 3,622+1,068 log(d1.3)i r=0,58 s=0,20
Branch DW=-12844,1+1795,9(d1.3)i r=0,71 s=10207,56
Leaves DW=1014,801+434,565(d1.3)i r=0,50 s=4319,37
Crown DW=-12990,7+2314,1(d1.3)i r=0,7 s=13601,87
Whole tree LogDW= 3,706+1,096Log(d1.3)i r=0,64 s=0,17

FW= fresh weight of tree components (kg), DW= oven-dry weight of tree components (kg), r= Coefficient of correlation (significant 0,01 level), s= Standard error

Production de gomme arabique par *Acacia senegal* dans les différentes situations pedoclimatiques de la zone soudanienne du Cameroun

Jean-Michel Harmand, B. Mathieu , C.F. Njiti , M. Ntoupka
CIRAD-Forêt Programme Arbres et Plantations Projet Jachère, BP 1386 Dakar, Senegal
Email: jean-michel.harmand@cirad.fr

Acacia senegal est une espèce ligneuse très répandue dans les zones pastorales d'Afrique sahélienne. Sa diffusion en zone soudanienne agricole en tant que jachère productrice de gomme arabique et restauratrice d'un certain potentiel de fertilité du milieu dépendra de ses possibilités d'adaptation et de production de gomme.

La présente étude a été menée en zones soudanienne et soudano-sahélienne du Cameroun entre les isohyètes 650 mm et 1250mm. Les plantations ont été réalisées de 1985 à 1989 et les essais de saignée de 1993 à 1998. L'étude concerne la croissance de l'espèce, le type saignée pratiquée, le choix de la date de saignée et l'influence des facteurs climatique et édaphique sur la production de gomme. Une comparaison entre différentes provenances étrangères et locale est également présentée.

L'espèce se montre bien adaptée aux différentes situations pédoclimatiques de la zone étudiée. On observe une meilleure production lorsque la saignée est réalisée en début de saison sèche au moment du changement de climat caractérisé par une chute de l'hygrométrie et une hausse de l'évaporation. De plus, le stade phénologique correspondant à un degré de défoliation de 50% semble être le moment opportun pour réaliser la saignée. Selon l'isohyète (650 mm à 1250 mm), la date optimale de saignée s'étale du 15 octobre à la mi-décembre.

Entre 600mm et 900mm de pluviosité annuelle, les productions moyennes de gomme (100-500g par arbre saigné) sont en général supérieures à celles que l'on rencontre en zone sahélienne du Sénégal entre 250mm et 400mm de pluie (45-350g par arbre saigné). En revanche, au dessus de l'isohyète 900mm la production de gomme apparaît plus aléatoire.

Dans toutes les situations, lorsque des perforations dans le bois ont été causées par des insectes xylophages de la famille des Bostrichidés, la production a été de plus de 500 g par arbre attaqué.

A l'échelle pluriannuelle, on ne perçoit pas de différence entre les types de sol, néanmoins la production annuelle se montre relativement constante sur sol argileux et beaucoup plus variable sur sol ferrugineux en rapport avec les conditions climatiques de l'année. Du point de vue climatique, une saison des pluies qui se termine assez tôt et un début de saison sèche chaud semblent favoriser la production de gomme. La provenance locale se montre en général plus productive que toutes les provenances introduites d'origine sahélienne (Sénégal, Soudan).

Les caractéristiques des échantillons de gomme de la provenance locale (nodules issus de saignée et amas issus de piqûres d'insectes) sont tout à fait classiques et représentatives des exsudats d'*Acacia senegal* de la ceinture sahélienne.

Pour finir, la viabilité économique des plantations est discutée.

Determinación de Zonas de Protección y de Reforestación en Colombia

Henry Jiménez Escobar
Universidad del Valle, Facultad de Ingeniería, A.A. 25360 Cali, Colombia
Tel: +57-2-321 21 97, FAX: +57-2-3396097, Email: hjimenez@mafalda.univalle.edu.co

La apremiante urgencia de implementar programas de recuperación de la cobertura boscosa de la zona montañosa de Colombia, ha creado la necesidad de establecer pautas y ayudas técnicas que apoyen de manera ágil y confiable la selección de áreas estratégicas para la conservación y la reforestación.

Para este propósito se inicia con la recopilación de la información general de la zona a estudiar, la cual una vez analizada inicialmente permite generar los vacíos de información; a partir de lo cuál se diseña un sistema de adquisición de la información faltante ó deficitaria, la cuál se obtiene mediante trabajo de campo directo, ya sea en campañas de medición, monitoreo ó reconocimiento en caso de aspectos biofísicos. Con la información de los diferentes aspectos, correspondientes a la cuenca hidrográfica, ó al territorio en estudio, se emplea un sistema de información geográfica como herramienta de comparación y evaluación.

En la determinación de los aspectos culturales, sociales y económicos, además de los informes oficiales é institucionales, se emplean censos, encuestas y foros con las comunidades. Los aspectos jurídicos son tomados de las normas vigentes y aplicadas al territorio respectivo. Se emplea información sobre los aspectos culturales, tales como la vocación y conocimiento forestal; los aspectos económicos relacionados con el tipo de actividades, seguridad, grado de pobreza, salubridad, infraestructura, composición, organización y características de las comunidades. Cada uno de estos aspectos permite zonificar el territorio estudiado.

Los aspectos relacionados con la cobertura de las tierras y su vocación, se comparan con las producciones hidrológicas, permitiendo así determinar áreas deficitarias en cuanto a cobertura boscosa. Esta información unida a las formaciones climáticas y características de los suelos ofrecen las condiciones para dar las recomendaciones de las especies recomendadas para las condiciones particulares. En este punto es conveniente tomar en cuenta las condiciones de mercado que tienen los productos y subproductos del bosque protegido ó la plantación establecida.

Después de haber evaluado y comparado las diferentes características sociales, económicas y biofísicas de la zona en estudio, se obtiene una primera aproximación en la determinación de áreas estratégicas para la conservación de los bosques ó para la reforestación, la cual se lleva a diferentes instancias para su ajuste, aprobación y puesta en marcha. Esta nueva etapa inicia con la consulta a funcionarios y técnicos de las instituciones del estado y de las empresas privadas, cuyas observaciones se toman en cuenta en la elaboración de nuevas versiones. Mediante talleres de participación de líderes representantes comunitarios, con representantes de las instituciones se presentan las observaciones y recomendaciones que alimentan el Plan de Manejo a ejecutar.

De acuerdo con la problemática de la zona en estudio, será necesario ó no, realizar un número variable de consultas, reuniones y foros entre comunidades, empresas é instituciones a fin de concertar un Plan de Manejo de las zonas de conservación y de vocación forestal é implementar su desarrollo; apoyo de programas é incentivos; de manera que se ajusten a los recursos del país y a las normas vigentes.

A pesar de las dificultades que implica el llevar a cabo el procedimiento de comunicación y concertación entre los actores de los territorios en Colombia, su culminación permite alcanzar un mayor compromiso de las instituciones y empresas; las comunidades desarrollan un mayor sentido de pertenencia con los proyectos y se presentan mejores condiciones para el éxito de los proyectos de conservación de los bosques ó de reforestación de áreas degradadas.

Ecological and Economic Evaluation in Monoculture Plantations in North - Western India

Ravinder K. Kohli, Kamaljit Kaur Sangha
Panjab University, Department of Botany, 160 014 Chandigarh, India
Tel: +91-172-546666, 547777, FAX: +91-172-541409, Email: kohli%botany@puniv.chd.nic.in

Man-made plantations are being raised world over particularly in tropics to meet the growing demands of society. The sustainability of these plantations depends upon a balance between various ecological (vegetational and geo-chemical) and economic considerations (direct and indirect valuation of various forest products). However, sustainability needs to be measured and defined carefully depending upon the characteristics of a given ecosystem and the demands of the local people. A comparative study of 8 and 20 (2 year old plantations of *Eucalyptus tereticornis* and *Dalbergia sissoo* was made in terms of growth, vegetation analysis and evaluation of various wood and non wood products including medicinal value, fodder value, ash content and amount of oil in case of *Eucalyptus*. The presentation discusses in detail the significance of various ecological and economic parameters and their importance in determining the overall sustainability of these plantations. Various methods were used for determining productivity and their use values. The productivity was studied on the basis of the mean values of merchantable height and diameter at the breast height whereas use values of timber and fodder were based on the local market price and shadow price in case of ash content. The study reveals that overall plantations of *D. sissoo* provide more economic returns than *E. tereticornis* when both tangible and intangible parameters are considered unlike the conventional view. In case of the 8 year old plantations, the total economic return from *E. tereticornis* were more than that of *D. sissoo* mainly due to high timber value which is nil in *D. sissoo* at this stage. However, in 20 year old plantations, *D. sissoo* provided three times more economic returns than the *E. tereticornis* which includes timber productivity, fuel wood productivity, fodder value and ash quantity. Further, the *D. sissoo* plantations support more understorey vegetation compared to *E. tereticornis* which further adds to its value because many of the understorey plants have medicinal value and some are ecologically important. The rich diversity and heterogeneity of vegetation under *D. sissoo* plantations make their ecosystem more stable and balanced. Further the plantations of *D. sissoo* have some added advantages such as shading and sheltering which attract the wildlife as well as the local people who relax under them and get rid of monotonous city life. Though these benefits are not priced but in any way increase the value of these plantations compared to *E. tereticornis*. Based on the study, it is, therefore, concluded that indigenous plantations of *D. sissoo* should be maintained and preserved as they are more beneficial ecologically as well as economically compared to exotic plantations of *E. tereticornis*.

Forest-based Development in Finland and Chile- A Comparative Analysis

Matti Palo, Gerardo Mery
Finnish Forest Research Institute (METLA), Unioninkatu 40 A, FIN-00170 Helsinki, Finland
Tel: +358 9 857051, FAX: +358 9 85705 717, Email: Matti.Palo@metla.fi

The purpose of our paper is firstly to review the forest-based development conceptual framework. The term forest-based development used in our study refers primarily to forestry and forest industries and their linkages with other sectors in promoting economic growth. Secondly, we review input-output and other studies and statistics in order to reveal the direct and indirect empirical linkages of forest sector with the other sectors in Finland and Chile. Thirdly, the forest-based development concept is broadened from the pure economic one to the sustainable forest management term with economic, ecological and social aspects. The preconditions for historical sustainable forest development are inspected in a comparative analysis of Finland and Chile.

Finland

In the first half of the twentieth century, from 70 to 90% of the total exports in Finland were composed of forest products. Later on, the economy has been diversified and the respective share has decreased to 29%, which is still the highest among the industrialised countries. Another unique feature in Finland among the leading forest product exporters has been that originally farmers and later also other private individuals have jointly owned about 60% of the forest. This fact has ensured that competitiveness in the stumpage markets and real stumpage prices have increased since the end of the 19th century. This again has enlarged the value of the standing forest.

The forest industries have been continuously expanding in Finland since the 19th century. Until the middle of the 20th century the domestic use of roundwood for fuel, construction, fencing and exports exceeded the industrial use. Since then the industrial uses and imports of roundwood have increased. Finland has only 23 million ha of forest or 1% of the world total but her share of the total global exports of forest products is 8.5% and 27% in printing and writing papers.

Forest degradation and deforestation took place in Finland during the 19th and early 20th centuries. A series of land reforms and effective implementation of new forestry laws along with rising stumpage prices and increasing incomes as well as industrial transformation took place in the first part of the 20th century. Consequently, at the latter part of the 20th century the volume of the growing stock and annual volume increment increased by 24 and 40% respectively. A series of forestry master plans were also designed and implemented. They contributed partly into this success.

Chile

The forest based-development in Chile is more recent than in Finland, where forest-based development has progressed during more than a century. In Chile a swiftly growth has happened mainly since the early 1970`s. The Chilean forest sector has been frequently cited as an example that illustrates the way in which a developing country can use the comparative advantages of growing plantation forests for the forest-based industrialisation and expanding exports.

Chile is one of the rare cases among developing countries where forest sector plays an important role in her economic development. The exports of forest products account to 10% of the total exports. The major articles are composed of pulp, newsprint, wood chips and roundwood. Private companies and individuals own most commercial forests. Plantation forests cover 2.3 million ha and are highly concentrated in few hands. Fast growing monocultures of Radiata pine plantations provide more than 80% of the total consumption of industrial roundwood. Nearly eleven million ha of natural forests have survived. Forest industrialisation has been dominated by a wood production criterion and sustainable natural forest management has been widely neglected.

Finland and Chile

The two countries are relatively small by population but relatively large by land area. Both have succeeded to capture internationally high shares of exports in forest products. In this process Finland has increased her semi-natural forest resources while Chile has decreased them but increased her plantation forests. In both cases increasing carbon stocks are taking place but some degradation in sustainability of biodiversity and social aspects is occurring.

In Finland both ownership of forests and industries have remained in domestic hands but in Chile widely also in foreign hands. Small farmers were originally the principal forest owners in Finland while corporations and rich individuals became the owners of plantations in Chile. This has contributed to unequal income distribution. Clear and strong private tenure and cost-sharing systems have been effective in expanding forests in both cases. In Finland domestic R&D has played a key role in creating a number of linked industries to the forest sector - so called forest cluster - which also have been successful internationally.

We produced primary results in revealed comparative advantage of 12 export tigers. This indicator was defined as the value of exports minus the value of imports in forest products divided by GDP. From 1980 to 1996 this indicator was about 10 and 1% respectively in Finland and Chile. This level was highest in Finland and fifth highest in Chile. The trends were respectively +0.3 and +1.4%.

Fodder and Fuel Inventory of Temperate Himalayas: Biomass Productivity in *Robina pseudacacia*

Hari Paul Sankhyan, Atul, and P.K. Khosla
University of Horticulture and Forestry, 173 230 Solan, India
FAX: 0091-1894-30511, Email: vc@hpkv.chd.nic.in

The temperate Himalayan forests face a heavy pressure from its inhabitants for meeting their timber and non timber needs, leading to severe ecological degradation. This in turn also affected the fodder and fuel availability for increased human and cattle population. These temperatures unlands are mainly comprised of coniferous forests while the broad leafed species, restricted to the moist southern slopes, contribute only 5% of the total vegetation. The plantation of fast growing multipurpose broad leafed species, yielding fodder and fuel, will not only fill this gap but also help to conserve and rehabilitate the ecosystem. With this objective in view a socio-economic analysis on demand and deficit of fodder and fuel requirements of the people was made for understanding the contribution of tree leaf fodder in meeting these exigencies. The share of leaf fodder came to 14% of the total fodder requirement while the demand deficit ranged from 32-40%. 77% of fuel wood is also met from the natural forests. The per capita consumption of fuel wood worked out to be 9.67 and 7.97 q/yr respectively in two mountain states of Indian Himalaya. The existing indigenous fast growing broad leafed trees such as maples, oaks, alder, poplar, elm, etc. are site specific, preferring moist ecological niches. In contrast to this introduction of *Robina*, an exotic from North America, naturalised in sub-tropical to temperate, dry temperate and cold desert conditions in the Himalayas, encompassing nitrogen fixing and sucking ability, is embodied with wide adaptability for pioneering all ecological niches. Its multipurpose uses, including fodder and fuel along with fast growth rate and deciduous nature makes and pasture/range lands. Locally it is also being employed as a substitute wood material for packaging of marketable fruit and vegetables. Short rotation age of *Robinia* can be used for innovative planning of farm lands and also for environmental and commercial forestry. Although, the cultural practices of the species have been worked but reliable data on the production of biomass and its distribution in different tree components, however, is not available. Forest inventory models, biomass production, wood characteristics and performance of *Robinia* plantation under four different ecological zones in four age groups and three DBH classes, were investigated. The biomass productivity was related with site specificity 10-year-old plantation from moist regime showed the maximum biomass in comparison to 22 year old plantation on the drier site. Rehabilitation of temperate forests with *Robinia* classified into ecological and economic models, as per the plantation objective is examined in detail. The significant correlation between DBH and biomass production indicated that the former can be employed as the lone indicator for estimating the biomass production under similar edaphic conditions. *Robinia* with multipurpose uses, wide adaptability and short rotation under favourable conditions, site rehabilitation characteristics offers an excellent broad-leafed substitute in the temperate Himalayas. The manuscript also includes the marketing channels for economic disposal of its timber and non-timber products.

A General Data Model in a Forest Resource Information System

Janne Sarkeala, Ari Turkia
Enso Forest Development Oy Ltd, Kuparintie 47, FIN-55100 Imatra, Finland
Tel: +358 40 5393324, FAX: +358 20 4624960, Email: janne.sarkeala@ensoforestdev.fi

A general data model for forest inventory has been prepared. The data model is based on the entity-relationship model and it can be implemented by a relational database management system. The data model can be used as such, without any structural modifications, for inventories based on various kinds and levels of sampling designs. The structure of the data model is fixed, but its design is very flexible; and there is no need to change the database structure when entering new types of attributes into the database.

The data model and its implementing database support different forest resource management systems from forest stand to national level. An inventory and management system based on a 100% tree tally is supported, as well as a system gathering information using a sparse sample plot network.

In addition to the standard field data, the data model includes modules for forestry models, calculations and reporting. Regression models are stored in the database with their formulae and restrictions and are directly linked to forestry calculations and field observations. Calculations are organised in the data model from tree level to forest stand and area levels, which allows a multitude of detailed and general calculations from single tree to long-term projection of tree or stand parameters. The calculations utilise methods that are specific by sampling unit type, and regression models that describe forest characteristics. Reporting is connected to the field data and to the outputs of the calculations. It enables definition of report layouts and their automatic population with the data of the database.

The data model has been applied in constructing forest resource information systems which integrate a geographic information system, a database management system, and computation and interpretation of remote sensing data. Forest resource information systems have been designed and implemented in various computer hardware and software environments, and on several levels of forest inventory. The data model supports the data needs of complex forest surveys, but it can also be applied to other uses of natural resource data management.

Close-to-nature-forestry and its Origins - The Permanent Forest Movement in Germany Between 1880 and 1930.

Irene Seling
Universidade Federal de Santa Maria, Departamento de Ciencias Florestais, Centro de Ciencias Rurais, Rio Grande do Sul, Brazil
Tel: +55 (0)55-220 8444, FAX: +55 (0)55-220 8695, Email: seling@creta.ccr.ufsm.br

Between 1880 and 1930 the permanent forest ("Dauerwald") was a leading idea in German forestry and forestry science. In the corresponding literature only forest-specific and mostly natural explanations (above all calamities in even-aged forests) are discussed to account for the formation of this leading idea. In contrast, in the study the thesis is supported, that natural, silvicultural or forest-specific explanations alone are insufficient. To comprehensively understand the formation and the history of close-to-nature-forestry, in addition a socio-historical reflection is rather necessary.

The early phase of the permanent forest movement between 1880 and 1920 was mainly dominated by discussions concerning the introduction of uneven-aged forest systems ("Plenterwald"). The term permanent forest ("Dauerwald") was first used in 1920, but only very abstract characteristics of permanent forest such as 'mixed forests', 'uneven-aged forests', 'health' and 'equilibrium of state' were named. The lack of a clear definition resulted in broad interpretations of this term by other authors. From the mid-twenties the permanent forest movement rapidly was losing the eminent influence it had up till then in the forestry public. A second movement arose during the National Socialism and a third in post-war Germany.

To understand the formation of the permanent forest movement, the situation of educated classes in Germany at the turn of century is analyzed from a mentality-historical view. Extensive social and economic change caused the educated classes to retreat to their traditionally accepted knowledge and values. The critique of culture was a reaction by the educated classes to the cultural and intellectual crisis. This critique of culture found expression through the foundation of numerous movements, as the 'life-reform-movement', the 'home-conservation-movement' or the 'youth-movement'. Forestry officials and forestry professors, as the representatives of the permanent forest movement, were members of the educated classes in Germany. The following five leading ideas of the permanent forest movement were analyzed:

Leading idea, description and interpretation

1. Aesthetics and harmony romanticization of country life ("Back to nature"), hostility towards urbanization
2. Demand for steady state Reflection of a capitalistic orientated view of forestry, protection against materialistic and especially financial demands towards the forest
3. Concept of Organism Unity of soil and stands, element of a naturalistic and biologistic trend in the views of the educated classes, 'organism' and the antonym 'mechanism' as key words of the conservative milieu in the Wilhelminian period and in the Weimar Republic
4. Essentialism and the idea of intuition Method to grasp the nature of forests, concept of intuitively placing oneself within nature in order to gain a better understanding of forest, turning away from rationality in favour of a pronounced emotionality
5. Darwinism and social biologism Social biologistic ideas as the result of the transfer of darwinistic concepts on society (people as an organism), naturalistic terminology filled with political meaning and societal reality was naturalized.

Literature research and analysis shows, that the permanent forest movement was a result of anti-modernistic, anti-progressive and agro-romantical considerations: thus a more reactionary than avangardistic critique of culture, which could also be found at that time. Numerous parallels can be found to other movements supported by the educated classes. These considerations lead to the result, that the permanent forest movement could be unterstood as a part of the typical culture-critical reform movements of the educated classes at that time. Apart from forest-specific reasons, mentalities of that time form the conditions and the basis for the formation of the permanent forest movement in Germany.

4.02.03 / 4.02.06 Update calibration and enhancement of forest inventories through the inclusion of remotely sensed data

Drawing Stand Profiles by a Computer Programme

Alper Aytekin, Selman Karayilmazlar, Erol Kirdar, Zonguldak Karaelmas
Zonguldak Karaelmas University, Faculty of Forestry, 74100 Bartin, Turkey
FAX: +90.0378.2277421, Email: Mehmet Sabaz [peyzaj74@turnet.net.tr]

A stand profile contains silvicultural and yield elements like stand density, crown closure, slope, exposure, relief, stand canopy projections, regeneration success, diameter, height and increment. Such as stated above, stand profiles that have wide contents, in practice, provide important clues at choosing and applying methods, and form an important ground to carry out more truth and productive studies, putting forward structural state of a stand with the stand profile previously, obtains advantages in cases of choosing a method and monitoring effects of the method on the stand structure and reduces faults.

Turkey's forest areas have very different stand structures depend on different ecological conditions. So forestry practices have important differences. The most suitable way to determine these differences before applying is putting forward stand profiles of the stands. For Turkeys forest managing, stand profiles have great importance because of significant differences among forested areas.

Nowadays, like every scientific fields, computer aided studies are increasing from day to day in forestry too. At forestry studies, one of the most suitable topics that can be realized on computer program is to draw stand profiles and to obtain three-dimensional appearance on the computer. Stand profiles prepared with the aid of computer provide many advantages to the forest managers such as learning of forest structure detailed and previously. These advantages become more important especially silvicultural practices. Thus, forest managers can watch effects if a chosen method on computer screen and can give up to apply the method because of its unsuitableness. Besides choosing of silvicultural regimes, allowable cuts can be determined with the stand profiles. Because a stand profile has a sample plot peculiarity.

Top and front view of stand profile can be monitoring with the aid of computer program. It can be changed tree data or removed on stand profile. Thus, last state of stand profile can be observed. Program is tested many experimental fields. It has been obtained successful results. Forestry will acquire time and new ideas will occur with the aid of computer program.

The Integration of Individual Tree Growth Model and GIS in Forest Ecosystem Management

Fong Long Feng, Shiuan - Der Lee
National Chung Hsing University, Dept. Forestry, Taichung, China-Taipeh
Tel: 886-4-2854060, FAX: 886-4-2873628, Email: flfeng@nchu.edu.tw

Growth model is very important to offer the reasonable projection and prediction of growing stock in the decision making of forest management. Individual growth model is used to simulate the tree crown, diameter of breast height and tree height of interested tree. The competition indicator (CI) of each individual tree were estimated under the concept of circular zone of influence with the size and distance of adjacent trees. The CI is used to judge the surviving growth and mortality risk of each individual tree. The growth pattern of individual trees in the stand reacted the complex growing history and the pattern of beginning stand. To study the description and analysis of spatial relationship are the most important direction in forest research. Geographic information system (GIS) is used to integrate tree location map and the attribute data of individual tree; the plot position map and stand attribute data; the landscape map and mosaic attribute data. The information of the status and change of spatial pattern in tree, stand and community, ecosystem and landscape levels could be analyzed and displayed in multi-scale maps. The spatial individual tree growth model and GIS database could be used to simulate the growing stock and stumpage price under different thinning criteria. The data of five different density plots of *Cryptomeria japonica* and *Cunninghamia lanceolata* were used to develop and simulate in different scenarios in the paper.

Keywords: Spatial analysis, Circular zone of influence, Individual tree location

Forest Plantation Assessment Using Remotely-sensed Data

Djafar Oladi
University of Mazandaran, Faculty of Agricultural Sciences, Post Box # 578, Sari, Iran
Tel: (98)2981-5, FAX: (98) 1291-33702

Effective plantation management requires frequent assessment of the divergence between expected and actual plantation development. A monitoring system based on satellite data collection can provide adequate information to address the above issue.

As the tree crowns expand it provides more light intercepting and reflectance surface. It is commonly observed that an inverse relationship exist between the overstory planted tree and their associated understory coverage (i.e. snow, shrub and herbs, etc.) in terms of their surface exposure. Given the fact that canopy reflectance of understory coverage dramatically affects the conifer-overstory reflectance, the objective of this study was to develop a monitoring system using the contrast between understory and overstory reflectance. This contrast, traditionally deemed "noise", changes over time in response to shifts of dominance of these two layers. This study has utilized this noise in such a way that canopy closure of plantations can be estimated, plantation disturbances and their locations can be displayed to plantation managers, and estimated, plantation disturbances and their locations can be displayed to plantation managers, and estimated canopy closure can be initialized in the tree allometric models to predict the dbh and height of plantation.

The proposed method was tested in a case study of planted black spruce (*Picea mariana* [Mill.] B.S.P.) on good and poor quality sites. Shrubs and herbs were the constant understory features against which the development of forest attributes was assessed. In this investigation, Thematic Mapper T digital numbers (DNs) were successfully correlated with canopy closure indices (i.e. canopy estimation model). TM bands 1, 2, and 3 were unsuitable for this purpose because of their small DNs range. TM band 4 had a very weak or nonexistent relationship at less than 0.6 canopy closure index, and an inverse relationship at greater than 0.6 canopy closure index. TM band 5 revealed a greater DN range and a stronger inverse correlation with canopy closure index than the five other TM bands. TM band 7 revealed a strong inverse relationship with canopy closure index. This band also revealed some potential for estimating canopy closure index. Both crown width and crown projection area revealed strong relationships with height and dbh.

The model's predictive capability was verified through a comparison on the estimated canopy closure index (initializing DNs of 1995 imagery into the 1994 model) with the 1995 measured canopy closure index. The estimated canopy closure index, for the stand developing normally, corresponded closely with the measured canopy closure index. However, the estimated canopy closure index, for the stands which had been disturbed, did not match with normality.

This study has demonstrated that the Landsat TM imagery is a valuable data source for monitoring forest plantations based on the contrast between understory and overstory reflectance.

4.02.05 Remote sensing and forest monitoring

Forest Types Delimitation on the Basis of Landsat TM Images

Maria Iracka, Tomasz Zawila-Niedzwiecki, Zbigniew Bochenek
Institute of Geodesy and Cartography, Institute of Geodesy and Cartography, Jasna 2/4 St., 00-950 Warsaw, Poland
Tel: .+48 22 828 0269 ext.105, FAX: +[48 22] 827 03 28, Email: miracka@igik.edu.pl

Keywords: Remote sensing, forest types

Information of forest areas deriving from satellite images under Polish condition are useful not only for enriching knowledge of weakly recognised forests, but rather for generalisation of detailed information collected by forest services and for illustrating their spatial distribution. General information of forest types and its distribution in Poland would be very useful for forest management being under process of bringing back of ecological balance in the forest communities. In the poster three examples of forest types delimitation are presented. In the supervised classification process of Landsat TM images different types of forest were discriminated in the different forest regions of Poland. For supporting supervised classification process the forest inventory information were used as: tree species, forest stand sites, age of the forest stands, proportion of stand mixture. In the result of classification activities the forest types maps were printed. These maps illustrate spatial distribution of different forest types which are determined by forest stands site and dominated species of trees.

Watershed Prioritisation - A GIS Approach

J. C. Sharma, J. Prasad, K. Rai Sharma and A.R. Bhandari
Computer and Instrumentation Centre, Solan - 173 230 Nauni, India
Tel: +91-1792 52459, FAX: 91-1792 52242, Email: jcsharma@yspuhf.hp.nic.in

In India the population explosion, changing lifestyles and increasing pressures on land for urban and industrial development call for the optimum use of the available land based on its inherent potential and limitations vis-à-vis maintaining a quality of environment. The amount of arable land is continuously shrinking due to human activities resulting in land degradation by various causes. Watershed is natural hydrological entity which has a large number of variables and its management, in its broadest sense, implies prudent use of soil and water, hence programs are required to protect the environment to sustain the productivity levels of soil by reducing land degradation.

For the formulation of proper watershed management programs, the information on vegetation status and soil erosion are very helpful in identification of sedimentation sources and planning of erosion control measures. The regular monitoring of watershed characteristics, biotic interferences and soil conservation measures taken up is very essential. Satellite remote sensing provides reliable scientific input and also addresses some of the parameters of models related to quantitative spatial erosional soil loss and the priority classification of sub-watersheds for taking up erosion control measures.

The studies were carried out to prioritise and recommend erosion control measures for Kawal Khad watershed located in district Solan of Himachal Pradesh , India using GIS approach. The land cover of the study area consists of mostly chir pine (*Pinus roxburghii* Sargent) and mixed forests. The area has got undulating terrain with steep to excessively steep slopes. About 20% of the area is under the degraded forests and scrubs with medium category erosion status and needs improvement on priority to check the erosional losses and maintain the productivity of land. One sub-watershed covering about 7% of the watershed area fell under very high erosion status and qualified for top priority treatment. Various management practices recommended include gully plugging, construction of check dams and gradient control structures, afforestation with suitable site specific species.

Concept of the Forest Thematic Maps of Landscape Parks Based on Satellite Images

Emilia Wisniewska
Institute of Geodesy and Cartography, Department of Cartography, Jasna 2/4 St, 00-950 Warsaw, Poland
Tel: (48 22) 827 03 28, FAX: (48 22) 827 03 28, Email: emiwis@igik.edu.pl

Keywords: forest cartography, remote sensing.

The proper and effective forest management can be performed, among others, thanks to the inventory of natural resources and our knowledge about different changes that constantly take place in our environment.

Our temporary and long term aims for forest management are defined basing on the information that is obtained from the inventory following a 10-year cycle.

To use the above information in an effective and operational way we must base the inventory results on geographic information system which stores the information on both spatial and descriptive database. Such a system enables not only a dynamic display and printout of maps and reports that present selected stands parameters but is also used to conduct complex spatial analyses. Another advantage of forest GIS is the possibility to insert some additional information about the given forest area e.g. archival and current satellite images and aerial photographs. The spatial analyses of gathered data allow to present e.g. the conformity of species composition with habitat, determination of the state of health of forest stands basing on satellite images, determination of forest condition zones in connection with the parameters of the forest stand and habitat contained in the forest management database. The use of remote sensing data allow updating the information collected on the ground. Remote sensing may also serve as a source of information for cartographic purposes.

The maps and analyses were prepared taking into consideration the needs of landscape parks for which it is extremely essential to determine their natural virtues, in order to evaluate their biodiversity and conditions of their natural environment.

Monitoring of Forest Decline in the Sudety Mountains of Poland with the Use of Remote Sensing and GIS - 25 Years of Experience

Tomasz Zawila-Niedzwiecki
Institute of Geodesy and Cartography, Forest Remote Sensing and GIS Unit, 2/4 Jasna St, 00-950 Warsaw, Poland
Tel: +(48 22) 827 0328, FAX: + 48 22 827 0328, Email: tzawila@igik.edu.pl

Since the middle of the seventies, decline processes have been observed in the spruce (*Picea abies*) forest of the Sudety Mountains in Poland. The main cause of these phenomena was the acid deposition transported by the wind from foreigner (Czech and German) and domestic factories, especially electric power plants based on sulphur contaminated lignite. Since the speed of decline processes was high and contaminated area was broad it was decided to use satellite remote sensing to evaluate health state of the Sudetian forests. First analyses were oriented to delineate the stands of different condition. Landsat MSS, TM, SPOT, Cosmos as well as ERS were used. Next step was to collect all existing data describing environment and its contamination, to analyse the forest state status versus different environmental aspects. So the use of forestry oriented GIS was necessary. The paper describes an evolution of the monitoring of area under study with the use of remote sensing and GIS. Experiences dated since 1976 have shown the changes in processing attempts and in defining forest classes derived from satellite images. Simple stratification of forest condition was replaced by deep analyses of multi-source and multi-temporal data stored in forest information system. Results of these analyses are presented in cartographic form as well as in statistics and are used not only by forest service for managing practices but also by environmentalists and spatial planners.

4.02.00 / 4.11.00 Design of small and large scale multipurpose forest inventories

Inventarios Forestales por Transectos Amostrales en Bosques de Galería

José Imaña-Encinas, Rodolfo de Oliveira Morais; Matthias Scheuber
Universidade de Brasília, Departamento Engenharia Florestal, Caixa Postal 04357, CEP 70919-970 Brasília, Brazil
Tel: +55-61-2733796, FAX: +55-81-3470631, Email: imana@unb.br

Bosques de galería son formaciones vegetales que crecen contornando los cursos de agua en la región de las savanas llamadas en el Brasil de Cerrado. Cuatro características definen esas formaciones arbóreas: a) se forma una faja de vegetación con un ancho que varia de pocos a algunas centenas de metros, dependiendo del suelo, relievo y microclima; b) presenta una considerable biodiversidad natural con cerca de 1400 especies entre angiospermas e pterofitas; c) la vegetación presenta una variación temporal y espacial, paralela y perpendicular a la dirección del curso de agua; d) recibe fuerte influencia antrópica. En el aspecto económico silvicultural, estos bosques son importantes por el potencial de producir troncos de alto valor comercial con dimensiones para el proceso industrial. Varias especies tienen alto potencial de utilización doméstica. En el aspecto ecológico abrigan y alimentan varias especies animales, especialmente aves y pequeños mamíferos, protegen los márgenes de los ríos y son mantenedoras de la calidad y cantidad de agua, recurso que en el futuro próximo será el bien más precioso. La necesidad de conocer intrínsicamente estos bosques se hace imprescindible. Con esos fundamentos se desarrolló dentro del principio de los inventarios forestales continuos un modelo por transectos que contemplase una gran cantidad de variaveis y permitiese obtener el respectivo cálculo del error de muestreo, característica inédita en los levantamientos por transectos. Se definió el transecto, una faja de muestreo de 10 metros de ancho, que corta transversalmente la formación vegetal. Tres conjuntos de variaveis de medición fueron contempladas: 1) relativas al sitio (largo y azimut del transecto, altitud, nivel de influencia antrópica, declividad), 2) datos dendrométricos (número del árbol, coordenadas de localización, identificación de la especie, DAP, otros diametros, alturas total y comercial del troco, diametro y posição de la copa en la estructura vertical, estado fitosanitario y variables de tiempos de medición), 3) variables dasometricas (suelo, temperatura, luminosidad, humedad relativa). Para la obtención

de los datos de campo se utilizaron instrumentos forcípulas, clinometros Suunto y otros de última generación (medidores de distancia de ultra-som). Se formaron grupos de campo de tres personas. Para la interpretación de los datos de campo fueron elaborados archivos en Dbase y ejecutados en SAS (Statistical Analysis System).

Este trabajo pretende mostrar la metodologia de captación e interpretación de datos de campo del inventario forestal de un bosque de galeria localizado en el Parque Nacional de Brasilia. Fueron instalados y medidos 19 transectos de muestreo distribuidos sistematicamente a cada 1000 metros, produciendo una intensidad de muestreo de aproximadamente 1%. El tiempo médio de medición consumido por transecto de 300 metros fué de 5 horas por equipo de tres personas. Fueron colectados 56237 datos que fueron estructurados en archivos Dbase, formando asi el correspondiente banco de datos. El modelo del inventario forestal se reveló eficiente, lo que justificó continuar testandolo y aprimorandolo en otras áreas localizadas en el Parque Nacional Chapada dos Veadeiros y del Rio Jardím (Brasilia).

La precisión de los diversos cálculos se fundamentan en el analisis del cáculo de proporciomes y fracciones estadísticas. Los resultados permitieron mostrar coerentes parametros de la gradiente temporal y espacial de la vegetação arborea asi como la variación parametrica de las alturas de los árboles en función de la distancia del rio. La composición floristica presenta grande variedad de especies, diferentes entre si, confirmando la existência de una rica biodiversidad vegetal en esas formaciones. Además de los parametros clasicos de los inventarios forestales como resultados volumetricos, el modelo de muestreo permitió efectuar interpretaciones de la fitosociologia. Concluyese que el modelo fué eficiente, permitiendo obtener consistentes resultados en la precisión requerida.

PPS Stratified Two-stage Sampling Technique for Assessment of Village Forest Resources in Bangladesh

S. S. Islam
Bangladesh Forest Research Institute, Post Box # 273, 4000 Chittagong, Bangladesh
Tel: (880 31)681578 (Office), FAX: (880 31)681585, Email: bfri@spnetctg.com

PPS Cluster Sampling, PPS Two Stage Sampling and PPS Stratified Two Stage Sampling Techniques were examined with field data of village wood and bamboo resources in computer. A study population of 900 households was formed in the district of Chittagong in Bangladesh. The five parameters under five variables were computed through Complete Enumeration. The parameters were estimated through the examined sampling techniques considering 250 sample households in each case. The estimates were compared with the population values on the basis of percentage accuracy, percentage standard error and 95% confidence interval. The population values under Complete Enumeration and the estimated values of the parameters under the selected sampling techniques are given for total number of trees as 17333 & 16087, total volume of trees as 9480 & 8479 m^3, and total volume of compact trees as 8308 & 7345 m^3, total number of bamboos as 53229 & 38598 and total number of palm trees as 4748 & 4318 respectively. PPS Stratified Two Stage Sampling was found to be suitable technique for assessment of village forest resources (wood and bamboo) in Bangladesh. The technique will be helpful for assessment and monitoring which are essential for village forest conservation and planning.

Information for Forest Sector Policy

Klaus Janz, Reidar Persson
National Board of Forestry, 551 83 Jönköping, Sweden
FAX: 46-36-166170, Email: klaus.janz@svo.se

If we examine the fields of forest inventory and the provision of data for forest policy making and public debate we witness, today, a number of contradictory developments and circumstances.

Both at national and international level there is a growing interest for broader, more accurate and more frequent information about forest and related resources. On the other hand the priority given to forest inventories is actually decreasing in many countries. Deforestation and forest degradation are major problems in many countries. Yet the forest inventories carried out in these countries are with few exceptions not designed to detect changes. The demand for new types of information (e.g. biological diversity, non-wood forest products, forest quality) has increased. On the other side concepts and methods to answer all the new questions are poorly developed. Studies about production and consumption of forest-related goods and services have become a priority in many countries and in international outlook studies. Yet statistics about forest resources and statistics about consumption and demand are often dealt with in different offices with little co-operation among them. Consequently it is rarely possible to express resources/production on one side and consumption/demand on the other side in comparable terms. In the same way there is much lip-service to the need of cross-sectorial approaches when dealing with matters such as forestry, agriculture, industrial development, environment, employment and rural development. However, the political environment does not favour the necessary cooperation across institutions, but rather competition and turf fights. There is almost complete agreement that democratic processes and participatory approaches should be prevailing in the development of policies and strategies in forestry and any other field. Yet systematic dissemination of full and correct information to the public are rather the exception than the rule. Recent decades have seen a rapid development of technical tools, e.g. remote sensing and Geographic Information Systems (GIS). Many forest inventories have been carried out using those new tools. Yet we observe that existing information is not used and that, at the same time, forest policy formulation is lacking relevant information.

The above circumstances and developments make it necessary to examine why information is needed at various levels, what information is needed and how information is used.

At national level the dominating use of forest and related information is the political process. A functioning political process is a condition for a country to develop a political will in the field of forestry. Steps in this process and the role of information in them are described. Examples are given of what information is required and how it enters the political process. It is argued that most countries need the following, in order to overcome the shortcomings mentioned:

- an Analysis Unit that analyses the forestry/land use situation and conflicts, identifies policy options and their implications and formulates scenarios
- a continuous National Forest Inventory (or some kind of inventory which is kept up to date)
- a Statistical Unit which collects information about consumption, production, social issues etc.
- a political process which formulates policies and decisions involving most stakeholders
- All four components must be in place. It is of little use e.g. to conduct a national forest inventory if some of the other components are missing. Therefore forest inventory specialists must be trained and encouraged to enter in a dialogue with users, to question the adequacy of standard methods and to help identifying gaps in useful information.

Forest Stand Growth, its Structure and Dynamics on Large-scale Forest Area. Method and Results

Andrius Kuliesis
Forest inventory and management institute, Ppramones 11a, 3031 Kaunas, Lithuania
Tel: 3707 756751, FAX: 3707 767986, Email: sek@mp.is.lt

Keywords: continuous forest inventory, stand growth balance, GIS

The estimation of total growth, its dynamics and use was based on application of sampling methods and the method of balance between the volume of increment of growing and ingrowing trees and volume of cut, dead or disturbed in any way trees.

Sampling scheme was based on choosing stands and trees representing large-scale forest areas. Sampling design contains three stage sampling units: sampling of plots in airphotographs, satellite images, ground survey sampling plots and sampling trees. The proposed system of allocation and measuring of trees per permanent plot guarantees an exact identification of all sampling units and measurement points on trees during regular remeasurement of invisible for the usual forest visitor plots.

Classification of the development of trees per plot from ingrowth, growing tree down to felled, dead and destructed decays was proposed and used in this work. System of volume and increment estimation of each tree per plot using regular remeasurements of diameter of each tree and other parameters (height, age of sampling trees and stands) was elaborated. Unified dendrometrical data processing system was based on general regularities and interrelations of the main parameters of trees and stands including regression functions.

The experiment was carried out in 1976-1996 in Dubrava forest, occupying an area of 5.7 thou. ha. Dubrava forest is representing Lithuanian forest, on the whole, by many stand and site parameters. The results of this study enable to predict the process of stand yield formation and to foresee measures for purposeful and multiple management of Lithuanian forests. In 1976 groups of permanent plots clustered by 4 into 250x250m size tracts were established. Tracts were distributed evenly in the forest by 1x1 km grid. A total of 188 invisible plots with 25-30 trees were identified at the time of each remeasurement. The plots after establishment were remeasured four times every 5 years. Total yield, net yield, ingrowth, the volume of dead and cut trees, as well as the volume of nonsalvable trees were estimated.

The established permanent sample plots on GIS base and collected data about the main characteristics of forest stands, their yield and dynamics during 1976-1996 serve as an excellent database for large scale forest resources dynamics modeling and further investigation of forest stand yield and its structure dynamics, combining field measurements and remote sensing methods.

Regular measurements by the proposed and approved sampling methods allowed to estimate Dubrava forest stand yield balance for two distinguished periods: 1976-1991 - normal growth and development of stands, as well as 1992-1996 - growth and development of stands under the influence of windstorm in 1992, drought in 1992-1995 and Ips typographus damages in 1993-1996.

Analysis of stand yield balance during the normal for stands growth and development period (1976-1991) allowed to estimate the real yield, intensity of tree mortality, reserve of sanitary cuttings, forest site productivity and its dynamics, to estimate the efficiency of intermediate cuttings in regulating species composition, stocking level and stability of stands, in increasing yield and changing stand structure.

Relationships of Stand Structural Diversity to Common Stand Measures

Valerie LeMay, Christina Kovacs
University of British Columbia, Dept. Forest Resources Management
Tel: (604)-822-4770, FAX: (604) 822-9106, Email: lemay@interchange.ubc.ca

The vertical and horizontal diversity (structural diversity) of stands affects the growth of trees and also the biodiversity of stands. The distribution of stems or basal area per unit area versus height, diameter, and species can be used as a measure of structural diversity. However, summary statistics which indicate the variability in these distributions (stand diversity indicators) may be more desirable. Two groups of summary statistics are suggested. The first utilizes an approach similar to that used to calculate a diversity index from frequencies by species. However, since both height and diameter are continuous variables, this approach requires grouping the height and diameter values into classes. Alternatively, the distribution can be modeled, and the parameters of the modeled distribution used as indicators of vertical and horizontal diversity of trees.

Several structural diversity indicators calculated from height/diameter/species distributions were examined for use in the University of British Columbia Malcolm Knapp Research Forest near Vancouver, B.C., Canada. Three of these indicators were then related to stand characteristics of average tree size and density, measured in ground plots, and also related to measures of species proportions, crown closure, and height classes measured on photographs. The suggested indicators are presented, along with the correlation results. Although the indicators relate to structural diversity, the addition of a measure of spatial distribution is desirable.

Image Analysis System for Crown Condition Assessment Using a Digital Camera, CROCO

Nobuya Mizoue
Kyushu University, Laboratory of Forest Planning, 6-10-1 Hakozaki, Higashi-ku, 812-8581 Fukuoka, Japan
Tel: +81-92-642-2867, FAX: +81-92-642-2884, Email: mizoue@agr.kyushu-u.ac.jp

Crown transparency has been visually assessed in forest health monitoring programs of many countries, but the data reliability has been questioned. The objectives of this study are to develop a new semi-automatic image analysis system for assessing crown condition objectively and efficiently using a digital camera and to discuss the usefulness and limitations.

Three popular automatic thresholding algorithms were applied to blue-filtered gray level images. As a result, the between-class variance method was most appropriate to generate the silhouette, and it was reproducible in terms of weather conditions. Two fractal dimensions of crown images, Ds for the silhouette and Do for the outline, were examined in relation to crown transparency (CT) using the Swiss and British standard photographs. Ds tended to decrease linearly with increasing CT, but some species showed no clear tendencies. Do tend to increase rapidly with CT at lower levels of CT, but after that, different tendencies were found between species, i.e. increase, decrease, or constant. These results suggested that Ds or Do alone was a poor measure of CT. I proposed a new index DSO (=Ds-Do), decreasing curvilinearly with CT and closing to 0 at highest levels of CT. DSO was suggested to be a useful measure of CT.

Based on above results, image analysis system for crown condition assessment CROCO was developed. It is composed of a Macintosh computer, a digital camera, the public domain NIH Image program and commercially available and popular software Photoshop, including 4-step procedures 1) image acquisition, 2) preprocessing, 3) thresholding and 4) calculation of DSO. The main features are that a digital camera is used and most of processing are automated using the macro language of NIH Image and the batch function of Photoshop, which enable us to analyze large numbers of images cost-efficiently. The precision of the system was examined in terms of weather conditions, camera angle (CA) and overlap rate with other trees (OR). The results suggested that CROCO produced accurate results (DSO) when CA was less than 45 degree and OR was 50% or less than 50% of crown width, and weather conditions did not influence the accuracy.

Relationships between DSO, dry weight of foliage (FM) and stem volume increment (VI) were examined using 32 trees from two Japanese cypress (*Chamaecyparis obtusa* ENDL.) plantations. It was interestingly that DSO was proportional to foliage biomass density, expressed as FM divided by crown surface area (CSA). In addition, FM was strongly proportional to a measure, CSA multiplied by DSO, which was also proportional to VI for each stand. These results suggested that actual foliage biomass, stem growth and growth efficiency (VI/FM) can be estimated non-destructively from DSO and crown size measurements.

In conclusion, CROCO has potential to analyze large numbers of images efficiently, but the applicability is clearly limited by visibility from the ground. However, combining CROCO with visual assessments of CT would most useful so that bias that each country or observer has may be removed. It was recommended that crown size measurements should be added to field surveys, since combining DSO with crown size measurements would enables us to estimate actual foliage biomass and stem growth.

Analysis of the Mortality Model in PrognosisBC

H. Temesgen, V. LeMay
University of British Columbia, Department of Forest Resources Management, 2nd Floor, Forest Sciences Centre Room 2045, 2424 Main Mall, Canada
Email: temesgen@interchange.ubc.ca

Growth model verification involves several interrelated steps and mensurational attributes. This is especially true for a mortality model. In this study, the predictive ability mortality model of PrognosisBC was verified for ten tree species.

Significant differences were found between the observed (PSP data records) and expected (PrognosisBC estimates) mortality rates by zones/subzones considered in PrognosisBC. However, there was no consistent over- or under-estimation of mortality within these zones and subzones. The highest difference was observed in IDFdm[2]. In the Nelson region, the differences between the observed and predicted mortality rates varied by species and diameter classes. There was consistent under-estimation of mortality for hybrid spruce (SE), white pine (PW), and subalpine fir (BL). On the other hand, there was consistent over-estimation of mortality for western red cedar (CW), Douglas-fir (FD), western larch (LW), and ponderosa pine (PY). No consistent estimation patterns were found for Western hemlock (Hw) and lodgepole pine (PL). In the Kamloops forest region, there was consistent over-estimation of mortality for the hardwood tree species (HM). No consistent under- or over-estimation of mortality was observed for the remaining tree species.

To alleviate this bias, average correction factors (CF-observed/predicted) were estimated by species and diameter classes. The predicted mortality for CF uses both the tree and stand based mortality functions of PrognosisBC. The CFs were, in turn, fitted as a function of the midpoints of the DBH classes.

Bivariate Distribution Functions in Assessing Leaf Area Distribution in Hybrid Spruce Crowns

H. Temesgen, V. LeMay
University of British Columbia, Department of Forest Resources Management, 2nd Floor, Forest Sciences Centre Room 2045, 2424 Main Mall, Canada
Email: temesgen@interchange.ubc.ca

Bivariate distribution functions provide: (1) flexibility in assessing the clumpy nature of foliage spatial distributions in tree crowns; and (2) more information than univariate distribution functions when the spatial distribution of foliage within a tree crown varies in both vertical and horizontal directions. In tree crowns, leaf area and leaf weight show high variability at different heights, relative horizontal positions, and cardinal directions of the crown. These high within- and among-tree crown variation have contributed to the difficulty of tree crown sampling and single tree leaf area estimation. On the other hand, the use of tree leaf area (photosynthetic surface area) as a response variable in analyzing the impacts of silvicultural treatments (e.g., fertilization and thinning) is increasing.

The objectives of this poster presentation are to describe the distribution of leaf area in hybrid spruce (*Picea engelmannii*glauca*sitchensis*) crowns and to analyze variability of leaf area in tree crowns. This paper/poster demonstrate how bivariate distribution functions are employed in assessing the vertical and horizontal distributions of leaf area at specified points in tree crowns.

Data were collected and three-dimensional analyses and displays were made to observe the variability and/or the trend of leaf area spatial distribution in tree crowns and to select models for assessing leaf area distribution. The bivariate Weibull and beta probability distribution functions were selected for predicting leaf area per centimetre (APCM) using relative heights (vertical position) and relative branch lengths (horizontal position) and their model parameters were related to tree attributes.

Results of this paper/poster indicate that horizontal and vertical distribution of foliage is highly variable throughout the crown. Three-dimensional graphs of APCM illustrated that APCM increases towards the top of the tree and the tip of first-order branches. Trees between 50 to 60 years of age showed the highest APCM, whereas trees older than 120 years showed the least APCM. The average leaf area per twig for the sampled first-, second-, third- and fourth-order branches did not show any trend with increasing or decreasing age classes (i.e., <20yrs, 40-60 yrs, and >120 yrs). Trees between 40-60 yrs of age showed the highest APCM, whereas trees older than 120 yrs showed the least APCM. This variation will have a large influence on the amount of light intercepted, crown transparency, radiation transfer, photosynthesis, and respiration by the foliage. The relative horizontal and vertical positions where maximum APCM values were obtained indicate the zone of maximum photosynthetic capacity in the crown.

Model estimates of APCM were more precise when branch position from the tip of the tree was expressed relative to tree height (zi1) rather than relative to crown length (zi2). Thus, the reference of a branch using zi1 instead of zi2 is suggested for single tree growth and yield modeling. The bivariate Weibull and beta distribution functions are suggested for APCM prediction as these models resulted in more precise representations of APCM within tree crowns than the univariate Weibull and beta distribution functions.

Height and Diameter Growth of Rubber (*Hevea Brasiliensis -Muell*) Plantations at Rmu Rubber Estate of Bangladesh

A. Wazihullah, M. Shahidul Islam
Bangladesh Forest Research Institute, Post Box # 273, 4000 Chittagong, Bangladesh
FAX: 880 31 681585, 681566, Email: bfri@spnetctg.com

Bangladesh, a land of about 125 million people having an area of 14.4 million ha has only 10% forest. About 25,000 ha of rubber plantations have so far been raised in the country of which 20,000 ha are managed by the Government owned Rubber Estates while the rest are under the Private Estates, Tea Estates and Private Small-holders. The Government owned Estates are the 12 Rubber Estates under Bangladesh Forest Industries Development Corporation (BFIDC) and the six under Chittagong Hill Tracts Development Board. The major rubber growing areas are located in the North-East, the South-East and the West-Central regions of the country.

A few hundred ha of these plantations had been raised in the early sixties most of which have gone out of latex production by the time. Considering the multipurpose uses and the recent trend about rubberwood, estimation of timber as well as prediction of growth and yield of these plantations have become an important researchable problem. A study was, therefore, conducted on the height and diameter growth of the rubber plantations at Ramu Rubber Estate during 1996. It is one of the 12 Rubber Estates managed by BFIDC located in the South-East region of the country. There is a total of 1027 ha of land under 20 different years of plantations in the Estate established from 1961 to 1995. The seedlings and clones used in these plantations are TJIR, GG-seedling and RRIM-600. Generally, an 8m-by-8m spacing was maintained in most of the plantations. The evaluation made from these plantations will provide an average picture of height and diameter growth performance in Bangladesh. Data on total height, merchantable log height and over-bark diameter (dbh) were collected from three sample plots of (36 plants each) from every year of plantations. As many of the rubber trees in the Estate were broken at the top by the cyclone of 1991 it was very difficult to get the total and log heights of each tree. Considering this fact, total heights and log heights of three dominant or co-dominant trees were measured from each sample plot while over-bark diameter at breast height (dbh) were recorded from all the trees. The total heights and the log heights of the rest trees of the sample plots as well as the subsequent mean growth performance of each plantation were then estimated from the regression equations developed from the height-dia relationships.

The regression equations developed from the sample trees are: (i) Total height (T/Ht) = 4.2027 + 0.4091*D/ob (r=0.99), (ii) Merchantable log height (L/Ht) = 0.6576 + 0.3468*D/ob (r=0.99) and (iii) Over-bark diameter (D/ob) = 6.5386 + 1.1463*Age (r=0.97). The estimated mean annual growth performance of 20 different plantations has been presented in a table. Among the plantations raised between 1961 to 1995, the youngest merchantable trees were found in the 7-year old plantations of 1989. While the mean total heights of the 1, 2 and 3-year old plantations raised in 1995, 1994 and 1993 showed an average of 3.4, 5.7 and 6.4 meters, the merchantable height of the 7-year old plantation was 10.3 meters. On the other hand, the oldest 35-year old plantation raised in 1961 had an average total height of 20.6m while the merchantable log height was found to be 14.5 meter. The over-bark diameters of the 1, 2 and 3-year old plantations were found to be 2.1, 3.8 and 5.4 cms while the youngest merchantable trees had an average of 15.0cm and the oldest showed an average of 40cm dia. The Two-way Frequency Distribution Tables prepared for different heights and diameter-classes for each age will reflect the timber volume in each year of plantation. The age-height, age-dia and also the height-dia relationships have been shown by line diagrams.

4.04.00 Advances in combining productivity and sustainability in forest management

Timber Production Possibilities and Capital Yields from the Norwegian Forest Area - Basic Information for Policy Formulation

Hans Fredrik Hoen, Tron Eid & Petter Ökseter
Agricultural University of Norway, Department of Forest Sciences, P.O.Box 5044, As, Norway
FAX: +47 6494 8890, Email: hans.hoen@isf.nlf.no

How intensive should a forest be grown? This is a fundamental question in the process of formulating policy guidelines for the management of a forest area, both at the individual property level as well as at the national level. The question is related to a number of factors; the objective(s) of the forest owner, the productivity of the forest land, the accessibility within the forest, assumptions regarding future prices and costs and the real rate of discount. This paper presents an applied analysis with the objective of mapping the possible future timber harvest and state on the productive forest area in Norway, given different levels of the required real rate of return on investments in timber production. The analysis is deterministic. The regeneration strategy is a key factor for the long run development of a forest and thus given particular attention. The analysis is restricted to deal with timber production only and maximisation of the net present value of the forest area is used as the objective function. The real rate of discount is varied and used as the driving force to find the best (optimal) level of intensity in silvicultural management.

Analyses are done with GAYA-JLP, a model based on simulation of treatment schedules for individual management units and linear programming for solving the management problem at forest level.

The analyses cover the productive forest area in Norway. This forest area is divided into 10 regions. Sample plots from the National Forest Inventory were aggregated into 1000 treatment units for each region, i.e. the entire forest area is described by 10000 units. Thus, a large amount of the variation regarding the current state of the forest area is represented. The forest management problems are solved at county level, while the country level results were obtained by summing over the individual regions. The following issues were emphasized in the analyses:

- provide a realistic description of the timber production possibilities of the productive forest area in Norway
- aim at consistency in forest treatments with respect to the real rate of discount
- maximisation of the net present value with, and without, a non-declining felling path constraint

The results include estimates on the possible development for a period of 100 years with respect to the volume of harvests and growing stock, according to different real rates of discount. Sensitivity analyses to estimate economically non-accessible areas and changes in the intensity in silvicultural investments due to different timber price levels are also provided. The total timber production for the period of 100 years increased with 15-20% when the real rate of discount was decreased from 3.5-1.5%p.a. The assumptions about regeneration are crucial for the results, and it is emphasised that the different options for natural regeneration is poorly supported by empirical knowledge. From a capital management point of view, the results are used to estimate potential losses in capital yield of adapting forest management strategies to a different real rate of discount than elsewhere in the economy.

The results from the project were provided to the Ministry of Agriculture during the work with the Report to the Parliament on the national forest policy, which was submitted to the parliament in December 1998. Despite the fact that the questions raised in this work is fundamental for an evaluation of the economic performance and profitability of timber production, these issues are not discussed explicitly in the Report to the Parliament.

Control of Sustained Yield and Productivity of Forest Designed Stochastically.

Jan Kouba
Czech Agricultural University of Prague, Faculty of Forest Science, Kamìck 129, CZ-165 21 Prague, Czech Republic
Tel: +420-2-24383712, FAX: +420-2-20923132, Email: kouba@lf.czu.cz

Forests are during their growth influenced by adverse natural factors the most important of which being damage caused by wind, fire, insects, snow, man, especially at last half century by industry, wars etc. These processes have a stochastical character and represent the main risk of forest management. The summing up of this risk into economical considerations and calculations is therefore of great importance for the improvement of control of forest sustainability and production. The long-term character of forest production requires a suitable organization of the forests as to their surface distribution according to age in order to attain steady and sustained forest production which should represent at same time a long-term maximum. Consequently, the age structure of the forest must be suitably arranged on the basis of optimum rotation period.

The author studied a lot of time the use of theory of random processes, especially of Markov chains (in close connection with theory of renewal and systems of differential equations), in solving these problems. Author's results (see literature) are referred in common with works of Suzuki in a number of European scientific articles and monographs.

On this base, a new theory of sustainable forest (normal forest) is offered, based on the consideration of salvage cutting, with help of the theory of random processes, in dynamic point of view.

A main part, the theory and estimation of forest calamities are dealt with. Here, the basic functions of the theory of reliability are used, expressed on the basis of Weibull's distribution - the basic types of damage of forests that cannot be more precisely defined.

Modeling the development and scenarios of sick forests by means of random processes is the next part of applications of this principle. A general model of the development of sick forests has the importance where nonhomogenous Markov chains are used.

A special part of this work is the theory of optimal steering of the process of adjustment to normal forest (sustained yield), defined stochastically. The process of adjustment is optimized by continuous linear programming where the criterial function maximizes the final felling by the time of adjustment period. There is possible a lot of other constrains taking into account (market and nonmarket conditions, standard economical constrains etc.).

Introducing an Approach for the Computation of Forest Allowable Cut

M. F. Makhdoum
Faculty of Natural Resources, Karaj, Iran
FAX: 98-21-658111, Email: makhdoum@nrf.ut.ac.ir

Traditionally, allowable cut (AC) in Iran is computed on the basis of average tree increment in a unit area of forest (Asli & Etter 1969). Then the average increment is simply multiplied by the area of forest district, which would result, the AC of the forest district. In this approach, the whole forest area is considered homogenous, when the AC is supplied for tree making in the later cutting operations. Such procedure has resulted in over cut in some areas, which are not ecologically capable areas it has caused undercut. A new approach is introduced to overcome these over and undercut in forest district of Iran. First, forest district is divided into homogenous areas of arbitrary ecosystems (Makhdoum 1992). Second, in every arbitrary ecosystem, forest ecological capacity would be evaluated, classified, and mapped. Then, for every capability classes of forest district the AC would be computed. By this approach tree marketing would be based on the actual forest ecological capabilities, which is shown on the capability map, rather than on an average figure for the whole district.

The Implementation of an Integrated Land Management Information System to support the Plan Sectorial Forestal del Entorno del Parque de Sierra Espuña, Murcia, Spain.

R. Oborn, Vila, C.
FORCE/Roak Associates Ltd., Spain

Sierra Espuña Natural Park is located in the province of Murcia on the Southeast area of Spain. As a consequence of a new natural resources management regime established in the region, an Integrated Land Management Information System (ILMS) was proposed in order to ensure that sustainable forest/environment management is achieved within the target area. The objective of the project is to formulate an integrated forest management plan over the total project area, which includes almost 15,000 ha of forested areas on which long, medium and short term forest management plans will be developed and analyzed. At the same time, the management of other lands with different uses and structures will be included in the planning process so that a global and integrated plan for forest, agriculture and other lands can be developed.

In order to achieve this, an Integrated Land Management Information System (ILMS) was proposed to support the implementation of the Plan Sectorial Forestal del Entorno del Parque de Sierra Espuña. The goal of the project is to improve the integrated management of forestry and other social-economical objectives of Sierra Espuña and surrounding areas. The territory to be managed is close to 30,000 ha within 3 different management zones as defined by the Sierra Espuña Natural Resources Management Plan (a legal document).

The ILMS is envisaged as an integrated system that will be used to support the planning, implementation and monitoring of multi-objective forest management activities for the Sección de Espacios Naturales, Unidad Técnica of Consejería de Medio Ambiente, Agricultura y Agua of Murcia Region, Spain. The ILMS will be used by managers for strategic, tactical, and operational planning and implementation, and operational control in the Unidad Técnica. Besides the databases and models required to support decision-making in the management process, ILMS will also include the ability to maintain data on current forest inventories and generate maps of spatially-oriented data. The two main components of the ILMS, which will be necessarily be linked, are an Integrated Forest Management System (IFMS©) of FORCE/Robak Associates, Ltd. and a geographic information system (CARIS©) of Universal Systems Ltd.

Contribution to a more Rational Management of Heterogeneous uneven-aged Forests in Rio Grande do Sul (Brazil)

Paulo R. Schneider, César A. G. Finger, Peter Spathelf
Universidade Federal de Santa Maria, Departamento de Ciencias Florestais, Rio Grande do Sul, Brazil
Tel: +55 (0)55-220 8444, FAX: +55 (0)55-220 8695,
Email: paulors@ccr.ufsm.br

The management of heterogeneous, uneven-aged forests is a major challenge of forestry in the outgoing 20th century. Estimates show that Brazil has about 546 x 106 ha of native forests. 68 x 106 ha of them seem to be currently available for wood supply (FAO, 1998). Many of the remaining native forests are in danger of disappearing due to timber exploitation and the advancing agricultural frontier. The new forest legislation, however, requires a management plan for native forests in order to attain sustained yields. Management of native forests is seen as capable of meeting the demands of society towards the maintenance of the principal forest functions. Furthermore, the discussion about certification of timber products increases the pressure for a management of native forests on a sustained basis. The management systems of heterogeneous forests are commonly classified in monocycle and policycle systems. In the former, the total amount of wood is removed in one operation; in the latter only proportions of the wood are cut in several and shorter cycles. Quite many policycle systems are used in practice, among them the Tropical Shelterwood System, the Malaysian Selective Management System or the Celos System of Suriname. Principal methods of regulation in heterogeneous and uneven-aged forests are:

- Transition matrix
- Diameter-limit-method
- Basal-area-maximum-diameter-q-approach.

Based on de Liocourt's observation of a reversed J-shaped stem distribution curve in Central European selection forests, the concept of the balanced forest was developed by introducing the regulation factor q. There, the ratio of the tree number in subsequent diameter classes remains constant. By setting a diameter goal and a remaining basal area of the stand, a balanced distribution of trees in a heterogeneous forest can be attained. This approach frequently has been denominated the "Basal-area-maximum-diameter-q-approach".

The intensity of intervention has to be determined on the basis of increment evaluation. The percentual volume increment, calculated on a species, or ecological group basis, seems to be a promising approach in order to determine the periodic allowable cut. With methods like the so-called "Mexican Method" (periodic increment is calculated with the aid of a compound interest formula), it is possible to determine the wood to be removed, so that the existing growing stock will not be affected during a planning period. This amount of wood has to be removed according to the desired stem distribution curve. Recommendations concerning silvicultural treatments are inevitable to promote growth and regeneration of desired (valuable) tree species.

A Review of Forest Management in Venezuela and Perspectives on Sustainable Development

Armando Torres-Lezama, Ramírez-Angulo, H. and A. D´Jesús
Universidad de Los Andes, Grupo de Investigación BIODESUS. INDEFOR. Facultad de Ciencias Forestales y Ambientales, Vía Los Chorros de Milla, Mérida, Venezuela
FAX: 58 74 714643, Email: torres@ing.ula.ve

Venezuela is considered a pioneer country in neotropics forest management. In 1970 the government awarded the first long term concession, 20 years after the first forest reserves have been created. At the same time, a Research Program with Management Purposes started in the Caparo Forest Reserve. During the first decade of this program the technical basis for the management of lowland forests in the north of the country were established. This knowledge was also used to initiate forest management in the south of the country, which possesses the highest proportion of the forest in Venezuela. After almost thirty years, however, forest management is the subject of severe criticism. In this paper we examine its strengths and weaknesses and propose solutions towards the building of sustainable development. Among the achievements during this period we mention the awarding of more than three millions ha of forest in long term concession with management purposes, the design and application of a forest stratification system of great utility for management planning, the development of economically successful forest regeneration methods and the carrying out of one of the most complete forest species trials in South America. Furthermore, the long term concessions in the lowland forests assured, or a time, their permanency. However, at present these forests have almost disappeared, due to strong human pressure and the scanty results of forest management. It was assumed that the benefits of forest management would be extended to the human population; unfortunately this expectation was not fulfilled. In reality, the social component received the least attention during the mentioned period. Furthermore, the forest sector's contribution to the country's Gross National Product did not increase, remaining as low as 1%. Similarly, the majority of the adopted forest regeneration methods were based on either the simplification or transformation of the forest, ignoring natural forest dynamics. This approach has generated strong criticism regarding biological diversity conservation. Likewise, the indiscriminate use of minimum felling diameter, inappropriate felling cycles and the application of selective logging methods characterized by deficient planning and high impact have led to forest deterioration, thus casting doubts on the ecological and economical sustainability of the system. Forest management flaws has been attributed to deficiencies in public and private forestry organizations and the existence of a political system that has allowed, or even stimulated, widespread corruption. Due to the seriousness of the situation, we propose a complete revision of forest management in Venezuela that should lead, among other goals, to the strengthening of the forest sector, the development of new policies on forest concessions, a more effective incorporation of local communities, a higher benefit for the country, and lower impact on the forest.

4.04.04 Economic planning systems for forest management

Does Standard Discounting Incorrectly Show an Advantage of Leveraging Forestry Investments with Debt?

W. David Klemperer
Virginia Polytechnic Institute and State University, Department of Forestry, Virginia 24061 Blacksburg, USA
Tel: 540-231-7267, FAX: 540-231-3698, Email: david.klemperer@vt.edu

Typically one uses a risk-adjusted discount rate (RADR) larger than the risk-free rate to calculate the net present value of a project with risky cash flows. In those cases, one can show a present value advantage of borrowing funds at a loan interest rate lower than the RADR. This results because, under the above conditions, the negative present value of loan payments will be less than the positive loan value. Using a zero inflation example for simplicity, at a 5% loan interest rate, annual payments on a \$100,000, 10 year loan will be \$12,950. Incorporating this loan into a discounted cash flow analysis using a 7% real risk-adjusted discount rate, the negative present value of loan payments is $90,955, or $9,045 less than the loan amount, thereby boosting the project's present value. However, the borrower should view loan payments as risk free cash flows based on a legally binding contract, in which case payments should be discounted with a risk-free rate, say 3%, which is lower than the risk-adjusted rate and lower than the loan interest rate. In that case, the negative present value of loan payments will exceed the loan value because the loan interest rate will be above the risk-free discount rate. For the above example, the negative present value of loan payments would be $110,466 at 3% interest, which is $10,466 more than the loan amount. Thus, the previously-calculated present value advantage of borrowing is really a disadvantage. Analyses show how results will vary depending on levels of relevant interest rates, inflation, income tax interactions, loan duration, project life, and the degree to which borrowing increases the overall risk of a project. Forest policy implications are that typical discounted cash flow analyses of leveraged forestry investments could make borrowing appear deceptively attractive. The result could be overpayment for leveraged investments in forested properties or forest management. The analysis raises interesting questions about economic efficiency. Do incorrect analyses of leveraged investments cause a sub-optimal distortion toward higher borrowing levels? Could the result be higher-than-optimal levels of leveraged forestry investment, strictly from a financial efficiency viewpoint? Further research is needed to determine the degree to which such inefficiency is manifested in actual practice in forestry and other investment areas.

4.12.00 Integration of GIS and Remote Sensing for Assessment of Forests and Landscapes

Assessing Biodiversity - SPOT Satellite Image Analysis for Tree Species Diversity in Uganda

Alfred de Gier, Joel Alimudoa Arumadri
International Institute for Aerospace Survey and Earth Sciences (ITC), Hengelosestraat 99 Post Box # 6, 7500 AA Enschede, Netherlands
Tel: +31 (0)53 4874309, FAX: +31 (0)53 4874399, Email: degier@itc.nl

One of the challenges of forest management is to satisfy both the need for forest products and to conserve biodiversity. A common approach is to spatially separate the forest into different management units, according to the assigned production or conservation function. This assignment should be based on information about the production and biodiversity status and potential of the forest. This study investigated the existence of possible relationships between the digital numbers (DN) and NDVI values of a SPOT XS satellite image and field-measured biodiversity indices. For this, the Shannon index, based on tree species? 10cm dbh in sample plots, was used. Moreover, an assessment was made of the GPS accuracy in field plot location. No good relationships could be established, leading to a further investigation in the biodiversity index itself that was used. Although no further improvement in the sought relationship could be established, a systematic analysis of the index behavior under a variety of species combinations showed that the Shannon index is not robust, and may have to be modified in order to represent the local tree species diversity.

Development of National Forestry Information System (A Case Study In Kelantan)

Noor Asma Bt. Hamid
Research Center for Forest Management, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6377233, Email: asma@psph.frim.gov.my

With a combination of techniques such as Remote Sensing (RS) and Geographical Information System (GIS), the development of forest information system becomes very useful in ensuring sustainable management of forest resources. In general, Forest Information System (FIS) should contain important information such as the extent and distribution of the forest resources, the various information on silvicultural and management practices as well as other forms of databases related to the production and economic aspects of the resources. The system should be comprehensive and can be used in assisting decision making process by the policy makers. This paper highlights a comprehensive Forest Information System based on a case study done in the state of Kelantan, Malaysia. The system is based on geo-referenced sampling and the combined use of multi-source data, e.g. remote sensing and Geographical Information System (GIS) in a PC environment. It is customized for forest resource inventories, management planning and monitoring of changes and dynamics of forest ecosystems. It can be flexibly applied to both strategic and operational planning. Advantages of Forest Information System (FIS) covers aspects as effectiveness, efficiency, and supplement of basic applications for forest benefits. On one hand, the Forest Information System (FIS) will facilitate integrated and flexible management of forest

resources both for strategic and operational planning at reasonable costs. On the other hand, the system can be modified for the purposes such as monitoring of forest dynamics and environmental changes.

Utilization Prospects of Digital Aerial Orthomosaics in GIS and FRIS

Tani Höyhtyä, Pekka Alajärvi, Janna Puumalainen and Stora Enso
Stora Enso Forest Consulting Oy Ltd, Kuparintie 47, FIN-55100 Imatra, Finland
Tel: +358 2046 24964, FAX: +358 2046 24960, Email: tani.hoyhtya@storaenso.com

The poster presents the latest developments of an airborne digital image acquisition, image mosaic creation and mosaic utilization. The developed methods are reviewed for their utilization potential in GIS (Geographical Information System) and FRIS (Forest Resource Information System) particularly in regions where the use of traditional optical remote sensing data is difficult, for instance in the tropics.

The poster would focus in the following issues: A) The small format digital aerial imagery itself, B) the creation of digital geocoded orthomosaics, C) the interpretation of mosaics and D) the utilization of mosaics in GIS and FRIS.

The system is in operational use and more than one million ha on four continents have been imaged and processed for forestry mapping, land use planning and monitoring of natural resources. Further developments are on way for A) conversion of the mosaicking software to be used for any aerial imagery data, B) digital false-colour imagery (RG+CIR) and C) image processing system based on parallel computers.

Satellite Remote Sensing Technology for Forest Type Classification and Inventory with Special Emphasis in Malaysia

Zailani Khuzaimah, Kamaruzaman Jusoff
University Putra Malaysia, Faculty of Forestry, 43400 Serdang Selangor, Malaysia
Tel: 603-9486101 ext. 2414, FAX: 603-9481522, Email: kamaruz@forr.upm.edu.my

In accordance with the national objective and priorities and in compliance to international agreements, the forests in Malaysia will continue to be managed not only to ensure the sustained supply of timber and non-timber products, but also to maintain environmental stability, provide sanctuary for wildlife, as well as to conserve biological diversity. In this endeavor, Malaysia faces serious challenges ahead which calls for further dedication, prudent planning and wise management. Issues ranging from the timely and cost-effective acquisition of inventory data, organization and proper management of the information, the development of sound plan and effective implementation on the ground, need to be adequately addressed. The advance in satellite remote sensing technology has provided one way to make monitoring forest activity easier. The objective of this paper is to highlight the application of remote sensing in forest type classification and inventory. The paper presented previous studies of using remote sensing data in forest type classification and forest inventory to estimate forest stand and timber volume. It can be concluded that satellite remote sensing has the most potential in forest type classification and inventory to be operationalized for macro-forest planning in Malaysia. However, high resolution remote sensing data such as THEMAP airborne data taken from aircraft need to be further investigated for the micro-planning of forest management due to its high resolution capability for tree counting and mapping.

Study of the Seasonal Changes of Spectral Reflectance of Forest Vegetation

Chinsu Lin
National Chiayi Institute of Technology, Dept. Forestry, 300 University Road, 600 Chiayi, China-Taipai
FAX: 886 5 2788724, Email: chinsu@rice.cit.edu.tw

Keywords: forest vegetation, remote sensing, spectral reflectance characteristics, seasonal change, and purified reflectance analysis.

This paper uses Landsat TM data to study differences of spectral reflectance and the spectral heterogeneity of different vegetation types caused by seasonal changes. It aims to find the best imaging season and sound data processing logic for monitoring forest vegetation. Results revealed that there is a significant influence of vegetative reflectance produced by seasonal change, yet the quantity changing in each TM band is not consistent. In spite of this fact, the basic reflection properties of visible and near infrared wavelength light are almost identical and distinguishable in a year's duration for both vegetation and bare land if viewed from the pattern of spectral reflectance curves. This implies that it is possible to detect illegal development in a forest with remotely sensed data. Photosynthesis can directly and indirectly affect the visible and near infrared reflectance of trees, such as conifers, broadleaf trees, and bamboo; while background materials can also enhance the spectral reflectance of grass as a result of the photosynthesis process. In spring, the beginning of the plant growth season, physiological processes rarely change the total leaf area and canopy structure; furthermore the solar elevation is high enough to decrease the shadow area in the spring image. These conditions indicate that the spectral characteristics of plants are most stable in springtime. Further considering the best classes divergence and classification accuracy of the spring image revealed in this study, one can conclude that spring is the most suitable season for detecting forest vegetation with TM data. In the presence of the relief effect in an image, the spectral reflectance deviation of an object always expands. The light reflectance purification method separates the reflectance of an object into 5 classes, and hence can minimize the data deviation of each class. Results also revealed that the purification method is better than the relative proportion transformation method in reducing terrain effects in this study; and hence one can use this logic to process multispectral scanner data to upgrade the accuracy of classification in forest vegetation monitoring.

An Investigation into the Potential of High Resolution Stereo Satellite Imagery (IRS-1C) for Forest Inventory

Holger Vogt
University of Stellenbosch, Remote Sensing/GIS, Forest Management Unit, Stellenbosch, South Africa
Tel: +27-21-8083325, FAX: +27-21-8083603

The deficiencies in detail and information content have so far imposed substantial constraints on the exploitation of satellite imagery as a mapping and measuring tool. In contrast, the new high resolution satellite imagery in marriage with a softcopy environment provides potential benefits such as improvements in accuracy, flexibility, efficient processing and reduction in cost.

The aim of the investigation has been twofold: firstly to scrutinise the performance of the DTM tools as provided by the Leica/Helava system centred on the extraction of terrain data from stereo satellite imagery (IRS-1C), and subsequently to perform a feasibility study on the application and/or development of a practically viable forest inventory design.

My approach used a softcopy photogrammetric workstation, IRS-1C panchromatic satellite imagery, and digital aerial imagery. The aerial images were obtained by scanning panchromatic aerial photographs at a nominal resolution of 15 micrometers. All the tests were carried out on a Leica/Helava DPW 770 softcopy workstation. The study was conducted over various sites in the Sabie area (Mpumalanga) in South Africa, where extensive man made forests (predominantly pine and eucalyptus) are to be found. An IRS-1C subscene representing an area of 70x70 km was chosen, for which a network of highly accurate ground control points were used as reference. The extraction of stand parameters such as tree/stand height was performed manually as well as automatically. The Digital Surface Models (DSMs), as representing the canopy structure of the stands, extracted from the IRS-1C imagery were validated through a comparison of the resulting contours with the corresponding contours generated by aerial photogrammetric methods.

The manual determination of tree/stand heights on the IRS-1C imagery yielded accuracies of up to 95% compared to the terrestrially obtained measurements. However, the results of the automatic extraction of height parameters in the plantations did not turn out to be very useful.

The prevailing situation in the forestry sector is characterised by the dependence on labour-, and cost-intensive inventory methods. The results are of considerable relevance to those concerned with the inventory of vast, inaccessible forest areas and for those searching for highly efficient, cost-effective schemes.

Monitoring Mangrove Deforestation Using Satellite Optical and Radar Data: A Case Study from East Kalimantan, Indonesia

Mahfud M. Zuhair, Yousif Ali Hussin, Michael Weir
The International Institute for Aerospace Survey and Earth Science (ITC), 7500 AA Enschede, Netherlands
FAX: (31) 53-4874-399, Email: hussin@itc.nl, weir@itc.nl

Mangrove forests are one of the primary features of coastal ecosystems throughout the tropical and subtropical region of the world. Mangroves are rich in biological diversity including many varieties of flora and fauna. Various kinds of fauna including shrimp, fishes, crabs, molluscs, mammals, reptiles, birds, insects and micro-organisms are also found in mangroves ecosystem. Mangrove forests have been utilized for food resources, firewood, charcoal, timber and other minor products. The mangrove forests are complex ecosystem because they represent an interface between two clearly contrast ecosystem. Firstly, terrestrial ecosystem represent by inland forest, and secondly marine ecosystem represent by community coral reefs and community sea grass meadows. Mangroves are very sensitive and fragile resources. If damaged, it will take a lot of efforts and time to bring back to a close to the original condition.

The pressures of increasing population, food production, industrial and urban development have caused a significant proportion of the world's mangrove resource to be destroyed. As population rose, the shortage of productive land in underdeveloped countries resulted in mangrove swamps being converted to agricultural purposes and the provision of fish and shrimp ponds for commercial production. Much of the reclaimed land proved unsuitable and today it lies derelict. To control or monitor or manage the mangrove forest, an up dated spatial information is essential. Remote sensing is an important source of spatial data. Two major remote sensing sensor systems exist: active sensors (using their own energy), and passive sensors (using natural solar energy). Radar is an active sensor, which transmits and receives a microwave signal. Some advantages of the use of radar in remote sensing are that it can be used during both day and night, has all weather capability (cloud cover, rain, fog, atmospheric dust, etc.), and its energy has the ability to penetrate through some surficial features.

The objective of this research was to monitor the mangrove deforestation using optical and radar satellite images. In this study, GIS approach was applied to investigate the mangroves deforestation in Delta Mahakam River, East Kalimantan, Indonesia. The main aims of this overlaying are to know how big the mangrove areas in Delta Mahakam River were deforested and to show where are the locations of the deforestation during period of 1982 to 1996. The result of overlaying showed that the total area of mangroves in Delta Mahakam River are increasingly depleted during 1982 to 1996. In 1982 the total area of mangroves area 96,228 ha and becoming 91,827 ha on 1994 and 78,799 ha on 1996. The results showed that deforestation in the Delta of Mahakam River altered the mangroves to: oil extraction areas, agriculture or orchard establishment and shrimp ponds establishment.

4.04.02 / 4.13.00 Sustainable forest management under conditions of growing global pressures

The Profit from Trust Thinning with GIS at the Forest Owners' Cooperative in Japan

Hiroshi Kondoh
Forest Management and Economics Laboratory
Kyushu Research Center, Forestry and Forest Products Research Institute
Kurokami 4-11-16, Kumamoto 860-0862, JAPAN
Tel : +81 96 343 3168, Fax : +81 96 344 5054, E-mail : kondoh@ffpri-kys.affrc.go.jp

Keywords : Trust thinning; Thinning profit; The forest owners’ cooperative; Geographic Information System (G.I.S); Personal computer

The profits that the forest owners’ cooperative makes from thinning with Geographic Information System(GIS), are considered. The forest owners’ cooperative in Japan, is founded on the Forest Cooperative Law. The forest owners’ cooperative is entrusted by the forest owners to execute forest operations, and make the forest operation plans. The amount of business at the forest owners’ cooperative is growing every year, so the cooperative is becoming the core of the forest enterprises in various regions in Japan. In the case of thinning by the Kuma-mura forest owners' cooperative in Kumamoto prefecture in Japan, thinning profit is found by deducting expenses from proceeds. The thinning evaluation record, made from the tally of these sales and expenses, becomes an estimate of thinning.

However, the calculation method becomes more and more complicated these days. One reason is the diversification of forestry machine to lighten the labor strength. For example, in extraction work on thinning, the group of laborers attached to the forest owners' cooperative can use the yarder(winch), crane truck or mini-forwarder to reduce man-hours. Similarly, in the work process, there are some methods which the group can select. The person in charge at the cooperative must consider which work methods will increase profit the most.

In making this calculation, the computer is useful. So, for utilizing a personal computer, an estimate making system has been developed. This system can freely change the variable of expense, average price of wood market necessary for sales calculation, etc. Therefore this system can simulate profits attainable by using various work methods or processes of thinning, simply and cheaply. And using the forest information system which applies the technology of GIS, the stands to be thinned, can be selected. In this study, with this information about these thinning stands and the estimate making system, the profits from thinning are evaluated.

In conclusion, thinning was carried out within a 100-meter range on either side of the spur road in process with GIS. By the simulation with GIS, a higher profit was obtained by group thinning than by individual thinning. The profit was higher with the mobile yarder than with the standard yarder. It was also noted that the spur road establishment enterprise costs were higher than the profit on thinning. Therefore, some financial support is necessary for the spur road establishment.

Economic Valuation of Carbon Sequestration by a Forest Stand: Precondition to the Political Use of Forestry against Greenhouse Effect

Jean-Luc Peyron, Jerome Besnehard
ENGREF/INRA, 14, rue Girardet, CS 4216, F-54042 Nancy, France
Tel: 00 33 (0)3 83 39 68 31, FAX: 00 33 (0)3 83 32 73 81, Email: peyron@engref.fr

Forestry is more and more considered as a useful and efficient tool that could help to stabilise atmospheric concentrations of carbon dioxide. More precisely, forest plantations could be marginally substituted to emission reductions. This possibility could be implemented by the way of either a taxation system or a real carbon market. It raises several questions of economic nature: governments have to determine the general frame in which this substitution would be authorised (possible locations, species and harvest schedules, surface area for hundred carbon tons emitted, harvest schedule, penalties following a contract breach); inside this frame, a firm would have to find the best choice; moreover, be it owner or manager, a forest operator could negotiate with an enterprise or a government the environmental advantage to sequestrate carbon dioxide.

A quantitative and integrated economic and biological forest model allows to answer such questions. It manages biological processes including stem, branch and root growth, leaf development and fall, mortality, humus mechanisms, wood decay and incineration. It takes into account not only forest stands but also economic activities that process, use, recycle wood and give to it a lifetime at the end of which carbon is sent back to the atmosphere. It is based on management costs, wood prices and carbon price or cost. It allows to analyse the cash flows generated by a stand during its rotation as such as the main physical and monetary carbon flows during the rotation and beyond. The present values of these flows can be simply calculated or optimised and provide the economic benefits of wood production, of carbon sequestration and of both phenomena.

Small sized broadleaves – added valued chains for a growing resource

Gero Becker und Volker Ehlebracht
Forest Products Laboratory University of Freiburg
Werderring 6, 79085 Freiburg i.Br., Germany
D-79085 Freiburg i. Br., Germany
Tel.: +49 761 203 3763
Fax: + 49 761 203 3764

Small sized broadleaves represent a substantial part of the forest resource world-wide. This is also true in Europe, where new silvicultural strategies promote broadleaves for ecological reasons. Therefore within the next decades, growing quantities of small sized broadleaved timber from thinning, plantations and copice forests, will come to the wood markets. In contrast to small conifer logs, small broadleaves still represent resource of a low value, substantial proportions are still used for firewood only. Today it is difficult to achieve a higher added value due to log and fibre characteristics: Small broadleaves usually show a bad quality in terms of straightness of the bowl, taper, branchiness and a very variable internal structure of the wood (fibre deviation, tension wood, short fibres) and bruncheness. There exists a conversion technique (sawmilling, pealing, slicing) especially adopted to small conifers logs, a comparable specialised technique for small broadleafs is still missing. In Germany in central Europe, beech (fagus sevatica) presents a remarkable part of small broadleafs. An integrated research concept had been developed an executed, which aims to overcome these ”natural” disadvantages of small broadleafs by the following steps: Analysing the future resource and the existing markets, testing developed cross cutting and sawing techniques for badly formed small broadleaf logs, analysing wood structural and fibre characteristics typical for small beech logs. Conclusions are drawn and strategies are developed to improve the added value of small sized beech logs at the different steps of the forest-wood-industry chain. Key-words: small sized timber, wood-quality, processing, added value, fagus silvatica.

Wood Identification for Utilization of Timber in Nepal

Lajmina Joshi
National Herbarium and Plant Labotories, Department of Plant Resources, Post Box # 3708, Godawary, Lalitpur, Nepal
Email: banaspati@flora.wlink.com.np

Nepal is rich in forest products. Different species of timber plants are extensively used, 85 species of timber trees are recorded. Among them more than 40 species are used for different purposes e.g. furniture, beam, poles etc. However due to technological limitation, there is under utilization of forest resources. The paper examines the problems and issues of timber identification in Nepal and works on the strategy for better utilization of timber products through technical capacity building and developing identification method.

Timber identification as a key role to effective utilization has not been given the much needed impetus. Many wood users are facing the problem of wood identification. The main problem of misidentification and underutilization and undergrading of timber species are the lack of timber identification manual, trained manpower, research and training facilities and modern equipment.

Treatability and CCA Preservative Macrodistribution in Rubberwood (*Hevea brasiliensis* Muell. Arg.)

Ismail B. Jusoh, D. Pascal Kamdem

Today, rubberwood is mainly used for furniture manufacture. However for rubberwood to be use exteriorly, preservative treatment is necessary. This study evaluates the treatability and macrodistribution of CCA component in rubberwood. Rubberwood samples were quarter-sawn cut into blocks of 35mm x 35mm x 125mm. Blocks surface were sealed to permit chemical penetration in only one or two direction at a time. A set of blocks were pre-steamed prior to sealing process. Treatability was measured by chemical penetration and retention of CCA type C after pressure treatment. Preservative distribution was evaluated through microscopic observations of CCA distribution in various tissues such as vessels, fibers, and rays. The penetration and retention in the radial direction was about 3 times higher in the

tangential direction. Longer pressuretime favors the penetration and retention of chemical in rubberwood. Complete penetration was achieved after 4 hours of pressure treatment. The CCA preservative components distribution patterns in different types of tissues will be observed. Complete data will be presented in the conference.

Current Status on the Subsistence Use and Trade in Mangroves along the Kenya Coastline

Albert Luvanda Makee
Kenya Forestry Research Institute, Post Box # 20412, Nairobi, Kenya
Tel: 254-154-32891-3, FAX: 254-154-32844, Email: kefri@arcc.or.ke

Mangrove exploitation has been going on for many years with exportation to the middle East in the first half or so of this century being most common. Mangrove forest are highly valued for their richness in biodiversity i.e. many species of fauna and flora. In the recent past there has been allot of debate on the exploitation and trade in mangrove products in the country. Many local people depend on this vital resource for their livelihood i.e. income and subsistence. In terms of the contribution to the household economy, the contribution of mangroves can be ranked second to fishing. Export trade in mangrove products played a significant role in the socio-economic status of the local people in this country until a ban was imposed in 1982.

A socio-economic survey was designed and carried out with the aim of developing an understanding of the current exploitation and trade dynamics of mangrove forests along the Kenya coastline which covers a distance of 874 Kilometres. This study, therefore, presents the state of information on the current mangrove cover, species, levels of exploitation in three districts and socio–economic implication of lifting the export ban. The study was carried out at three levels where the focus was on the mangrove managers, licensees/merchants, and the local communities. Personal observations and information on secondary data have been incorporated.

The results revealed that mangrove resources are not being utilised on sustainable basis as a result of the increasing population and the expanding tourism industry. There are nine different species of mangroves in Kenya with *Rhizophora nucronata* and *Ceriops tegal* being the most abundant and highly exploited. The annual off-take in terms of poles and posts was estimated at 6,610 scores , 8,704 scores and 23,428 scores as reported by the Forest Department, mangrove dealers and the local communities respectively. The three major products in order of importance from mangroves are: poles and posts, firewood and wood for dhow ribs. Poles and posts are classified into seven different classes based on their diameters. A large consignment of mangrove poles and post were being smuggled into the market without the knowledge of the Forest Department as revealed from the study. Apart from incidences of over exploitation, the other threats include: encroachment from private developers, salt farming and development of fish/prawns farms. These threats have hence attracted a lot of interest from a number of institutions though with very little taking place on the ground. Attempts have been made in the area of rehabilitation though much still needs to be done. The study does conclude by recommending that the lifting of the ban on the export of mangrove products should be based on concrete scientific information like on the silviculture and ecological parameters, consultation with stakeholders, reforming current regulations and policies and the local demand.

Potential Equipment For The Cutting Of Oil Palm Fibres For The Wood Composite Industry

Mahmudin Saleh, Mohd. Nor Mohd. Yusoff
Forest Research Institute, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 03-636579, Email: Mahmudin@frim.gov.my

In Malaysia, the oil palm plantation covering an area of approximately 2.5 million ha will generate large quantity of residues in the form of trunks, fronds and empty fruit bunches (EFB), which can be considered as an alternative raw material for the wood composite industry, particularly particleboard and medium density fibreboard (MDF). For the period of 2001-2005, approximately 10.7 million tonnes of trunks, 262 million tonnes of fronds and 18.7 million tonnes of EFB will be made available in Peninsular Malaysia. Currently, there are 8 particleboard mills and 9 MDF mills, with a total capacity of 600,000 m^3 and 1 million m^3 per annum respectively. Over reliance on rubberwood as the raw material would cause these industries less competitive in future. This would possibly due to among others, scarcity of the rubberwood supply, increase in manufacturing cost as well as market demand for diversified products. Therefore, it is timely for industries to consider using oil palm fibres as another source of raw material. Recently, more concerted efforts to improve the existing technology of processing oil palm fibres have been shown by R&D institutions and private sectors. In view of the high silica and moisture content of the material, emphasis has been on reducing wear and tear of the cutting tools and producing fibres of desired sizes. Thus, this paper will highlight FRIM's experience in assessing the prototype of fibre cutting technology which is commercially viable for the wood composite industry. In addition, this paper will also discuss the reliability, flexibility and conformity of the prototype in processing oil palm fibres to be used in the particleboard and MDF industries.

Keywords: oil palm fibres - particleboard - medium density fibreboard (MDF) - processing technology - cutting technology - prototype

Pulping of Jute Plant by Neutral Sulphite Anthraquinone Process

Mohamed Shafi, A.F.M. Akhtaruzzaman, J. Main
Bangladesh Forest Research Institute, Post Box # 273, 4000 Chittagong, Bangladesh

Today, by far the largest amount of pulp is produced from wood, but interest is growing in the utilization of non-wood fibres. In many countries, the wood supplies will not continue for long to meet the rising demand for pulp and paper. In many countries wood is not readily available for pulp making. In such a situation non-wood fibre like jute plant may be a valuable source of pulp raw material.

Several studies were previously conducted on pulping of jute plant by the alkaline processes. But the response of the plant to alkaline pulping is poor. Neutral sulphite anthraquinone (NS-AQ) process has proved more advantageous over the alkaline processes with retted jute bast fibre. Hence, the response of jute plant to this process needs to be investigated.

It has been observed in this study that NS-AQ process responds well in pulping of jute plant. The process is capable of producing a significantly higher yield compared to the alkaline processes. The physical strength properties of NS-AQ jute plant pulp stand in between hardwood and softwood kraft pulps.

Success of commercial utilization of jute plant in pulp making largely depends on effecient means of collection, transportation and storage of the plant. Hence due attention to these problems must be given.

How Wood and Paper Products are Meeting a New Societal Need by Sequestering Carbon

Kenneth E. Skog
USDA, Forest Products Laboratory, One Gifford Pinchot Dr., WI 53705 Madison, USA
FAX: 608-231-9508, Email: kskog@facstaff.wisc.edu

The 1997 Kyoto Conference of the Parties to the United Nations Framework Convention allows the possibility that countries may be able to offset emissions of carbon to the atmosphere with sequestration in forest or other sinks in order to meet objectives to reduce net carbon emissions to the atmosphere. A number of studies worldwide have suggested that accumulation of carbon in wood and paper products may be a significant and growing sink of carbon. This paper reviews research that has evaluated how carbon is accumulating in products in the United States and projects future accumulation using Forest Sector models that project forest products production and use.

The paper provides historical estimates and projections of U.S. carbon sequestered in wood and paper products, and compares them to amounts sequestered in U.S. forests. There are large pools of carbon in forests, in wood and paper products in use, and in dumps and landfills. The size of these carbon pools is increasing. Since 1910, an estimated 2.1 Pg (billion metric tonnes) of carbon have accumulated and currently reside in wood and paper products in use and in dumps and landfills, including net imports. This is notable compared with the current inventory of carbon in forest trees (13.8 Pg) and forest understory, floor, and soils (24.3 Pg) (Birdsey and Heath 1995). On a yearly basis, net sequestration of carbon in U.S. wood and paper products (additions including net imports, minus emissions from decay and burning each year) is projected to increase from 61 Tg/year in 1990 to 74 Tg/year by 2040, while net additions (sequestration) in forests is projected to decrease from 274 to 161 Tg/year. One Tg is one million metric tonnes. Net sequestration is increasing in products and landfills because of an increase in wood consumption and a decrease in decay in landfills compared with phased-out dumps. Annual additions to forest, products, and landfill carbon stocks are slightly greater than annual drain of carbon from the atmosphere. Forest, and product and landfill stocks increased 333 Tg/yr in 1990, while net drain to forests, products and landfills was 331 Tg/yr in 1990. This difference is because net additions to stocks includenet imports while annual drain from the atmosphere does not. We can increase additions to the stock of carbon in products, landfills and forests while satisfying the same projected needs for wood and paper products (with same net imports) by 1) shifting product mix to a greater proportion of lignin-containing solid wood, paper, and paperboard products, which decay less in landfills, 2) increasing product recycling, and 3) increasing product use life. Carbon dioxide equivalent emissions would also be reduced by the actions noted above which increase stocks. Emissions would also be reduced by increasing landfill CH}{\fs22\sub 4}{\fs22 burning in place of fossil fuels.

Heartwood Proportion Models for Pine

Jori Uusitalo
University of Joensuu, Faculty of Forestry, Box 111, 80101 Joensuu, Finland
FAX: +358 13 251 3590, Email: jori.uusitalo@joensuu.fi

Keywords: Cambium age, Heartwood, Radial growth rate

The durability of Scots pine (*Pinus sylvestris*) heartwood far exceeds that of other Finnish commercial timbers. Obviously, there would be general interest among lumber buyers, window and outdoor woodwork manufacturers in buying pine heartwood as a separate item if it were available. The biggest obstacle to better utilization of such lumber is the difficulty of separating heartwood in the sawing process. In this poster a set of models is presented that allows us to predict heartwood taper for Scots pine (*Pinus sylvestris*) while handling the tree at harvest if the age of the tree is known. The study material comprises 59 sample trees from five Scots pine *(Pinus sylvestris)* stands in southern Finland.

In accordance with many previous investigations the number of rings in heartwood of any tree height is under a control of time and is thus best predicted by cambium age. The results suggest that the heartwood start to form at the age of 20-21 and increases by circa two-thirds year rings annually after it has been initiated. In order to apply this model in practise we need accurate estimates for the cambium age and the radial growth rate.

If tree age at the stump height can be given from other sources (e.g. historical records), cambium age for any height of the tree can be predicted by tree age and stem taper values (i.e. height and corresponding diameter) provided by the harvester head. In order to predict the heartwood taper, we not only need to know the number of rings in the heartwood but also how fast the diameter of the tree has been grown up to this stage of life. The cumulative radial growth rate for certain height and distance from the pith can be derived from cambium age and corresponding stem taper values.

The residual analysis suggests that the set of models created slightly overestimates heartwood radius with small diameter values and correspondingly underestimates heartwood radius with big diameter values. On the other hand, the set of models gives slightly biased results (+1,5 mm). The root mean square error (RMSE) for heartwood radius with the current data is 10.7 mm which means roughly 2 cm in diameter.

Demand Analysis and Policy Discussion of Pulp and Paper in China

Wu Xiaoli, Junqi Wu
Chinese Academy of Forestry, Division of Science-Technology Policy Research, Wan Shou Shan, 100091 Beijing, China
Tel: 86 10 62994229, FAX: 86 10 62889022, Email: dydam@caf.forestry.ac.cn; guxpf@public.fy.hz.zj.cn

Along with the rapid advancement of the national economy and the sharp increase in demand for paper products, China's pulp and paper industry has scored remarkable development since the mid-1980s. In 1994 the production of paper products reached 21.38 million tons nearly tripling the production in 1981.

Despite of the rapid development in China's pulp and paper industry in recent years, the domestic market demand can not yet be met not only in quantity, but more importantly, in quality and variety the end users require. Due to the fact that 60% of the raw material for pulp making in China is crop straws, wood pulp (including imported wood pulp) only makes up about 14% and waste paper 25%, sufficient quantity and high quality paper and various special paper products can not be produced in China at present. Each year China spends more than US$ 3 billion on the import of wood pulp, paper and paper products totaling almost 4 million tons. However, the excessive import not only intensifies the burden of the country's foreign exchange, but also restrains the development of pulp and paper industry in China to some extent.

As a country with big population and limited forest resources, China must further develop its pulp and paper industry under the principle of sustainable development. According to the national plan, it is expected that the consumption for paper and paperboard will be increased from 29.789 million tons in 1994 to 71.728 million tons by 2010, and the production capacity of paper and paperboard by year 2010 is expected to reach 40 million tons, of which 22% should be from wood pulp. The major challenge is how to find a proper way to increase the supply of pulp and paper products so as to satisfy the growing demand by the rapid growth of the national economy and the improving of living standard of the people under the condition of limited timber resources.

This paper analyzes the present status and the trends of production, consumption and trade of pulp and paper products in the world and in China, and put forward resources, industry and trade policy recommendations including the development of pulpwood plantations, restructure of pulp and paper industry and trade, etc.

Forest Products Research in IUFRO: History and Future in Meeting Society's Needs

Robert L. Youngs, John A. Youngquist
Virginia Polytechnic Institute and State University,
Brooks Forest Products Center, Virginia 24061-0503
Blacksburg, USA
Tel: 540 231 8868, FAX: 540-231-8868, Email: ryoungs@vt.edu

When silviculture researchers in central Europe were gathering together to form IUFRO in 1892, forest products researchers were occupied with making useful forest products and conserving the forest resource through wise use. Forest products researchers did not become an active part of IUFRO until 50 years later. Research in forest products was stimulated by World War I and II-wood was essential for airplanes, ships, packaging, construction, and derived products. As World War II drew to a close, the newly established United Nations provided a forum for bringing together efforts that would encourage world stability and peaceful development. Utilization of forest resources was an important element in this effort, and those involved in this area found common ground. Initial efforts were focused on mechanical conversion of wood, but wood quality, wood chemistry, and wood protection soon captured the attention of researchers.

Meanwhile, IUFRO had been growing in both size and scope. The organization recognized the need to include the effective utilization of forest products, together with other aspects of forestry, as a key element in ensuring that forests could meet the increasing demands of society. Thus, forest products research was incorporated as Section 41 of IUFRO at the XI Congress in Rome in 1953. This program was greatly expanded at the XIII IUFRO Congress in Vienna in 1961.

The rapid growth in size and scope of IUFRO during the next decade led to a complete reorganization, which was formalized at the XV Congress in Gainesville, Florida in 1971. From this arose Division 5, which included subject groups on wood quality, wood engineering, wood protection, and wood processing, each with several specialized working parties, and a project group on properties and utilization of tropical woods. All of these reflected the increasing scientific and technical needs for wise use of the forest resource in both domestic and international industry and the increasing trade in forest products from the tropics as well the industrialized world.

Since that time, the program of Division 5 has broadened to recognize new needs for research on forest products as scientists in various parts of the world have sought a forum for sharing ideas, notes, and accomplishments. The results have been many: (1) new knowledge of wood quality factors, (2) new approaches to the efficient use of wood as an engineering material, (3) effective processing methods to deal with the growing diversity of resources, processing conditions, and product needs, (4) effective, environmentally friendly methods of wood protection, (5) new concepts related to composites of wood and other materials, (6) methods for dealing with the growing trade in tropical woods, (7) more efficient use of wood for energy, (8) better understanding of non-wood products, their sources, and their derivatives, (9) improved use of bamboo and rattan, (10) new advances in growth ring analysis, and (11) broader understanding of marketing techniques to effectively match products to consumer needs.

We face new challenges as we consider the future of forest products research in IUFRO. No major problems are purely technical and disciplinary-they are social, economic, psychological, and traditional. Here are some points we should consider as we plan for what will be reported at the XXII Congress and beyond:

- Develop depth and disciplinary strength within our groups and working parties, but join with others in this and other Divisions to focus on solutions to problems.
- Plan joint efforts to identify and solve forest-related problems, rather than limit efforts to meetings for sharing information.
- Develop planning and management techniques that are uniquely adapted to voluntary organizations.

- Strengthen channels for communication and for transmitting and discussing information.

CIRAD Creates A Molecular Data Bank Of Wood Decaying Fungi

Alba Zaremski, Marc Ducousso, Yves Prin et Daniel Fouquet
CIRAD-Forêt Programme bois,CIRAD-Forêt, Maison de la technologie, 73, Rue Jean-Francois Breton, BP. 5035, 34032 , France
FAX: 04 67 61 65 60, Email: alba.zaremski@cirad.fr

Keywords: wood protection, molecular data bank, wood decaying fungi

The early detection of wood decaying fungi is a major challenge for wood preservation for the future. Molecular studies of nuclear rDNA can be used as a tool to get an accurate characterization of wood decaying fungi using only 10 to 100 mg of fresh vegetative mycelium. Thus, using PCR, it is now possible to characterize fungal rDNA directly on contaminated woods.

The necessity to have a molecular data bank of these fungi in order (i) to assess the name of a species and/or (ii) to know whether it is a virulent species or not, is clearly demonstrated. One hundred and three species of wood decaying fungi responsible of cubic and white rots from the CIRAD wood preservation laboratory collection have been characterized.

First data of this molecular data bank concern restriction profiles of the internal transcribed spacer (ITS) of rDNA. The amplified region include intergenic spacers ITS1 and ITS2, the 5.8S ribosomal small sub-units and parts of 25S and 18S ribosomal. This region has been digested using restriction enzymes TaqI, Sau96A and AluI. That way, more than 250 different profiles have been identified. In the next future, ITS sequences, other rDNA sequences (e.g.: 18S and/or IGS) and partial sequences of ligninase and cellulase genes will be introduced into this molecular data bank.

This data bank will allow to control fungal strains used during normalised tests in laboratory (natural durability and tests of effectiveness of products). Furthermore, this work might conduce to the elaboration of a method of early detection and accurate identification of fungi decaying wood before fungi have reached an advanced stage of development.

5.01.00 Wood quality

The Effects of Beating Load Programs on Bleached Kraft Pulp Physical Properties

Ahmed S. Abdullah
University of Mosul, College of Agriculture and Forestry, Forestry Department, Hammam Al-Alil, Mosul, Iraq
Tel: 603 6342 633, FAX: 603 6367753, Email: abdrazak@frim.gov.my

Keywords: Pulp and Paper; Physical Properties; Beating

Gradual beating effects on fiber length distribution, breaking length and folding endurance of bleached Kraft pulp at different freeness levels were compared with the same physical properties at the laboratory standard beaten bleached Kraft pulp.

Analyses of variance showed that long and short fiber percentages were significantly affected by beating load program. In addition to fines percentages, they were significantly affected by freeness, too.

Gradual beating give the highest mean of long fiber percentage (75.5%) and the lowest mean of short fiber percentage as well (6.9%). The highest percentage of long fiber (77.1%) was at 53 SR (Schopper-Reigler) freeness of gradually beaten pulp.

Breaking length and folding endurance of hand sheet papers were significantly affected by beating program and freeness level. Gradual beating gave the best mean of breaking length (8680m) and folding endurance (654 double fold). The highest value of breaking length (9087m) was obtained from pulp gradually beaten to 63 SR freeness, and the highest value of folding endurance (711 double fold) was obtained from pulp gradually beaten to 53 SR freeness. Breaking length and folding endurance of standard beaten pulps were decreased when the freeness increased more than 43 SR.

Mathematical models were obtained for the relationships between studied pulp strength properties on one hand and fiber length distribution and freeness level on the other. The interrelationship equation between breaking length and folding endurance was obtained for both standard and gradually beaten pulp.

The study showed that pulp physical properties were highly related to controlled beating which maintains the highest possible ratio of long fiber and lowest ratio of short fiber at high level of freeness, increasing of fines ratio didn't show the drawbacks of short fibers ratio increasing.

Wood Quality of Black Locust (*Robinia pseudoacacia* L.) from European Clones and Natural Populations

S. Berti, N. Macchioni, M. Negri, C. Passialis, C. Pollini, E. Voulgaridis
IRL/CNR - Wood Research Institute, Via Barazzuoli, 23, 50163 Firenze, Italy
FAX: +39.055.670624; Email: berti@service.area.fi,cnr.it

Within the framework of the European INCO-Copernicus research program on Black locust (*Robinia pseudoacacia* L.) resources for degraded area rehabilitation, basic and applied technological wood properties of *Robinia* are studied by a pool of Italian and Greek laboratories. The program in progress foresees to assess the wood quality on standing trees and on small specimens of selected clones and European natural populations by the means of both non-destructive (ND) field tests and laboratory tests. Four main topics are scheduled within the research programme: 1) basic technological properties on cores and on small specimens, 2) non-destructive tests on standing trees, 3) early evaluation to estimate the minimal age suitable for wood testing and finally 4) industry-oriented tests. The ongoing standard tests are providing data about basic properties of the material, such as shrinkage and density characteristics of juvenile wood, anatomical properties, sapwood/heartwood proportion. The early evaluation tests are scheduled to estimate the minimal age suitable for investigation on technological properties carried out on young clones coming from genetic selection. These tests will be performed on disks from Hungarian clones 10 and 15 years old. Juvenile wood will be studied by measuring the length of fibres and the anatomical features. Density, shrinkage and sapwood/heartwood proportion will be evaluated and/or measured in order to check the lower age of *Robinia* stem for carrying out technological tests. Moreover, the wood quality will be performed during field tests by means of some non-destructive testing methods on standing trees selected for cut. The methodologies that will be used are: Resistograph (drilling device), Ultrasonic apparatus for standing trees testing, instrumented hammer for sonic analysis on standing trees, and the Fractometer (mechanical tests on cores). The data collected from the above listed instruments will be correlated to the data collected from the wood characterisation tests. The aim of industry-oriented tests is to carry out some tests to improve the industrial uses for Black locust timber. Some properties, such as gluing and drying processes are critical in this species forward the industrial uses. Therefore gluing and diffusivity tests are scheduled. According to potential final uses, standard gluing tests will be performed on two groups. In the first group ordinary specimens will be tested. In the second group the specimens will be soxhlet treated to decrease the wood extractives content before gluing tests. Diffusivity tests will be performed on small size specimens. These tests will provide indications about the drying aptitude of Black locust timber. Drying process will be then performed.

Gains potentiels par la réduction des coûts de la non-qualité dans l'industrie du panneau de fibres

Ghislaine Miranda Bonduelle, Graciela I. B. de Muñiz, Umberto Klock, Arnaud Bonduelle
Universidade Federal do Paraná, Departamento de Engenharia e Tecnologia Rurais, Rua Bom Jesus 650/ CEP 80030-010, 80030-010 , Brazil
Tel: +55-41-3522443, FAX: +55-41-2532332, Email: gislaine@floresta.ufpr.br

Mots clefs: Coûts de la non-qualité - Industrie du panneau de fibres - Qualité.

L’analyse économique des coûts permet d’aider la prise de décisions, de fixer les prix et de déterminer les choix entre les solutions alternatives pour la production ou pour de nouvelles implantations (Gormand, 1986). Les systèmes actuels d’information comptable d’une entreprise ont une lacune importante pour le bon développement de la gestion de la qualité d’une entreprise: les coûts de la non-qualité n’apparaissent pas de forme explicite dans les rapports comptables. L’évaluation de ces coûts est nécessaire parce que, même s’ils n’existent pas dans les systèmes comptables, ils font partie des charges de l’entreprise. Un coût de non-qualité est le résultat provenant d’une organisation qui ne produit pas correctement du premier coup (Juran, 1979). L’évaluation des coûts, visant son contrôle, est facteur de survie de l’entreprise. En effet, on peut affirmer que la non-qualité diminue la performance économique potentielle de l’entreprise.

L’objectif de ce travail est de quantifier les gains potentiels qui peuvent être obtenus quand, après la détection des coûts de la non-qualité, les causes analysées permettent l’adoption des mesures correctives qui engendrent la suppression qui génère ces coûts.

Le travail fût réalisé dans une usine de panneaux de fibres durs dans laquelle était implantée un système de détection des coûts de la non-qualité (CNQ) sur l'ensemble des étapes du processus de fabrication: transformation du bois en fibres, formation du mat, pressage, séchage, découpe et conditionnement.

Pour chacune des étapes, la quantification et l'analyse des causes les plus importantes engendrant la déclassification des panneaux au triage et au conditionnement ont été effectué au moyen des outils de la qualité tels que le brainstorming, les graphiques de Pareto et d'Ishikawa. Avec les données obtenues (coûts de production, volume mensuel des déclassés au triage et au conditionnement), nous avons pu calculer les gains en terme de réduction des coûts qui pourrait être obtenue par l'élimination des causes et nous les avons comparés aux coûts de détection des non-conformités du processus.

Parmi ces anomalies, 33% étaient dus à la déclassification de panneaux tachés. Par ailleurs, le coût de la déclassification représentait 0,074 US$/ton en sortie de séchage, alors qu'il représentait 0,53 US$/ton au conditionnement.

Les gains obtenus à ces étapes ont été, respectivement, de 200 kUS$/mois et de 11 kUS$/mois. L'utilisation du calcul des gains potentiels et de la marge de bénéfice de l'entreprise ont démontré que, si la production était effectuée « correctement du premier coup », il serait possible d'obtenir une marge théorique bénéficiaire de 7%.

Les économies provoquées avec la suppression des causes de la non-qualité peuvent facilement compenser le coût de la détection des anomalies du processus, réduisant ainsi les coûts de production proprement dits et disposer d'un produit plus compétitif.

Research on the Properties and Utilization of *Paulownia* Wood in China towards the 21st Century

Xinfang Duan, Delong Chang
Chinese Academy of Forestry, The Research Institute of Wood Industry, Post Box # 18, 100091 Wan Shou Shan,Beijing, China
Email: liusq@wood.forestry.ac.cn

Paulownia is one of the most important fast-growing trees in the world. IT is naturally distributed in China, Japan and Korea and have been introduced to Southeast Asia, Australia, New Zealand and Europe. *Paulownia* is abundant in China and farmers like to plant. Research on wood science of *Paulownia* play an important role in the efficient utilization and development of the new wood products. The research results also benefited to the other countries with introduced *Paulownia*. Chinese scientists first described the wood anatomical features in 1936 and in 1944 the physico-mechanical properties of *Paulownia* was first studied. Until the end of 1970's, research had made great progress. Recent work mainly focus on wood variation, secondary processing, and the mechanism of the discoloration of *Paulownia* and its control. The main research results obtained since 1970's consist the following: (1)Determined the main wood properties including anatomical features, physical-, mechanical-, chemical- and machining properties of 9 species of *Paulownia* grown in China; (2)Progress on the theory of wood discoloration and its control in *Paulownia* because the discoloration problem has influenced the end use in producing wood products and wood processing such as wood drying and plywood making;(3)Obtained the wood variations relationship for several species and selected the best hybrid clones from the new breeding clones from the view of wood quality;(4)Developed processing technologies for wood drying, plywood, MDF and particleboard and furniture and chemical utilizations.

Considering the development trend of research in wood science and the problems that affect woodworking , utilization and silvicultural management of *Paulownia* trees, the important research in the future should strength focus on: to study the *Paulownia* discoloration control technology of *Paulownia* wood, to improve the wood quality through genetic and silvcultural improvements, to carry on research on modification of *Paulownia* wood.

Keywords: *Paulownia*; Wood Science; China

Within Species Variations of Standing Tree and Wood Quality in a Tropical Rainforest (French Guyana)

Meriem Fournier-Djimbi, Isabelle Bonjour, Lionel Demay, Sebastien Soufflet
Gonzague Muller de Moroguez, Jacques Beahchene, Jean Marc Bouvet
Ecole Nationale du Genie Rural des Eaux et des Forêts, Centre de Kourou, BP 316, 97379 Kourou, France
Tel: 0594 32 26 75, FAX: 0594 32 43 02, Email: fournier@engref.fr

A better knowledge of wood biodiversity and the increasing of the number of species used are needed for a sustainable harvesting of tropical rain forests. Therefore, research activities on forest products from natural tropical rain forests has focused on the species level: botanical identification, mean wood properties of species, promotion and marketing of secondary species.

However, a sustainable harvesting of natural forests involves an increasing of wood value (standing tree prices) and a decreasing of logging and processing wastes. Thus, forest managers and timber harvesters are more and more interested in wood variations appraisal within trees for the most important (i.e. of higher value and not too rare) species, especially in French Guyana where forests are managed and production costs high.

Different works are in progress and concern:

General diagnosis of main defects for each species. Studies are done in timber yards and sawmills, and also experimental forests.

The main defects are identified: decayed hearts in most of the species, buttresses or grooved trunks (Wacapou: *Vouacapoua americana*) insect decays (Louro Vermelho: *Ocotea rubra*, Mandioqueira*: Qualea spp, Ruitzerania spp*) compression failures silica content, and thick sapwood in basralocus (*Dicorynia guianensis*), ring shakes of Bacuri (*Platonia insignis*) felling shakes in Walaba (*Eperua sp*.), *Wacapou (Vouacapoua americana*). Most of these defects vary a lot within sites and trees.

Description of wood variations and relationships with environmental and growth conditions. In order to explain the spatial variations of these defects, trees are sampled in order to analyze the influence of diameter, soil (or ecological coherent unit including soil, topography), architectural development, growth rate. As the number of sources of variations can be great, preliminary tests are done, using the knowledge acquired in the previous diagnosis and sampling the extreme conditions. Growth rates and tree ages are estimated through tree ring analysis.

Development of methods of quality appraisal in standing trees

As the results of previous studies are not always clear, simple and easy to apply for a reliable appraisal and cartography of wood quality. Direct methods, applicable in inventories, tree by tree, are tested. Visual observations are decomposed and classified in order to allow reliable appraisal. However, some hidden defects cannot be assessed in this way. Felling shakes can be predicted by growth strains measurement. As the estimation of heart decays is of great importance, some temperate technologies are tested: ultrasonic waves are not simple to use as they require a calibration of the propagation time versus the decay amplitude on a great number of trees and give a poor information on the form of the cavity. Special penetrometers must be built, as commercial apparatus are not adapted to tropical conditions up to now. Sapwood thickness can often be measured by increment cores.

Improved Utilisation of Non-Conventional Timbers in India

Bhupendar N. Gupta, K.S. Shukla
Dr. Y. S. Parmar University of Horticulture and Forestry,
Post Box # New Forest, H. P. -173 230 , Nauni, Solan, India
Tel: 91-0135-759382, FAX: 91+1972+52242, Email: Guptab@yspuhf.hp.nic.in

Shortage of wood in general and of conventional timber species in particular is being experienced in India. To narrow the gap between supply and demand, plantations of fast growing species are being raised in a big way. Timber from industrial plantations is, often, deprived of quality due to saw milling practices which compromise strength properties in favour of timber recovery, variability in strength properties as compared to naturally grown timber. Predominance of juvenile wood poses problem in sawing and subsequent drying, and also variability in gluing behaviour. Research is being pursued to evolve technologies for processing of such species so as to improve their suitability for various end uses. *Eucalyptus* hybrid (eucalypts), *Populus deltoides* (poplar), *Hevea brazilensis* (rubberwood) etc., are some of the species which have been upgraded and find use in building construction, furniture and joinery, value added packaging like pallets, cable drums and other items. Special sawing techniques have been developed to reduce warp in converted material from eucalyptus, poplar etc., which have high growth stresses. Treatment methods to treat refractory species like eucalyptus have also been developed which have been adopted by the industry to affect economy in use. Rubber wood has also emerged as an acceptable alternative to conventional forest species. It has also been attempted to up-bring colour, texture and decorative features in plain looking plantation timber through ammonia fumigation alone and after bark extract swabbing to match conventional timbers like teak, rosewood, etc. Efforts have been made to develop composite wood products to supplement solid wood as they have the option of using inferior woods, small wood, lops and tops, wood waste and also agricultural residues. As composites have a large potential to reduce the wood content in engineered wood products, it is essential that the cost of manufacture is kept low. A major component in costs of such composites is the government levies on raw material as well as the manufactured products. A variety of reconstituted wood products like plywood and allied products, fibreboard, particleboard, laminated veneer lumber (LVL) from plantation species, structural wood from lops and tops from poplar and eucalyptus, etc., have been developed. Properties of such products can be monitored to make their best use even for structural purposes. For economic production of reconstituted wood products, it is essential that cost component of adhesive is reasonable. Efforts have, therefore, also been made to substitute phenol in phenolic resins with naturally occurring phenolic substances. Cashew nut shell liquid (CNSL) based adhesives; both cold and thermosetting have been developed by condensation with aldehyde using variety of catalysts. Tannin based adhesives using bark extract from *Acacia mollissma*, *Shorea robusta*, wattle (*Acacia mearnsii*), and myrobalon nuts (*Terminalia chebula*) and thiolignin isolated from *Pinus roxburghii*, lignin from spent black liquor of *Eucalyptus* hybrid, *Dendrocalamus strictus* etc., have been tried to substitute phenol in phenolic resin with promising results. Multivalent phenol or tar acids, a coal tar distillation product, has also been studied for substituting phenol in PF resin with encouraging results. The industry has adopted use of lignin, tar acids and other natural phenolic constituents from CNSL in making board products.

Maximization of Lumber Yield (Case Study of a Tropical Ghanaian Sawmill)

Charles K. Gyamfi, K. Frimpong-Mensah
University of Science and Technology, Department of Wood Science and Technology, Kumasi, Ghana
Tel: 233-51-60381, FAX: 233-51-60137, Email: ckgyamfi@avuust.africaonline.com.gh

Lumber is an important wood product accounting for over half the total earnings of the forest products export from Ghana. Lumber yield study was conducted in a sawmill in Kumasi, Ghana to assess the existing mill performance in the conversion of tropical hardwood logs. Twenty seven logs comprising ten logs of Obeche (*Triplochiton scleroxylon*), ten logs of Iroko (*Milicia excelsa*) and seven logs of Mahogany (*Khaya ivorensis*) were selected for the study. A mean lumber yield of 39.39% (standard deviation, 4.69%) was determined for the hardwood species. This value appeared to have been influenced by the availability and quality of logs, condition of sawmill machines, processing efficiency, mill operatives and contract specifications. Regression analysis indicated significant (5% level) effect of log diameter on lumber yield. Good correlations were observed between log diameter and lumber yield with R square values of 0.51, 0.81and 0.77 recorded for Obeche, Iroko and Mahogany respectively. Procedures anticipated to maximize yield of lumber were recommended.

Biological and Chemical Investigations of the Composition and Distribution of Accessory Compounds in Discoloured Beechwood (*Fagus sylvatica* L.) after Felling

G. Koch, J. Bauch, and J. Puls
Federal Research Centre of Forestry and Forest Products, Institute of Wood Biology and Wood Preservation, Leuschnerstr. 91, 21031 Hamburg, Germany
FAX: 040-7252 2835, Email: gkoch@aixh0401.holz.uni-hamburg.de

The discolouration of raw timber of beechwood (*Fagus sylvatica* L.) after felling and, in sawn logs or boards, after steaming and drying is of considerable economic importance due to the increased demand of lightly and uniformly coloured wood in Europe.

In order to provide practical procedures and techniques for its prevention, individual studies have to be carried out on the biological and chemical characteristics associated with the different types of discolouration. For this reason, it is necessary to identify these discolourations as either physiological processes already initiated in the living tree or as biochemical and chemical reactions during storage or steaming and drying. As soon as the specific reaction mechanisms and accessory compounds responsible for discolouration are identified, methods for its prevention can be developed.

In order to characterize the different reaction mechanisms and accessory compounds, sections from stored, steamed, and kiln-dried beechwood logs were selected. For the study of the distribution of accessory compounds on a cellular level, sections were prepared from cambium to pith. This study on the cellular level was extended to a subcellular level by using UV-microspectrophotometry with a special scanning technique which allows scanning of transverse sections with a characteristic wavelength. The accessory compounds of the acetone and methanol extracts were separated by high performance liquid chromatography and qualified with a diode array detector. The element content of inorganic compounds in discoloured beechwood, which might be involved in discolouration, was analyzed using optical emission-spectroscopy with an inductively coupled plasma flame (ICP-OES).

The light microscopical investigations revealed that the accessory compounds responsible for the discolouration of beechwood were mainly restricted to the axial and ray parenchyma cells. The intensity of discolouration is correlated with the concentration of the deposited accessory compounds. The enrichment of the accessory compounds in the parenchyma cells indicates that the discolouration was initiated by physiological reactions depending on the oxygen potential in the vessels. By using UV-microspectrophotometry, the content of the accessory compounds was determined separately in parenchyma cells and the lumen of vessels. The interpretation of the UV-absorption spectra reveals that the isolated extractives in the parenchyma cells and in the lumen of vessels can be detected as phenolic compounds. Additionally, differences in the intensity of UV-absorption of the accessory compounds in the parenchyma cells and the deposited extractives in the lumen of the vessels can be proved.

The separation of the acetone extractives of discoloured beechwood shows different low molecular phenols such as catechin, 2,6-dimethoxy-p-benzochinon, syringic acid, taxifolin, taxifolin glycoside, conidendrin, and eugenol. Some of the isolated compounds represent dimeric structures, which are similar to parts of the lignin molecule. Furthermore, the element analyses of the inorganic components indicate an increasing mineral content especially in the transition zone of discoloured tissue.

From the present study, there is a hint to the possibility that the different kinds of discolouration in stored, steamed, and kiln-dried beechwood are caused by the synthesis of phenolic and flavonoid accessory compounds in parenchyma cells, due to different processes.

Variación de las propiedades físicas y químicas de la madera de *Pinus elliottii* Engelm. y *Pinus taeda* L.

G. de Muniz, GM de Bonduelle, U Klock. A Bonduelle
Universidade Federal do Paraná, Departamento de Engenharia e Tecnologia Rurais, Rua Bom Jesus 650, CEP 80030-010 , Brazil
Tel: +55-41-3522443, FAX: +55-41-2532332, Email: gbmunize@cce.ufpr.br

Palabras claves: *Pinus elliottii*, *Pinus taeda*, densidad, contracción, contenido de humedad, analisis qúimicas, madera juvenil y adulta.

El presente trabajo tuvo por objetivo el estudio de las propiedades fisicas y quimicas de las maderas de *Pinus elliottii* Engelm y *Pinus taeda* L. procedentes del Bosque Nacional de Irati, Paraná, Brasil. Fue estudiada la variación de las propiedades en la dirección radial (madera juvenil y adulta) y en diferentes alturas del fuste (5%. 25%, 50%, 75% de la altura comercial).

Las propiedades físicas estudiadas fueron: densidad básica, contenido de humedad y contracción radial, tangencial, longitudinal, volumetrica y coeficiente de anisotropia. Las determinaciones quimicas realizadas fueron solubilidad de extractivos en agua caliente, de acuerdo con las normas ABTCP-M4/68 y solubilidad en alcohol-benzeno ABCP M 6/68. Fueron analizados modelos de regresión para las diferentes y posiciobes del árbol y las relaciones entre ellas.

La variación del contenido de humedad en las especies estudiadas es considerable, tanto en el sentido radial como en altura. La variación mas significatiba fue encontrada en la faja de transición de la albura (120%) para el duramen (30-60%), aumentando también en relación con la altura. La densidad básica decresce con la altura del fuste. La disminución entre la altura relativa 5% (1,30m) y la altura comercial (diámetro en la Hc = 5cm) fue aproximadamente de 18%. Tambien los valores de la densidad há variado considerablemente en el sentido horizontal del tronco, donde existe un aumento en el sentido medula corteza. En la parte externa (madera adulta) de las dos especies fue aproximadamente de 22-23% mayor do que la madera juvenil.

Las contracciones volumetricas máxima, radial y tangencial determinadas para la madera juvenil y adulta confirman las diferencias existentes entre las mismas, aumentando en el sentido médula – corteza, disminuyendo con la altura; la contracción longitudinal y la anisotropia de contracción presentarón un correlación inversa con la densidad.

La tendencia general observada es de un aumento en el contendio de extractivos a medida que aproxima a la médula., siendo que los mayores aumentos se producen en la madera juvenil, debido a la formación de duamen, donde se acumula mayor cantidad de extractivos y resina. Existe una tendencia bien definida en cuanto a la altura en el árbol, verificandose que el contendio medio de los extractivos disminuyen con el aumento de la altura.

El análisis de los modelos de regresión, para estima las caracteristicas en relación el sentido radial, edad y altura del fuste, en las dos especies, mostraron coeficientes de determinacion satisfactorios.

The Relationship Between Strength and Some Anatomical and Physical Properties of Typical Tall Coconut (*Cocos nucifera* L.) Varieties in the Philippines

Rolendio N. Palomar, Fernandez, Virgilio A.
University of the Philippines Los Baños, College of Forestry and Natural Resources
Tel: 049 536 3432, FAX: 049 536 3206

The natural variations of strength and related properties of about 80-year old trees from three (3) varieties of tall coconut stems were investigated. The properties were determined from test on small clear specimens in the green condition. The mechanical properties studied include stress at elastic limit, modulus of rupture, and modulus of elasticity in static bending; shear parallel to grain; maximum crushing strength, fiber stress at proportional limit, and modulus of elasticity in compression parallel to grain; and compression perpendicular to grain. The related properties closely examined include anatomical (fibrovascular bundle frequency and fiber dimensions) and physical (specific gravity, shrinkage and fiber saturation point) properties.

The San Ramon variety significantly showed higher average values in all the mechanical properties investigated than the Baybay and Laguna varieties, the former having longer and thicker fibers and higher specific gravity but had lower fiber saturation point than the other two varieties. However, the anatomical, physical and mechanical property values of the Baybay variety appeared not to be significantly different from the values of the Laguna variety.

Regardless of varieties, the coconut trees with brown nut color showed markly higher values of mechanical properties than those with green nut color, the former exhibited longer and thicker fibers but indicated lower fiber saturation point than the latter.

For all the varieties, both brown and green nut colors the values of strength properties markedly increased radial from the core of the dermal portion of the stem and tended to increase with increasing height level.

Variance component analysis revealed that the main factor that affects the anatomical, physical and mechanical properties is the radial segment. Although the affects are significant for variety and nut color, the variance contributions were found to be relatively small.

Coconut lumber taken from the dermal portion of the first and second logs of the stem (i.e. 6 to 8 meters from the butt can be safely used for structural purposes particularly in low-cost house construction while the dermal section can be utilized for non-load bearing structures.

Key Properties and Quality of Larch (*Larix* spec.) Concerning End-User Requirements

Stefan Pelz
University of Freiburg, Forest Products Laboratory, Werderring 6, 79085 Freiburg, Germany
Tel: +49 761 203 3769, FAX: +49 761 203 3764, Email: pelzstef@ruf.uni-freiburg.de

Wood of Larch species is becoming of a strongly increasing importance in the field of wood building technology in middle, eastern and northern Europe. Main reasons are the high natural durability of the heartwood which allows to avoid the application of chemicals for wood-protection and the excellent performance regarding density, MOR and MOE as well. However a big uncertainty can be stated for the larch wood processing industry because of less detailed information about big range of roundwood and sawn wood properties which have to be regarded while processing larch wood. There is a demand to describe the quality of the resource "Larch" systematically and sufficiently in terms of custody requirements. There are less studies done, which are describing roundwood and timber properties detailed with the intention to gain predicting simulation models for wood quality of certain Ressource locations.

The objective of the presented study is to provide information on the properties of Larch timber out of the South West Region of Germany which is relevant for ensuring the quality required by different construction techniques. Roundwood was taken from stands with a typical range of site qualities and space regimes. Stem dimensions were selected according to mostly common roundwood-sizes covering a BHD range of 20-60 cm. Stem characteristics like crown dimension and shape, stem dimension and taper, knottiness, eccentricity and defects were measured. A survey on experiences and key-problems of larch processing enterprises in Germany, Austria, Denmark and Switzerland provide important aspects for a purposeful analysis of properties. According to the chosen "End-user-groups" the trees were cut into beams and boards of different dimension. The products were taken from different tree heights and radial positions. In addition clear specimen were formed from the boards and beams. At both industrial dimensions and clear specimen as well the following properties were analysed: Density, static and dynamic modulus of elasticity (MOE), modulus of rupture (MOR), tension strength, shrinkage and warp. Visual and automatical (Machine-Stress-Rating) grading procedures were done according to bending strength, dynamic MOE, static MOE, density and different visual aspects. The mechanical properties were found to be on a very high level, strongly influenced by compression and juvenile wood. The performance of mechanical behaviour marks a distinct transition zone between juvenile and adult wood at a cambial age of 15 years. Warp is the main reason for grading into lower classes.

Further steps are done to describe the influence of sites and space regimes detailed and to complete and improve methods to locate juvenile and compression wood. Consequences for wood processing are analysed and recommendations are given.

Pulp and Paper Properties of *Acacia mangium's* Forest Plantation Thinning Residual

Ibrahim Rushdin bin
Universiti Sains Malaysia, 11800 Pulau Pinang, Malaysia
Tel: 604-6577888 ext. 2113, FAX: 604-6573678, Email: rushd@usm.my

Acacia mangium forest plantation at Kamasul's Compensatory Forest Plantation is thinned four times during a rotation. The thinning residual is low in strength and small diameter and is not suitable either for saw or veneer logs, therefore one of the potential utilization is for the production of pulp and paper. The objectives of this study are to determine the variation in pulp yield and quality caused by alkaline pulpings and the effect of beating on pulps' properties. In this study, thinning residual of 9 years old forest plantation was pulped by soda, soda-AQ and kraft pulping. The pulps were evaluated using the method of a standard beater evaluation (Lampen mill). The kraft pulp was also evaluated by using different beater apparatus (PFI mill, valley beater and disc refiner) and the properties of laboratory-made paper were compared to machine-made paper. The pulp screened yields are ranging from 44.98% to 51.46% and kappa number from 23.1 to 55.7. As the beating period increased, the handsheets' properties changed, and the rate of changing depends on the pulping method. At the freeness of 350 CSF, the tear indexes are ranging from 5.8 to 10.1 mNm^2/g, the tensile indexes from 75 to 115 Nm/g, the burst indexes from 3.5 to 7.4 kPam^2/g, and folding endurance from 40 to 1093. Different beating apparatus gave different strength value development. These are due to different degree of fibre shortening, external/internal splitting and fines production. There were differences in properties between machine-made and laboratory-made paper. The machine-made paper was found to have a lower bonding index than the laboratory-made paper eventhough they were made from the same stock.

Wood Anatomy of Malaysia *Grewia* and *Microcos* (Tiliaceae)

R. C. K. Chung, S.C. Lim
Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia
Email: richard@frim.gov.my

The generic delimitation between *Grewia* L. and *Microcos* L., established by Linnaeus in 1753, has been the subject of controversy and confusion in past few decades. Many botanists either sunk *Microcos* into *Grewia* or segregated *Microcos* from *Grewia*. Recent studies on wood anatomy showed that the Malaysian species of *Microcos* can be consistently distinguished from those of *Grewia* species by the distribution and size of vessels, presence or absence of vascular/vesicentric tracheids, and some other anatomical features.

5.01.02 Natural variations in wood quality

Within and between Trees Variability of Mechanical Properties, Colour and Natural Durability in Coppice Trees of Chestnut

Olivier Dumondeaud, Bernard Thibaut
Université de Montpellier, 2, Place Eugène Bataillon, 34095 Montpellier Cedex 5, France
Tel: 33.4.67.14.34.83, FAX: 33.4.67.14.47.92, Email: dumonceaud@lmgc.univ-montp2.fr

Chestnut in mediterranean regions is almost always cultivated in coppices giving only small diameter logs appropriate to fence, posts and pols. Today most industrial products of this kind for exterior use are made from conifers after pressure treatment with CCA preservatives. For environmental reasons these treated woods should be as limited as possible to uses where a strong controls possible both at manufacture and recycling state. Both high natural durability and low sapwood thickness are interesting factors for chestnut coppices for exterior round wood uses. Experiments on selected representative plots and trees shows that chestnut is very often in the higher class of natural durability

and have good longitudinal mechanical properties. Although it has low mechanical strength in perpendicular to grain direction. Variations of properties are rather small within the tree, but significative differences can be found between trees for most of the properties, so that it can be useful to select the best ones for the highest risk situations.

Surface Analysis Of Oil Palm Fibre Using X-Ray Photoelectron Spectroscopy (XPS)

M. Ambar Yarmo, Sarani Zakaria and Amelia Suib
Universiti Kebangsaan Malaysia, Faculty of Physical and Applied Sciences. Pulp and Paper Laboratory, 43600 Bangi Selangor, Malaysia
Tel: 03-8283261 / 3211, FAX: 03-8292415, Email: sarani@pkrisc.cc.ukm.my

The surface analysis using X-Ray Photoelectron Spectroscopy (XPS) technique were used to determine the binding type of carbon and oxygen in samples extracted oil palm fibre empty fruit bunch (EFB). The method were used to find information of chemical composition C18 and O19 photoelectron peaks deconvolution technique gives several new peaks. Both C18 peak and C18 showed 3 types of carbon binding. Each binding energy of new peaks are compared to reference showed EFB sample composed of C18 of C-OH, -C-O-, -COO and -Ca and oxygen (O18) of -O, H2O, -O-H, -O=C and C-O-C type.

Relations de la couleur du bois avec quelques parametres anatomiques pour quatre essencis de bois tropicaux

J. C. Goncalez, Janin G., Keller R.
Universidade de Brasília, Departamento de Engenharia Florestal, Brasília, Brazil
Email: goncalez@unb.br

Le travail de recherche, développé au laboratoire de Qualité des Bois – INRA à Champenoux (France), porte sur quatre essences de la forêt amazonienne: Fava Amargosa (*Vataireopsis speciosa* Ducke); Jequitiba Rosa (*Cariniana micrantha* Ducke); Peroba d'Agua (*Rauwolfia paraensis* Ducke) e Peroba Mico (*Aspidosperma macrocarpum* Mart). Les paramètres mesurés de la couleur sont: la clarté (L), la coordonnée a* (coordonnée rouge-vert), la coordonnée b* (coordonnée bleu-jaune), la saturation (C) et l'angle de teinte (H). Le calcul des paramètres a été réalisé selon le système CIELAB, 1976. Il montre les corrélations existantes entre les variables de la couleur et quelques éléments anatomiques pour les quatre essences en fonction des directions radiale et tangentielle.

Pour l'espèce *Fava Amargosa*, présente en direction radiale, la clarté (L) augmente avec la hauteur et la largeur des rayons ligneux et diminue avec la longueur des fibres et la hauteur du parenchyme axial. On peut donc supposer que cette coloration brun jaunâtre est une conséquence des corrélations suivantes: - corrélation négative entre a* et la largeur des rayons, ainsi que entre a* et la hauteur de la série du parenchyme axial; - corrélation positive entre b* et la largeur des rayons ligneux. Dans la direction tangentielle, l'espèce *Fava Amargosa* présente une clarté qui est corrélée négativement avec la longueur des fibres et la hauteur de la série du parenchyme axial. La coordonnée b* est corrélée positivement avec l'épaisseur de la parois des fibres. Ces corrélations aident à caractériser la coloration brun-jaunâtre claire dans cette direction.

L'espèce *Jequitiba Rosa*, présente en direction radiale, la clarté (L) est corrélée négativement avec la hauteur et la largeur des rayons. Cette corrélation négative peut être expliquée par la coloration rouge plus foncée des rayons ligneux par rapport au reste de la masse du bois de l'espèce. La corrélation entre la coordonnée a* et la largeur du rayon confirme ceci. Etant plus foncée, les rayons se présentent en petite proportion par rapport aux autres éléments anatomiques du bois, ce qui explique la dominance de la coloration rouge claire. Dans la direction tangentielle, la clarté est corrélée négativement avec la longueur des fibres et la hauteur de la série du parenchyme axial. Les coordonnées a* et b* sont corrélées avec l'épaisseur des parois des fibres de façon opposée, c'est-à-dire au fur et à mesure que l'épaisseur des parois des fibres augmente, la couleur rouge augmente aussi, alors que la couleur jaune diminue. Ceci peut aider à comprendre la coloration rougeâtre plus claire de cette direction par rapport aux deux autres. L'épaisseur des fibres sert souvent de "guide d'ondes" pour absorber les rayons lumineux, donc diminuer la clarté (L).

Pour l'espèce *Peroba Mico*, en direction radiale, la clarté est corrélée négativement avec la longueur des fibres et positivement avec la hauteur du rayon. La couleur jaunâtre dans cette direction augmente avec la hauteur des rayons ligneux. Dans la direction tangentielle, l'espèce *Peroba Mico*, montre une corrélation positive entre la clarté, la largeur et hauteur des rayons. Les coordonnées a* et b* sont corrélées positivement avec l'épaisseur de la paroi des fibres. Ces corrélations contribuent à l'explication de la coloration jaunâtre plus claire dans cette direction.

Pour l'espèce *Peroba d'Agua*, direction radiale, la largeur des rayons est corrélée positivement avec L, b* et H et négativement avec a*. C'est-à-dire que la coloration typiquement jaune de cette direction est expliquée surtout par l'épaisseur de la parois des fibres et par la largeur des rayons ligneux. Dans la direction tangentielle, la clarté est corrélée négativement avec la largeur des rayons et la hauteur du parenchyme axial. Celle-ci est aussi corrélée positivement avec les paramètres a*, b* et C. La hauteur du rayon ligneux montre des corrélations positives avec a* et C. Ces corrélations sont les principaux responsables de la coloration jaune dans cette direction.

En conclusion, les éléments anatomiques montrent des corrélations intéressantes avec les paramètres de la couleur. Ces corrélations aident à expliquer la variation de la couleur dans chaque direction pour l'espèce en question. Ces corrélations sont variables d'une espèce à l'autre et d'une direction à l'autre.

Dans la direction radiale, la largeur et la hauteur des rayons ligneux ont un rôle très important pour aider à expliquer les paramètres, clarté et les coordonnées a* et b*. Pour la direction tangentielle, les corrélations des paramètres de la couleur avec les éléments anatomiques sont très variables, il faut considérer chaque cas à part.

Mots-clés: Bois Tropicaux, Couleur, Anatomie, Correlations

Juvenility in Rubberwood (*Hevea Brasiliensis*) and its Relation with the Physical and Mechanical Properties

Mohd. Hamami, Roslan, M., Mohd. Zin J. and Zaidon A.
Universiti Putra Malaysia, Department of Forest Production
43400 Serdang Selangor, 43400 Serdang Selangor, Malaysia
FAX: 603-9432514, Email: hamami@forr.upm.edu.my

Knowledge on anatomical, physical and mechanical properties of wood is necessary in assessing the potential utilisation of wood. The main objectives of this study are to determine the cellular composition and anatomical properties variations of juvenile rubberwood (*Hevea Brasiliensis*) in the selected clones and age groups. Another objective is to determine the structure of juvenile wood in relation to physical and mechanical properties. Three different clones, PB 359, PB 366 and RRIM 600 from two age groups, namely 10 and 22 years old were selected from Golden Hope Plantation Bhd. Three trees were felled for each clone and age group. Each tree was divided into three portions along the height namely, stump (S1), trunk (S3) and branch (S5). Outer and inner samples along the radial position were chosen for comparative studies on the anatomical, physical and mechanical properties. All samples for each test were prepared in accordance with the British Standard (BS 373: 1957) specifications.

Juvenile wood from the 10-year old, *Hevea* trees of the clone PB 359 exhibited the highest values for fibre length (1152.16µm) and initial moisture content (60.36%). Clone PB 366 showed the highest values in fibre proportion (53.83%), MOR (112.49N/mm^2), MOE (9149.90N/mm^2), and compression parallel to grain (50.64N/mm^2) whereas RRIM 600 possessed the highest value in fibre diameter (25.27µm), lumen diameter (12.28µm), shear parallel to grain (17.87N/mm^2), tangential shrinkage (2.13%) and radial shrinkage (0.99%).

For mature wood of 22-year old, clone PB 359 showed the highest values in fibre length (1248.69µm), initial moisture content (65.96%), radial (0.69%) and longitudinal shrinkage (0.34%). Clone PB 366 possessed the highest value in fibre proportion (47.32%) and MOR (137.60N/mm^2), whereas clone RRIM 600 showed the highest value in fibre diameter (24.61µm), specific gravity (0.61g/cm^3), tangential shrinkage (1.49%), MOE (10422.48N/mm^2), compression parallel to grain (64.05N/mm^2) and shear parallel to grain (20.57N/mm^2).

All clones from the 22-year old age groups showed higher values for the fibre length, proportion of rays, moisture content, specific gravity, MOR, MOE, compression and shear parallel to grain when compared to similar clones from the 10-year old age group. For both age groups, the values for fibre length, fibre diameter, lumen diameter, cell wall thickness, vessel diameter, proportion of rays, specific gravity, MOR, MOE, compression and shear parallel to grain at the trunk (S3) section were higher compared to the stump (S1) and branch (S5) sections.

The mechanical strength of the wood was found to be affected by fibre length, fibre diameter, cell wall thickness, proportion of fibres and specific gravity. Based on mechanical strength, 10-year old juvenile rubberwood is suitable for the manufacturing of pulp and paper, solid wood products and medium-density fibreboard. Clone PB 366 is suitable for sawn timber due to the superior mechanical strength. Clone PB 359 can be processed to pulp

and paper due to its lower lignin content and higher alpha-cellulose and hemicellulose contents. Branch wood (S5) possess similar anatomical, physical and mechanical properties to the trunk (S3), and is also considered suitable for industrial utilisation. The stump (S1), however possess lower mechanical strength properties and is not recommended for industrial utilisation.

Quality Parameters of the Wood of Oak (*Quercus petreae* Liebl. and *Quercus robur*) in Variation of the Ring Width and Plantation Patterns

Markus Metzger, Gero Becker and Stefan Peters
Albert-Ludwigs-Universität Freiburg, Institut für Forstbenutzung, Werderring 6, 79085 Freiburg, Germany
Tel: +49-761-203-3764, FAX: +49-761-203-3763, Email: fobawi@ruf.uni-freiburg.de

Due to a changing economical environment the European forest owners start to think about rotation cycles as an economical variable. This is true even for oaks which are traditionally managed in very long rotation periods of 240 years and more with the objective to produce big high quality logs. Today more advanced growth concepts with a shorter rotation time of about 180 years and various plantation patterns are under discussion but still with the unchanged goal to produce big timber with a diameter of 60cm and above. The consequence is a much wider width of the annual rings. The effect of these wider rings on wood and veneer quality is not known so far.

Material

Altogether 60 trees from four stands with a well known history (190 years old) were selected, covering the dbh range from 40-70 cm. The ring width ranged between 1mm for the lower end and 2mm for the upper end, thus representing the natural differentiation which is representing the different growth concepts. After felling external log quality was assessed. Two logs from different heights in the were cut and sawn into boards or sliced into veneer. Two discs each from the top and bottom of every log were cut to evaluate selected wood properties on a laboratory scale.

Results

Sawn timber quality

The quality of the boards from trees with wide rings (lower and upper sections) was significantly better than for the narrow ring trees. The knot free volume of the boards was significantly higher, and they showed less rottened knots. Out of the upper sections of the narrow ring trees few boards could be sorted into the highest quality class.

Veneer quality: The surface quality (roughness) of industrial sliced veneer showed no significant difference between wide ring trees and narrow ring trees. This was also true for upper and lower sections. But within each section an influence of the radial position was found. In contrary to veneer surface roughness microtome cut reference cubes showed a roughness which is caused by wood anatomical properties. This is the roughness that can be reached with an optimised cutting process. The comparison of the roughness of wide ring trees and narrow ring trees rings showed a difference: The wide ring trees rings were significant less rough than the narrow rings. An additional analysis of individual ring width showed that the roughness decreased with increasing ring width.

Conclusions

Oaks which were grown with a relatively wide spacing had a significantly higher volume of logs, boards and veneer. The comparison of quality parameters of industrial sliced veneer produced from upper and lower sections of trees width wide and narrow ring width showed that there are only slight differences. For practical purposes it can be said that there is no difference between the two analysed ring width groups. Although the evaluation of the laboratory sample cubes show that the roughness is clearly linked to ring width: Wide year rings result in a significantly lower roughness than narrow year rings. The roughness caused by an industrial cutting process is overlaying the roughness caused by wood anatomical structures. Alltogether, an increasing ring width within the investigated group as a result of a higher speed of growth does not have negative consequences for the wood and product quality of oak.

Red Heartwood in Trees of Beech (*Fagus sylvatica* L.)- Occurrence, Biological Causes and Consequences for Utilisation

Ute Seeling
University Freiburg, Forest Products Laboratory, Werderring 6, D-79085 Freiburg i.Br., Germany
FAX: +49 761 203 3763, Email: fobawi@ruf.uni-freiburg.de

Beech (*Fagus sylvatica* L.) is the most important broadleaf species in Germany and the area of beech stands shall even increase - following advanced silvicultural programs. The wood of beech is highly appreciated in the furniture industry and just now a very modern light wood species. The most important so called wood defect is the red heartwood that often occurs in older beech trees (more than 80 years). Red heartwood leads to a severe devaluation of the stems. In this context interdisciplinary investigations about the occurrence, the biological causes and the consequences for utilisation are just going on and the results shall be presented in this paper. The open questions are: when does red heartwood occurs, how is the coloured heartwood developing in the standing trees, and is there any possibility to use this timber for high-quality products?

In the past the formation of red heartwood was often correlated with the age as well as with the dimension. But for the modern silvicultural strategies that deal with uneven-aged mixed stands the correlation between tree architecture and the formation of red heartwood is the most interesting aspect. The possibilities to influence or even to avoid red heartwood by special silvicultural strategies are actually evaluated. Most important in this context is the aspect how the stands of beech shall be treated when the first time during a thinning the harvested trees show the red heartwood. The transfer of the empirical results will be reached by modeling. Besides marketing aspects for red heartwood of beech are evaluated. The formation of red heartwood doesn't influence wood strength or elasticity but for special processing (drying, impregnation) the great number of thyllosis' are quite negative. But most important for the furniture industry is that the red colour is not stable under UV-light. So the end-user prefers today light wood of beech trees. Only a very small percentage of beech trees with red heartwood are actually used for the production of very individual, handmade furniture. The surface is often treated by oil or wax, but the problem how to protect the strong red colour over years is not yet solved.

Tree Stands on Peatland, Quality of Wood Raw Material and Suitability for Different Use Objects

Marketta Sipi, Juha Rikala
University of Helsinki, Department of Forest Resource Management, Post Box # 24, FIN-00014 Helsinki, Finland
Tel: +358-9-1917655, FAX: +358-9-1917755, Email: mhsipi@LadyBird.helsinki.fi

Keywords: drained peatland; Norway spruce; Scots pine; sawn timber; quality; wood property

According to the National Forest Inventories forest drainage seems to be a major factor for the increased volume growth observed in the Finnish forests. The real contribution of the increased growth is, however, heavily depending on timber assortment distribution as well as the quality and usability of the wood raw material. This knowledge has to be considered insufficient. Most of the tree stands on drained peatland are reaching the logging maturity thus their importance for mechanical wood industry is growing.

The aim of this study is to clarify the most important external and internal quality properties of Norway spruce (*Picea abies* (L.) Karst.) and of Scots pine (*Pinus sylvestris* L.) timber trees growing on drained peatlands. The suitability of wood raw material for sawn timber and its further processed products are examined as well as the differences in quality properties between tree stands on peatland and mineral soil.

Study material was collected from two different kinds of sites of Norway spruce and two sites of Scots pine. Five sample plots were chosen to represent each site. Part of trees was measured and graded and a part was felled for study trees on each sample plot. Data of the study trees were registered and the stems were cut into butt, middle and top logs. Furthermore logs were sorted according to size, top diameter, length and external quality properties. To study the wood properties sample discs were taken from butt end of each log and from top end of top log. The diameters with and without bark, the eccentricity of pith, the amount of heartwood and compression wood, defects in discs, density, growth ring width and the amount of latewood were measured in the laboratory. Logs were sawn using normal blade settings.

Sawn timber was graded before and after drying according to grading rules of Nordic Timber. Centre yield was also graded according to Nordic stress grading rules. Special attention was paid to the properties affecting the quality. Sawn timber was kiln dried to 20% final moisture content. The changes in timber quality during drying and factors affecting them were studied.

According to preliminary results, the wood properties are in accordance with those referred in literature. Basic density of spruce is nearly constant in the longitudinal direction of stem, whereas basic density of pine decreases from butt to top. In the radial direction the basic density increases slightly from pith to bark in both tree species. Exceptional phenomenon can be found at stump height, where the basic density first decreases strongly and then increases towards bark. The variation in single density samples was quite extensive. The highest heartwood percentage of cross-section area was found at about 10% height in spruce stems and at about 20% height in pine stems. It has to be noted that both basic density and amount of heartwood depend e.g. on the geographic location, age and growth rate. The amount of compression wood was surprisingly small.

Study on Pulpwood and Mechanical Properties of Three Tropical Acacias

Fangqiu Zhang, Chenzuxu Yangmin, Searle, Suzettele, Jiayu, Bai
Institute of Tropical Forestry, Longdong, 510520 Guangzhou, China
FAX: 86 20 87725622, Email: acaciard@public.guangzhou.gd.cn

Wood density, fiber and mechanical properties of *Acacia mangium*, *A.auriculiformis* and *A. crassicarpa* from two sites, tropical area and subtropical area, were determined and analysed. The results showed that there were remarkable difference in wood density, fiber length, fiber width, MOE, MOR and crushing strength among species, provenances individuals and sites. Three species with 0.38-0.56g/cm^3 wood density, 1.0-1.3mm length and 16.5-20.0 µm width of fiber, are all suitable for pulpwood, but *A. craasicarpa* is the best one, *A. auriculiformis* is followed and *A. mangium* is the worst. The mechanical properties of *A. auriculiformis* and *A. craasicarpa* are quite similar, they are all better than *A. mangium*. The correlations between growth and wood properties for different provenances within same species were not significant. The selection of species, provenance and individual for wood improvement are all effective.

5.01.04 Biological improvement of wood properties

Exogenous Influences on the Cambial Growth Dynamics of Plantation-grown *Swietenia macrophylla* King., *Carapa guianensis* Aubl., and *Cedrela odorata* L. (Meliaceae)

O. Dünisch, J. Bauch, J. Puls, L. Gasparotto
Hamburg University, Institute of Wood Biology, Leuschnerstr. 91, 21031 Hamburg, Germany
FAX: 7252 2835, Email: jbauch@aixh0401.holz.uni-hamburg.de

The present study on exogenous influences on the cambial growth dynamics of plantation-grown *Swietenia* macrophylla King., *Carapa guianensis* Aubl., and *Cedrela odorata* L. was initiated by the urgent demand for reforestation of degraded areas of the Central Amazon. The investigations were carried out from 1995 until 1999 at the experimental site of the EMBRAPA Ocidental located 25 km north of Manaus, Brazil (3ø08'S, 59ø52'W). At a plantation of *Swietenia*, *Carapa*, and *Cedrela* established in 1992, the significance of mineral elements, water and light for the cambial growth dynamics of these species was studied. During the experimental period of four years, the mineral element supply of the soil and the element content of different plant fractions were investigated in monthly intervals. The distribution of mineral elements in the cambial region was investigated also on a subcellular level by Energy-Dispersive-X-Ray analysis (TEM-EDXS). The water supply of the trees was studied in terms of tensiometer measurements and xylem sap-flow-measurements (Granier sensors). The study of the leaf water potential was carried out by means of a Scholander pressure chamber. The significance of light intensity for the wood formation of the trees was studied with PAR-sensors. The cambial growth dynamics of the trees was identified by means of dendrometer measurements, the pinning method and the repeated collection of cambium and xylem samples obtained by a microborer (diameter of the samples 1.4mm). The lignification of the cells was studied on a subcellular level by UV-spectrophotometry.

Mineral element analyses indicated a high K, Mg, and P demand of *Swietenia* and *Cedrela*, compared to *Carapa*. During the dry period from July until November, a strong reduction of periclinal cell divisions and even an extended cambial dormancy of *Swietenia* and *Cedrela* were observed on poor soils, compared to *Swietenia* and *Cedrela* grown on more fertile soils.

A reduction of the soil water content during the drier season from July until November (montly precipitation less than 150mm) led to a strong reduction in water uptake and to an increase in the leaf water potential (dry period > 30 bar, wet period 2-12 bar) of *Swietenia* and *Cedrela*. Even in short time periods with a reduced soil water supply, formation of parenchyma bands and a dormancy were induced at the cambium of *Swietenia* indicating high sensitivity of the wood formation of this species towards drought.

Light intensity measurements and the analysis of reserve carbohydrates indicated a strong light demand of *Swietenia* for photosynthesis and carbohydrate production. Consequently, in plantation systems with strong shadow, the cambial growth of *Swietenia* was strongly reduced compared to *Swietenia* grown under full light conditions. In contrast to that, the intra annual growth dynamics of *Carapa* trees were only slightly influenced by a 50% reduction of the light intensity.

Quality and Properties of Wood Species from Natural Forest: Evolution of the Test Methods - Relation between Quality and Uses Application to Brazilian Timber Species

Jean Gerard, Meriem Fournier, Patrick Langbour, Bernard Thibaut
CIRAD-Forêt, 73 rue J.F. Breton - BP 5035, 34032 Montpellier Cedex 1, France
Tel: 33-(0)467616516, FAX: 33-(0)467615725, Email: jean.gerard@cirad.fr

Technological characteristics of timber species from natural forest are commonly considered as weakly variable at the level of the botanical species. These properties change little with time, and data and information given ten or fiveteen years ago into technical documents are quite similar to those which are given nowadays. However, some changes have been occuring during these last years, in relationship with the evolution of the test methods and procedures, but also with the own quality and origin of the woods which are presently marketed.

Recently, some physical and mechanical properties were still measured in a routine way, and the laboratory tests results (splitting test, resistance to perpendicular traction determined according to standard procedures) were distributed and mentioned in technical documents intended for wood industry. These information must help to select the most suitable uses of woods, and to assess woods behaviour during processing according to their characteristics.

Nevertheless, it frequently appeared that a part of these data were not really relevant and consequently of relative interest for wood processing industry and final users. On the other hand, complementary properties and parameters as fissility, sensitivity to air humidity give more indications about the ability of any wood to process well or to pose any problem.

In the field of processing, especially for sawing, drying, machining, finishing, gluing, wood industry particularly needs and asks information and technical help about the parameters to apply to optimize these operations. The compatibility between woods and finishing products, the life span of these products after applying (in particular for exterior uses), the possibility to glue some species considered to be unsuitable (Ipe, Cumaru, Jatoba) must be more widely studied to enlarge the range of possible or potential uses.

Other topics as the measurement and quantization of wood color linked to its changes with time for exterior uses are being investigated in order to help architects and construction companies to do the best choice when selecting timber species for wood building.

Quality Assessment Of Planted Coconut Wood (*Cocos Nucifera*) Linn.

Mohd. Hamami, Irene, S.I.L. and Jasmine K.Y.L
Universiti Putra Malaysia, Department of Forest Production, 43400 Serdang Selangor, 43400 Serdang Selangor, Malaysia
FAX: 603-9432514, Email: hamami@forr.upm.edu.my

The studies are essential as to determine the prospect of utilising *Cocos nucifera* Linn. wood as supplement timber to our hardwood due to the diminishing supply of the conventional wood. An assessment on anatomical, physical and mechanical properties of coconut palm (*Cocos nucifera* L.) was carried out on a 30-year old and a 50-year old stem. Variation of both coconuts palms in fibre dimension; metaxylem, vascular was the important physical properties measured was specific gravity by the water displacement method. The mechanical properties assessed were static bending, compression parallel to grain and shear parallel to grain.

Three discs each measuring 5 cm were taken from three different height level: bottom, mid level and top portion. Sample blocks measuring 5x5x10mm were taken from both outer and inner regions of each disc. Macerated fibres were used for fibre dimension measurements and analysed using image analyser. The specimens were obtained from billets sawn at the butt, middle and top of the trunk with two billets from each position. The wood from the outer and inner were taken as testing samples. Mechanical testings were conducted in accordance to the British Standard (BS 373.1957) for testing Small Clear Specimens of Timber by using the Zwick 1974 Universal Testing Machine (UTM).

The results showed that high concentration of vascular bundles occurred at the outer part of the stem and the amount increased with stem height. The mean number of vascular bundles for 30-year old and 50-year old stems was $93/cm^2$ and $84/cm^2$ respectively. The fibre length for both trees showed an increase value towards outer region and decrease over stem height. It ranged from 1.97mm to 2.14mm in 30-year old stem and 1.78mm to 1.90mm in 50-year old stem. Fibre diameter and fibre-wall thickness showed an increasing trend from the top portion towards the bottom while it decreased towards the core. The mean lumen diameter increased over stem height as well as from the inner to outer region for both trees. However, there was no significant difference in all properties measured between the 30-year and 50-year stem. The mean diameter of metaxylem decreased over stem height for the 30-year old stem but it showed an inconsistent trend for the 50-year old stem. However, The mean diameter of metaxylem showed an increase value towards core for both trees.

It was found that specific gravity of the outer wood range between 1019.70 kg/m^3 to 614.286 kg/m^3 and 1017.16 kg/m^3 to 826.317 kg/m^3 for wood aged 30 and 50 years old respectively whereas the inner wood were mostly less than 500 kg/m^3 for age group. Mechanical strength increased from core towards outer wood but decrease as the height increase. The butt billets of both trees exhibit the most superior strength value with MOR range as height increased, decreasing from 121.20 MPa to 61.71MPa and 142.20 MPa to 71.46 MPa for outer wood of stem aged 30 and 50 years old respectively.

Most strength values obtained for the outer wood were about twice as compared to the inner wood. The analysis of variance at $P<0.05$ indicated significant differences between all properties of outer and inner wood. There was also significant differences when comparison in properties was made between the different aged *Cocos nucifera* Linn. wood. The analysis between properties and stem height showed significant differences at $P<0.05$. Strong correlation was also found between the density and bending strength as well as the density and modulus of elasticity (MOE). When compared to the properties of Heveawood of aged 25, all properties except the MOE of *C. nucifera* wood is superior than Heveawood. The study indicated that attempts to utilise *Cocos nucifera* Linn. wood as conventional wood exhibit great prospect due to a number of its features that makes it a unique source of wood materials.

Physical and Mechanical Wood Properties of *Melia Azedarach* L. Planted in Areas in the North of Vietnam

Frantisek Hapla, Do Van Ban
University of Göttingen, Institute of Wood Biology and Technology, Büsgenweg 4, D-37077 Göttingen, Germany
FAX: 0049/551-393543, Email: fhapla@gwdg.de

Forest products and wood-based industry are of great importance for Vietnam. They considerably contribute to the economic development and meet the needs of the growing population regarding merchantable wood, fuelwood and wood-based panels. *Melia azedarach* is mostly planted along the rivers, as solitaire or in rows at a wide spacing along the roads and tracks or in gardens. Regarding the possibilities of its utilization *Melia azedarach* so far belongs to the lesser known species.

The goal of the extensive investigation in the main wood technological properties of *Melia azedarach* was to infer better yield and possible uses of the timber. Substantial investigation in physical wood properties (wood density, swelling and shrinkage) as well as in mechanical wood properties (tensile, compressive, bending and shear strength) were carried out on twenty sample trees from two different sites (Dong-ngac and Tay-tien) in the delta region of the river Song-Hong. The results of the investigation revealed that the wood of *Melie azedarach* possesses good dimensional stability and mechanical strength properties (medium till high strength class) and therefore is suited for many-sided use in interior wood work and for light and medium timber construction. *Melia azedarach* as a timber tree is a possible substitute for many endangered species in the Vietnamese natural forests.

The results of the investigation constitute an important basis for estimating the possible uses of *Melia azedarach* timber based on scientifically ascertained data. A high timber quality orientated silvicultural treatment of this species contribute to the improvement of the converted timber and fuelwood supply of the rural regions in Vietnam. By the development of adequate forest management conceptions *Melia azedarach* as light demander could be cultivated in plantations with increasing yield in view of high timber quality.

Technological Characterization and Development of the Uses of South American Tropical Timber Species

Patrick Langbour, Jean Gerard
CIRAD-Forêt, BP 701, 97387 Kourou Cedex, France
Tel: (0) 594 32 09 60, FAX: (0) 594 32 32 81, Email: langbour.p@cirad.fr

The technological properties of more than 200 timber species from natural forest of Central and South America have been studied in the laboratories of CIRAD-Forêt. Around two-thirds of them come from Brazil. The disciplines concerned are wood anatomy, sawing, drying, machining, physics and mechanics, preservation and natural durability.

These studies aim to identify the best suited utilizations of woods according to their qualities, to supply relevant data and usable information on wood properties and utilizations to the wood sector operators, and to contribute to enhance the acceptance of lesser known species by final users.

They have been carried out in close cooperation with partners from different origins, among others, INPA, EMBRAPA, Eldorado Firm, Instituto Brasileiro de Desenvolvimento Florestal in Brazil, the Guyana Forestry Commission, the Escuela Nacional de Ciencias Forestales in Honduras, the French Guiana Region, the Tropenbos Foundation in the Netherlands, the International Tropical Timber Organization.

Various kinds of outputs have been produced:

- Guide on Major Timber Trees of Guyana - Timber Characteristics and Utilization
- Technical sheets "New marketable Timber Species from South-America"
- Tropical Timber Atlas of Latin America
- Identification Atlas for Woods from Amazonia and Neighbouring Regions
- Diagrams of Technological Characteristics of Tropical Timbers: Volume VI - Brasilian Timbers
- Data Base on Technological Properties of 200 Tropical Timber Species

These documentary outputs are widely utilized by wood industry in the producing countries (Brazil, Guyana, French Guiana) and in the importing countries. Moreover, they constitute basic technicals tools for CIRAD-Forêt in the framework of the technical assistance operations carried out at the demand of wood firms.

Considering the evolution of the international timber trade and taking into account the institutional and industrial demand, the CIRAD-Forêt has begun to enhance its actions on South American tropical timber species to improve their utilizations. Based on all the data ever obtained, they will be carried out in the framework of a R&D project entitled Development of the technological knowledge on timbers species from natural forest and rational uses of their variety.

This project is organized according to three main stages:

- Technological study of commercially less accepted species from Tropical America.
- Analyze of processing and marketing sectors in order to optimize the utization of these species.
- Technical assistance to the primary processing industry so that to improve the quality of the products.

Basic Density and Strength Properties of *Grevillea robusta* Cunn. Grown in Agroforestsry in Moshi District, Tanzania

F.B.S. Makonda, Hamza, K.F.S.; Ishengoma, R.C., Mosha, S.
Sokoine University of Agriculture, Department of Wood Utilization, Faculty of Forestry and Nature conservtion, P.O. Box 3014 Chuo Kikuu, Morogoro, Tanzania
FAX: 255-56-4648, Email: forestry@sua.ac.tz

Basic density and some strength properties *Grevillea robusta* Cunn. grown in agroforestry in Moshi district, Kilimanjaro region, Tanzania were studied. The relationships between these properties were also determinded. The study area was divided into low and high altitudinal zones. Ten sample trees aged 26 years, five from each zone, representing the entire diameter range were selected. Three disks measuring 5 cm in thickness were cut from each sample tree at 1.3m, 45% and 755 of total tree height for basic density. A two metre long central board which included the pith was cut at 1.3m up-wards for strength properties. Standard methods were used in the determination of these properties. The basic density was found to be 500 and 460 kg/m^3 for low altitude and high altitude trees respectively with average basic density of 490 kg/m^3. The difference in density between the zones was statistically significant ($p<0.05$). Within tree basic density variation i.e radial and axial, was also significant at $p<0.01$. With exception of cleavage, other studied strength properties (Modulus of Elasticity, Modulus of Rulpture, Work to maximum load, Total work, Compression and shear strength) decreased uniformly from the pith outwards. Cleavage increased from the pith to about 20%, then decreased slowly to 40% followed by sharp decrease towards the bark. Positive regression coefficients were found between basic density and all strength properties studied. Recommendations on the efficient utilization of timber of *G. robusta* have been included in this paper.

Effect Of Thinning on The Anatomical Characteristics and Properties Of Beech Wood (*Fagus Orientalis* L.)

Ali Rafighi
Gorgan University of Agricultural Sciences and Natural Resources, Post Box # 634, Gorgan, Iran
Tel: 0171-27867, FAX: 0171-50651, Email: irgouni@dci.iran.com

When thinning is a forest stand, growth condition is going to better for root and crown of remaining trees. Therefore thinning causes spreading of crown size, increasing of leaves number and also branches diameter, so far by reason of this environmental factor effects on cambium activity is considered that the production of wood increases to comparison of before the thinning. With precise comparison of beech wood anatomical characteristics and properties (*Fagus orientalis* L.) between 10 trees in thinned and 10 trees in dense stand of natural forest from P.F.P. (Pajim Forest Project) in BEHSHAHR region in the north of IRAN was studied the following factors like as: Growth diameter of trees, Fiber length, Number of vessel and fiber permm^2, Fiber and vessel diameter, Number of cell in uniserate ray, Fiber coarseness ¸, Number of fiber per gram of wood (Ng), Fiber thickness index (T), Findings show growth diameter of trees in thinned forest is more than the dense one. Tree shape in thinned forest is more conical,meanwhile in dense stand goes toward cylidrical form.

Fiber length in trees of thinned stand is longer than dense but in spite of this difference there is no significant difference between them. Number of fiber per mm^2, average fiber and vessel diameter and average ray height in thinned stand show increas but in contrast high decrease of vessel number obtained per mm^2, so according to T test trial and analysis of variance was found significant difference between thinned and dense forest, and for the rest of factors which were pointed (e.g. Number of ray per mm length, Average ray width, Number of call in uniserate ray), there were no significant difference. In the other hand the results shows increasing in fiber thickness index (T) and fiber coarseness¸ and decreasing in number of fiber per gram of wood (Ng) in thinned forest which are the most important factors relating to pulp and paper making process and the signifying of difference shows that the thinning has positive effects on the properties of wood.

The Effect of Growth Site and Felling Time and Timber Drying on the Wood Properties of Norway Spruce and Scots Pine

Pekka Saranpää, Jaakko Repola
Metla - The Finnish Forest Research Institut, PO Box 18, FIN-01301 VANTAA, Finland
Email: pekka.saranpaa@metla.fi

The aim of this study is to find out variation in wood properties between different growth sites and the effect of felling and storage times on discolouration during drying. The effect on the quality and end-use value of wood raw material is discussed in another presentation (Sipi and Hemmilä). Knowing the effect of these variables on the quality and properties of sawn timber and end-use products the trees can be felled timely and the wood raw material can be delivered directly to its most suitable end-use target. The use of wood material can be optimized and the benefit of wood material can be maximized. This is important especially for high quality joinery timber.

The study material is collected from two sites of Norway spruce (*Picea abies* [L.] Karst.) and two sites of Scots pine (*Pinus sylvestris* L.). Sites with a high site index and with a low site index were included. We had three felling times: winter, spring and autumn. Part of the logs felled in spring were stored under sprinklers (wet storage) for 6 weeks.

Data for the study trees is registered at the felling site either from trees, logs or discs. The discs of 2-5 cm thickness are taken from the butt end of each log and from the top end of each top log. Age, stem height, crown ratio, diameter, amount of compression wood and sapwood/heartwood are measured. Disks are transported to the laboratory for measurement of growth ring width, basic density and wood moisture content from pith towards bark.

In each stand two dominant trees were selected as sample trees in each cutting seasons. The cutting seasons were winter, spring and autumn. Part of the spring felled trees were stored under sprinklers. The wet storage lasted six weeks. The sample trees were felled and sample disks were taken from log ends for the detailed laboratory studies of wood properties. The logs were cant-sawn with a circular saw in the field. The dimension of the side yield was 25 x 100mm^2 for both tree species. The dimension of centre yield was 38 x 100mm^2.

The temperatures used for kiln drying were: 50, 70, 90 and 110°C. Winter and spring felled specimens (one group of each) were also air seasoned. One group from autumn felling was also vacuum dried at 70°C. The drying schedules in kiln dryings were common schedules used in industry for 38mm thick boards. The surface colour of every board was measured both before and after drying with a Minolta spectrophotometer CM-525i at 6 points in each board.

Drying temperature is most significant factor causing discolouration of boards. Discolouration in sapwood increased remarkable at temperatures above 70°C. At elevated and high temperature drying the lightness of boards significantly decreased. The winter felling showed increased disclouration of boards sawn from both Scots pine and Norway spruce. There were no significant differences between sites of different site index. The relationship between wood properties and discolouration will be discussed.

The Effect of Growth Site and Felling Time on the Quality and End-use Value of Sawn Timber of Norway Spruce and Scots Pine

Marketta Sipi, Timo Hemmiä
University of Helsinki, Department of Forest Resource Management, Post Box # 24, FIN-00014 Helsinki, Finland
Tel: +358-9-1917655, FAX: +358-9-1917755, Email: mhsipi@LadyBird.helsinki.fi

Keywords: Norway spruce; Scots pine; growth site; felling time; sawn timber; quality; small log

The aim of this study is to find out how different growth sites and felling times effect on wood quality and end-use value. The quality and usability of thinning trees are at the moment quite unknown and very controversial question in Finland. Thus one purpose of the study is to clarify the properties, quality and suitability of thinning trees for mechanical processing.

The study material was collected from southern Finland from four different thinning stands of Norway spruce (*Picea abies* (L.) Karst.) and of Scots pine (*Pinus sylvestris* L.) at four felling times: winter, spring, summer and autumn. The purpose was to have two comparable pairs of growth sites for each species. From each stand 8-10 sample trees were felled at four felling times during 1999. Data of the sample trees were registered at the felling site: age, stem height, crown ratio and diameter at breast height (1.3m). Stems were cut into normal butt, middle and top logs and also into so-called small logs. Growth ring width, basic density and moisture content from pith to bark and amount of compression wood and heartwood are further analysed in the laboratory from sample discs taken from the end of each log. Logs were sorted according to size, top diameter, length and external quality properties using criteria common in Finnish sawmills. Logs were sawn using normal blade settings and sawn timber was kiln dried mainly to 16-18% final moisture content. Sawn timber was sorted before and after drying according to grading rules of Nordic Timber. The changes in timber quality during drying, factors affecting them and their correlation with wood properties are clarified. Especially deformations of planks and boards during drying are studied closely as well as the effect of felling time on deformations and other quality properties of timber.

The following preliminary results are based on sawn timber quality of 150 Norway spruce small logs, top diameter 145-163mm over bark and length 3.1-5.8m. Each log was sawn to two 44*100mm planks. Wane and other defects caused by sawing technique were ignored in grading.

The quality of sawn timber is clearly better in the less fertile first thinning stand than in the more fertile one. The best timber quality comes from the trees the size of which is a little smaller than the average size in the stand. Timber quality is poorest in the small logs of the biggest trees. Dry and sound knots are the worst defects in sawn timber. However the medium-size trees of the less fertile stand give the best quality. The high density of stand and incomplete crown cover explain partly the poor sawn timber quality of more fertile stand. Generally in a dense stand shading dries efficiently the lower branches of a tree but the dead branches do not fall away why dry knots are not covered.

The differences in sawn timber quality between the two later thinning stands are rather small. The amount of the best timber quality is quite big and nearly the same in both stands. In the less fertile stand the biggest trees and in the more fertile stand the smallest trees give the highest share of the best timber grade. Sound knot is usually worst defect in sawn timber. Dry knot is most harmful in the smallest trees of the less fertile stand. Exceptionally the number of sound knots and not the size is worst defect in sawn timber from the biggest trees of the less fertile stand.

Sorting of Spruce Wood Raw Material for Pulp and Paper Products

Jari Sirvio

Properties of paper products are highly dependent on the properties of fibers used in manufacturing, and on the properties of the network formed by the fibers. The requirements for functional behaviour of paper vary between paper grades, and thus, also the critical properties of raw material. It is commonly known that the wood properties vary between tree species. Besides, within each tree species the fiber properties do vary within and between individual trees, even between trees of similar genotype. The knowledge of the variation in fiber properties is essential when sorting the wood raw material for optimal paper products. By selecting an appropriate raw material source, or by mixing two or more raw material sources using optimal proportions, may lead in savings in material and processing costs, in a better control of pulping and papermaking processes, and in a higher quality of the end-product.

The objectives of this study were to find out, (1) what is the amount of variation in fiber dimensions, (2) how does this variation relate to growth mechanisms of trees, (3) which are the sorting criteria for varying fiber dimensions, and (3) how affects the sorting of wood raw material on the variation. The study concentrates on Norway spruce (*Picea abies* (L.) Karst), because of its wide use in pulp and paper products in Finland. Two independent sample series were collected at varying vertical and horizontal locations from several Norway spruce trees. The amount of variation in fiber length, perimeter, and cross-sectional cell-wall area was of same magnitude within and between the samples, each consisting of five growth rings. The amount of variation in cell-wall thickness and cross-sectional compactness ($4\pi A/P2$), indicating fiber flexibility and collabsibility, was clearly higher within the samples than between them.

Four hypotheses were formulated concerning the control of the variation between the samples. On the basis of the experimental materials it was concluded that (1) the maturation processes contributing to fiber dimensions are localized in the growth meristems rather than throughout the entire tree, (2) the amount of production, i.e. the size, is at least an as good indicator of the maturity as the age, and (3) the fiber dimensions are highly related to the cambium maturity, but also the growth rate has an influence on them. In the case of cell-wall thickness and cross-sectional compactness the influence of the growth rate was greater than the effect of maturity.

Based on the results obtained, an application for sorting Norway spruce raw material was developed. In this application the average fiber properties of individual trees and logs, as well as the distributions of fiber properties, are predicted using rather easily measurable tree or log parameters, namely the diameter and the age of a tree or a log.

The consistent results obtained from the two independent sample series indicate, that the studied phenomena are characteristic for Norway spruce. This supports the feasibility of utilized methods and the use of this application in practice.

The results indicate that for chemical pulps of high fracture energy requirements trees or logs of large diameter and high age, consisting of long fibers, should be used. Young and fast-grown trees or logs, consisting of low compactness fibers, are suitable for chemical pulps of high tensile strength requirements. Old and slow-grown trees or logs are also suitable for newspaper, because their thick-walled fibers fibrillate effectively, and thus form strong pulp, during mechanical pulping. On the other hand, young and fast-grown trees or logs are suitable for optically effective mechanical pulps for SC- and LWC-papers.

Still a lot of research remains to be done within the field of wood raw material classification for papermaking purposes. The other tree species may respond differently to the growth mechanisms, the co-operation of sorted raw material groups and the pulping processes need to be studied, and, finally, the optimal fiber and fiber-network properties for different paper grades need to be clarified.

Anatomical Physical Properties of Wild Pear, *Pyrus communis* L.

Ibrahim Tümen, Harzemsah Hafizoglu, Gökhan Gündüz
Zonguldak Karaelmas University, Faculty of Forestry, 74100 Bartin, Turkey
FAX: +90.0378.2277421, Email: Mehmet Sabaz [peyzaj74@turnet.net.tr]

The pear wood is valuable especially in joinery work and was used in historical buildings and door restoration made by Kündekâri technique originating from Anatolian Seljuks and Ottomans.

Pyrus communis L. wood has a homogeneous and diffuse porous structure. Vessels are individually arranged and there is no group formation. Earlywood vessels arranged tangentially in annual ring border. In early wood radial vessel diameter was found to be 46.55±6.17µm, tangential 35.06±3.50µm. Likewise, in latewood radial and tangential vessel diameters were 32.03±3.84µm and 26.11±3.48µm, respectively. Procumbent (horizontally elongate) parenchyma form homocellular rays. Most of the rays were biseriate, but multiseriate rays were also observed. Maximum height of the ray parenchyma cells was 35. There were 15 rays in 1mm and 68 in 1mm^2. The results were compared with those of other hardwoods. Generally the tips of fibrils are sharp. Ratio of fibril/vessel is 1.93. The length of fibril was found to be 1.001mm, the width 20.78µm, the lumen diameter 6.84µm and the wall thickness 6.97µm. The results indicated that the width of annual ring was 1.81mm and the latewood 0.873mm.

Oven-dry specific gravity of *Pyrus communis L.* wood was determined to be 0.655 g/cm^3 and the air-dried specific gravity 0.676 g/cm^3. Average volumetric shrinkage value was 13.848% and the volumetric swelling 16.640%. The volume-weight value was determined to be 0.547 g/cm^3.

Key Words: Pear, *Pyrus communis L.*, Kündekâri, Vessel, Ray, Specific gravity.

Models of Knot Properties as a Basis for Optimising the Utilisation of Scots Pine Timber

Geir I. Vestol, Olav Høibø, Ola Øyen
Norwegian Forest Research Institute, Høgskoleveien 12, N-1432 As, Norway
Tel: +46 64 94 90 00, FAX: +46 64 94 29 80, Email: geir.vestol@nisk.no

The quality requirements of blanks for window production are rigorous. The most important wood properties are knots, checks and heartwood. Since the variability in these properties normally is large and unknown, the yield is rather low. This affects the economy of the production, and in turn the prices of the raw materials and of the products. This study was a part of a project with aim to increase the yield in production of blanks for windows. The specific aims of this part was to analyse the difference between forest types, and to propose a method for optimising the cross cutting of trees into logs with respect to the knot structure. 30 experimental trees were sampled from three sites in eastern Norway. The site indexes, defined as dominant height at 40 years age, were F11 (Sites 1 and 2) and F17 (site 3). At site 1 the soil was deep but poor while at site 2 the soil was shallow and open bedrock was frequent. The knot structure was described as the radial extension of knots at various vertical positions. In the lower 5 m of the tree, a whorl was sampled from each 0.5 m, and from the rest of the tree for each 1.5 m. In the sample whorl knot length was measured as radial distance from pith to where the knot was enclosed by the wood. The stem radius was measured just above each measured knot and the mean knot proportion (KNPROP) was calculated for each whorl. The vertical trend of this quantity was described mathematical at each single tree: where z is distance from stump height. From this model the vertical position where KNPROP reached fixed levels was calculated. This model was used to propose log lengths for each individual trees, by setting KNPROP= 0.7 which is the position of the sawn surface closest to the pith. The average log lengths were 3.89 m at site 1, 1.16 m at site 2 and 6.05 m at site 3. It proved that site 2 did not have trees suitable for this product. The surface of the cylinder from this point and down to the stump was simulated for each tree and in average 5% of the knots were visible on the surface. Finally, the point was related to crown characteristics and a method for cross-cutting the stems into logs was proposed.

Fiber Morphology in Relation to the Handsheet Properties of Thirty-seven Sumatran Hardwoods

I-Chen Wang, Yu-Chang Su
Taiwan Forestry Research Institute, Division of Wood Cellulose, China-Taipeh
Email: hhwang@mail.npust.edu.tw

A total of 37 hardwoods, belonging to 20 families, including 9 species of Dipterocarpaceae grown in the native forests of Sumatra, Indonesia were sampled, each species with 2 to 5 stem bolts. Fiber morphology of each species were analyzed in detail. After kraft pulping, standard handsheets were prepared from each species, and the results evaluated in light of their fiber morphological characteristics. The species have an average fiber length of 1.33mm, width of 25.3µm, cell wall double thickness of 10.82µm. Secondary fiber parameters such as slenderness ratio, Runkel ratio, flexibility index and coarseness were also derived, when physical properties of the handsheets were regressed with the fiber morphological parameters, except for tearing strengths, most didn't show discernible correlations with them, suggesting that interfiber interactions are more important in handsheet strength development than individual fiber characteristics. Fiber morphological

properties thus would be a poor predictor for papermaking potential of the hardwood pulps studied.

Mechanical Properties of Naturally Curved Growth Chestnut (*Castanea Sativa* Mill.) Trees Used for Wooden Ship Building

Hikmet Yazici, Hasan Vurdu, Ayben Kili
Zonguldak Karaelmas University, Faculty of Forestry, 74100 Bartin, Turkey
FAX: +90.0378.2277421, Email: peyzaj74@turnet.net.tr

In our country, especially in the Black Sea Region, Chestnut tree is the species used commonly for wooden ship manufacturing because of strong and high quality of the wood material. In this study, patterns were prepared test specimen from Chestnut tree with unstraight bale tensile wood and normal wood that occurred at he opposite direction to tensile wood. On the specimens, tensile strength parallel to grain, bending strength, compression perpendicular to grain and Brinell-Hardness values have been determined and compared with each others. Results indicated that there were considerable differences between tensile wood and normal wood in mechanical properties. Compared with normal wood, percentages of sorption in tensile wood were low in parallel to grain, radial and tangent directions, whereas Brinell-Hardness value was found higher. From mechanical properties tensile strength, shearing strength and bending strength are higher in normal wood than tension wood.

Guianese timber in construction: an example of an individual dwelling

Michel Vernay, Jacques Beauchêne
Cirad-forêt, Programme Bois, TA 10/16, 34398 Montpellier cédex 5, France
Tel : 33 4 67 61 65 65, Fax : 33 4 67 61 65 60, E-mail : michel.vernay@cirad.fr

Keywords: Tropical woods, building construction, structural timber, wooden house, French Guiana

The state of affairs established by the CIRAD-Forêt Guyane Wood Programme during on site quality control operations as part of the SPIOM (Overseas Pilot Innovation Sector) scheme between 1990 and 1995 has prompted the authors to put forward a better suited use of Guianese timber in construction, by way of a building project. This project is the culmination of an approach whose primary targets were:

- to encourage the use of locally available construction material
- to develop the timber sector and the local economy
- to encourage timber processing as end products
- to use quality wood
- to offer people in the trade better knowledge about Guianese timber

Characteristics of the main species selected:

Using the example of a building made with a system of posts and beams, based on traditional Guianese architecture, it is possible to highlight the characteristics peculiar to the different types of Guianese wood. Depending on the technique in question, the construction system proposed helps builders to apply "the right species in the right place" - there being eight selected species and several economic and technological criteria.

The availability of the species is a major criterion. In French Guiana, just three species represent 65% of current production. Certain species which are sometimes plentiful in forests, such as the Wapa (20% of the volume inventoried), are little used, and should be used for specific purposes (roof shingles); other less common species should find a slot based on available quantities.

The mechanical features of the different types of wood and the performance of each Guianese species are described and compared to two major families of metropolitan species frequently used for structural purposes: oak and "the softwood". The species selected for the project all have mechanical properties greatly superior to those soft metropolitan wood. This "advantage" should help architects to optimize their geometric calculations and produce more accurately dimensioned structural pieces.

Implementation limitations:

The application of wood in the natural climatic environment of French Guiana can only be planned on a year-in-year out basis if certain elementary rules governing the construction plan are laid down. Examples include : the choice of orientation of the building in relation to prevailing winds, protection of façades, insulating or protection of the building against the risk of "termites", architectural design doing away with any "water trap" risk which might lead to deterioration by rot-causing fungi, and so on.

The natural durability of the species proposed is a crucial factor in the Guianese context, and makes it possible to offer an initial solution to these risks. The concept of biological risk classes is determined by the situation of each constructional element in use. Many Guianese species have a place in construction as a results of their natural durability. The aesthetic look of some species also helps to lend a decorative role to structural pieces and to certain filling elements (frames, visible structure, clapboards, cladding).

The architecture proposed retains certain fundamental configurations which help to combine the material with functionality and comfort (steep wooden roofing, height beneath ceilings, natural ventilation), while at the same time stressing the "long-lived" aspect of the structure.

This project highlights the possible uses of one of French Guiana's main resources, wood, in a context of eco-materials for construction, where the main being sought is that the buildings constructed should last a long time.

5.03.00 Protection of Wood from decay and fire

Preservative Treatment of Golla Cane (*Daemonorops jenkinsiana*) by Pressure Process

K. Akhter, M. Younus-uzzaman, M.H. Chowdhury
Forest Research Institute, Post Box # 273, 4000 Chittagong, Bangladesh
FAX: 880-31-681566/681584/681584, Email: bfri@spnetctg.com

The treatability of Golla Cane (*Daemonorops jenkinsiana*) has been studied by pressure process using water-borne preservatives. Samples of three different lengths were treated at different pressure and duration to evaluate the feasibility of preservative treatment. It was observed that the complete penetration was not possible for 3m length sample using 7kg/cm^2 pressure and 1 hour duration. Samples of small (1m) and medium (2m) length can be treated satisfactorily by the pressure process following a moderate treatment schedule with conventional water-borne preservative.

Variation in Nitrogen Content in Wood Samples of Three Clones of Rubber (*Hevea Brasiliensis*) Trees in Malaysia and its Effect on the Activity of *Botryodiplodia theobromae, Aureobasidium pullulans* and *Aspergillus niger*

A. J. Ashari, J. Palfreyman & A.H.H. Wong
University of Abertay Dundee, School of Molecular and Life Sciences, DD1 1HG Bell St. Dundee, Scotland
Tel: +44 1382 308651, FAX: +44 10382 308663, Email: J.PALFREYMAN@mail1.tay.ac.uk

A wide variety of wood-inhabiting fungi adapted the nitrogen (N) content of their mycelium to that of the substrate on which they grow. This study is of importance since the low nitrogen content in wood is a major limiting factor controlling fungal decay. The present study was conducted to determine the variability of N in three selected rubberwood clones (GT1, PB217 and RRIM600). The activity of the fungi was examined for 4 weeks on 40x20x5mm wood samples, inoculated with the test fungi (*B. theobromae*, *A. pullulans* and *A. niger*), and placed in a humidified petri dish assembly under aseptic conditions. The sapstain was quantitatively assessed by spectrophotometry. The mean nitrogen content of clone RRIM 600 (1.06mg/g) was significantly higher than clone GT1 (0.73mg/g) and PB217 (0.78mg/g). *B. theobromae* spread significantly faster on RRIM600 (4.3 days) than PB217 (5.6 days) and GT1 (5.8 days). The prominent blue stain of *B. theobromae* is significantly darker (absorbance: 56.5%) when compared with *A. niger* (38.24%) and *A. pullulans* (35.88%). Clone RRIM600 (41.85%) had significantly higher mean darkness when compared to clone PB217 (38.49%). N content does affect rate of mycelial growth and staining.

Keywords: clone, nitrogen, sapstain, Hevea brasisliensis, quantitative assessment.

Antifungal Activity of Sesquiterpenoids from Taiwania (*Taiwania cryptomerioides* Hayata) Heartwood

Shang-Tzen Chang, Sheng-Yang Wang, Chi-Lin Wu, Pin-Fun Chen and Yueh-Hsiung Kuo
National Taiwan University, Department of Forestry
FAX: 886-2-23654520, Email: peter@ms.cc.ntu.edu.tw

The antifungal activities of cadinane skeletal sesquiterpenoids from Taiwania (*Taiwania cryptomerioides* Hayata) heartwood were demonstrated and compared. By spectral analyses, the absolute structures of three main cadinanes, namely T-cadinol, T-muurolol, and *-cadinol, isolating from Taiwania with HPLC, were identified. The total amount of these cadinanes was also quantified by using GC. The results showed that the total amount of cadinanes extracted from heartwood with n-C6H14 (6.49 mg/kg, based on wood weight) was much more than the essential oils that collected by water distillation from leaves (0.04 mg/kg), sapwood (0.36 mg/kg), or heartwood (1.77 mg/kg). Moreover, results obtained from the antifungal assays demonstrated that the order of antifungal index of three compounds for both *Coriolus versicolor* and *Laetiporus sulphureus* was *-cadinol>T-cadinol>T-muurolol*. -Cadinol completely inhibited the growth of *C. versicolor* and *L. sulphureus* at 100 ppm. Comparison of the configuration of these cadinanes reveals that cadinanes skeletal sesquiterpenoids with an equatorial hydroxyl group at C-9 and a trans configuration at the ring junction, *-cadinol exhibited the strongest antifungal activity.

Preservative Treatment of Rubber Wood: A Way to Couple Quality with Production

T. K. Dhamodaran, R. Gnanaharan
Kerala Forest Research Institute, Wood Science Division, Peechi-680 653 Kerala, India
Tel: +91-487-782061, FAX: +91-487-782249, Email: libkfri@md2.vsnl.net.in

Rubber wood is a prime timber resource in the ASEAN countries and also in India. Industrial utilisation of this perishable timber is mainly through vacuum-pressure impregnation of preservatives such as borates or copper-chrome-arsenates (CCA). The moisture content of wood at the time of treatment, the impregnation schedule and the concentration of treatment solution are the parameters that affect the quality of treated wood. The best option for an economical and quality production is to use the right concentration of treatment solution rather than reducing the moisture content of wood, or increasing the duration of the impregnation schedule; as the latter utilise additional energy. Extensive work was carried out at the Kerala Forest Research Institute on the effect of various treatment schedules, moisture content of wood, concentration of treatment solution and the thickness of wood as well as their interactions on the achievement of desired dry salt retention (DSR) of preservatives in the treated rubber wood led to development of an economical schedule of 15 minutes initial vacuum of 85kPa followed by a pressure of 1000kPa for 15 minutes and a final vacuum of 85kPa for 5 minutes (denoted by 15'/15'/5'). This time-and energy-saving schedule was found to achieve desired threshold level of boron preservative in the treated wood [0.2% boric acid equivalent (BAE) in the core with an overall retention of 0.4% BAE and about 6.5 kg/m 3 DSR]. Further, the schedule enabled treatment of rubber wood in any moisture condition [air-dried to green], provided the right concentration of treatment solution was employed (3-6% BAE). As CCA is still under use for protecting perishable timber for exterior applications, the applicability of the schedule 15'/15'/5' was tested for CCA impregnation of rubber wood. It was able to give the desired DSR level (about 6.5kg/m^3) in any moisture condition, provided the right concentration of treatment solution was employed (3-6%). The applicability of this short duration schedule has been tested in commercial scale treatment plants for both boron and CCA chemicals. The retention of chemicals in the treated wood was chemically analysed and found satisfactory. At present, different industries employ lengthy schedules for the treatment of rubber wood with boron or CCA. Adoption of this newly developed short duration schedule can couple ensured quality with higher production and can save energy in the rubber wood industries.

Keywords: Preservative treatment of rubber wood, Boron and CCA preservatives, Treatment schedule, Moisture content, Concentration of treatment solution.

Heartwood in Pine (*Pinus radiata* D. Don) Growing in Chile: A Contribution to the Durability

Ana Maria Fernandez, L. Salvo, P. Navarrete
BIO-BIO University, Wood Engineering Department, Avenida Collao 1202, Concepción, Chile
Tel: 56-41-261683, FAX: 56-41-323333, Email: afernand @pegasus.ubiobio.cl

Keywords: durability, *Pinus radiata*, heartwood

The study, inserted in a complete caracterization about the pine (*Pinus radiata* D. Don) growing in Chile, is related with the heartwood developed (% of the log diameter) for three age of trees (20, 25 and 30 years old) for different sites in one zone of the country (sandy).

Samples about 3x3cm by diameter length, were cutted including the pith of the log at BHD (Breast height diameter). The indicators to determine the heartwood presence were selected in relation with other studies (Kutscha, 1962; Poblete, 1991; Dietrichs, 1964; Chattaway, 1952; Rudiger, 1975; ASTM 3507-92). The normalized is done with ferric chloride at 10% concentration and the reaction was evidenced when brown color is developed in the heartwood zone. After that, the annual ring involved were measured by WINCELL software (Regent, 1998) in both sides of the sample.

The earlier results observed was a high variation for the bad sites in relation with the heartwood percentage (24.2-32.5%) and for young trees (20 years old). When the tree is older the heartwood zone reaches to 43.2% of the diameter (30 years old for the good sites) and only 38.9% for the bad sites at the same age.

Like a contribution to the pine durability studies and with the aim to decrease the pine preservation treatment usually used in construction, we exposed for a month pine samples, including heartwood and sapwood, to mold (*Penicillium* spp) using a standard methodology and the results have been variable. The older trees present a durability higher than younger ones. The difference between sites was difficult to determine. The relationship with another pines extracted from different zones was not established yet.

The Influence of Gaseous Oxygen Concentration on Fungal Growth Rates, Biomass Production and Wood Decay

S. Mahmoud Kazemi, D.J. Dickinson and R.J. Murphy
University of Mazandaran, Dept. Forestry, College of Agricultural Sciences, Post Box # 578, Sari, Iran
Tel: +98 251 935877, FAX: +98 251 935877

The effect of air and several levels of O_2, on fungal growth rates, biomass production of mycelia, and wood decay were investigated. The best technique for daily measuring of fungal growth in anaerobic condition was found to be by using 40mm petri dishes which attached to the walls of the jars. At the end of the test period, the same petri dishes were also used for determining the dry weight of the fungal mycelia. The results showed that 5% O_2 was very favourable for white and brown rot fungi. When O_2 reduced from 1% to 0.01%, fungal growth and dry weight of mycelia were steadily decreased. In the case of soft rot fungi, decreasing of oxygen, was not caused which to create big differences between their growth rates and biomasses.

When *Basidiomycetes* transferred on beech and Scots pine, air was best condition for their degradation. On the other hand, reduced O_2 (0.25, 1, 5, and 10%) caused wood decay to be decreased. However, weight losses by soft rotting fungi, in air and other levels of oxygen, all were below 5%.

Keyword: Oxygen, *Coriolus versicolor*, *Coniophra puteana*, *Chaetomium globosum*, Biomass production, Wood decay

The Manufacturing of Fire-retardant Plywood and its Efficiency on Fire Resistance

Sheau Horng Lin, Hsiu Hwa Wang
National Pingtung University of Science and Technology, Department of Forest Products, Taipeh, China
Tel: (08)7740407, FAX: (08)7740407, Email: lsh@mail.npust.edu.tw

Keywords: Oxygen index, Flame inhibition parameter, Fire retardant, Plywood, Surface flammability test.

Red lauan and radiata pine veneers were used as raw materials, soaked with eleven chemical mixtures, at 10% concentration to screen out potential fire retardants by oxygen index (OI) method. Three screened mixtures (designated as D, G, and I) of higher OI, together with CNS Type C (designated as C) were impregnated into veneers to produce 10mm thick fire-retardant plywood. The spread amount of melamine-urea-formaldehyde (MUF) adhesives varied from 161.5 to 204.5 g/m^2 during manufacturing. A 3rd grade incombustibility national standard was used as a criterion to test the combustibility and fire-retardancy improvement of each treatment. The flame inhibition parameter for the selected D, G, I and C mixtures were 0.98, 0.98, 0.95, and 0.94 respectively for red lauan, and 1.21, 1.18, 1.30, and 0.94 respectively for radiata pine. These showed that D, G and I results were much encouraging than the recommended C as one of the national standards. The improvement in fire-retardant efficiency of the treated plywood on surface combustion for the three screened mixtures at 183.0 g/m^2 MUF spread amount were: 0.34-2.79 sec (kg/m^3)-1, 3.87-8.75°C. min (kg/m^3)-1, 1.45-2.08 (kg/m^3)-1, 2.40-3.93 sec (kg/m^3)-1 and 0.23-0.39% (kg/m^3)-1 respectively when ignitability, heat release, smoke generation, afterflame time and weight loss percentage were considered. The application of G and I not only showed a better improving efficiency for the treated plywood in fire retardancy than current standard (C), their estimated least absorption amount required to meet the 3rd grade fire-retardant specification were also 15.1% less than that for C. Therefore, the two screened fire retardants (G and I) formulated in this study are the best choice in terms of economics and fire-retardancy improvement.

Natural Durability of Ten Bolivian Hardwoods

Regis B. Miller, Willy Stockman, and Frederick Green III

USDA Forest Service, Forest Products Laboratory, One Gifford Pinchot Drive, WI 53705-2398 Madison, USA

Tel: 608-231-9200, FAX: 608-231-9592, Email: rmiller1@facstaff.wisc.edu

Evaluating natural durability is important for the efficient and wise use of tropical woods. Generally, natural durability is determined in field stake tests that require many years of exposure especially for moderately durable or very durable woods. For our study, we selected the following commercially available and lesser known Bolivian species: *Amburana cearensis, Anadenanthera colubrina* (syn: *A. macrocarpa*), *Aspidosperma cylindrocarpon, Astronium urundeuva, Caesalpinia pluviosa, Diplotropis purpurea, Guibourtia chodatiana, Phyllostylon rhamnoides, Schinopsis quebracho-colorado*, and *Tabebuia* spp. (*lapacho* group).

Two matched sets of heartwood samples (blocks 19mm [3/4 in.] on each side) of the Bolivian species and sapwood control samples of red pine (*Pinus resinosa*) and yellow birch (*Betula alleghaniensis*) were prepared. Each set contained four replicates for a total of eight samples per species. Both sets were placed in standard soil-bottles (two blocks per bottle) in a decay chamber (25ø C and 80% RH) and exposed for 12 weeks to pure cultures of two brown-rot fungi (MAD 6137, *Tyromyces palustris* and MAD 617, *Gloeophyllum trabeum*) and one white-rot fungus (MAD 697, *Trametes versicolor*). After 12 weeks, one set of samples was removed, ovendried, and weighed to determine weight loss. This procedure follows the normal ASTM soil-bottle test. After weighing, the ovendried samples were steam sterilized, transferred to freshly prepared soil-bottles, and returned to the decay chamber for an additional 12 weeks. The other set of samples was not ovendried, but was steam sterilized, transferred to freshly prepared soil-bottles, and returned to the decay chamber for an additional 12 weeks. After the second 12-week period, both sets of samples were ovendried and weighed.

After the first 12 weeks, all Bolivian species showed less than 13% (mostly less than 10%) weight loss to the white-rot fungus (*Trametes versicolor*). For both brown-rot fungi, *Phyllostylon rhamnoides* had more than 30% weight loss. In all other Bolivian species, *Tyromyces palustris* caused less than 18% weight loss, and *Gloeophyllum trabeum* caused less than 10% weight loss. We compared our soil-bottle test results to reports in the literature. In some cases, the literature reports laboratory, graveyard, or stake tests, but more often, the literature only cites general observations and experience in service as the information sources. For *Caesalpinia pluviosa*, *Guibourtia chodatiana*, and *Phyllostylon rhamnoides*, very little information was available. For *Aspidosperma cylindrocarpon*, we compared our results with results from a 1970 soil-bottle test. In both studies, the white-rot and one brown-rot fungus (*Gloeophyllum trabeum*) caused less than 10% weight loss. However, in 1970, Tyromyces palustris caused 8% weight loss, and in our study, it caused 17% weight loss.

With ASTM designation D-2017-63, all species were highly resistant to white-rot, except *Amburana cearensis*, which was only resistant. All species were highly resistant to the brown-rot fungus *Gloeophyllum trabeum*, except Phyllostylon rhamnoides, which was moderately resistant. For the brown-rot fungus *Tyromyces palustris*, the highly resistant species were *Astronium urundeuva*, *Caesalpinia pluviosa*, *Schinopsis quebracho-colorado*, and *Tabebuia* spp. (lapacho group); the resistant species were *Amburana cearensis*, *Anadenanthera colubrina*, *Aspidosperma cylindrocarpon*, *Diplotropis purpurea*, and *Guibourtia chodatiana*; and the moderately resistant species was *Phyllostylon rhamnoides*. Results from the second 12-week period are pending, which might show some additional species separation for durability.

The Possibility of Some Sulawesi Wood Species for Substitution of Marine Construction

Mohammad Muslich
FRIM, Malaysia
Email: iufroxxi@frim.gov.my

This study was conducted to provide basic information on the treatment of sixteen Sulawesi wood species using Cooper-Chrome-Boron preservative. Sixteen wood species of Sulawesi were planned to final specimen dimension of 2,5 cm x 5 cm x 30 cm, and were drilled at the middle (the diameter of hole around 1 cm). Then all specimens except control, ulin (*Eusideroxylon zwageri* T.et B.), besi (*Metrosideros petiolata* Kds.) and Kandole (*Diploknema oligomera* H.J.L.) were treated by full-cell process with pressure 150 Psi about 4 hours. All specimens (control and treated) consisted of thirty specimens for every species. Each of these was differentiated into three groups and arranged into rafts. Group I was installed in the sea for 4 months, group II was installed for 8 months, and group III was installed for 12 months. The test agains marine borers was conducted in the waters of Ballang Lompo Island. At the end of the treatment for every group, observation of specimens were conducted by spliting each specimen into two parts and determining the attack intensity using the Nordic Wood Preservation Council (NWPC) standard No. 1.4.2.2/75. The attacking borer species can be identified from the traces of boring hole, type of cutting ang pallet on the aatacked specimens. The results of the study indicate that preservation were able to prevent manine borer attack. All the untreated specimens were attacked by marine borer, especially kolaka (*Parinari corymbosa* Miq.), kandole (*D. oligomera* H.J.L.), besi (*M. petiolata* Kds.) and ulin (*E. zwageri* T. et B.). On the other hand, those treated specimens showed greater resistence to marine borer attack. Moreover, *P. corymbosa* Miq., *D. oligomera* H.J.L., *Pterocarpus indicus* Willd. *Eucalyptus deglupta* Bl. and *Elmerrillia ovalis* Dandy. can substitute marine wood species such as *E. zwageri* T.et B., *Metrosideros petiolata* Kds., *Vitex cofassus* Reinw. and *Tectona grandis* L.f. Untreated wood specimens were attacked by *Bankia cieba* Clenth/Turner., Teredo bartschi Clapp., Dicyathifer manni Wright. belongs to Teredinidae family and Martesia strata Linne. belongs to Pholadidae family. There were no symptoms of crustacean infestation on the specimens. However, many crustaceans were found clinging to on the specimens when they were taken from the sea. This crustacean belongs to *Sphaeroma sp*.

Keywords: Sulawesi wood species, preservation, marine borers, Indonesia.

The Influence of Hygroscopic-range Moisture Content on Treatability of Red Maple

Ashgar Omidvar, Marc H. Schneider
University of Agricultural Sciences and Natural Resources of Gorgan, Gorgan, Iran
Email: irgouni@iran.com

The objective of this study was to measure the effect of moisture content (MC) on treatability of red maple (*Acer rubrum* L.). The MC variation studied was in the hygroscopic range, i.e. between about 0 percent and 30 percent MC. Treatability indices studied were penetration, retention, and distribution. Polymerizable monomer was used as the impregnation fluid. It was polymerized and its location was studied using microscopy. Impregnations were carried out in different flow directions.

Results showed that treatability indices increased with decreasing MC. A significant difference was found between retention at 30 percent MC and other MC levels. Penetration depth in radial flow at different MC had the same trend as retention, i.e., inverse relationship with MC, but in other flow directions penetration did not change with MC. Distribution of fluid was best when penetration had occurred radially and tangentially. Since retention and penetration in tangential flow were better than those in radial flow, the best treatment was thought to occur in tangential flow.

Changes on the Structure of Ring Porous Tree Species Caused by High Temperatures

A. Osvald, O. Korytarova
Faculty of Wood Sciences and Technology, Technical University of Zvolen, Dept Fire Protection, T.G. Masaryka 24, 960 53 Zvolen, Slovakia
Tel: +421 (0) 855 5335111 ext. 367, FAX: +421 (0) 855 5325811, Email: osvald@vsld.tuzvo.sk

High temperatures, in some materials, really mean change of the crystallitic structure, state of matter, or changes on chemical composition. In wood, it is the temperature of about 200°C which causes the changes. The process of ignition and burning of wood is influenced mainly by the individual chemical composition and physical properties. This work is concerned with a more detailed study of the influence of structure of individual ring-porous tree species on the process of burning. The following tree species have been chosen:

- Sessile oak - *Quercus petraea* (Mattusch.) Liebl.
- Mountain elm - *Ulmus Montana* Stokes
- European ash - *Fraxinus excelsior* L.
- Black locust - *Robinia pseudoacacia* L.

These tree species were exposed to radiant heat sources with the intensity of 750 W. The process of heating was controlled in order to prevent the ignition of specimens and to observe only the influence of the radiant heat. In general, it can be concluded that the source caused changes in structure being macroscopically observed as colour changes. Boundaries of these changes limited zones of our observation. Individual microscopic observations are shown in various figures.

Laboratory Assessment of CCB as an Alternative to CCA Against Drywood Termite, *Cryptotemes cyanocephalus*

Salamah bt. Selamat, Ho Yen Foon, Shaharuddin Hashim, Faizah Abood
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, FAX: +603-6367753, Email: salamah@frim.gov.my

Copper-chrome- arsenic (CCA) is the most established wood preservative in this country especially for termite protection and for ground contact application. The termicidal properties of this formulation derives from arsenic compound. However, due to various criticisms with regard to possible danger associated with the arsenic content either for mammal and environment, other woodpreservative such as copper- chrome-boron(CCB) has been tested as an alternative to CCA. The study based on the laboratory scale is included the leaching properties of the individual salt of copper, chrome, arsenic and boron and their effect on one of the two species of drywood termites encountered in Peninsular Malaysia, *Cryptotermes cyanocephalus*. The chemical content in the treated wood block will be expressed in kg m-3 and the effect of CCA and CCB on the *Cryptotermes cyanocephalus* will be expressed in percentage of weight loss.

Improved Preservative Delivery and Treatment System for Timber Treatment

Clarence Tan, L.T. Hong
Fernz Timber Protection and Forest Research Institute Malaysia, 52109 Kuala Lumpur, Malaysia
Email: Hong Lay Thong [honglt@nt1.frim.gov.my]

Copper-chrome-arsenic (CCA) preservative for timber treatment has been used in Malaysia for more than thirty years. This preservative is utilised in the vacuum-pressure treatment of hardwoods for use (mainly) in construction. The timber preservation industry has progressed rather slowly both in terms of technology and productivity when compared to the other timber processing sectors.

Since its introduction CCA has been sold to the end-users in drums of (mainly) 100 kg in the form of a paste. The problems associated with handling the paste formulation at the treatment plants include, hardening of the paste during storage, disposal of the drums after use, spillage and difficulty in transferring to the mixing tanks and concerns on safety of the workers.

An improved delivery system for CCA, which has been used in Australia and New Zealand, was introduced to the timber preservation industry in Malaysia in recent years. The system overcomes some of the problems associated with the handling of "paste formulation" and will thus improve the health and safety of workers as well. The system consists of the delivery of an aqueous formulation of CCA of known strength to the end-user. This product is contained in a delivery tank and every batch (tank) delivered to the customer is sampled for analysis at the factory before delivery to ensure that the concentration required and other specifications of the CCA preservative are met. At the treatment factory the treatment plant facility is modified to accommodate the mechanical transfer of the CCA solution delivered to ensure minimal handling by the operators and less impact to the environment. This system fits in with the "Responsible Care" initiative adopted by chemical companies to continuously improve environmental health and safety performance of the industry. The improved delivery system will also ensure a greater consistency of quality of treatment, which is vital in improving the quality of timber treatment in the country. The paper describes the improved delivery system and discusses the advantages compared to the existing system that is practised now.

Performance of Treated *Gigantochloa scortechinii* in 24 Months Ground Contact Tests

Razak Wahab, Richard J. Murphy
Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603 6367753, Email: razakw@frim.gov.my

Bamboo has been widely used in the construction and dwelling purposes for hundreds of years. However, recorded information on their performance in the ground contact tests are lacking. A study was conducted on the ammoniacal copper-quat and copper chrome arsenic treated *Gigantochloa scortechinii* in a ground contact tests in Melaka, Malaysia. The tests covers the different ages of the bamboo culms, treatment techniques, type of chemical and the strength of chemical used. The result of the study indicated that the 4 year-old bamboo stakes were more durable than the 2 year-old. Stakes treated with CCA performed slightly better than the ACQ treated stakes. The stakes treated with CCA at all levels of chemical strength performed extremely well having little decay. While stakes treated with 2%, 4% and 8% ACQ performed well in the test. On the culms portion, the result indicated that the stakes taken at the top were more durable than the stakes taken from the middle and bottom.

Micrographic Evidence for Degradation of Rubberwood (*Hevea brasilliensis*) Fibre Walls by the Common Sapstain Fungus *Botryodiplodia theobromae*

A. H. H. Wong, A.P. Singh
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +60-3-6342633, FAX: +60-3-6367753, Email: andrew@frim.gov.my

Keywords: Blue-stain, Sapstain, *Botryodiplodia theobromae*, Rubberwood, TEM, *Hevea Brasiliensis*, Cell wall degradation, Fibre lumen wall erosion, Soft rot decay.

Sapstain is a serious biological degradation in newly felled (damp) sapwoods of saw logs and sawn timbers in the humid tropics that needs to be overcome during primary processing of these timbers. Some fungi of the Ascomycotina and Deuteromycotina groups are the causal agents, however in the tropics, the Deuteromycete *Botryodiplodia theobromae* appears to be dominant. The resultant bluish discoloration (termed Blue-stain) of the otherwise natural light/cream-coloured sapwood, is clearly unsightly in decorative wood products. In Peninsular Malaysia, freshly-felled plantation-grown Rubberwood (*Hevea Brasiliensis*) represents the many species of light native hardwoods which are readily susceptible to bluestain. Normally blue-stain in such woods is controlled using proprietaryanti-sapstain preservatives and/or prescribed timber drying schedules, and therefore the possibility of other forms of degradation by this fungus is not considered. Recently however, *Botryodiplodia theobromae* has received renewed interest worldwide because of its ability to significantly degrade wood cell walls in certain sapwood species as well as the gelatinous (i.e. non-lignified) fibres of "tension wood cells", appreciably reducing certain wood strength properties. Similarly, evidence for degradation of the normal (i.e. lignified) fibre walls in rubberwood by *B. theobromae* needs to be satisfactorily obtained, via light microscopy and transmission electron microscopy (TEM) of the wood after exposure to *Botryodiplodia theobromae* for about four weeks. Light microscopy revealed relatively large diameter hyphae to be abundantly present in parenchyma cells. The hyphae were also present in other types of wood cells, including fibres. TEM provided evidence of degradation of the normal fibre walls in rubberwood in the form of lumen wall erosion (type-2 soft rot decay). The fibre walls were thinned in the region of contact with fungal hyphae which appeared flattened when in contact with the wood cell wall suggesting enzymatic action of the hypha as a mode of lumen wall erosion. Another novel feature of hyphal activity was the direct penetration of hypha into and traversing lignified fibre wall. These observations suggest that the ability of *B. theobromae* to degrade lignified wood cells walls should be viewed with concern when utilising rubberwood after prolonged exposure to this fungus.

5.04.00 Wood processing into the next millenium

Cleaner Production In The Pulp and Paper Mills In Malaysia

Yusoff Mohd Nor Mohd, Mahmudin Saleh
Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6342633, FAX: 603-6367753, Email: mdnoor@frim.gov.my

The pulp and paper industry is normally associated with the high consumption of water, energy and chemicals which can be expected to contribute to substantial environmental impacts unless it is properly managed. For the last three years, the industry particularly in the Asian region has adopted and practised the concept of cleaner production, which was advocated by NIEM (Network for the Industrial Environmental Management) under the UNEP (United Nations Environment Programme). Cleaner production in this context refers to the continuous application of an integrated preventive environmental stratefy to processes, products and services to improve eco-efficiency and reduce risks to humans and the environment. In 1996 three mills in Malaysia became the pioneer of cleaner production in the pulp and paper industry. To date a total of eight mills have participated in the cleaner production programme. Training on the concept of cleaner production was carried out by holding workshops and conducting mill audits. For each mill a cleaner production team o about 10 members comprising personnel from functional divisions of the mill was formed. During the conduct of the mill audit, all cleaner production options were noted. The options generated were discussed and classified into environmental and economic benefits were reported by the mills involved. This paper will discuss the methodology in conducting the cleaner production exercise in the mills and also the barrier expected during the implementation. This paper will also highlight success of the participating mills in conducting cleaner production mills in conducting cleaner production and the benefits gained in terms of environmental and economics.

Studies on Uses of Alternative Extenders for Plywood Manufacture

Setsuo Iwakiri, Alexsandro Bayestorff da Cunha, Carlos Eduardo Camargo Albuquerque, E. Gorniak, Lourival Marin Mendes
UFPR, Rua Bom Jesus, 650, 80035-000 Curitiba Juveve, Curitiba, Brazil
Email: cunhaale@floresta.ufpr.br

The purpose of this work is the testing of alternative extenders in the adhesive composition, replacing wheat flour in the urea-formaldehyde formulation to give similar, or better, properties and efficiency as the tradicionally used wheat in the plywood industries. Moreover the other objective of this work has been the manufacturing of plywoods, using alternative extenders in the adhesive formulation, and the shearing tests in the glueline.

The alternative extenders used in this work were: wheat flour, soya and oat. The selection of these flours was based on the market available facilities and on accessible price. The resin used was urea-formaldhyde and the catalyst was sulphate of amonium based.

The plywood production employed 30×30×0,2cm veneers of *Eucalyptus cloeziana*, and 320g/cm² of spread amount (double line). The shearing tests were realized in a universal machine of mechanical tests. The statistics outline was of randomic type, and variance analysis was made through F and Tukey-tests at 5% probability level.

The oat (24,80kgf/cm²) is statistically equal to the wheat samples (testimony) at dry conditions. The soya treatment presented the highest medium value (14,89kgf/cm²) of shearing at wet conditions, but, at dry conditions, presented the lowest medium value (17,82kgf/cm²).

From the results, it was brought to a conclusion that the soya treatment at wet conditions presented the highest value of shearing in the glueline, followed by oat and wheat values. The soya treatment at dry condition presented lowest values than the others, because this treatment presented a mixture with a very high viscosity.

Therefore it is recommended studies with new formulations, changing the percentual quantity of extenders in these adhesive formulations, in order to find an ideal consistency, with a better flow, transfer, penetration, wetting and solidification of the adhesive, when applied over veneer surface as well as an appropriate relationship with the glue applicator rollers.

Influence of Steaming on the Chemical and Physical Properties of Wood

Wen da Lu
Northeast Forestry University, 150040 Harbin, China
Tel: +86-451-2190394, FAX: +86-451-2110146, Email: lwda@mail.hrb.hl.cninfo.net

The green wood of *Larix gmelinii* were exposed to steaming at normal atmosphere from 1 to 96 hours and the influence of steaming on the chemical and physical properties of wood were analyzed. The results of the experiments are given as follows: (1). Steaming is a nessary pretreatment process for lumber drying of *Larix gmelinii*, during steaming the resin contained of wood were removed and the water soluble matters which are mainly arabinogalactan were removed too, the PH of wood was reduced from 4.85 to 3.9, the color of wood became darker; the holocellulose content showed a slight decrease and the lignin content increase gradually; the hemicellulose were changed large, a small amount of them were degradated violently and removed from the surface of sample. (2). The air density, specific gravity and the equilibrium moisture content (EMC) of wood were reduced with the steaming process; for the beginning 1 hour of steaming, shrinkage (tangential, radial and volumeric) reduced slightly, then increased, the maximum shrinkage value arrived at 64 hours of steaming.

The Utilisation of SDR (Saw-dry-rip) Concept to Processing Sawnwood from *Eucalyptus cloeziana* F. Muell.

Claudio Henrique Soares Del Menezzi, Marcio Augusto Rabelo Nahuz, Mario Rabelo de Souza
University of Brasilia, Forest Engineering Depto, P.O. Box 04357, 70919-970, Brazil
Tel: + 55-61-3072800, FAX: +55-61-34754558, Email: cmenezzi@zaz.com.br

The mechanical processing of eucalypts wood is problematic due to the high levels of growth stresses. Those stresses cause splits and warps during sawing and resawing, with reduction in the yield of sawed wood. The main objective of this work was to study a method to reduce the intensity and frequencies of those defects, mainly during the resawing operation of sawnwood from *Eucalyptus cloeziana*. The tested method, called SDR, based on the concept of saw-dry-rip, consisted in saw the logs and resaw the boards in the final dimension only after air drying. For comparison, another method was used, called conventional, where the boards ripping was made right after sawing the logs. Six trees were collected from where it was obtained 12 logs (1st and 2nd logs). The logs were transported by truck to the Instituto de Pesquisas Tecnológicas do Estado de Sao Paulo (IPT), where they were sawed in a reciprocating gang saw. The boards originated from six logs were immediately resawed in a multiple circular saw, characterising the conventional method. The remaining boards were resawed after air drying, characterising the SDR method. The defects were evaluated after resawing and also after air drying. The evaluation consisted of determination of the deflection produced by the respective defect. The pieces produced by both methods were also classified to evaluate their quality. The SDR method, was effective in the reduction of the frequency and intensity of crook in dry ripped boards for both positions, in comparison to the conventional method. For bow, the SDR method reduced its frequency slightly, but it was not effective with the specie and it increased the intensity of the defect. However, the SDR method reduced in 62% the rejected pieces in comparison to the conventional method. After the pieces classification by crooking, it was observed that the SDR method produced dry ripped boards with better quality than those produced by the conventional method. However, when classified by bowing, the dry ripped boards produced by the conventional method presented better quality than those produced by the SDR method. It was observed, also, that the log position in the tree didn't influence the intensity of the defects in dry ripped boards produced by both methods. Concluding, it is recommended the SDR method to processing sawnwood from *E. cloeziana*.

Warp Curvature of Scots Pine Sawn Timber Predicted by a Density-based Model

Michael Öhman, Jan Nyström
Lule University of Technology, Div. of Wood Technology, SKERIA 3, S-931 87 Skellefte, Sweden
Email: Micael.Ohman@tt.luth.se

The result of this study shows that there is a good agreement between the warp curvature of bow and spring and the density distribution within dried sawn timber of Scots pine. The density distribution is expressed as the distance between the density centre of gravity and the geometrical centre of gravity in thin cross sections over the length of the sawn timber. The result is based on two Scots pine (*Pinus silvestris*) studs of the dimension 50 by 125mm and a length of approximately 150 cm and a moisture content of 6.5%. The two studs contain varying amounts of compression wood both in respect to each other and within themselves. In this study the model assumption is based on the difference in moisture related longitudinal shrinking properties between normal wood and, primarily, compression wood. Especially the latter shows a positive correlation between density and shrinking property. The denser the compression wood the higher its volumetric density, up to 1.8 times as high as normal wood, due to an increase in cell wall thickness. The relation between density and the longitudinal shrinking property of compression wood makes it possible to use the density distribution as an indicator of warp curvature within the dried sawn timber. The hypothesis is that asymmetrically distributed differences in the longitudinal shrinking properties of the material must act on the cross sections to develop a warp of the sawn timber. For example, if compression wood with greater moisture-related shrinking properties than normal wood is located close to one side of the cross section, the longitudinal shrinkage will be asymmetric and the plank as a whole will warp towards the compression wood. The larger the amount of dense compression wood the higher the degree of asymmetricality and thus the more rapid the change of the total warp curvature. On the other hand, if the compression wood is symmetrically distributed in the cross section no warp of the plank will occur since the total shrinkage is symmetrical irrespective of the amount of compression wood present. Both the warp of, as well as the density distribution within, the sawn timber were measured with the aid of a medical CT-scanner, Siemens Somatom AR-T. The CT-scanner measures the average density in small volume elements with a resolution of 0.3 x 0.3 x 5mm, one scan per cm over the whole length of the stud. To quantify the degree of asymmetric density distribution in each cross section of the plank, the distance between the geometrical and density centres of gravity is calculated for each CT-scan. Since the CT-scans are evenly distributed over the length of each stud they can be regarded to be approximately continuos measurements of the density distribution within the stud. The calculated distance between density and geometrical centres can furthermore be regarded as the second derivative of an unknown function, by integrating the distances twice, the curve form of the function is revealed and is used as the prediction of the stud's warp of curvature.

The Use of Nigerian Grown '*Hevea Brasiliensis*' in the Mechanical Wood Industry

Babatola Olufemi
Federal University of Technology, Department of Forestry & Wood Technology, Post Box #v 704, Akure, Nigeria
Email: kadeba.b@akure.rcl.nig.com

The weaknesses and shortcomings of *Hevea Brasiliensis* as raw material for household wood products were examined. These include: availability for mass production, the tree size, susceptibility to insect and fingal attack, seasoning defects, dirt absorption and the resistance of the populace to embrace it. The physical and mechanical properties were studied to rank it with trees from natural forests, which are facing depletion. The wood at 12% moisture content has a density of 640 kg/m^3. The bending strength and modulus of elasticity were 65 N/mm^2 and 9250 N/Nm^2 respectively while the compression parallel to grain is 32 N/mm^2. The total shrinkage was 3%. These properties point to its bright future as an acceptable addition to the species that are presently used in the Nigerian wood industry. On the bases of these findings some solutions were recommended:

1.A survey of available plantation and year of planting of different stands. New establishments must be preplanned for mechanical processing when the latex production becomes unrentable.

2.Small dimension machines must be procured to handle the conversion into useable boards. Many of such machines are now available for different processes in the wood industry.

3.Apart from the available preservatives, timely seasoning after conversion has shown a lot of promise in preventing discoloration and even some beethe attacks.

4.Conversion into short lengths have prevented warping, while longer dimensions can be achieved by the use of established technology of lamination.

5.The presence of large vessels is the main cause of obsorption of dirts and this can be prevented by end coating with sealers to fill up the large vessels.

6.The more publicity given to the products through exhibitions can assist in convicing people more so that species from the natural forests are dwindly by the day.

Planing Characteristics of some Ghanaian Lesser-Used Timber Species

Wilson Francis Owusu
Forestry Research Institute of Ghana, University P. O. Box 63, Kumasi, Ghana
Tel: 233-51-60123/60373, FAX: 233-51-60121, Email: forig@africaonline.com.gh

Keywords: Planing, Characteristics, Lesser-Used timber species, Ghana.

The current rate of expansion of the Timber Processing Industries in Ghana coupled with the dwindling nature of the primary species has made the current Annual Allowable Cut insufficient to satisfy the increasing demand. One major area, which has been highlighted in forest policy, is the introduction of Lesser-Used Timber Species (LUS). This is to broaden the natural resource base and to conserve the biodiversity of the major commercial timbers, particularly the six endangered species of Mahogany (*Khaya* spp.), Wawa (*Triplochiton scleroxylon*), Odum (*Milicia excelsa*), Sapele (*Entandrophragma cylindricum*), Hyedua (*Guibourtia ehie*) and Utile (*Entandrophragma utie*). Knowledge on the working qualities of timbers as well as improved fabrication techniques is of paramount importance. Therefore, lack of information concerning their machining properties will be an obstacle to their use. It is therefore necessary among other properties, to establish the planing characteristics of the LUS to enhance their promotion both locally and internationally.

The study sought to determine the planing characteristics of sixteen species classified as Lesser-Used timbers, which were selected, based on their relative abundance by volume in the Ghanaian natural forests.

Under an ITTO sponsored project PD179/91, the species were obtained from both the dry and moist semi-deciduous forests in Ashanti and Western regions of Ghana where most of the country's timber is obtained. Fifty test samples were prepared for each test operation. A Planer machine with one 2-knife cutterhead was used. Four cutting angles, three feed speeds and one cutterhead speed were considered. Each test sample was examined for planing defects using a hand lens and graded.

From the results, chipped and torn grain defects were prevalent on *Danta, Dahoma, Okan, Celtis, Essia*, *Opepe* and *Ayan*. Raised grain was observed on only Yaya and Sterculia (white). More defective samples were noted on all the species as the cutting angle increased form 15 to 30°. The high-density species like *Afena*, *Okan*, and *Essia* require cutting angle of 150 or less in order to avoid some of the planing defects. *Ceiba, Bombax, Antiaris, Canarium* and *Ofram* are planed to a better quality within a wide range of cutting angles. Low feed speeds of 6m/min & 9m/min and high cutter marks of 43 & 29 per 25mm generated high percentage of good to excellent samples for all the species. The rate of generation of defective samples is higher with cutting angles of 30o and 25o at feed speeds of 6m/min and 9m/min as density increases. Planing quality decreases with increasing density using feed speeds of 6m/min, 9m/min and 14m/min.

Performance Testing for Furniture - A Quality Control and a Marketing Tool

Heok-Choh Sim, Mohd Arshad Saru
Forest Research Institute Malaysia, Consultancy Services Unit, Kepong, 52109 Selangor, Malaysia
Tel: +60 3 6342633, FAX: +60 3 6379575, Email: simhc@frim.gov.my

Keywords: Furniture, Performance testing, Performance standards, Quality control.

The designing and manufacturing of furniture are governed by two broad categories of standards. The first category of standards specifies the various dimensions and design details, while the second category specifies the performance requirements for various types of furniture. Performance testing to evaluate the capability of a piece of furniture to perform its intended functions is an important step in the designing and manufacturing of furniture. It will ensure that the furniture has been designed and manufactured to meet specific performance requirements. Simulating the loads and forces that a piece of furniture will be subjected to during its service life, the various performance tests mirror image the behaviors of the furniture performing the intended functions. Weaknesses and defects detected by these tests could assist the designer and/or manufacturer to improve subsequent production. In addition, most standards will have different levels of performance requirements that can be used to classify furniture into different categories according to frequency of usage, or different market segments. The certificate awarded to furniture that passed the tests is therefore a testimony guaranteeing consistent quality and reliability of the piece of furniture. This testimony can thus further enhance the marketability of the product besides boosting the reputation of the designer/manufacturer.

Mechanical Processing and Products of Birch, Aspen and Alder

Marketta Sipi, Jari Kivistö
University of Helsinki, Department of Forest Resource Management,
Post Box # 24, FIN-00014 Helsinki, Finland
Tel: +358-9-1917655, FAX: +358-9-1917755, Email: mhsipi@LadyBird.helsinki.fi

Keywords: birch; aspen; alder; wood property; mechanical prosessing; wood product

The utilization of birch (*Betula verrucosa*, *Betula pubescens*), aspen (*Populus tremula*) and alder (*Alnus incana*, *Alnus glutinosa*) in mechanical wood industry in Finland is imperfect. At the moment birch is the most important species and it is mainly used in plywood industry but also in furniture and parquet. The use of aspen and alder is considerably lesser. The problems concerning mechanical processing and the insufficient knowledge of wood raw material properties of these species have restricted the use of them and lowered the value of raw material. However, during last few years an interest in more effective utilization of these species has increased. The first paper mill using aspen as raw material has started in 1997. The growing and use of aspen is increasing and therefore it is even more important to know the use possibilities of aspen also in mechanical wood industry. Birch as well as aspen and alder could be widely used, if their properties, mechanical processing and suitability for different products were better known.

The aim of this study is to clarify the mechanical processing properties of birch, aspen and alder, on the one hand their effect on the quality of end-use products and on the other hand their dependence on raw material, the properties of tree stem and growth site and on wood procurement. The most suitable end-use products for each species are defined considering the properties of raw material, end-use products and processing and the profitability of manufacturing.

The annual use and the most common and potential use objects for birch, aspen and alder as well as the worst problems related to the raw material and manufacturing of products were clarified using literature, inquiries and interviews. The results of this survey have indicated that most of the problems appear in sawing, planing and especially in drying. Deformations, shakes, cracks, colour changes and differencies of moisture content after drying are the most typical problems that affect the quality of the wood raw material of birch, aspen and alder. The problems are often the same regardless of which end-use product is manufactured. According to this survey the most suitable end-use product for birch is furniture, for aspen sauna benches and panels and for alder panels and furniture.

According to the results of this survey the empirical part of the study concentrates on the most promising end-use products of birch and grey alder and solves the problems appearing in processing of them. The most essential processing methods to concentrate on are drying, planing and gluing. The focus changes according the species, end-use product and processing problem. One of the most important tasks is to compare the high-frequence-vacuum drying to the typical condense drying. Another project is studying the aspen and common alder wood properties after warm air drying, condense drying and high-frequence-vacuum drying. In addition to the planing and gluing also the heat treatment will be one of the subjects.

The study increases knowledge of the possibilities to use birch, aspen and alder wood in mechanical wood industry. The most suitable end-use products for the species, their quality and processing properties and profitability of processing are clarified. Recommendations to process the wood raw material of the species are compiled. Birch, aspen and alder may be better utilized in mechanical wood industry, the use of them may increase, new products may be found and for example in the furniture industry they may replace foreign species.

An Approach to the Surface Hardness Enhancement of Chinese Fir Wood

Shuhong Wu, Sun Zhengyuan, Li Botao
Chinese Academy of Forestry, Institute of Wood Industry, 100091 Beijing, China

The paper involves a research on the effects of two kinds of pre-treatment on the surface hardness enhancement of plantation Chinese fur wood. It was designed that wood surfaces pre-treated with laser incision and chemicals were penetrated with Hardening Treatment Solution (HTS) in 1-2mm to enhance the wood surface hardness. The heartwood that is penetrated difficultly was used as sample in the experiment. It was found through a lot of experiments we made: 1) When incised with laser vertically to the growth direction of tracheids beneath wood surface in 1-2mm, then HTS was applied to sample by means of vacuum, the uniform penetration was formed in 20 cells depth. The wood surface hardness was changed from less pencil hardness 6B to H or HB. 2) After chemically pretreated, HTS was penetrated uniformly on the wood surface in 4 cells depth under vacuum. 70% of earlywood lumens was filled with HTS in 10-20 cells depth. The wood surface hardness achieved to pencil hardness 2B to 3B. 3). Regarding to enhancement of wood surface hardness, it plays more important role to achieve the uniform penetration than to obtain deeper penetration and increase the weight gain of HTS.

Floorboard Manufacturing from Small Diameter Coppice Trees of *Quercus ilex* from Southern France

Bernard Thibaut, Jean Gerard,
CIRAD-Forêt, 73 rue J.F. Breton - BP 5035, 34032 Montpellier Cedex 1, France
Tel: 33-(0) 467616516, FAX: 33-(0)467615725, Email: jean.gerard@cirad.fr

Quercus ilex is a very widely spread species in southern France and north Africa. In French Mediterranean regions, since fifty years, both surfaces and standing tree volume are strongly growing as shown by the three last successive forest inventories. Wood from *Quercus ilex* has both a very high specific gravity and hardness, but its specific modulus is rather low. Besides, its light colour, its smooth grain and its figurative aspect are interesting to respond to the present demand of raw material from flooring industry.

A study has been launched to determine for this species the availability level in forest, the optimum processing parameters, the technological characteristics according to the local origin, and the economic feasibility of floorboard manufacturing at a regional level. Wood privates firms specialized in fuel wood logging, timber sawing, joinery and floorboards manufacturing which have shown an interest in this project have been involved and associated to the operations. Several plots have been sampled in the Languedoc-Roussillon region in order to select trees representative of the regional forest resource quality: larger diameter trees from parks, remaining trees from ever exploited coppices for fuel wood, small diameter trees from young coppices.

Sawing tests have shown that yields widely vary according to the origin of the trees, their quality, but the diameter has a low effect on this parameter. Bandsaw with stellite must be used but even though hardness is very high, this wood did not appeared very abrasive and did not require particular sharpening operation. Boles are not straight. Thus, sawing of short length logs leads to obtain higher yields, but needs adapted saw carriage. This wood is considered as very "nervous" but small size elements as floorboards dried well with very few distortions and splits. Economic study highlighted that flooring made in *Quercus ilex* has to be considered as an up-market product, at the same level that some tropical wood flooring which are in great demand because of their interesting aesthetic appearance.

Kraft Pulping of "*Acacia ferruginea*" for Paper Making

Zakaria Sarani, S. Chun
Universiti Kebangsaan Malaysia, Faculty of Physical and Applied Sciences (FSFG), Bangi, 43600 Selangor, Malaysia
Tel: 010-16-3-8293261/3211, FAX: 010-60-3-8292415, Email: sarani@pkrisc.cc.ukm.my

Keywords: tensile strength, tear index, opacity, burst index, folding endurance

Acacia ferrugenia, posses a medium size tree, quite straight with 9-12 meters in height. Its leaves will fall from time to time. The bark is gray in color, with bipinnate leafs and pale yellow flower. Like other hard wood material, which contains high amount of lignocellulosic materials, this species is found to be one of the best raw materials for pulp and papermaking.

The present study was conducted to determine the mechanical and physical properties of paper produce using Kraft pulping for this species. The normal conventional methods were followed: 13% of alkali active (NaOH), 25% sulfidity (NaS) were cooked together with 600g. *Acacia ferrugenia* wood chips for 3.5 hours. The ratio of liquid to wood chips oven dry weight was 3.5:1. After removing the black liquor, the pulps were wash thoroughly with plenty of water and were spin-dried. The pulps were beat at 3,000, 6,000 and 9,000 rpm and tested for physical properties such as tensile strength, folding endurance, burst, tearing and others.

The yield obtained was 39.5%; with the kappa number value was 24. The CSF at non-beating, 3,000, 6,000 and 9,000 were 649, 490, 342 and 244 respectively. The tensile strength, folding endurance, tearing strength and burst index at 64 g m^{-2} for non beating, 3,000, 6,000 and 9,000 rpm were as followed: - tensile strength indexes (Nm/g) results were 29, 67, 80 and 83 respectively. Tearing indexes (mNm^2g-I) were 2.8, 8.5, 8.9 and 8.4 respectively. Burst indexes were ($kPam^2g$-1) were 0.7. 3.6, 4.6 and 4.8 respectively. While the folding endurance results (numbers of fold) were 2, 35, 124 and 135 respectively. The bond strengths (Mpa) were 5, 13, 21, and 25 respectively. The air permeabilities (seconds) were 2,4,14 and 23 respectively. The fibers lengths were in between 0.8 to 1.23mm, with the density of $1.1.gcm^3$. The paper opacity was 90% for all beating parameters.

The results suggested that this species is suitable as an option for raw material in paper making which could be included in the mix tropical pulp in which currently produce by one of the integrated paper mill in Malaysia.

Cellular Manufactoring System and its Computer-aided Application in a Furniture Factory

Ercan Tanritanir
University of Istanbul, Faculty of Forestry, Department of Forest Products Industry, Orman Endüstri Müh. Böl., 80895 Bahçeköy Istanbul, Turkey
Tel: 00 90 0212 226 11 03 / 353, FAX: 00 90 0212 226 11 13, Email: ercantanritanir @ usa.net

Keywords: Cellular Manufacturing System, Group Technology, Furniture Industry

Recently, market demands compel the firms towards producing a variety of goods in smaller quantities. For this reason, many companies, which manufacture a variety of products with large quantities, suffer from many problems in designing, planning and production stages. Cellular Manufacturing System (CMS) and Group Technology (GT) suggest radical solutions to these problems. CMS and GT have been increasingly arousing interest in many countries and wide variety and successful applications are especially known in Japan and USA. CMS is an accepted solution to the problem of productivity in batch-production systems. Parts are classified into part families and machines into machine cells, based on the sameness or similarity of operations. GT is a manufacturing philosophy. It emphasizes that many problems are essentially similar and collecting the similar problems in a group and finding just one solution to them provide us with time and effort saving. The classification method is used to group parts into part families based on their design features. Since the GT problem is NP complete, heuristic algorithms are most likely to be used for solving large-scale industrial problems. The grouping results lead to the physical machine layout and/or logical machine layout. The latter is used when the production content changes rather frequently. In this case GT makes the tool management and part scheduling easier and this improves the efficiency of production planning and control.

The aim of this study is to simplify the part flow, save area and shorten the transportation distances by the help of CMS and GT. Here, clustering problems were solved by using King's Algorithm. The computer program written in BASIC is introduced into seven stages.

- Entering the data
- Running the program
- Solving the assignment problem by using King's Algorithm
- Determining the machine cells
- Determining the part families
- Solving the problem of common facilities
- Determining the performance of CMS

This manufacturing system was established in a furniture factory by setting up four different cells using group technology clustering technique. The layout of the machines within the cells were U-shaped layout. Later, CMS was simulated by Siman simulation language and determined its performance. It has appeared that performance values of CMS are suitable to apply.

Having CMS, the flow of parts was simplified, the transportation distances between machines were shortened about 44.3% and, the area needed for the production was reduced by 36%.

5.04.06 Wood drying

Influence of Moisture Sorption on the Physical-mechanical Properties of Caoba (*Swietenia macrophylla* King) Wood.

Rosven Arévalo, Roger Hernandez
Université Laval, Département des sciences du bois et de la forét, G1K 7P4 Québec, Canada
FAX: (418) 656-3177, Email: sbfrhe@hermes.ulaval.ca

Caoba wood is appreciated for its dimensional stability. This stability is associated to the moisture sorption properties of wood, which gives adsorption and desorption curves from the oven-dry and green initial conditions, respectively. Wood in service is exposed to a range of relative humidity. Twelve matched groups of thirty adjacent specimens each of caoba wood from Peru were selected to perform moisture sorption tests at 25°C. These experiments were combined with dimensional measurements and perpendicular to the grain tangential compression tests. For a given equilibrium moisture content, tangential and volumetric swelling were greater after desorption than after adsorption. When equilibrium was reached by gaining moisture, the wood was stiffer in tangential compression compared to when the equilibrium was reached after losing moisture. This behavior, called second-order effects of moisture sorption, has been established for the physical and mechanical properties of caoba wood. The swelling effects are proportionally greater in the tangential direction of the wood than in its radial axis. It seems that second-order effects of moisture sorption associated with tangential to grain compression strength are not explained by those related to the transverse swelling of wood.

Effect of Haze on Solar Timber Drying

K. S. Gan, K. Choo
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: 603-6342-633, FAX: 603-6367753, Email: ganks@nt1.frim.gov.my

Solar radiation is an important factor in solar timber drying. Its availability is subject to seasonal variations and thus the solar drying performance is predictable to a certain extent based on annual weather data. Malaysia is a maritime country located in the tropics, the climate is characterized by uniform temperature, high humidity and abundant sunshine throughout the year. The performance of solar timber drying is not expected to have high variation. However, the effect on the performance due to factors such as prolonged haze is not reported. A substantial amount of solar radiation is reflected or filtered by the suspended particles during hazy weather conditions. This study investigates the solar drying rates of timber dried under normal and hazy weather conditions experienced in Malaysia.

The solar dryer used in this study is a modified greenhouse type solar dryer. A solar collector is incorporated into the roof system of the dryer and there is recycling path below the solar absorber. Two axial fans are installed at the central wall dividing the drying chamber into two compartments.

Solar drying trials of kapur (*Dryobalanops aromatica*) were carried in the Forest Research Institute Malaysia during normal and hazy weather conditions. Each trail comprised 4 m^3 of kapur of dimensions 30x125mm. The timbers were filleted with 25x25mm stickers into two stacks. The weight or moisture loss of the whole timber stack was monitored continuously using load cell measurement. The moisture content of the timber at any time during the drying process was calculated based on initial moisture content determined using the oven drying method. The air speed through the timber was maintained at about 3m/s throughout the drying process. Due to high ambient relative humidity, venting was carried out between 10.00h and 12.00h and again between 14.00h and 16.00h daily except when it rained.

The average ambient temperature and relative humidity were not significantly different for the two drying periods. However, the average daily solar radiation during hazy weather condition was 56% lower than that during normal weather condition. The solar drying rate of kapur during hazy weather condition at below the Fibre Saturation Point (FSP) was found to be about half the drying rate at normal weather condition. For drying at above the FSP, the drying rate under hazy condition was 45% lower than the normal drying rate.

Rapid drying of Laser-incised Sugi Square Lumber by Steam Injection

N. Hattori, Soga, K., Ando, K., Kitayama, S., Yamauchi, H. Kawai, Y., and Kobayashi, Y
Tokyo Noko University, Faculty of Agriculture, 3-5-8 Saiwai-cho, 183-8509 Fuchu, Tokyo, Japan
Tel: +81-42-367-5719, FAX: +81-42-334-5700, Email: hattori@cc.tuat.ac.jp

Keywords: Laser incising; Square lumber; Steam injection; Drying

Drying of laser-incised square lumber has been tested by an induction heating method such as microwave and high-frequency heating. It became clear that water comes out drastically from laser-incised holes and thus laser incising can be used as a pretreatment method for rapid drying by induction heating. However, a laser-incised hole acts only an outlet of water in lumber for these drying methods. So, we tried to give another role to a laser-incised hole using a steam injection press.

Several posts of Sugi (*Cryptomeria japonica* D. Don, Japanese cedar) square lumber were used as a specimen. Specimens of 60 cm long by 100mm wide by 105mm thick were cut out from 105 by 105mm, 4 m length square lumber. Thin sections from both ends of each specimen were cut to measure the initial moisture content and its distribution. Their moisture content ranged 88 to 167% before laser incising. Specimens were incised through 105mm thickness by CO_2 laser with incision density of 5,000 and 10,000 holes per square meter. All ends of specimens with and without incising were sealed with silicon adhesive. Steam of 120, 140 and 160°C was passed through the incised holes of a specimen with a steam injection press. Injection times were a time till a specimen reaches the steam temperature, two and four times as much as the time. Temperatures at the center of a specimen were monitored with a thermocouple during the steam injection. The weight of a specimen was measured several times interrupting the injection during the whole process. Average moisture content and its distribution of a specimen were measured at thin sections cut from the specimen after cooling sufficiently. Five hours of continuous injection with 140° was also achieved measuring the weight change.

The temperature of a specimen reached at almost the same temperature as the injected steam within a few minutes for the steam injection of higher temperatures. The densely incised specimen showed faster temperature rise and milder distribution of moisture content. A trial of 140°C steam injection lowered the moisture content of a specimen from about 100% to about 30% within 300 minutes.

Market-orientated Process of Defining Timber Processing Value in Sawing: The Case of Grey Alder (*Alnus incana*)

Timo Kärki
University of Joensuu, Faculty of Forestry, Post Box # 111, 80101 Joensuu, Finland
Tel: +358-13-251 3611, FAX: +358-13-251 3590, Email: timo.karki@forest.joensuu.f

Utilization of so-called special timber has been an increasingly interesting issue in the official discussions of Finland and strategic plans of the small and medium-sized saw mill industries during the recent years. Despite the interests of many parts in the forest sector, only a small part of the research has been focused on this issue. Utilization of the special timber is naturally a more marginal alternative than that of the timber of the three main species in Finland, pine, spruce and birch. However, product diversification provides small saw mills with considerable benefits.

The purpose of this study was to construct the requirements for the quality of saw logs of grey alder and to determine the industrial value of the stems for mechanical wood processing. The goals were achieved by researching following issues:

1. Inventory of the resources of alder in Finland: forest areas and timber volumes.
2. Sampling experimental forest stands and alder trees in each stand for the study.
3. Measurement of the external quality factors of the experimental alder trees.
4. Determining the significance of external quality and dimensions (diameter, length) of the logs of alder for sawing.
5. Determining the relationships between the value of sawn goods and the external quality factors of trees and logs.
6. Exploring the potential markets for the mechanical products of alder by a limited market analysis in Central Europe.

The results showed that in the current market situation, the small saw mills operating with the main species, especially pine and spruce, are not able to compete with the big saw mills as regards the production of so-called bulk sawn goods. Despite the slow speed and low yield in sawing alder, the production is profitable, because raw material is fairly low-priced but the products have relatively high prices. This study yields essential information to predict the quality of alder for sawing by using the external characteristics of the trees. Furthermore, this information can be used to channel the raw materials of alder to the most suitable production from the entire start of wood procurement.

Use of Sago Flour as an Alternative Filler to Wheat Flour in Plywood Manufacturing

Nigel P. T. Lim, Peter C. S. Kho & Siti Hanim Sahari
TRTTC, Forest Department, Km. 10, Old Airport Road, 93660 Kuching, Malaysia
Tel: +60-82-612109, FAX: +60-82-612490, Email: trttc@po.jaring.my

The feasibility of using sago flour as an alternative filler to replace wheat flour in the manufacture of plywood in Sarawak is investigated. From the determination of viscosities of varying quantities of sago and wheat flour, straight sago flour having low viscosity is not suitable but a partial replacement of up to 50% may be possible and needs to be explored. The trial was conducted by fabricating five-ply plywood test panels using an urea formaldehyde-melamine urea formaldehyde adhesive resin mix, varying quantities of sago and wheat flour and Red Meranti (*Shorea* spp) veneers for surface and core layers. The test specimens from these panels were tested for tensile shear strength and wood failure in accordance to Japanese Agricultural Standards (JAS) for their relative compliance. A comparison was also carried out with that of a commercially produced plywood sample. Generally, all the test specimens can fulfill the minimum strength requirement stipulated in the Standards. The preliminary investigation shows that sago flour can be used as a partial replacement for wheat flour.

Effect of the Knife Jointing on the Gluing Properties of Sugar Maple Wood

Gerson Rojas, Roger Hernandez
Université Laval, Département des sciences du bois et de la forét, G1K 7P4 Quebec, Canada
FAX: (418) 656-3177, Email: sbfrhe@hermes.ulaval.ca

Jointing is a common practice required to produce a same cutting circle for all knives mounted over a cutterhead of a peripheral knife planer. This is also realized to refresh slightly dulled knives. The jointed land at the cutting edge has a 0° clearance angle, but becomes negative due to the workpiece motion as well as the cutting edge wear occurs. The jointing operation could crush the superficial layer of the planed board, affecting its quality and performance at service. Four jointing land widths were considered to evaluate their influence on the gluing properties of sugar maple wood. Knives were used up to four levels of wear. The results showed that a wider jointed land decreased the surface quality at different degrees in terms of the gluing shear strength performance. The effect of knife jointing was more evident where the moisture content of the samples fluctuated.

The Formaldehyde Emission of Plywood Made from Different Wood Species and Glue Types

Adi Santoso, Paribotro Sutiguo
Forest Products Research and Development Center, Post Box # 182, Bogor, Indonesia
Tel: 62 251 326378, FAX: 62 251 313613, Email: slitbang @ indo.net.id

Experimental plywood were made from tusam (*Pinus merkusii*) and manii (*Maesopsis eminii*) glued with Urea Formaldehyde (UF), Melamine Urea Formaldehyde (MUF) and Phenol Formaldehyde (PF). The formaldehyde emission determined by desicator method according to American Standard and Japanese Standard. Plywood made with PF glue has the lowest formaldehyde emission (1.49-0.63 mg/l), whereas plywood made with UF has higher formaldehyde emission (0.49-6.63 mg/l), and if using MUF glue the formaldehyde emission is in between (0.42-4.69 mg/l). The reason is free formaldehyde content of UF resin is higher than that of MUF and PF resin, while free formaldehyde content of MUF is higher than that of PF resin. The formaldehyde emission of plywood made from manii (0.26-2.99) is lower than formaldehyde emission from tusam plywood (0.42-6.63 mg/l). The extractives content, which solved in alcohol-benzene of tusam (6.40%) is greater than that of manii (1.27%). These extractives have non-polar properties, so that could not bond the free formaldehyde of the resin.

Keywords: formaldehyde emission, glue types, plywood, wood species, desicator method.

5.04.08 Milling and machining

Machining Properties of Plantation White Spruce Wood

Cecilia Bustos, Roger Hernandez, Yves Fortin
Universite Laval, Departement des sciences du bois et de la forét, G1K 7P4 Québec, Canada
FAX: (418) 656-3177, Email: sbfrhe@hermes.ulaval.ca

The machining properties of wood vary with the type of cutting process as well as with factors related to the raw material. The machining properties of white spruce wood coming from plantation were evaluated according to the ASTM D 1666-87 standard. The cutting processes studied were as follows: planing, boring, mortising, turning, and shaping. Wood specimens were machined at 8% of moisture content using the different tools and visually graded on a scale of 1 to 5 (excellent or defect free to very poor). The results were generally reported as the percentage of defect free specimens. For the planing test, four rake angles and four feed speeds were used in order to evaluate the influence of these variables on the surface quality. In that case, the maximum depth of the defect due to planing was also measured for each cutting condition. The preliminary results obtained in the planing test show that a 15 degree rake angle yielded better results than rake angles of 20, 25 and 30 degrees.

Optimizing the Sawmills' Activities Through Simulation Software

Sorin Chiorescu
Lulea University of Technology, Division of Wood Technology, Skelleftea Campus, Skeria 3, 93187 Skelleftea, Sweden
Tel: +46-910-585351, FAX: +46-910-585399, Email: Sorin.Chiorescu@tt.luth.se

The increasing demand for wood based products and their large spectrum of utilization has been along the time one of the major cause of the world deforestation phenomenon. Therefore nowadays it becomes more and more evident that only a judicious management of our forest resources and a tenacious enhancement of the conversion chain from forest to the end-users can avoid the uncertainty of our forests' future.

The numerous researches carried in the field of the improvement the sawmills' activity have clearly shown that one efficient instrument in the betterment of the wood conversion sector is the simulation technique. This kind of approach is an effective tool in studying and understanding how different parameters affect the sawing process in its entirety.

In our study the number one target was to simulate the whole production of a sawmill for one-year period and to confront the results with the real output data obtained in the sawmill. This comparison will further allow us to have a good overview upon the sawmill's production process and in the same time to settle which and were improvements have to be done both on the simulator and sawmill's chain.

In the first step the work was based on the data from the Swedish Stem Bank, which is a unique database for different silvicultural and wood properties. The basis of the Stem Bank project is

computer tomography (CT) scanning of 200 carefully selected Scots pine (*Pinus sylvestris*) stems from 33 plots all over Sweden. This technique allowed us to measure in a non-destructive way the internal defects and the outer shapes of the logs.

In the next step, in order to be able to utilize the parameters files issued from de CT-scanner a software for the simulation of the log disintegration, the virtual-SawMill (vSM) has been developed. The simulation model is written in the C++ language primarily for Macintosh computers. The vSM has an "open architecture", that gives the possibility for users to add their own code for different applications.

The volume of logs virtually sawed with the vSM corresponds to the total volume of the row material sawed annually at a sawmill in Northern Sweden. The distribution of the logs (in both case Scots pine) in quality and diameter classes has been the same in both situations.

5.04.10 Production systematics

Effect of Tree and Log Characteristics on Quality of Radiata Pine Random Width Boards

Rado Gazo, Robert Beauregard
Purdue University, 1200 Forest Products Bldg, IN 47907-1200 West Lafayette, USA
Tel: (765) 494-3634, FAX: (765) 496-1344, Email: radogazo@fnr.purdue.edu

This paper links radiata pine characteristics selected from the grower's perspective to the quality of random width boards for appearance markets. It also describes the effects of pruning, log height class, and saw pattern on frequency of occurrence of defects, average defect size, and percentage of clear wood area in random width radiata pine boards.

The first objective was to analyze the potential of standing tree characteristics that can be observed by tree growers as predictors of board quality parameters. Although this "shooting from the hip" estimating approach yields only approximate results, several board quality parameters, such as trends in frequency and average area of defects can be predicted. For example, the smaller the tree diameter at breast height, the higher the frequency of intergrown knots in boards from both pruned and unpruned logs of that tree; a large tree diameter at breast height signals large areas of clearwood in side boards from pruned logs, etc. A database of 392 random width radiata pine boards (17.10 m^3 or 7,245 board feet) was used for the analysis. These boards came from 10 different clones of New Zealand *Pinus radiata* D. Don. Thirty one percent of the boards came from pruned logs while the remainder came from unpruned logs. Nine defect categories were identified.

The second objective was to analyze the effect of log and processing characteristics on board quality parameters. Generally, all defects except resin pockets were less frequent and smaller in boards from pruned logs. Resin pockets, on the other hand, were more frequent in boards pruned logs and had larger average area than in boards from unpruned logs. Boards from pruned logs also had a higher percentage of clear wood area. Apart from a few exceptions, increasing log height class of unpruned logs caused higher defect frequency, larger average defect size and smaller percentage of clear wood area. Of two saw patterns, cant and live, the live saw pattern resulted in higher defect frequency, larger average defect size and smaller percentage of clear wood area. This occurs because boards from the center zone are included in live sawing.

Using Information Technology (IT) in Forestry - A Case Study

W. C. Woon, Poh, L.Y. and Maizurah, Ishak
Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603-6342633, FAX: +603-6365687, Email: woonwc@frim.gov.my

This paper discusses the results of a case study carried out jointly by the Forestry Department of Peninsular Malaysia (FDPM) and the Forest Research Institute of Malaysia (FRIM) into the use of Information Technology (IT) in forestry. The case study was initiated to explore the possibility of using IT to capture the information gathered through the Sawmill Shuttle Returns IV maintained by the FDPM.

The FDPM was concerned over the long lagged time (often 6 to 9 months) needed to process and produce the various statistics and reports required from the Sawmill Shuttle Returns. Furthermore, it was found that the system of reporting was rigid and information that is outside the prescribed format could not be obtained easily. It was realized that an efficient data processing system is needed to ensure that timely and accurate reports are generated for management purposes.

This led to the development of the Sawmill Information System. This paper described the problems encountered during the planning and development stages and the importance of getting the users involved at all stages. The case study indicated that training of users in the use of the

Sawmill Information System was a major factor that contributed to the success of the system. User's initial resistance to change (old work habits) and unfamiliarity of new system was a major problem encountered.

Data validation and accuracy of the data improves tremendously with the implementation of the system. Data captured could be immediately validated, by running the data validation menu and errors could then be corrected.

5.04.12 Surfacing and finishing

Evaluation of Chemical Staining as Wooden Furniture Finish

K. Frimpong Mensah
University of Science and Technology, Institute of Renewable Natural Resources, Kumasi, Ghana
FAX: 233-51-60137, Email: ust lib@ust.gn.apc.org

Staining of wooden furniture to enhance its appearance has been a long established practice in Ghana. Stains are applied to change the colours of inexpensive wood, as well as to improve the uniformity of colour, particularly in wood that has a naturally variegated colour.

The three commonly used conventional strains in the country are the oil, water, and the non-grain raising. There are a number of constraints found associated with the use of these stains on Ghanaian Wood Species. These include non-uniformity of colour, bleeding solubility in the coats, penetration, grain raising and rate of drying.

The paper assesses the application of the conventional stains in the furniture industry. Methods of application of the stains include base staining to the prepared wood surface or the tinting of compatible lacquer before spraying. Chemical stains on wood prone to fungal attack deteriorates faster than wood surfaces exposed to sunlight. The utility consideration of cleanliness or resistance to water and steam are of greater importance to customers of stained wood for kitchen, bathroom and nursery furniture, than the aesthetic value of the wood. Stain durability factors need further study particularly for the Lesser Utilised species for furniture.

Analysis and Calibration of Time Dependent Colour Changes on Wood Surfaces with PLS and Multiplicative Signal Correction

Olle Hagman
Lulea University of Technology, Div. of Wood Technology, Skeria 3, S-931 87 Skelleftea, Sweden
Email: Olle.Hagman@tt.luth.se

Partial Least Squares to Latent Structures (PLS) (Martens & Naess, 1989) and Multivariate Image Projections to Latent Structures (MIPLS) (Hagman, 1996) are methods introduced in chemometrics (Espensen et al., 1992) and in multispectral image analysis and classification of wood (Hagman, Grundberg, 1993). PLS strategies make it possible to handle multivariate data and identify and separate noncorrelated mechanisms within the image data set such as physical properties, fibre direction and moisture content, or chemical properties such as chemical composition and concentration.

In reflectance spectroscopy, Multiplicative Signal Correction (MSC) was introduced as a method to correct for light scattering variations. In diffuse reflectance spectroscopy, light scattering leads to interference effects that have both an additive and a multiplicative component effect and hence cannot just be divided away with a shading calibration operation. Both offset and scaling must be estimated and corrected for. The basis for MSC is that the wavelength dependency of light scattering is different from that of chemically based light absorbency. Thus, many wavelengths can be used to distinguish between light absorption and light scattering (Martens et al., 1989f). Using MSC on spectroscopic data reduces the physical mechanisms and reveals the apparent chemical variations, thus making the final model less complex.

When using an imaging spectrometer (Hagman, 1997) such as the PGP together with CCD-cameras(Hagman, 1997) or a smart sensor (Hagman, 1996) an interference problem is apparent that might be a problem when modeling and that perhaps can be corrected for by means of MSC. Scattering effects may also be corrected for. On the other hand, the literature survey indicated a rather monotone chemical composition and colour for wood, thus with relatively large in-tree variation, indicating that the model may have to take all sorts of variations into consideration to be successful. This paper reveals two tutorials when correcting for spectral changes in the wood surface when interacting with production processes and storage, indicating possibilities to calibrate for time dependent spectral changes in the wood surface.

These are:
-Changes in the colour spectrum for scanned wood surfaces induced by artificial drying and surface treatment.
-MSC correction for time-dependent behaviour of wood surfaces interacting with the surrounding atmosphere.

The Economics of Rubberwood Abrasive Sanding Processes

J. Ratnasingam, H.F. Reid
Universiti Putra Malaysia, Faculty of Forestry, 43400 UPM Serdang, Selangor, Malaysia
FAX: +603-9432514, Email: jswaran@forr.upm.edu.my

The use of Rubberwood (*Hevea Brasiliensis*) in the manufacture of wooden furniture has grown tremendously over the years, especially in the South East Asian region. The wood, a plantation wood resource conforms to the requirement of being environment friendly wood resource. Despite its wide acceptance as a furniture raw material, its use in the manufacturing process is plagued with low yield. Poor rough mill conversion and the inconsistent sanding quality has been cited as the primary attributes of this problem. This study attempts to provide some insight into the fundamental sanding characteristics of the material, using variables commonly employed within the industry. The material is sanded using a twin head wide belt sander, and the economics of the process was evaluated from three perspectives, i.e. namely sanding performance, surface quality and cost. The results suggest that when sanding solid Rubberwood, the optimal feed speed of 10 m/min provides the best sanding performance. Further, silicone oxide mineral based coated abrasives perform up to 17% better than aluminium oxide mineral based coated abrasives when sanding solid Rubberwood. The abrasive belt life is prolonged and optimised, when the feed speed is maintained within the 10 m/min range. From the quality dimension, a sequence of sanding grits will provide the best surface quality. From the study, a grit sequence of 120-150-180 is recommended for sanding of bare solid Rubberwood. The results of this study has several industrial implications. Firstly, in order to reduce the inconsistent sanding quality of the material, the feed speed must be kept lower than what is currently practiced within the industry. A feed speed of 10 m/min has been found to provide the best result. Secondly, silicone carbide mineral based coated abrasives gave better performance on solid Rubberwood. This suggests that the use of such coated abrasives will improve the productivity of the process as a whole, by lowering the cost. Thirdly, keeping the feed speed within the recommended range will enhance the belt life, which inevitably reduces the cost.

5.04.13 Industrial engineering and operations

Multistage Optimization Technique for Enhancing the Profitability of Vertically: Integrated Wood Products Manufacturing Operations

Honorio F. Carino, Donald Bruce Willis III
Auburn University, School of Forestry, AL 36849 Auburn, USA
FAX: (334) 844-4221, Email: carino@forestry.auburn.edu

This paper presents a solution technique for dealing with complex production and inventory problems inherent in vertically integrated wood products manufacturing operations. More specifically, a linear programming (LP) model of a multistage production-inventory system will be presented. The efficacy of such a model in generating objective information for making management decisions will be discussed through a case study involving an integrated hardwood lumber-cabinet manufacturing operation in the southeastern region of the United States of America. To be underscored is the invaluable assistance that the model provides in increasing or maximizing system profitability through the resolution of many important issues including the following:
1) desired level of production and end-of-period inventories at each stage of the integrated operation in each planning period;
2) desired quantity of finished products to be sold in each planning period;
3) level of resource utilization at each stage and the incremental cost and benefit of providing additional resources or productive capacity at each stage; and
4) impact of changes in manufacturing variables and input/output pricing and quantity on system profitability.

Using the model, it was determined that under current operating conditions the study mill would be economically better off (approximately 156% increase in net revenue) operating at full capacity (20,000 board feet of lumber per 10-hour shift) and implementing a two-week instead of the traditional one-month minimum log inventory policy. Furthermore, another 12% increase in net revenue would be realized if input logs have a 12-inch instead of the usual 10-inch minimum small-end

diameter. Also, the model proved to be very useful in analyzing log procurement issues such as determining the most profitable species, sizes, and grade of logs that should be procured and what could be offered as maximum price premium incentives to ensure the delivery of these logs and still achieve a target return on investment. Through parametric analysis, it was also determined that system profitability is most sensitive to sawmilling cost, kiln-dried lumber prices, and log input prices. Furthermore, it was determined that small improvements in lumber recovery and drying degrade percentage would result in large increases in net revenue for the current mill setup. For instance, a 6% improvement in lumber recovery would increase net revenue by about 20% and a 6% reduction in drying degrade would increase net revenue by more than 30%.

An Optimization Model in Plywood Production By Minimum Cost

Selman Karayilmazlar, Alper Aytekin
Zonguldak Karaelmas University, Faculty of Forestry, 74100 Bartin, Turkey
FAX: +90.0378.2277421, Email: Mehmet Sabaz [peyzaj74@turnet.net.tr]

In this study, a linear programming model was based for an integrated plywood plant with minimum cost-producing both veneer peeling and plywood. This model comprised two stages and the first stage was (n1) the production of veneer peeling. Obtained boards from (n1) would be used for different thickness plywoods in second stage (n2). It was desired that, the demand for each plywood kinds would be compensated at right time in the certain period. Sources, such as machine times using in each stages at different production centers (headquarters), raw materials and opportunity of style production, were known. Intention of study was compensated the demand of plywood in different thickness with minimum production and inventory cost in accordance with source restrictions in each stages.

Le reflet de la qualité sur le volume d'affaires d'une industrie de parquets au Brásil

Daniele Previdi Olandowski, Ghislaine Miranda Bonduelle
Universidade Federal do Paraná FUPEP, Rua Bom Jesus, 650-Juveve, 80.835-010 Curitiba-PR, Brazil
Tel: (5541) 342.3435, FAX: (5541) 242.1834, Email: ms@softall.com.br

La qualité et la productivité deviennent de plus en plus les préocupations essentielles d'une organisation qui cherche le succés. Un des grands pas a donné pour produire efficacement et pour que le process soit économiquement viable, est la detection de la non-qualité, l'analyse des côuts et l'implantation des mesures préventives, évitant les défauts et les gaspillages inutiles en matériaux et en hommes affectés a la retouche des erreures et aux piéces de réchanges.

Les pertes dans une entreprise peuvent encore servir de base pour la prise de décision par la direction de l'entreprise (TORRES JUNIOR, 1993) mais aussi comme une arme contre l'implantation d'un système de Qualité (BONDUELLE, 1997).

Dans cette étude, l'objectif principal a été de determiner la non-qualité et le côut qu'il implique dans le processus productif de l'industrie du bois notamment dans le demain de l'équarissage (rabotage, tronçonnage).

Ce travail fût realisé dans une entreprise fabriquant du parquet en bois massif situé dans la commune de São José dos Pinhais dans l'état du Paraná au Brésil. Cette entreprise utilize du bois de diverses espéces telles que jatobá (*Hymenea* spp), cabreúva (*Myrocarpus* spp), tauari (*Couratari* spp) goiabão (*Pouteria* pachycarpa) et angelim (*Hymenolobium* spp) dont la production finale est classée en 2 qualités: extra (10 choix) et commerciable (20 choix).

De juin a aôut 97, il a été collecté les données du secteur du rabotage et du tronçonnage de l'entreprise en question, Avec les informations de base fournies par l'entreprise, telles que les dimensions des piéces avant, pendant et aprés l'usinage, nous nous sommes fixés une méthodologie de travail, adaptée au système d'évaluation des côuts de la non-qualité (Norme AFNOR NFX50-126) en considerant les particularites de l'industrie brésilienne.

L'étude experimentale a englobé les données de production de 8 raboteuses et 5 tronçonneuses en considerant chaque machine comme un échantillon, réalisant 8 répétitions par échantillon respectant une heure de prise de donnée. La fonction des tronçonneuses concernait déja une reprise du bois en sortie des raboteuses.

Nous avons obtenu un rendement de bois rabotés de 68.64% de bois que ont été classifié extra et 15.58% commercial resultant un rendement total de 84.22% sachant que les 15.78% restant se divisent en 4.45% de rebuts et 11.33% de retouche. De ce dernier pourcentage, nous retrouvons les bois rejetés en tant que extra mais qui, repris, peuvent être vendu comme commercial. Pour ce retravail il y a perte a 2 reprises: les bois n'est pas vendu au prix du produit extra, e il y a de plus, necessité de reprendre les produits à la tronçonneuse additionant d'avantage de côuts au process.

Les calcules efectués ont montré que le côut de la non-qualité est l'equivalent a 18% du volume d'affaires de l éntreprise.

Les causes de la non-qualité du processus de rabotage est en raport a mauvaise qualité de la matiére-premiére et aussi aux arrêts, consequence d'un manque de plannification de la production. Le temps d'arrêt machine équivaut à 16% du temps total du travail corresponant au temps utilisé pour alimenter les machines, par manque de matiére-prémiere, pour classer les produits suivants 2 qualités et par d'autres raisons diverses liées a non-qualité.

Nous pouvons concluir que est important qu'il existe un système de gestion efficace de l'entreprise, coordonant la production et le marché dans lequel elle fait compétition.

5.05.00 Composite and reconstituted products

On the Wettability of Medium Density Fiberboard

Marius Barbu, Helmuth Resch and Marcus Prukner
Institute für Wood Research, Univ of Agriculture,
Gregor Mendelstr. 33, 1180 Vienna, Austria
Tel: +43 1 47654 4250, Email: barbu@edv1.boku.ac.at

Keywords: MDF, Wettability, Surface tension, Contact angle, Roughness, Profile density.

The wettability, density and roughness of surfaces of MDF were measured on samples cut from them either in the press direction or at right angle to it. The boards had been manufactured industrially using different amounts of urea-melamine-formaldehyde resin and mixtures of spruce and beech wood.

The wettability was expressed in terms of critical surface tension according to the method by Zisman using contact angle measurements. When using water-isopropanol mixtures, the longer term static measurement of the contact angle provided a good indication of the wettability and penetrability of MDF surfaces while, in the shorter term, the dynamic contact angle measurements seemed somewhat more accurate.

It could be shown that the surface tension was more closely correlated with the density of the boards' surfaces than with their roughness. Values of surface tension of MDF were lower than those reported on particleboards and solid wood.

Hydration of Gypsum bonded Agroforest-waste Composites

Tsai-Yung Chen, Hsu, Chun Hsiung
National Chung Hsing University, Department of Forestry, 250 kuo-kuang Road, 402 Taichung, Taiwan, China-Taipeh
Email: tychen@dragon.nchu.edu.tw

For this study the plaster used as binder raw material, under the conditions with different water-gypsum-ratio (0.65,0.75,0.85,0.95) and three kinds amount slurry (50g, 100g and 150g) to examine their hydration temperature of pure gypsum slurry. The results showed that the hydration temperature increased, when the water-gypsum-ratio decreased and slurry amount increased. When the hydration time between 40 and 53 minute, it showed the temperature peak for 47–54°C. The water-gypsum-ratio 0.65 as example to test the hydration phenomenon during 5 steps (A-stage forming time, B-stage start-bonding time, C-stage surface-curing time, D-stage temperature peak meeting, E-stage end-bonding time). After examinated by CHUNG-HSING simple hydration tester, the moisture content showed 73.4% at A-stage and 17.9% at E-stage. When the water-gypsum-ratio of plaster as 0.65 bonded Agro-forest-waste to make cylinderic sample (diameter 7 cm, amount 150g) the mixed ratio from Agro-forest-waste to gypsum as 5:100, 15:100, 25:100 and 35:100. The results showed that the rice hull particles as fast one curing (38 to 58 minute, hydration temperature from 39 to 50C), secondary wood particles (from 64 to 125 minute, hydration temperature from 37 to 53C). If the using amount with more gypsum, it could find higher hydration temperature.

Surface Roughness of Medium Density Fiberboard and Hardboard

Salim Hiziroglu
Michigan State University, Department of Forestry, Michigan 48824-1222 East Lansing, USA
FAX: (517)432-1143, Email: hizirogl@pilot.msu.edu

In wood composites such as medium density fiberboard (MDF) and hardboard, surface roughness plays an important role when these panels are used as substrate for thin overlays or to have acceptable surface finish for furniture industry. Any irregularities on the surface will show through thin overlays reducing quality of finished products.

The objective of this study is to quantify surface roughness and stability of commercially produced MDF and hardboard panels by using stylus and pneumatic methods. Measurements were taken on 15 cm by 15 cm board samples. Six roughness parameters, namely average roughness (Ra), mean peak valley height (Rz), maximum peak-to-valley height (Rmax), reduced core roughness (Rk), reduced valley depth (Rvk), and reduced peak depth (Rpk) were obtained from the stylus method and statistically compared to roughness values from pneumatic Sheffield Tester. Density profiles of each type of board were also determined on a X-Ray device if there is any relationship between surface roughness and density characteristics of the samples.

Based on results of this study, both methods can be used to evaluate surface roughness of MDF and hardboard as a quality control tool. It also seems that measurements from two different techniques can be related each other. Consequently, roughness values of such products can be geometrically interpreted from pneumatic measurements.

Medium Density Fibreboard from Oil Palm Lignocellulosic Materials

Mok Poh Koh
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603 6342633, FAX: +603 6365793, Email: kohmp@frim.gov.my

The Malaysian oil palm industry generates a substantial amount of lignocellulosic residues in the form of trunks; fronds and empty fruit bunches. Currently these residues are either burnt or used for mulching in the fields for the next crop rotation but these methods are not sufficient and the residue are creating environmental problems as well as expenses to dispose. These materials are however potential stock that can supplement the wood resources for wood industry especially for wood-based panel products (e.g. particleboard and medium density fibreboard - MDF).

Medium density fibreboard (MDF) is a reconstituted or composite panel product that is manufactured from fibres obtained by fibresing wood or plant materials under heat and pressure. A bonding agent or resin is used to coat the surface of the fibres. The resinated fibres are dried and then formed into a mat, which is finally hot pressed to form a homogeneous board. The density range is usually between 660-850 kgm-3.

The manufacturers of mouldings and strips first used MDF. It is ideal not only for lacquering but also for covering with veneer and these films. Since MDF is composed of a densely compressed and finely distributed fibre structure across the entire profile of the board, the homogeneous edges permit many types of machining operations such as sawing, moulding and boring to take place. It is also possible to cut patterns directly into the boards.

Formaldehyde Emission From Wood Based Panels Of Tropical Timbers

Mok Poh Koh, Thomas Fok
Forest Research Institute Malaysia (FRIM), Kepong, 52109 Kuala Lumpur, Malaysia
Tel: +603 6342633, FAX: +603 6365793, Email: kohmp@frim.gov.my

Methods for the determination of formaldehyde emission from wood based panels are presented. The effect of wood species on the formaldehyde emission values are discussed with reference to plywood manufactured from tropical hardwood veneers. Efforts to reduce the overall formaldehyde emission values are also discussed. It is found that the lighter coloured tropical woods in general give relatively higher formaldehyde emission values than darker coloured woods and that any of the three procedures: glue modification, incorporation of formaldehyde captors and a combination of both are equally as effective to reduce the formaldehyde emission values to acceptable levels.

Medium Density Fiberboards From Plantation Grown *Eucalyptus saligna*

Andrzej M. Krzysik, John Youngquist, James Muehl, Fabio Spina Franca
USDA Forest Service, Forest Products Laboratory, One Gifford Pinchot Drive, WI. 53705-2398 Madison, USA
Tel: 608 231 9582, FAX: 608 231 9398, Email: jayoungq@facstaff.wisc.edu

The production of industrial wood from natural forests is predicted to decline in the future due to a number of factors. Some of these include changes in land use patterns, depletion of resources in many parts of the world, and the withdrawal of forest areas from production in order to provide for environmental, recreational and social needs. There is a shortage of information on the suitability of fiber from many plantation grown species for alternative composite products.

This research was conducted to determine the suitability of plantation grown *Eucalyptus saligna* from Brazil as a raw material for medium density fiberboards (MDF).

Panels were made and tested using 10 percent phenolic resin, and 1 percent wax. The thickness of experimental panels was 6mm, 13mm and 19mm. The mechanical, water resistance and dimensional stability properties of panels were tested according to American Society for Testing and Materials (ASTM) standards.

Test results showed that nearly all mechanical properties of the panels at three tested thickness levels were above minimum requirements for interior and even exterior MDF specified in the ANSI-AHA standards.

This laboratory study indicates that it is entirely possible to make MDF type panels using wood fiber from *Eucalyptus saligna*. Additional work is needed to ascertain the performance of MDF panels from this species when pilot and production scale trials are conducted.

Preliminary Assessment of *Acacia mangium* grown in Sarawak, Malaysia for Manufacture of Oriented Strand Board

Nigel P. T. Lim, Y. K. Pek & Hideaki Korai
TRTTC, Forest Department, Km. 10, Old Airport Road, 93660 Kuching, Malaysia
Tel: +60-82-612109, FAX: +60-82-612490, Email: trttc@po.jaring.my

Three-layer Oriented Strand Boards (OSB) with target board densities of 600, 700 and 800 kg/m^3 were made from 12-year-old *Acacia mangium* wood strands of mean dimensions 42.5mm length, 9.7mm width and 0.7mm thickness using melamine urea formaldehyde resin as binder. Two sets of boards were fabricated, one with resin adhesive used homogeneously at 10% for all layers and another with 12% and 5% resin for surface and core layers respectively. The mechanical strength and dimensional stability properties of these boards were determined and compared for their relative compliance to Base particleboard Type 24 -10 of Japanese Industrial Standard JIS A 5908-1994. For bending strength test, two types of specimens, namely parallel with and perpendicular to the direction of strands were prepared. These boards were found to satisfy most of the minimum strength requirements stipulated in the Standard. An increase in board density generally increases the mechanical strength properties and reduces thickness swelling. The discussion also included a comparison of their board properties with that of *Pinus radiata*. The preliminary findings are that 12-year-old *Acacia mangium* is a suitable material for OSB manufacture and possesses better dimensional stability than *Pinus radiata*.

Improvement of *'Quebracho blanco'* Sawn Timber Stability by Using Vegetable Tannin Solutions

Rolando Martinez
ITM, FCF, UNSE, Avenida Belgrano (S) 1912, 4200 Santiago del Estero, Argentina
Email: rhm@unse.edu.ar

In the Chaco Region of Argentina, several valuable wood species have been misused in spite of their good technological properties, because of certain timber limitations such as log size, difficulty of drying and stabilizing, etc. One of these hardwoods is "Quebracho blanco" (*Aspidosperma quebracho blanco* Schlecht. *Apocinaceae*), that is also one of the most abundant wood species in Argentina. At present the main uses of its timber are pallets, wire fences sticks and charcoal.

In this work the authors show laboratory results of the improvement of the dimensional stability in quebracho blanco small planks by impregnation in green condition with a 30% cold water commercial vegetable tannin solution using a modified Bethel process, with a preliminary 130 mb vacuum and a work pressure of 9 Kg/cm^2 and 10 -15 minutes times. After that, the planks were oven dried at 50o C temperature until constant weigth was reached.

In general this technique is found promissory as a cheap, environmentally friendly non conventional technology to prevent shrinkage and swelling and improving the dimensional stability 70% up. However as a result of the process, light timbers become dark red in colour. Because of that, at present the authors are carrying out a special research in order to prevent this disadvantage (colour change).

Keywords: Quebracho blanco. dimensional satability. vegetable tannins.Chaco Región.

Modulus of Rupture and its Importance in the Design of C4(M) Particleboard Used in Domestic Flooring

Odette Moarcas, Mark Irle
University Transilvania Brasov, Romania
FAX: +44-(0) 1494-524392, Email: omoarc01@buckscol.ac.uk

The research work presented into this paper is part of a bigger project called "Determining and modeling the effects of concentrated loads on C4(M)- 18mm thick particleboard". Some objectives of this project are; to determine the effects of concentrated loads in the critical areas, of a particleboard floor, which are the unsupported Tongue and Groove (T&G) joints and then to create a FE model of the T&G joint and its behaviour. In the design of floor decking the Modulus of rupture (MOR), often referred to as bending strength, is specially important not only in calculating design values (according to EC5), but also in predicting the ultimate failure strength of the material. A good agreement between the MOR values derived from the standard three-point bending test and the ultimate failure strength, of the boards subjected to a centred concentrated load was found. This fact was further used in a simplified design method based on the equivalent beam concept. This method relates the complex problem of a plate subjected to a concentrated load to the classical bending calculations of a beam of same span and an equivalent beam width for which the ultimate bending strength are equal. Finite element analysis has been used to determine the maximum tensile stress on the bottom face of particleboard plates subjected to a central concentrated load of 1kN (within the elastic range of deformation). The span of the plates was kept constant while the width was increased up to four times the span size. The equivalent beam width values were increasing up to a width/span ratio of 2 after which they stayed constant (about 0.7xspan). This fact shows that the upper limit of the equivalent beam width is the value for which a full-plate effect is reached.

Effect of Compaction Ratio on Oriented Strandboard Properties Made from Sengon and Tusam Woods

Hadi Sutrisno, Yusof Sudo Hadi, Paribotro Sutigno and Budi Prihanto
Winaya Mukti University, Faculty of Forestry, Bandung, Indonesia
Tel: 62 22 798260, FAX: +62-22-7500936

Three layer oriented strandboard with perpendicular to grain orientation of each layer were made from sengon (*Paraserianthes falcataria*), tusam (*Pinus merkusii*), and mixing of equal parts of both species. Phenol formaldchyde was used as adhesive, the amount was 6% based on oven dried strand, and added with 0%, 1% and 2% paraformldehyde as hardener based on liquid adhesive. Oriented strandboard size was 40 cm by 40 cm by 1 cm with pressing temperature 150°C, and pressure 25 kg/cm^2 for 15 minutes with compaction ratio 1.1, 1.3, and 1.5. This experiment used three factors, i.e. wood species, compaction ratio and percentage of hardener. The wood species affected the physical and mechanical properties of the oriented strandboard. Compaction ratio and percentage of hardener affected these properties, except moisture content. Interaction of these three factors affected physical and mechanical oriented strandboard properties, except thickness swelling. The physical and mechanical properties of oriented strandboard improved as compaction ratio and percentage of hardener increased. Oriented strandboard made from tusam at 1.5 compaction ratio and 2% percentage of hardener had the best physical and mechanical properties.

Oriented Strand Board: A New Outlook for Malaysia

Paridah Mohd Tahir, Siffian Misran
University Putra Malaysia, Faculty of Forestry, UPM Serdang, Selangor, 43400 Kuala Lumpur, Malaysia

The demand for plywood is expected to decline over the next 10 years, caused by the rising prices of good quality logs. As an equivalent product to plywood, OSB is rapidly increasing its market share of the world's structural market. Malaysia, with the reputation of being one of the leading wood panel exporters, has greater opportunity to establish OSB mills compared to the other Asian countries. Since the technology does not differ much with that of particleboard MDF, OSB production could be commercialised immediately. Two important factors to be considered for the manufacture of OSB in Malaysia are (1) wood raw material and (2) market potential. Most of the plantation wood species which are currently categorised as "utility grade" such as *A. mangium. A. Crassicarpa*, *A. Auricurliformis*, scenting and rubberwood, can be used for OSB manufacture. Hence, converting these woods into OSB of structural grade gives added value to the end products. OSB is set to win over customers from plywood and particleboard traders due to lower raw material cost and to wider product range. Some of the applications for OSB include timber frame housing , furniture, and automative, panelling, concrete formwork. Shuttering boards etc. This replacement trend is made easier by continuing attempts to improve quality and by the introduction of quality assurance programmes, as well as by the establishments of standards for OSB in Europe and UK.

5.05.01 Lignocellulosic-based composites

Moisture Resistant Oil Palm MDF

R.E. Cameron, R. Maylor
Dyno Industries, 43 Shipyard Road, 628135 Singapore, Republic of Singapore
Tel: +65 265 0388 (main), FAX: +65 265 7973 / +65 264 2362, Email: ron.maylor@ap.dynoasa.com

Malaysia is the world's largest producer of crude palm oil with about 2.5 million ha of oil palm, *Elaeis guineensis*, under cultivation. The oil palm industry generates about 30 million tonnes of residues annually. Much of this material (the fronds, empty fruit bunches and trunks) contains valuable fibre that can be utilised for the production of medium density fibreboard (MDF).

After several years of laboratory and pilot plant work culminating in full scale factory trials in 1997, a commercial plant to manufacture MDF panels from oil palm fibre was set up in Gemas, Malaysia. This plant uses the empty fruit bunches as the fibre source.

Although low cost MDF panels suitable for interior use have now been successfully produced, there has been little work undertaken on the use of oil palm fibres to make moisture resistant products. These products have added-value and are more suited for high humidity, wet and exterior type conditions.

This study describes work comparing the performance of several types of moisture resistant oil palm MDF products. Particular emphasis is on the type and application of the adhesives for optimum performance and properties with oil palm fibre.

In particular, the study compares the properties of panels produced with melamine-urea-formaldehyde (MUF) and phenol-formaldehyde (PF) binders and the effectiveness of the glue system and gluing conditions for an oil palm MDF process with respect to: physical properties, water resistance and durability.

The results show that the European V313 requirements for internal bond and thickness swell are not difficult to meet with these resins, the German V100 is met by the more durable of the resins and the wet bending strength requirements of the Japanese JIS5905 demand the most durable resins at high loadings, particularly for the highest moisture resistance class.

Keywords: Oil palm, moisture resistant MDF, melamine-urea-formaldehyde, phenol-formaldehyde.

Bamboo Cement Board

Joseph Fuwape
Federal University Akure, Dept. Forestry and Wood Tech., P.M.B 704 Akure, Nigeria
Email: fuwape.b@akure.rcl.nig.com

The compatibility of portland cement with finely ground bamboo was determined. Hydration tests were conducted to determine the maximum hydration temperature and the time required for the mixture to attain a maximum hydration temperature. The pulverized bamboo was subjected to such treatment as hot water extraction and the use of chemical additive, calcium chloride to enhance its compatibility with cement. The untreated bamboo was observed not to be inhibitory to cement setting but the addition of chemical additive substantially improved cement setting time. Air-dried bamboo flakes were used for board production at cement-bamboo ratio 3:1, 2.5:1 and 1:1 at nominal board density of 1,200 and 1000 Kg/m^3 respectively. The effects of cement/bamboo ratio and board density on bending strength, internal bond and thickness swelling of cement bonded particleboard from bamboo were investigated. The boards produced at cement-bamboo ratio 1:1 failed due to poor bond strength. The bending strength of boards produced at 3:1 and 2.5:1 bamboo-cement ratio increased with bamboo-cement ratio. There were no significant variations in the internal bond strength of the boards irrespective of bamboo-cement ratio. Boards produced at 3:1 cement-bamboo ratio and 1000 kg/m^3 nominal density had the lowest mean thickness swelling.

Production and Utilization of Wood Briquettes from Sawmill Residues in Nigeria

Joseph Fuwape
Federal University Akure, Dept. Forestry and Wood Tech., P.M.B 704 Akure, Nigeria
Email: fuwape.b@akure.rcl.nig.com

Wood is the major source of domestic fuel in the rural areas in Nigeria. About 86% of people in Nigeria use wood for their domestic cooking and for keeping their surroundings warm. The annual consumption of fuelwood in the country is about seventy million cubic metres. The current rate of fuelwood utilization in Nigeria and several tropical countries surpasses the rate of production of wood in plantations and natural forests. Thus there is the problem of deficit supply of fuelwood in some parts of the country. The main objective of the study is to produce briquettes from wood residues in the forest industries for fuelwood supply to areas where there are acute shortage. It was estimated that about 55% of wood biomass processed in the sawmill end up as mill residue. It is expected that the problem of deficit in supply of fuelwood would be alleviated if wood briquettes are produced from about 1.72 million m^3 of wood wastes generated in the wood industries in Nigeria per annum. Wood residues from forest based industries in Nigeria were assessed in terms of availability, combustion characteristics and their potentials for energy production. Wood briquettes were produced from air-dried sawdust and carbonized wood samples collected from sawmills in Akure, Nigeria. Locally produced starch from cassava and clay were separately used as binders at 15, 30 and 40% weight of substrate. Combustion related properties of the briquettes, Viz: moisture content, heating value and energy captured during water boiling tests were determined. The moisture content of the air-dried briquettes ranged from 13 to 17%. Starch bonded briquettes generally had lower moisture content than clay bonded briquettes. The gross heat of combustion of the briquettes ranged between 19.50 and 20.20 MJ/Kg. Briquettes produced from carbonized wood had comparatively greater gross heat of combustion than ordinary sawdust. The highest energy captured during water boiling test, 2.67 KJ/g was recorded for starch bonded briquettes while the least energy captured 1.43KJ/g was recorded for clay briquettes. Briquettes produced from starch based carbonized wood had the best combustion characteristics. The burning properties of starch bonded briquettes were generally better than those of clay based briquettes. Clay based wood briquettes were cheaper and more attractive to the rural people because of the simple production technique. Urban dwellers prefer starch based charcoal for domestic cooking and barbecue production. All the charcoal briquettes produced have high heat of combustion and low ash content.

Research on Medium Density Fiberboard Manufacturing Possibilities from Cotton Stalks (*Gossypium Hirsitum* L.)

Ayhan Gencer, Hüdaverdi Eroglu
Zonguldak Karaelmas University, Faculty of Forestry, 74100 Bartin, Turkey
FAX: +90.0378.2277421, Email: Mehmet Sabaz [peyzaj74@turnet.net.tr]

Raw materials in the world are gradually decreasing. As the population increase will enhance raw material consumption, maximum gain must be obtained from natural sources. When using initialized cotton stalks in the manufacture of medium density fiberboard (MDF) a new solution will be found for raw material shortage.

In this study, cotton stalks obtained from Adana province were used as raw material. 8% and 10% urea formaldehyde resin and 3.25 hydrous ammonium as a strengthening agent were used on the basis of dry fiber weight. Also 1% paraffin solution was used as hydrophilic material on the basis of dry fiber weight. 15% moisture content chips were cooked under 7 atmosphere pressure during 3 minutes and defibered by a defibrator in two minutes.

Chemical analyses results of cotton stalks which is volume density of 0.286 (g/cm^3) were as follows: cellulose content 51.8%, holocellulose 76.8%, lignine 20.7%, pentosan 22.3%, alchol benzene solubility 3.8%, ash content 2.6%. Specific gravity values obtained were higher than expected. Moisture content values vary between 5.38% and 6.00%. Within 0.05% confidence limit there was no significant difference water absorption swelling with specific gravity and resin ratio used.

At 8% resin ratio minimum and maximum bending strength were 12.283 (N/mm^2) and 21.009 (N/mm^2) respectively. On the other hand at 10% resin ratio the same values were 15.054 (N/mm^2) and 23.085 (N/mm^2) respectively. Bending strength was increased with resin rate used and specific gravity. The same result was obtained from perpendicular traction strength. Traction strength values at 10% resin ratio were higher than those of 8% resin rate.

Oriented Strandboard from Pinus taeda and Aspidosperma quebracho blanco Schlecht.

Juan Carlos Medina
Facultad de Ciencias Forestales, UNSE, Avenida Belgrano 1912 (S), 4200 Santiago del Estero, Argentina.
Tel-Fax: 0054 385 4221787, E-mail: medinadiodato@yahoo.com

The results of the evaluations of some mechanical properties of oriented strand board from *Aspidosperma quebracho blanco* Schlecht (QB) and *Pinus taeda* (P) are presented in this paper.

The panels were built using a mixture of strands of both species in different proportions to establish the maximum quantity of strands of QB that it can be used in the production of OSB panels.

The values obtained from the machanical tests were analyzed through technical statistics in order to identify the best panels. The experimentals values were compared with those demanded by the Canadian norm CSA O437.0.

As expected, the statistical analyses showed that no single panel is the best for all tests. However, based on the comparations with the values demanded by CSA O437.0, it can be concluded that it is possible to elaborate OSB panels with a mixture of two kinds of strands with the quantity of white quebracho in it, not exceeding of 40% for the external layer and of 60% for the internal layer.

Effects of Density Profile on the Dimensional Stability of Particleboard and Fiberboard

Ee Ding Wong, Shuichi Kawai, Min Zhang and Qian Wang
Universiti Putra Malaysia, Faculty of Forestry, 43400 UPM Serdang Selangor, Malaysia
Tel: +60-3-9486101(ext. 2410), FAX: +60-3-9432514, Email: edwingw@hotmail.com

Two types of particleboard and fiberboard, namely homo-profile and conventional boards, were produced via manipulation of hot pressing method, using lauan (*Shorea* spp.) particles/fibers and isocyanate resin. The density profile of homo-profile board is homogenous and flat, whereas that of conventional board resembles a typical U-shape. Further, the density profile of the conventional board was varied by changing the hot pressing method and mat moisture content.

After conditioning at 20+- 1øC and 65+-% relative humidity (RH), the changes in board thickness and weight of 50mm by 50mm specimens were determined after each stage of dry/wet cycle. In addition, the equilibrium moisture content, thickness changes, and linear expansion (LE) of 50mm by 300mm specimens were measured after exposure to 33.66 and 95% RH levels.

Generally, particleboard recorded higher thickness swelling (TS) and water absorption compared to fiberboard irrespective of density profile. Specifically however, conventional particleboard had a higher TS than homo-particleboard, whereas a reserved trend was observed in fiberboard. Under increasing RH, except at 95% RH, particleboard registered higher LE than fiberboard, irrespective of their density profiles. Homo-profile particleboard had a higher LE than conventional board, but fiberboard showed reversed trend. Peak area was found to affect the TS of board, but no specific trend was observed for density profile-LE correlation within the conventional boards.

5.05.02 Recycling and recycled products

Potential Utilisation of Mill Residues in Peninsular Malaysia

Ir. Tai Kah Kee
Jalan Sultan Salahuddin, Forestry Department Peninsular Malaysia, 50660 Kuala Lumpur, Malaysia
Tel: +603-298-8244, FAX: +603-292-5657

This paper discussed the major findings conducted by Malaysia-DANCED project 'Study on Extraction and Processing of the Forest Residues and Small Dimension Logs in Peninsular Malaysia'. The objective of the project was to optimise the utilisation of forest residues including small dimension logs and mill residues as raw materials in Peninsular Malaysia for sustained social, economic and industrial benefits. The State of Terengganu was chosen as the area for pilot study. Among others, the major activities were to survey the quantity of mill residues available in Terengganu during primary processing and to recommend the future industrial use of these mill residues. Log production in Terengganu has been gradually declining from 1.50 million mü in 1990 to 0.76 million mü in 1998, at a rate of 82,000 mü per year. With the decreasing log production, it has become increasingly urgent to address the issue concerning the large amount of logging residues and also mill residues. The study shows that forest residues constitutes about 2 times the volume of logs removed in Terengganu and the available mill residues including bark constitutes about 1/3 of the volume of logs processed in sawmills and plywood mills. Mill residues are presently being used for kiln drying to generate steam, moulding, finger jointing and downstream processing to produce blockboard. Recommendations are being made by the project to convert the mill residues to wood chips or as fuel in co-generation plant to produce steam and electricity. The wood chips produced can be exported by chartered vessel or used locally as raw materials for manufacturing particleboard, floorboard and medium density fiberboard.

Changes of Wood Components of Sugi (*Cryptomeria japonica*) Chip under the Treatment of Garbage-degradation - Their Effect on Recycling-

Kinji Shimada, Atsushi Kato, Yoichi Tomimura, Kengo Magara
Forestry and Forest Products Research Institute, P.O.Box 16, 305-8687 Tsukuba Norin Kenkyudanchi, Japan
Tel: +81-298-73-3211, ex. 523, FAX: +81-298-73-3797, Email: kshimada@ffpri.affrc.gp.jp

The treatment of waste is one of the most serious problems. In particular, the treatment of garbage (food related organic waste) is the most difficult problem because it easily rots and smells. Previously, ability of newly developed system for garbage degradation reported. In this system, sawdust plays an important role as excellent bioreactor and the residual sawdust changed into effective fertilizers or soil-conditioners.

This paper deals with the possibility of wood chip (Sugi: *Cryptomeria japonica*) instead of sawdust and the characterization of physical and chemical properties of wood chip.

It was found that wood-chip also can adapt to the bioreactor, being a matrix for the biodegradation of garbage in the container. The residual chip showed the properties of flexible, thermal softening and de-watering. In addition, binderless board can be made from this chip by hot pressing at 150 degrees centigrade.

To investigate the change of wood main components and extractives, in addition to chemical, elemental and microscopic (under polarized light) analysis, the alkaline-nitrobenzene oxidation products were analyzed by means of GLC, 3H-, 13C-NMR spectroscopy.

Following results were obtained.

* Crystal structure of cellulose was partially changed.

* Hemicellulose was partially hydrolyzed.

* Lignin was polymerized with condensation reaction.

* Norlignan (extractives) was also polymerized and changed to methanol insoluble fraction.

These facts would effect on the physical properties of the surface of chip. In this report, it is evidenced that considerable chemical and physical changes in wood chip caused by biological reaction under the treatment of garbage-degradation and the newly obtained properties of chip will influence new recycling process.

Modification of Lignin Containing Wood Processing Wastes for Plant Development Activation. Environmental Impact

Galina Telysheva, Galina Lebedeva, Tatiana Dizhbite, Uldis Viesturs
Latvian State Institute of Wood Chemistry, 27, Dzerbenes St., LV-1006 Riga, Latvia
Tel: +371-7545142, FAX: +371 7 310135, Email: ligno@edi.lv

Review of new data in lignin behaviour in soil and its influence on development of plants, including wood species, and soil quality has shown that lignins potentially could fulfil all functions of humic substances (accumulative, transport, regulative, protective and physiological). Activity of lignins in these lines depends, from one side, on their structure and chemical properties, i.e., biological and chemical prehistory and, from other side, on soil characteristics and species of plants.

At present investigations of silicon role in soil biocenosis and plant development is of special interest due to the novel data obtained on this element necessity for full cycle of plant ontogenesis as well as increasing soil silicon deficiency. In spite of high total silicon content in soil (33%) the content of it in form available for plants is very low (1-3%). The most intensive desilication is taking place under conditions of hot and humid tropical climate. However silicon-deficient soils exist also within the moderate temperate climate zone.

The present study is focused on the modification of wood processing wastes with silicon containing compounds, aimed at obtaining of plant growth activators and/or complex organic fertilizers of high efficiency. Wastes/by-products of chemical and mechanical wood processing: kraft lignin, hygrolysis lignin and wood sawdust were the objects for modification with silicon-containing organic and inorganic oligomers. Effect of products synthesized was tested under indoor and outdoor conditions on agricultural and ornamental plants, including tropical plants, and on silvicultures planted into swar-podzolic soil or different soil substrata. Plant samples were taken at varying dates during one/two growing season for biometric measurements, estimation of the root system development, chemical and biochemical analysis (silicon, nitrogen, chlorophyll, carotenoids, amino acids, auxins content). Soil samples were characterized with soluble silicon content, mobility of macro- and micronutrients, microbiological activity, humic substances composition. Consideration of the unmodified/silicon-modified lignin containing products (LP/LSP) effect was made on the basis of LP/LSP complexing and sorption properties, functionality and structural characteristics and data of an analysis carried out according to the methods used for the characterization of the humus group composition. Further amorfization of lignin matrix under influence of modification due to formation of Si-O and Si-O-Si bonds resulted in a faster turnover of LSP in soil than unmodified lignin samples. A gradual silicon transfer into soil solution has been proved by analysis of soil and plant samples. Positive influence of LSP on plant development was higher than the additive effect of unmodified lignin-containing products and silicon-containing compounds used for modification. LSP promoted rootability of plants, production of more strong and vital sprouts/seedlings, development of a vigorous and branched root system and the ground part of plants, enhance crop yields.

The results obtained have shown that plant's resistance against diseases and stress (e.g. transplantation), temperature fluctuations and drought enhances, food value of agroproducts goes up, the quality of ornamental plants improve (increase flower size and blades area, strengthening floriferous stems, prolonging the blossoming period) when LSP are used. Results of LSP application for silviculture growing from seeds have shown that 1 years old spruce plants have better developed root system (root mass and amount of secondary roots increased), the diameter of stem increases and amount of plant defeated by *Fusarium* sp. decreases. Besides above mentioned positive influence on plant development, significant environmental impact from LSP application covers increase in microbial activity of soil, positive changes in macro- and micronutrient mobility, including release of phosphorous from its insoluble compounds, suppressing of phytopathogenic microflora development and enhanced ability for decontamination from soil pollutants. Usage of wood processing wastes modified with silicon-containing compounds for production of new wood and other phytomass and soil quality improvement enhances the harmony of wood processing industry with environment.

5.05.03 Wood/Non-wood combinations

Investigation of the Possibility of Use of Cotton Stalks in Particleboard Manufacture

Hamed I. El-Mously, M.M. Megahed and M.M. Rakha
Ain shams University, Center For Development o Small Scale Industries and Local Technologies, 1 El Sarayat St., Abdou Pasha Sq., Abbassiah, 11517 Cairo, Egypt
Tel: +(202)2842472, FAX: (202) 2842472, Email: cdsilt@idsc.gov.eg

Cotton is one of the main agricultural crops being cultivated in Egypt. The annual yield of cotton stalks (CS) from about 420,000 ha of cotton being cultivated annually is estimated to be 1.6 million tons (air-dry weight). Cotton stalks are an important lignocellulosic renewable resource in a country that suffers from an acute shortage of wood resources. Cotton stalks were traditionally used as a fuel in rural ovens. This traditional pattern of CS utilization is associated with the renewal of the cycle of cotton boll worm, which resides in the unopened bolls in CS, causing an annual crop loss of about 20%. As a result of the cotton boll damage, CS are being burned after cotton collection. This practice is very environmentally unfriendly and uneconomic. This study suggests the use of CS as a furnish in particleboard, especially in light of the fact that particleboard factories in Egypt face an acute shortage of furnish supply. Field experiments have indicated the possibility of the use of tractor-operated threshers and bale presses in the milling and transformation of CS into bales of appropriate dimensions, weight, and bulk density (~0.25 ton/m^3) for transport to particleboard factories. This method will guarantee lower investment in equipment, lower energy and transportation costs, and labor opportunities in villages. Laboratory particleboard specimens were manufactured from air-dried CS (~10% MC). CS pieces were processed by a hammer mill, and the resulting particles were classified via a sieving unit into coarse and fine particles. The particle mix was blended with a urea-formaldehyde resin in a blender, hand-formed into a mat, and introduced into an automatic press using a wet cycle to cope with the large MC of the CS particles. One- and three-layer specimens were thus prepared. In a series of experiments on the one-layer particleboard, CS were used with the leaves and bolls intact. CS particleboard specimens were manufactured under different pressing conditions (25 to 35 kg/cm^2) and glue levels (9 to 14%). Static bending (SB), internal bond (IB), face strength (FS), and thickness swelling (TS) tests were conducted on CS particleboard specimens and the density of the specimens determined.

The values of modulus of rupture (MOR) varied from 18.1 to 24.1, 11.7 to 18.5, and 11.3 to 15.7 N/mm^2 for the three-layer, one-layer, and one-layer CS particleboard with leaves and bolls, respectively. The density varied from 0.7 to 0.8 gm/cm^3 for all board types. The values of the modulus of elasticity (MOE) varied from 2,457 to 3,237, 1,698 to 2,727, and 1,779 to 2,406 N/mm^2 for the three CS particleboard types. The values of IB varied from 0.64 to 1.1, 0.70 to 0.74, and 0.86 to 1.21 N/mm^2. The values of FS for the three-layer CS particleboard varied from 1.38 to 1.72 N/mm^2. The values of TS after 2 hours varied from 3.6 to 8.3, 7.1 to 26.1, and 8.4 to 14.0 percent for the three investigated CS particleboard types. These results indicate that the three-layer CS particleboard fully satisfies the requirements of the Egyptian standard 906/1991 for particleboard (similar to BS 5669-1979). Under most of the investigated conditions, the one-layer CS particleboard satisfied the requirements of the aforementioned standard. An increase in adhesive level had a positive significant effect on MOR, MOE, IB, and TS for all board types. The addition of leaves and bolls decreased the mechanical properties but improved the TS of the CS particleboard. The results from this study suggest that there is a real potential for the use of CS particleboard in the manufacture of three-layer particleboard without any sacrifice in product quality.

Bio-concrete. Wall Elements Produced from Wood Residues

Katia Manzanares Ayala, Digna Velazquez Viera
Forestry Research Institute, Calle 174 no. 1723 entre 17b y 17c, Habana, Cuba
Email: elias@ip.etecsa.cu

Experimental small manufacture of hallow and massive blocks (bioconcrete) are described with the objective to find a solution to the utilization of waste forest biomass at saw mill industry and to use this potential raw material source in low cost housing in order to improve local people conditions. This study was conducted by mineral bonded wood composite methods using *Pinus caribaea* More. chips mixed with slaked lime and Portland cement weighed proportion 1:1:1,5. The production of blocks consisted of a modular frame measuring 40 x 20 x 15 cm compacted by hand and cure at temperature room. Details are given of the properties of prototypes and raising partition wall based in comparison with the conventional Cuban ways of masonry. The results indicate that incorporating chemical aggregates (CaOH2) as a partial substitute of cement consumption was possible to obtain acceptable mechanical and physical properties of specimens. The wood cement blocks exhibited high dimensional stability when exposed to 24 water soaked and mean modules of rupture (MOR) ranged from 1,0-1,5 N/mm^2. It is concluded that the blocks technology involves minimal investment and therefore offers an important alternative from building process by forest products as well as confirmed the favorable influence of use of waste residues from biomass exploitation and sustainable forest.management. Also, this technology can be used as a rapid technique for production of wood blocks while the sawmill residues are being produced.

Compatibility of Some Wood Species With Portland Cement and its Enhancement Using Varies Treatments and Chemical Additives

Mabrouk Megahed Megahed, M.L.M. El-Osta, Nasser, R.A.
Alexandria University, Tech. Department, Fac. of Agriculture, Tech. Department, Fac. of Agriculture, 21545, Alexandria, Egypt
FAX: +(203) 5971780, Email: Mmmegahed_a@yahoo.com

Hydration and compression experiments were carried out to investigate the compatibility of wood-cement mixtures made of four wood species, namely, eucalyptus (*Eucalyptus camaldulensis*), casuarina (*Casuarina glauca*), European redwood (*Pinus sylvestris*), and poplar (*Populus* spp) as affected by treatments (hot water and 1% NaOH solution extraction), and chemical additives (CaCl2 based on 3% of cement weight).

Based on the results obtained from hydration and compressive strength experiments under untreated conditions, poplar and European redwood showed the same behavior in hydration and compressive characteristics and they classified as suitable under limited conditions, while eucalyptus and casuarina behaved differently and they need some treatments to improve its compatibility with cement. Substantial improvements in cement setting can be achieved by using either hot water or 1% NaOH treatments, specially for eucalyptus and casuarina that reclassified them from unsuitable to suitable under limited conditions. However, slight improvement in compatibility were obtained for poplar and European redwood. The addition of CaCl2 to either untreated or treated wood enhances compatibility of wood-cement mixtures.

Hydration characteristics had high correlations with compressive strength characteristics and they can be used as suitable estimates for the compatibility of wood-cement mixtures.

Properties of *Acacia catechu* Kraft Fibre As A Reinforcement In Wood Plastic Composites

Zakaria Sarani, Sahrim Ahmad and Hew Peng Koon
Universiti Kebangsaan Malaysia, Faculty of Physical and Applied Sciences (FSFG), Bangi, 43600 Selangor, Malaysia
Tel: 010-16-3-8293261/3211, FAX: 010-60-3-8292415, Email: sarani@pkrisc.cc.ukm.my

The main objective of this project is fabrication and improvement of the mechanical properties of wood base composites blend with LLDPE as a binder. To approach the aesthetics value of wood, a newly found natural fiber, *Acacia catech* had been utilized to maximum weight fraction in the matrices of LLDPE and comparison had been made with the weight fraction of synthetic fiber kevlar 49. Besides of this, theoretical and practical formulation had been established for the pulping processes and to obtain better quality of fibers and composite, fibers separation system and modified compression mold were conceptually designed and fabricated. Since the reliability of characteristics would determine accuracy of estimation, relationship between impact properties to tensile strength and strain, as well as modulus of composite to Brabender rotor's torque were established. By utilizing micromechanical approach (Page Theory), the bond strength within fibers and tensile strength of *Acacia catech* fibers were found. Further mechanical improvement had been carried out on the aspect of reinforcing interfaces properties of *Acacia catech* fibers with LLDPE after the main weakness of this composites was found as due to poor interaction of *Acacia catech* fibers with LLDPE. In this study, compatibility of silane Z6032 that has been found hypothetically capable to couple the lignin of natural fibers had been used to treat the wood fibers. The interaction between wood fibers and LLDPE was observed using SEM, impact and tensile tests.

Effect of Exposure Conditions on the Durability of Oil Palm Fibre Cement Composites

Rahim Sudin, R. N. Swamy
Wood Chemistry Division, Forest Research Institute Maylasia (FRIM),
Kepong, 52109 Kuala Lumpur, Malaysia

The durability of oil palm fibres cemes composites produced from oil palm trunk (OPT) and found (OPF) fibres was determined. Both OPT and OPF fibres produced by an oil palm fractional, possess fibres length 15-21mm length and 0.2-0.5mm thickness were used as reinforcement material in fibre-cement composites. The durability of these composites on internal and external exposure to typical Malaysian weather conditions was evaluated based on the retention or loss of their mechanical and physical properties for a period of up to 300 days. Results showed that generally the MOR, MOE and tensile strength properties of OPT fibres cement composites increased during the early stage of exposure before they slowly decreased towards the later stage of exposure. However, in the case of OPF fibre cement composite, all the MOR, MOE and tensile strength were generally lower than in OPT fibre cement composite during the initial stage before slowly increasing towards the later stage of the exposure. The water absorption of the OPT and OPF fibre cement composite was significantly higher during the early stage of exposure prior to stabilising after nearly 300 days of exposure. An almost similar trend was observed on the thickness swelling of the composite after soaking in water for 24 hours. The density of the composites increased as the duration of exposure increased. Generally, the mechanical and physical properties of both OPT and OPF fibres cement composites satisfied the minimum requirements of the Malaysia Standard (MS 934:1986) and International Standard (ISO 8335:1989) specifications for cement-bonded particleboard.

5.05.04 Modification of lignocellulosics

Crystallinity Of Oil Palm Empty Fruit Bunch Treated By Steam Explosion Process

Mohamad Deraman, Sarani Zakaria
Universiti Kebangsaan Malaysia, Department of Physics and Material Sciences Program,
43600 Bangi Selangor, Malaysia

Oil palm empty fruit bunch (EFB) is a by product of palm oil, and is available in large quantities (about 8 millions ton per annum) at palm oil mills.

Due to its natural properties, low cost and readily collected and continuous supply at palm oil mill, the EFB has been seen as a potential precursor for making products based on lignocellulosic materials. For this purposed the precursor has to be processed, for example through refining for making medium density fiber board, pulping for making paper and stem explosion for cellulose production. In this study, the EFB fiber were refined, classified into different fiber length and added with a minimum amount of deionized water for steam explosion treatment which was conducted at 190°C and 210°C for 10 minutes. The treatment at 210°C was found to break the EFB-fibers into individual libriform fibers. The crystallinity of cellulose in the untreated and treated EFB fiber was estimated using X-ray diffraction technique. The results show that the cellulose in untreated EFB. Treated at 190°C and 210°C have 36.42 and 47% crystallinity respectively. This indicates that the steam explosion process increases the crystallinity of cellulose in the EFB-fibers.

Modified Wood by High Temperature Heat Treatment

D. Dirol, G. Labat, M. Vernois, P. Girard, S. Mouras and P. Permadi
Centre Technique du Bois et de l'Ameublement, 10 Avenue de Saint-Mand,, 75012 Paris, France
Tel: +33 1 40194806, FAX: +33 1 40199297, Email: michel.vernois@ctba.fr

The poor dimensional stability of wood under variable atmosphere and the low durability of many species have originated research for stabilization treatment inducing the limitation of moisture absorption of the lignocellulosic material. One of the processes under study for the last decade in France and in Europe consists in submitting wood to heat treatment at temperatures ranging from approximately 180-250°C depending on the type of species and the physico-mechanical characteristics to reach. This theme was the subject of a European research program in which several research centers and private companies from the industrial sector participated.

The main objective is to reduce the hydrophilic behaviour of wood by modyfing the chemical structure of some of its components through heat treatment in controlled atmosphere in the form of a soft pyrolysis reaction.

The way the pyrolysis is conducted and the selection mode of the various parameters involved in the process have an influence on the characteristics of the final product. Operating conditions are essential, and such parameters as atmosphere-temperature-processing time-rate of heating-species-weight and dimension of the pieces-original moisture of the wood should be taken into acccount, for they can strongly affect the final properties. The aim is to reach the optimum balance between the improvement of the moisture resistance and the decrease of the mechanical characteristics depending on usage. The way hardwood and softwood species are affected by those parameters is reviewed. It has been observed that when submitted to heat treatment at high temperature, the kinetics of humidity absorption is noticeably modified resulting in a major reduction of the volume retraction and a lowering till a certain extent of some mechanical properties, depending on the treatment applied.

On the whole, the results show a weakness and a loss of plasticity of the wood treated at such temperatures, which especially affects tensile strength. The mechanical loss does not impede non structural uses. However, it's imperative that this property be taken into account for applications requiring high level mechanical characteristics in bending and tensile strength.

One of the potential ways of conferring an enhanced value to the wood through heat treatment concerns species with low natural durability, especially those which are resistant to conventional treatment by impregnation. Resistance testing on wood rotting fungi responsible for decay showed that spruce, fur, poplar and some tropical species as for example *Curupixa* had developed strong resistance to fungi after heat treatment at 250øC for twenty minutes. Trials performed on Scotch pine sapwood heated at 260øC for 15 minutes gave excellent results as well. Beech treated at 250øC resists quite well to cubical butt rot which is very active in tropical regions.

On the contrary, heat treatment does not improve resistance to termites.

Improved durability results from the combination of two factors induced by thermal treatment:

A noticeable reduction of moisture absorption. Rot fungi need a minimum of 20% of humidity to develop. elimination of some of the nutrients required by wood rotting fungi.

It should be noted that heat treatment induces chemical modifications in the wood which are responsible for the darkening of the original colour over the whole material.

This research has highlighted the potential of the process as well as some limitations at the present state of the art.

The different industrial processes in use today in Europe are described:

- processes under inert nitrogen atmosphere
- processes under low oxygen mixture
- processes under saturated water vapour atmosphere
- treatments which consist of two stages, one hydro-thermal stage followed by a dry atmosphere stage.

Technological solutions in terms of process control are dicussed.

The applications targeted by the different processes are thoroughly addressed as well as the corresponding market opportunities.

Modification of Wood by Treatment with Low Molecular Phenol-formaldehyde Resin Properties Enhancement of Neutralized Phenolic-resin and Resin Penetration into Wood Cell Walls

Takeshi Furuno, Yuji Imamura, Hiromu Kajita
Shimane University, Faculty of Science and Engineering, 690-8504 Matsue, Japan
Tel: +81 852 32 6563, FAX: +81 852 32 6123, Email: t-furuno@riko.shimane-u.ac.jp

Keywords: Low molecular phenolic resin; Resin penetration; Cell wall; m-bromophenol-formaldehyde resin; Dimensional stability; Decay resistance.

To enhance the dimensional stability and the biological resistance, the low molecular-weight phenolic resins of conventional alkaline type and neutralized type were impregnated into Japanese cedar wood (*Cryptomeria japonica* D. Don) and heat-cured.

The treatment with the neutralized type resin retained the original wood color whereas the alkaline one changed the color of wood to red-brown. The concentrations of the resin solutions and the weight gains due to resin loading of wood after treatment were highly correlated, and the target resin loading could be assessed from the solution concentration. High dimensional stability at 60% of antiswelling efficiency was attained when both types of resins were impregnated at about 30% resin loading and no significant difference was recognized between the two. To suppress the decay attacks by the brown-rot and white-rot fungi, 15% and 10% resin loadings due to treatments was required for the neutralized and alkaline types of phenolic resins, respectively.

On the other hand, the penetration of resin into wood cell walls was investigated by means of light microscopy, scanning electron microscopy, and electron probe X-ray microanalysis, using m-bromophenol-formaldehyde resin with three different number average molecular-weights as a signal of bromine to detect the presence of resin.

The phenolic resin with small and middle molecular-weights (290, 470) proved to penetrate mostly into the cell walls, contributing to the enhancement of dimensional stability and decay resistance in resin-impregnated wood. Also, for phenolic resin with large molecular-weight (820), the resin components with smaller molecular-weight only was suggested to be present in the walls, having little contribution to the dimensional stability.

Wood Torrefaction in Europe: An Overview and its Perspectives

P. Girard, P. Permadi, S. Mouras, A. Napoli
CIRAD-Forêt, Maison de la Technologie, 73, Rue Jean-Francois Breton, BP. 5035
Email: gerard.j@cirad.cirad.fr

Torrefaction is a thermal treatment with the temperature higher than drying but lower than carbonisation. This treatment produce wood with different properties than untreated wood due to chemical modification. In France, this treatment in the beginning has been studied for energy purpose then later it has been developed for improving the quality of wood as lumber. Some research conducted in CIRAD show that torrefaction can be utilize as alternative treatment for improving the quality of wood in term of durability and dimensional stability although it reduces some mechanical properties. The aim of this paper is to present an overview of wood torrefaction which include torrefied wood properties identification, the review of development of its technologies and its market opportunities in Europe.

Catalytic Degradation Processes of Cellulose

D. Meier, O.Faix, S. Radtke, G.Dobele, G.Rossinskaja, G.Telysheva
Federal Research Centre for Forestry and Forest Products, Institute for Wood Chemistry and Chemical Technology of Wood, Leuschnerstr. 91, D-21031 Hamburg, Germany

Keywords: cellulose, pyrolysis, 1,6-anhydrosaccarides, levoglucosan, levoglucosenone

Commercialization of thermochemical processing of renewable biomass is of increasing interest owing to production of biooil which is an alternative to oil. Beside energy production the conversion into valuable chemicals is of special interest due to the higher-added value. The thermal degradation monomeric products of cellulose such as 1,6-anhydrosaccharides, levoglucosenone and levoglucosan are the most important ones. Unique biologically active and biodegradable oligomers and polymers, identical with natural compounds, can be synthesized on the basis of 1,6-anhydrosaccharides.

The present investigation concerns both the studies of the thermal degradation process and the composition of the main volatile products of slow and fast pyrolysis of various celluloses impregnated with phosphoric acid (3.5-7 mass% on raw material). The studies involved several types of microcrystalline cellulose, celluloses obtained from sulphate and sulphite pulping as well as recycled cellulose.

We have shown that two main competing reactions such as dehydration and depolymerization are catalyzed in the presence of phosphoric acid. During catalyzed slow pyrolysis within the temperature range 200-300°C dehydration reactions are prevailing due to re-esterification reactions. Under conditions of catalytic slow pyrolysis levoglucosan never formed and levoglucosenone was the main product of cellulose depolymerization. The maximum levoglucosenone yield, more than 20 mass % on cellulose was observed at 350°C.

At fast heating rates (fast pyrolysis) the total yield of volatile products increases, and their composition as compared with slow pyrolysis is redistributed. Both 1,6-anhydrosaccharides (levoglucosan and levoglucosenone) are simultaneously detected. Their mass ratio in the bio-oil can be regulated by varying the impregnation and pyrolysis conditions. Total levoglucosan and levoglucosenone content in biooil is 75-85 rel. % irrespective of the impregnation conditions and cellulose structure under investigation.

It has been shown that the biooil yield during cellulose catalytic fast pyrolysis depends on cellulose supramolecular structure and polymerization degree and are determined by a series of factors regulating the development of depolymerization and dehydration reactions. Among these factors, the amount of phosphoric acid applied for the impregnation and the temperature of impregnated cellulose pre-treatment are the main ones. The highest yield of levoglucosenone (30 mass% on cellulose) has been observed from microcrystalline celluloses.

Preparative obtaining of levoglucosenone was carried out using a fast pyrolysis installation with a fluidized bed reactor and it was shown that this valuable monomer can be produced with the yield of more than 20 mass% on cellulose from different cellulose containing raw materials including recycled cellulose.

Probing Red Maple Pit Membrane Pore Size at Fiber Saturation Point and Oven Dry Using Polystrene Macromolecules

Ashgar Omidvar, A. A.R.P. Van Heiningen
University of Agricultural Sciences and Natural Resources of Gorgan, Gorgan, Iran
Email: irgouni@iran.com

A modified solute exclusion technique was used to pressure impregnate a polystyrene molecular weight (MW) series dissolved in styrene into red maple samples at approximately the fiber saturation point (FSP) and oven dry (OD). Radial penetration was less than tangential and FSP less than OD. There was a marked change in radial OD penetration at 900,000 MW. There was no marked penetration change with MW in the tangential direction at the higher MW tested.

Corona Treatment: Applications to Wood Material for the Improvement of its Protection

Ludivine Onic, Xavier Deglise , André Merlin , Tohru Uehara
Université Henri-Poincar, Nancy I / ENSTIB, Laboratoire d'étude et de recherche sur le matériau bois, B.P. 239 54506, VANDOEUVRE, France
Email: Deglise Xavier [Xavier.Deglise@lermab.u-nancy.fr]

Keywords: Wood; Protection; Corona

Plasma treatment and corona discharge treatment are widely used in polymer industry, in metallurgy or in card board and paper production, to improve adhesion of resins, to clean the surface or to deposit a new film with well-defined physical and chemical properties. The films of polymers such as polypropylene, polyethylene and polyvinylchloride are treated in a few seconds, and are wetted by ink, varnish or glue. For wood material which is porous and which have a complex and variable chemical composition, our interest is to find a convenient, easy, cheap technology to activate its surface, different from the others existing treatments.

Plasma treatment was recently used in wood industry. Particularly, oak is well-known to be difficult to glue or to varnish sometimes. For the present research, oak is selected and is treated by a corona discharge. The first step is to build a corona treatment apparatus, then the treatment procedure is adapted for wood materials and the surface energy of treated surfaces are characterized by the wettability as a function of various parameters (time and voltage of corona treatment, nature of gas). The corona treatment system is composed of a generator, a transformer, and a closed cell in which two rectangular inox plates spaced by 6mm for the electrodes are settled. The electrodes are covered with glass plates. A wood sample is introduced between these two glass plates. The samples are treated at voltage between 9 and 15 kV up to two hours in dried air or in nitrogen gas. Contact angle measurements involve a 5Aø thickness outer layer; and the wettability of wood is improved by the corona discharge treatment, not in a few seconds like for synthetic polymer films, but in a few minutes. Cosine contact angle increases as an exponential function with time, and attains a plateau after 30 minutes of treatment. The high voltage treatment is more drastic than low voltage treatment. In the same way, dried air treatment improves the wettability better than nitrogen treatment. In summary, the most efficient parameter is the treatment time, voltage and nature of gas have a very small influence. As a conclusion, the optimum conditions for the wettability are: 5 minutes at 9 kV in dried air. These results are in agreement with those of some reports. The presence of ozone in air corona discharge treatment can explain a better oxidation of the wood surface. But the nitrogen gas is more efficient than the oxygen gas to create radicals to the surface, which can react after with air to oxidize the surface. Other applications are also possible for corona discharge treatments. Wood material is dimensionally stabilised by thermal treatment. Wood is placed during half an hour at 150øC, but, unfortunately, its surface energy is lowered. Corona discharge treatment is able to increase the wettability of this thermal treated wood. A polyethylene-wood surface composite is also possible by treatment of wood in ethylene gas. Wood is then becoming waterproof. These few applications, not only for treatments for synthetic polymers but also for woods itself, are evidence of a large perspective in wood industry for corona discharge treatment. A good wettability is necessary for improving the adhesion of a varnish and the durability of outdoor panels. A wood protection without varnish is also possible by the formation of a polyethylene film on the wood surface.

Dimensional Stabilization of *Aspidosperma quebracho-blanco* with Polyethylene Glycol

José J. Paz, Sanabria, Ernesto O.
UNNE, Facultad de Agroindustrias, Cte. Fernandez No 755, 3700 Pcia. Roque Saenz Pena - Chaco, Argentina
Tel: 54-03732-420137

Keywords: *Aspidosperma quebracho-blanco*; PEG; Impregnation; Dimensional stability; Shrinkage

Nowadays, the most abundant species of the region of the "Parque Chaqueno" in Argentina is *Aspidosperma quebracho-blanco* Schlecht. This species is used mainly in the making of pallets and charcoal in spite of its characteristic pale yellow colour and high density, which are highly sought after within the national and international floor and furniture markets. It cannot be used for production of high added-value goods because of its dimensional instability.

The aim of our investigation was to examine the use of organic polymers and impregnation processes to dimensionally stabilise *Aspidosperma quebracho-blanco* for application in high added-value goods.

In this research we used sawn samples which were the same size as those used in industry. These had a radial cut and were impregnated in their green condition using the Bethell method. Treatments were done in a pilot plant using polyethylene glycol (PEG) with molecular weight of 300 and 600 at different concentrations and different treatment times. The samples were dried to 10% moisture content and then stabilised under specific Argentine Institute of Material Rationalisation (IRAM) standards. Each of the treatments was performed under a full factorial experimental design.

To measure the influence of PEG treatment on dimensional stability, differential swelling and shrinkage coefficients were adopted as control parameters. These parameters were analysed using the adopted experimental design and results were compared with those of untreated samples. The PEG treatment method produces the cell wall bulking which keeps the wood in its swollen condition, even after drying. In this way shrinkage can be totally or partially eliminated.

The best differential swelling and shrinkage coefficients (0,069% and 1,95% respectively) of the species *Aspidosperma quebracho-blanco* were achieved by impregnating the wood with PEG 600 using a 50% aqueous solution following the Bethell process at a pressure of 12 kg/cm^2 over two hours. These results represent a decrease of 58,7% in swelling compared with the untreated samples.

The best dimensional stability was achieved with a PEG 600 retention of 73,7 kg/m^3 in the impregnated wood, which would allow its use in some industrial applications.

Determination of Diffusion Properties, Sorption and Permeabililty to Gases on *Popula Robusta* after Thermal Treatment at High Temperature

P. Rousset, P. Perre, S. Desobry, S.Guilbert
CIRAD-Forêt, Maison de la Technologie, 73, Rue Jean-Francois Breton, BP. 5035, 34032 Montpellier Cedex, France
Email: gerard.j@cirad.cirad.fr

One of the selection criteria for packaging materials intended for fresh foodstuffs is the knowledge of their functional properties and, more particularly, their properties regarding gas and water vapour flow. Depending on the external conditions, the relevant physical properties that characterise the ability to mass migration are permeability and mass diffusivity. Consequently, the knowledge of packaging materials implies the determination of these parameters as well as the effect of its structural and morphological characteristics that affects these properties.

Poplar wood, *Populus*, used in packing was classified among materials suitable for food contact. The chemical modification, with partial deterioration of its components, during a thermal treatment at high temperature (200°C) under inert atmosphere enhances the material behaviour (better durability and dimensional stability) but also significantly modifies its diffusion properties, sorption and permeability to gases and water vapour.

The objective of this study is to quantify this effect. The gaseous permeability is determined on samples of green poplar (content moisture: 20 and 12%) and on the same samples after thermal treatment. The sampling has been determined in order to perform the same comparison for mass diffusivity. The stake of this study is to open new ways of valorisation for this specie in the domain of light wooden packaging.

5.06.00 Properties and utilization of tropical woods

The Lesser-used Timber Species of Ghana. A Success Story

A.G. Addae-Mensah
Forestry Research Institute of Ghana, University P. O. Box 63, Kumasi, Ghana
Tel: +233 51 29655, FAX: 233-51-60121

The alarming rate at which the primary wood species have been dwindling from the Ghanaian forest has been a topic for discussion for sometime. Many serious debates have been held within the timber industry sector since the early 1990s with emphasis on the imminent shortage of raw material supply to the industry. As a consequence of these debates, this project proposal was designed to address the utilisation of the Lesser-Used (LUS) and Lesser-Known (LKS) timber species to replace some of the primary species.

The general aim of the project was to encourage the forest products industry of Ghana and the sub-region to better utilise their forest resources in order to help aide the development of the Ghanaian society while also attaining ITTO's target 2000 i.e. to achieve complete sustainable forest management by the year 2000. Specifically the overall objectives were to find a way of removing pressure from the over exploited primary species like the Mahoganies, Irokos etc. by increasing the use of Lesser-Used species whose availability was considered to be of potential economic interest and whose properties could match those of the primary species.

Due to the complex nature of the project, the work was divided into three main components:-

1. Forest Ecology - to study the ecological impact on the forest, the rivers and wild life after extracting the various species.

2. Wood Technology, Processing and Product Development - to look at the physical and mechanical properties of the wood, the wood machining characteristics as well as the product development expertise.

3. Forest Products Marketing - to study how best the species and products from them can be market

14 LUS of Ghana were selected from three ecological forest zones of Ghana for the studies, i.e. The wet evergreen forest zone, the moist evergreen forest zone, and the dry semi-deciduous forest zone.

The felling damage assessment indicated that the falling tree creates more opening per felled tree perha followed by skid trials and roads. The regeneration studies which followed indicated that disturbance due to logging markedly reduce pre-existing tree seedlings in falling gaps and skid trial, but the stimulation of new seedlings establish significantly exceeds the loses.

Product development was concentrated on outdoor furniture i.e. mostly garden furniture. It was identified among others that garden furniture wood be the most suitable prototype furniture to be able to compete well on the wood market. Furniture products from Kyenkyen (*Cylicodiscus gabonensis*), Celtis (*Celtis mildbraedii*) and Essia (*Petersianthus macrocarpus*) turned out to be most suitable for various outdoor or garden furniture. Other products which also attracted interest were Deckboards for gardens. Parquet flooring and pallets. A new method of production using dowels was introduced.

Formal market research conducted in the user countries of UK, USA etc. revealed that most important factor for successful marketing was reliable and continued source of supply satisfying a given level of quality, good technical data and a good introductory discount pricing. Results of the studies and the spontaneous positive reactions from the industry and the market give a clear and solid indication that LUS has a future as raw material for a wide range of products. The introduction of new production techniques e.g. dowel joints deserve a continual dissemination to the industry. Transfer to dowel joints could result in a raw material savings of about 15% and increase productivity.

Physic-Mechanicals Properties of the Wood Related Growth to *Eucalyptus grandis* and *Eucalyptus urophylla*, used as Indicators for Lumber Production

Maria de Fatima Christe Adorno, José Nivaldo Garcia
ESALQ/LCF, Post Box # 9, 13418-900 Piracicaba/SP, Brazil
Tel: 55 194308638, FAX: 55 19 430-8666, Email: mfcadorno@warp.com.br

The wood industries trends has been based in replacement forest which increasing is fast. The *Eucalyptus* genuses exploration attend quite soon to the genetic improvement and because of it a well stablished handling is very important. There is a growing demand by the wood processing industry to change and improve the quality of the *Eucalyptus* spp. lumber resource, as the brazilian native trees will be no longer put a wiser use in the future, since the brazilian government efforts is trying to protect them. At this moment, the genetic improvement has been closely associated to the biotechnology and molecular genetics, so the association of these techniques seeks selection and gains and a considerable advance on chronologic time, as well.

On the other hand, the interaction between biometric genetic and sylviculture assure a higher proportion of solid products associated with a high agregate value, enphasizing this activity by a genetic improvement (for sawmill), as in Brazil, so far, standing forest is destinated in its great totality for pulp and paper industry.

This study was carried out using 18 clones of *Eucalyptus grandis* and 15 of *Eucalyptus urophylla* as genetic material, where was studied the wood properties and lumber defects related to growth stress, aiming to evaluate their responses to the genetic improvement techniques, especially the variabilities causes seen on this genus timber, that is supposed to be reserved for sawmill.

With the objective of getting selection gain on those properties or defects, it were studied 11 genetic variables, among them, saw timber yield, end splitting log and lumber, shear, deflexion, basic density, compression, traction strenght, bend strenght and modulus of elasticity. From this, it was possible to get genetic correlations and so the research on the wood features in which the measurements are easier, show the best genetic variable, leading to a more efficient selection program.

The mechanical properties and also the defects from growth stress are highly heritable and so lead to a wood technologic quality breeding program. It's very important to emphasize that there's no correlation between any of those properties or defects in relation to the phenotipics tree features, that permits the wood technologic quality improvement from a basic population composed only by well perfomed trees. There are high genetic correlations between these defects derived from growth stress, what permit the technologic improvement troughtout indirect selection.

The main purpuse of this work is to present these research results well detailed, showing the heritable values to the wood technologic characteres, as well all favorable genetic correlations which have been found between them.

Near Infrared Analysis as a Rapid Screening Tool for Some Major Wood Characteristics in *Eucalyptus*

Henri Bailleres, Fabrice Davrieux, Federique Ham-Pichavant
CIRAD-Forêt, Maison de la Technologie, 73 rue J.F. Breton BP5035, 34032 Montpellier Cedex 1, France
Tel: +33 4 67 61 44 51, FAX: +33 4 67 61 57 25, Email: Henri.bailleres@cirad.fr

The ability to assess wood quality is of primary importance to the forest industry. In the case of intensive management forest such as clonal plantations of *Eucalyptus* where the heterogeneity of the raw material is huge, it is fundamental to be able to predict whole-tree values for wood properties from non-destructive samples. For some wood characteristics conventional methods of measurement are too time-consuming and expensive. One of the methods most likely to be adaptable to rapid measurements on wood is Near Infrared (NIR) diffuse reflectance spectroscopy. NIR spectroscopy is known for its good ability to identify compounds as it is mentioned in a lot of publications. This study evaluated the ability of NIR spectrosocopy for the assessment of some major wood characteristics within a full-sib family of a hybrid *Eucalyptus*. NIR diffuse reflectance spectroscopic methods is used for substitution of conventional wood analysis procedures. In this paper, the data are analysed using principal component analysis (PCA), the Mahalanobis distance and partial least squares regression (PLSR) models for measuring eight characteristics from the eucalyptus wood's NIR reflectance spectra. These characteristics are:

- Extractives content
- Lignin content
- Relative proportion of lignin monomers
- Basic density
- Longitudinal growth strains
- Shrinkages in longitudinal, radial and tangential directions
- Modulus of elasticity
- Fracture energy

The first four characteristics are linked with pulp industry, the last five properties are linked with solid wood uses. On 300 samples coming from 200 trees, visible and NIR reflectance spectra are observed on a scanning spectrophotometer, and span the 400-2500 nm range. Calibration models are produced using partial least squares regression and the resulting models are validated using test sets. The root mean square error of prediction (RMSEP) is discussed. The results are critically examined.

TECFLOR: A Dream Which Became Reality

Laercio Couto, Wayne Hausknecht, Gary Cantrell, Carlos Gilberto Marques
Federal University of Vicosa, Department of Forestry, Society for Forest Research, 36571-000 Minas Gerais, Brazil
FAX: 55 31 891-2166, Email: lcouto@mail.ufv.br

In 1994, after doing some prospective work in Russia and Chile, the President of Gutchess International Incorporated-GII from Cortland, New York, USA, decided to analise the potential of the eucalypt plantations in Brazil for solid wood products. From 1994 to 1997 several forest companies and eucalypt plantations were visited personally by the President of GII and his brazilian adviser from the Department of Forestry of the Federal University of Vicosa. After choosing the three most promising companies and their eucalypt plantations, the President of GII hired two new consultants an specialist in wood technology and an expert in sawmill design and operation to compose his team. Several tests were conducted at the three chosen spots where the eucalypt logs were sawn according to the specifications of the future and desired products. The results shown that eucalypt plantations in Brazil are a very good source of raw material for solid wood products even to replace valuable tropical timber such as mahogany. Drying and preservation treatments were developed by the expert in wood technology of the State University of New York at Syracuse and Morrisville. In 1997 a joint venture was formed by GII and Aracruz Celulose S.A. and TECFLOR Industrial Ltda was founded. This new company, perhaps the biggest and most modern eucalypt based sawmill of the world is located in Posto da Mata at Mucuri in South Bahia. TECFLOR will start operating in march this year and will put on the domestic and international market 76,000 cubic meters of kiln dried and treated eucalypt sawntimber when fully operating. This will promote a very strong influence in the furniture and construction sector of the Brazilian economy in the next years.

Technological Valorization of the Four Lesser Known Species of the Amazonian Forest

J. C. Goncalez, Keller R., Janin G.
Universidade de Brasília, Departamento de Engenharia Florestal, Brasília, Brazil
Email: goncalez@unb.br

The wide forest patrimony of the Amazonie places the Brazil in a well known worldwide position, not only because of its wood potential, but also because of its ecological and social importance. The basic condition for economical and ecological utilizations of the Amazonian forest is its sustainable management which the technological characterization of the unknown species is part of. The technological characterization of four unknown species in the national forest Jamari - Rondonia - Brazil: Fava Amargosa (*Vataireopsis speciosa*), Jequitiba Rosa (*Cariniana micrantha*), Peroba d'Agua (*Rauwolfia paraensis*) et Peroba Mico (*Aspidosperma macrocarpum*) according to there anatomy, chemical components, color and there physical and mechanical properties allow us to determine the potential utilization. The major part of our study was to determinate the variability of anatomical elements, chemical composition and color as well as their correlation with wood physical and mechanical properties so as to characterize the wood's technological quality.

In order to ameliorate the existing technics, some new ones were used such as image analysis, quantitative colorimetry and ultrasons. The main causes of the variability of wood physical and mechanical properties, are anatomic elements and chemical elements especially wood extractives.

The results of this study show that these four species have good technological properties and could be valorized in differents sections of wood industry. These promissing new technics, practical, fast and accurate, are not yet known in Brazil.

Keywords: Forest Amozonian, Fava Amargosa, Jequitiba Rosa, Peroba d'Agua, Peroba Mico, anatomy, chemistry, colorimetry CIELAB, image analysis, physical and mechanical properties, ultrasonic technique and utilization

Recent Developments in the Utilisation of *Acacia catechu* Wood

A. N. Kaushal
Dr. Y.S. Parmar University of Horticulture and Social Sciences, Department of Forest Products, 173 230 Nauni-Solan, India
Tel: +91-1792-20614, FAX: +91-1792-52242, Email: fpu@yspuhf.hp.nic.in

Acacia catechu (Khair) has got importance, as its heartwood is used for katha and cutch extraction. The former is mainly used for chewing with betel nut and later for dying and tanning. The annual turn over of these industries is more than two thousand million rupees. The spent heartwood chips as well sapwood which form about 85-90% of total weight are considered as waste.

Recent research findings has shown that the yield of katha and cutch can be increased by maintaining the moisture content of the wood with better storage condition of wood as the yield is directly related with the moisture content. The chip size has also got positive correlation with the yield of extractives and proper size recommended is of 0.75-1.00mm thickness.

The spent heartwood chips as well as sapwood can be utilized for the preparation of kraft paper using sulphate pulping, as such or on mixing with other cellulosic materials like bamboo.

The hardboard prepared separately from spent chips and sapwood without using any sizing agent do not confirm the requirement of specification of their water absorption, however paraffin wax emulsion as sizing agent improved the water resistance characteristics. The water resistance characteristics of oil tempered board are also satisfactory. The oil tempered hard boards also match the requirement of Indian standard specification for modules of rupture.

Based as the rate of heat evaluation of wood cement system, it has been found this spent chips of *Acacia catechu* after katha extraction are compatible with cement for wood cement composite. The compatibility can further be enhanced by using calcium chloride as additive.

These experimental finding clearly show that the yield of katha and cutch (extraction) can be increased with proper storage of raw material and having 0.75-1.00mm thickness of chips. The waste sapwood as well as spent chip can be used as a raw material for paper, hard board and wood cement composite industries.

Natural Durability of Some Common Timber Species of Sarawak in Marine Environments

Wang Choon Ling, Kandau Jenang
Timber Research and Technical Training Centre, Forest Department, Km. 10, Old Airport Road, 93660 Kuching Sarawak, Malaysia
Tel: 082-612211 (O), FAX: 082-612490 (O), Email: trttc@po.jaring.my wcling@pc.jaring.my

A total of 28 hardwood and 1 softwood species of Sarawak were assessed for their natural durability in marine environments. The results indicate that none of the species was durable. Belian (*Eusideroxylon zwageri*) the most durable timber species of Sarawak, has a durability of 4 years. Three species failed within 1 year while the majority (23 species) failed in less than 0.5 year. Siliceous timber such as Kembang semangkok (*Scaphium macropodum*) has a mean durability of 1.5 year. The test specimens were destroyed by a combined action of teredine borers and pholad.

Keywords: Natural durability, timber species of Sarawak, marine environments, marine borer.

Variation in Wood Characteristics of *Robinia pseudoacacia* Linn. Managed under High Density Short Rotation System

Kulwant Rai Sharma, P. Sharma
Dr. Y.S. Parmar Univ Horticulture and Social Sciences, Dept Forest Products, PB # Nauni- 173, 230 Solan, India
Tel: 1792 52495 (o), FAX: +91-1792 52242, Email: fpu@yspuhf.hp.nic.in

About 78% of Indian population reside in rural areas and are dependent largely on biomass to meet their requirements of energy for daily chores. The commercial sources of energy like fossil fuels, natural gas, coal, coke and electricity influence the urban centres of industrial production though contribute but insignificantly towards the rural population. This leads to the destruction of forest so much that they are now confined to remote and inaccessible areas only. The rhythm of growth in the forest is slow and scarcely perceptible. The per capita forest cover is only 0.09ha in India as against the world average of 1.0ha and the growing stock of our forest is only 32m^3/ha as compared to world's average of 110m^3/ha. The productivity of our forest is only 0.5 m^3/ha which is far behind the world average of 2.1m^3. Today the consequences of this all are reflected not only in the wide gap between demand and supply of forest based products but ecological disasters as well. To counteract this impending crisis a strategy that envisage improving productivity of lands already under agriculture and forests and reclaiming lands so as to reduce deforestation, needs greater impetus.

Research on trees is a multidisciplinary long term effort and the task of producing fuel wood in large quantities cannot be solved entirely through long term research programmes. So, the use of fast growing and high yielding plant species managed with intensive cultural operations in tree farming have opened up new vistas in wood biomass production. High density short rotation (HDSR) and short rotation intensive culture (SRIC) are considered the befitting systems having potential for producing more biomass per unit area and time. So, it was thought imperative to study the effect of HDSR *Robinia* plantation on wood properties for maximum benefits.

In the present investigations fibre length, specific gravity, calorific values, extractives and lignin content of wood decreased with the sampling height while holocellulose and pulp yield observed positive relationship with different levels of height. The effect of density was found non-significant for specific gravity and calorific value of wood. Extractives increased with the increase in spacing. Hollocellulose and pulp yield has exhibited positive relationship with spacing, however, on perha basis the yield was more for lower spacing.

Meeting Needs for Wood Products in Vietnam

Hao C. Tran
USDA Forest Service, Post Box # 96090, 20090-6090 Washington, D.C., USA
Tel: 202-205-1293, FAX: 202-205-1530, Email: htran/wo@fs.fed.us

Since 1994, the author has developed several contacts during several field visits to Vietnam. The paper is a synthesis of professional experiences working with Vietnamese government and university scientists, as well as international partners including the International Crane Foundation, the Royal Holloway Institute of Environmental Research, Counterpart International, and the US forest products industry. The paper will address the key environmental issues that Vietnam faces, the opportunity for utilization research to meet the needs for wood products, and opportunities for trade with Vietnam as an emerging market. As a case study, the author will focus on utilization of Melaleuca sp. surrounding the Tram Chim National Park in the Mekong Delta as a key element of sustainability.

Tram Chim National Park contains the last remnant of the original patterns that once characterized the vast Mekong Delta, which has been extensively modified, primarily for rice agriculture. After the war and upon intallation of strategically placed dikes and replanting of melaleuca, a flock of Eastern *Sarus* cranes returned in the dry season. Since then, the area has attracted international attention, especially the investment by the International Crane Foundation. Recently, the Vietnamese Government declared Tram Chim a national park because of its uniqueness as the only remaining wetland forest in the Mekong Delta. The central management issues for this national park are: 1) Water management, 2) Fire Management, 3) Control of *Mimosa pigra* and 4) Socio-economic development in the buffer zone.

Water management has been the key issue since the beginning. The system of levees and dikes enables park personnel to mimic historic hydrological patterns, although the debate about these patterns and target conditions has been intense. Nevertheless, it is clear that maintaining high water levels throughout most of the park, intended to avoid fire, is degrading the melaleuca and other plant communities that are essential as shelter and food for the crane. The realization that a dry season must be restored to save the park is now shared, with trepidation because of a lack of fire control experience, expertise and equipment. A decision had been reached to begin a drawdown of the water level to coincide with the next dry season. Prescribed fire will be conducted in small steps to gain expertise and to reduce fuels. Meanwhile, Mimosa pigra, a non-indigenous species, has spread throughout the drier areas of the park and the surrounding rice fields, and it threatens to dominate the vegetation once water levels are drawn down. Kakadu National Park, in Northern Australia, has initiated a management program to combat a similar invasion of this species, involving management of water and fire. A strategy for controlling it has been proposed by the Head of Wetland Research at Kakadu, Max Finlayson, and a public education effort is being launched to involve people in the buffer area to take appropriate actions to control its spread.

5.06.02 Quality teak timber from plantations

Veneer/Gluability of Brazilian-Grown Teak

Peter B. Laming, G.Welgemoed
Wageningen Agricultural University, Division of Wood Science, Sub-Dept. Forestry, Post Box # 324, 6700 Ah Wageningen, Netherlands
Tel: +31 317 478078, FAX: +31 317 483542, Email: peter.laming@hk.bosb.wau.nl

Teak (*Tectona grandis* L.f.) is one of the world's best known and most highly valued timbers. Being native to south-eastern Asia and being planted extensively in many other tropical areas, plantations in Brazil, in the southern part of the state of Mato Grosso, near Caceres, are relatively unknown. Industry orientated research results of young teak material from Latin-American plantations, independent of growth areas, are rather scarce.

For the benefit of different end-uses of decorative plywood panels in western-Europe, sliced veneer from about 12 years' old Brazilian-grown trees, was tested for their suitability of surface veneer in industrially manufactured plywood. The aim of this test was to perform a comparative test of the gluability of veneers of surface veneer quality as obtained from the Brasil-grown teak trees in particular relation to the traditional teak veneer as obtained from mature trees grown in south-east Asia (Myanmar, in particular). Industry orientated tests were performed by gluing 18mm thick ornamental plywood panels from Brazilian and south-east Asian sliced veneer, respectively, and produced under the practical conditions as ruling in a large-scale and high-quality plywood factory. Type of glue and pressure conditions were in agreement with the usual production methods for such a type of composite.

For examning the bonding qualifications, samples were tested in accordance with the European standard EN 314-1. The test results of this informative project show the following qualitative indications:

- there are hardly or no differences in the bonding quality between plywood manufactured from the Brazilian and the south-east Asian sliced teak veneers
- there are no signs that any pretreatment of the surface of the Brazilian teak veneer, is required
- there are no significant indications that veneer of the juvenile trees of Tectona grandis produces a qualitatively lower grade of bonding strength in the plywood than in such a product made from veneer obtained from Asian mature trees.

5.06.03 Improving the utilization of plantations of Eucalypts

Variability of Selected Wood Basic Properties within a Full-sib Family of a Hybrid *Eucalyptus*

Henri Bailleres, J.P. Bouillet, N. Ognouabi, D. Verheagen, P. Vigneron
CIRAD-Forêt, Maison de la Technologie, 73 rue J.F. Breton BP5035, 34032 Montpellier Cedex 1, France
Tel: +33 4 67 61 44 51, FAX: +33 4 67 61 57 25, Email: Henri.bailleres@cirad.fr

In making recommendations for the development of sampling strategies it is important to understand the patterns of variation of the wood properties of interest. Information on the variation of important properties across sites, and within and between trees, is vital to obtain the best commercial advantage from the plantation resource of *Eucalyptus*. In this study the variation in several wood properties within a full-sib family of a hybrid *Eucalyptus* (*E. grandis* x *E. urophylla*) is examined. This family comes from the second generation of the plant breeding program leaded by CIRAD/UR2PI in Congo Brazaville. 200 trees are assessed for the following major characteristics for practical use:

- Longitudinal maturation strain
- End splits proportion
- Modulus of elasticity
- Shrinkages (L, R)
- Basic density
- Fracture energy
- Lignin content

For end splits proportion the measurements are recorded on three logs per tree. All the measurements are performed at the same height (2m), and excepted for lignin content and longitudinal maturation strain, all the measurements are sampled along a diameter of the stem. This procedure allows to compare the pith-to-bark variation of the properties between the trees, due to the juvenile effect. The objective of this study is to describe the variability of the properties measured within the full-sib family and also to describe conceptual patterns of variation, and then develop a general mathematical equation that accommodates the variation. The discussion examines how this model is affected by genotype, in order to select clonal material for commercial plantations. Some consequences for plant breeding strategy are also discussed.

5.07.00 Energy and chemicals from forest biomass

The Carbohydrates in the Oil Palm Trunk and Sago Waste and their Potential Utilisation

Putri Faridatul Akmar, John F. Kennedy
FRIM, Kepong, 52109 Kuala Lumpur, Malaysia
FAX: 603-636 5793, Email: puteri@frim.gov.my

Preliminary studies has shown that the carbohydrates in the oil palm trunk and sago waste are more labile to acid and alkaline conditions compared to those of other dicotyledons. Both palm trunks contain higher short chain and less crystalline polysaccharides. A large number of chemicals can be derived from the monomeric sugars of these polysaccharides. Fine chemicals and industrial intermediates could be produced by fermentation, oxidation, dehydration and/or hydrogenation processes. Xylans and xylooligosaccharides can be converted by chemical or enzymic hydrolysis into xylose and subsequently into a whole range of fuels and chemicals while glucose from the glucans could be used as fermentation substrates for production of cellulolytic enzymes, biodegradable polymers, citric acid and others. Many studies have been carried out to convert these material into value added products. Though the processes were technically feasible, they were not economically feasible due to the low yields of products. The yields can be improved if basic information on the carbohydrates present is known.

This study looked into the basic structures of the carbohydrates of both palm wastes. The types of glycosidic linkages of the carbohydrates of both palm trunk wastes were determined using methylation analysis. The method involves total methylation of the free hydroxyl groups followed by hydrolysis of the methylated derivatives. Hydroxyl groups formerly involved in the interlinkages were characterised and identified using GCMS. The nature of sugar residues occurring as non-reducing end groups, chain units and branch points were then established.

The partially methylated constituents afforded by the water insoluble material of both palm trunk wastes were similar. In sago palm waste more than half mole percentage of $(1\rightarrow4)$-linked glucopyranosyl residues were afforded whilst in the fibre samples of the oil palm trunk only 33.5% were afforded. The methylation data also suggested that the oil palm trunk waste contained a higher percentage of hemicelluloses as shown by the variety of other sugar residues afforded. The (1→4)-linked xylopyranosyl residues was found to be afforded in quite a substantial amount by the fibres of the oil palm trunk indicating the presence of xylans. The (1→3)-, (1→5)-, and (1,3,5)-linked arabinosyl residues were also found particularly in the parenchyma sample but in much lower percentage. Other sugars residues such as t- Araf, t-Xlyp, t-Glcp and (1→6)-Galp were also afforded during the methylations. These were the side chains or end group of the branched polysaccharides.

Due to the heterogeneity of the samples, a large number of possible structures could be drawn from the methylation data. In order to elucidate the model structures of the polysaccharides and to establish their relationships, selective fractionation by purified enzymes is recommended prior to the analysis of the dissociated fragments. The possible linkages obtained would be useful for the selection of solvents for sequential fractionations and/or enzymes for structural analysis. Data obtained in this basic characterisation studies of these carbohydrates would enable researchers not only to explore potential products from these carbohydrates but also to develop efficient fractionation and saccharification methods which could optimise the yields of monomeric sugars. Cost effective utilisation of these carbohydrates can only be achieved by integrated applications and processes.

Biomass Energy Conservation in the Sudan

Hanadi Awad Alla
Forests National Corporation, Ministry of Agriculture and Forests, Khartoum, Sudan
Email: Hanadiawad@hotmail.com

Forests provide < 80% of the total energy needs of the population in the Sudan in the form of charcoal and firewood. Due to inefficient burning of charcoal and firewood, greater areas of forests have been depleted. The objective of the present study was to establish other more efficient and less depleting biomass energy substitutes for the current extremely inefficient ones. Cotton stalk charcoal briquette produced low-density charcoal but it proved to be very effective in the local mubkhar stove as well as in the improved mud stoves and ceramic stoves. Bagass/Molasses fuel blocks are 21x14x8 cm and weigh 2.2 kg. Most of the blocks produced are being purchased by bakeries and brick kilns in Khartoum and Wad Medani area. The cost of this alternative source of fuel is about 25% lower than the cost of using fuel wood. For sustainability, the Forests National Corporation constructed a commercial unit in Geneid sugar mill near the sugar cane factory to reduce the cost of transportation. Carbonization and briquetting of lentil stalks with the use of agglomeration was very competitive in price to charcoal. Other fuel alternatives were also discussed including non biomass energy alternatives.

L'Hévéa en Cóte d'Ivoire du Latex au Bois d'Oeuvre une Reconversion Prometteuse

Kouassi Achi Edi, Assand, Ahoba
CNRA (Centre National de Recherche Agronomiques), 08 BP 33 Abidjan 08, Cote d'Ivoire
Tel: +225-44 28 58, FAX: +225-44 21 08, Email: dominique.louppe@cirad.fr

Avant 1990, environ 66.000 ha de *Hevea brasiliensis* avaient déjà été plantés dans le tiers sud de la Côte d’Ivoire pour la production de latex pour alimenter l’industrie du caoutchouc naturel.

La production de latex baisse avec l’âge des arbres et surtout à partir de 25 à 35 ans. Les plantations sont alors renouvelées avec des clones issus d’amélioration génétique nettement plus productifs. La Côte d’Ivoire a aujourd’hui, à l’hectare, une des meilleures productions mondiales de latex.

Pour renouveler les peuplements d’hévéa peu productifs, ils sont exploités à blanc étoc et de nouveaux clones sont plantés. Cette opération met sur le marché de gros volumes de bois qui est généralement mal valorisés. De nombreuses grumes transformables restent sur les sites d’abattage. Pendant longtemps, ce bois n’a servi que de source d’énergie pour les ouvriers avec peu de retombées économiques pour les planteurs industriels.

Pour la période 1990-1995, le volume grume de bois d’hévéa annuellement exploité était estimé à 40.000 m^3. A partir de l’an 2000, chaque année, environ 120.000 m^3 grumes d’hévéa seront exploités. Leur utilisation comme bois d’énergie n’est économiquement pas souhaitable. A la demande des planteurs d’hévéa, mais aussi à celle des industriels du bois ivoiriens qui sont confrontés à la raréfaction des bois de forêt naturelle, la division de recherche de technologie du bois du CNRA (Centre National de Recherches Agronomiques) a entrepris des études pour valoriser au mieux cette matière première abondante.

Des essais technologiques, de transformation et mise en oeuvre ont été réalisés au laboratoire du CNRA. Ils ont permis de définir les conditions optimales d'utilisation de l'hévéa de Côte d'Ivoire comme bois d'oeuvre notamment les contraintes de séchage et les problèmes de préservation du bois.

Hevea brasiliensis est parfaitement apte à être transformé en produits semis finis (frises, lattes, chevrons, coursons, bois massif reconstitué, etc.). Ces produits peuvent alors être utilisés par l'industrie pour fabriquer divers produits finis tels que: ameublement, articles ménagers, menuiserie intérieure, panneaux lattés, etc.

La forêt naturelle ivoirienne s'appauvrissant en bois tant en quantité qu'en qualité, l'exploitation du bois d'hévéa peut être une alternative pour les industriels du bois accompagnés par la recherche qui leur proposera des itinéraires adaptés.

Mots clés: *Hevea brasiliensis*, bois d'oeuvre, transformation industrielle, Côte d'Ivoire.

Soils stabilized with wood tar for forest road application

D.C.M. Fernandes, Machado, C.C., Lima, D.C., Jucksch; I.
Federal University Vicosa, 36571-000 Vicosa, Minas Gerais, Brazil
Tel: 031 899 1193, FAX: 031 899 2478, Email: machadoc@mail.ufv.br

The purpose of this study was to analyze the behavior of soil-wood tar mixtures from a forest road Brazilian application perspective, considering the following engineering parameters: CBR, unconfined compression strength and Atterberg limits: liquid limits (LL) and plastic limits (PL). Three soil samples from Vicosa county, Minas Gerais State, Brazil, classified by the HRB system as A-7-5 (16), soil 1, A-7-5 (10), soil 2, and A-2-4 (0), soil 3, wood tar contents of 0.25%, 0.5%, 1%, 2%, 4% and 6% and the AASHTO standard compaction effort were considered thorough the laboratory testing program. The preliminary data obtained in the research program support that addition of wood- tar to the soils was responsible for no significant changes in theirs Atterbergs limits and minor increase in theirs CBR and unconfined compression strength.

Key Words: Forest roads, soil-wood tar mixtures, CBR, Unconfined Compression Strength, Atterberg limits.

Utilization Possibilities as an Coloring Substance of *Rhododendron ponticum* L. Flowers.

Gükhan Gunduz, Hasan Vurdu, Ibrahim Tümen
Zonguldak Karaelmas University, Faculty of Forestry, 74100 Bartin, Turkey
FAX: +90.0378.2277421

The aim of this study was to assess the utilization possibilities of *Rhododendron ponticum* L. extracts, which is an undesirable plant in the forest, as coloring matter for anatomical and cytological experiments. Collected flowers from mountainous regions of Bartin - Kumluca were sorted to different parts (petal, stalk, petal and stalk), and their extractions in alcohol, alcohol -benzene, and hot water were carried out. As a result of UV spectrum evaluation; peonidin, chlorophyll and carotenoids were detected. According to the results obtained, the amounts of matter dissolved in alcohol, alcohol-benzene and in hot water vary between 28,83-33,57%; 23,30-23,47%, 33,44-41,82% respectively.

Very low coloring effects were obtained with alcohol and alcohol-benzene extract solutions of *Populus nigra* L. tissue samples. Whereas, more coloring effect was obtained with hot water extract solutions of the same species. Consequently, as hot water extract solutions contain more coloring matter and are more suitable for coloration. It is concluded that further detailed studies need to be done to determine what are the effective dye pigments.

Influence of Selected operational Parameters on the Composition of Oil Produced from the Fast Pyrolysis of *Pinus radiata*

Branko Hermescec
The University of Melbourne, Department of Chemical Engineering, Parkville Vic. 3052, Melbourne, Australia
Email: B.Hermescec@landfood.unimelb.edu.au

The derivation of fine chemicals produced from the pyrolysis of biomass has inspired much interest in the scientific community. However, the inherent complexity and thermal instability of pyrolysis oils have hindered progress in this endeavour. The objective of the current research was to optimise the pyrolysis process such that the yield of low molecular weight phenols was maximised and the complexity and thermal instability of the oil was minimised.

The research was conducted on a bench scale fluid bed fast pyrolysis system deigned by Resource

Transforms International (RTI) LTD. The main operational parameters investigated were reactor temperature (250-320oC), reaction atmosphere composition, sample residence time, sample particle size (150-500*m), sample moisture content (oven and air dry) and product collection method. The reaction atmosphere was varied from inert to 20% oxygen. The sample residence time was controlled by the fluidising gas velocity. The product collection apparatus consisted of a specially designed quench/solid residue collection system and an electrostatic precipitator designed by RTI LTD. The feed stock used was milled *Pinus radiata*.

The product oils were analysed by GCMS and the data statistically compared with the operational parameters. It was found that the yield of phenols was inversely proportional to feed stock particle size. The moisture content was found to have little effect on the yield of phenols or on the complexity of the oil. The specially designed quench/solid residue collection system yielded a simpler liquid product. It was also found that the presence of oxygen caused an increase in the yield of phenols.

Unused Potential of Estonian Forests for Energy Production

Peeter Muiste, Ülo Kask
Estonian Agricultural University, Kreutzwaldi 5, 51006 Tartu, Estonia
FAX: +372 7 421053, Email: peeter@eau.ee

Based on profound analyses in 1996, the allowable annual level of cutting for Estonian forests securing the sustainable and environmentally friendly management of forests was determined to be on the level of 7,8 Mm^3s (million solid cubic metres per year). Though the Estonian forest industry has developed successfully during the years after re-establishment of political independence, as the level of cutting has tripled since the year 1992 and reached the level of 6 Mm^3s by the year 1998, the allowable limit has not exceeded yet. The growing cutting level has made possible to make investments to wood processing. The sawmill industry, where the technology has been modernised and the production per year has grown from the level of 0,2 Mm^3s in 1993 to 0,8 Mm^3s in 1998, has developed most rapidly. As a consequence, the share of rough logs in total Estonian wood export has dropped from 54% in 1992 to 29% in 1998. The pulpwood is mainly exported today, but the resources are sufficient to develop instead of this the local pulp industry.

A remarkable progress can be mentioned also in the utilisation of wood for energy production, but probably here are the biggest unused resources for the future. To guarantee the energy supply and relatively low price of that, during the first years of independence a lot of attention to conversion of boilers from Russia imported fossil fuels to wood and peat was given. A certain progress was achieved, as the number of wood-fuelled boilers increased and correspondingly grew the heat production based on wood fuels- from 384 GWúh in 1993 to 1148 GWúh in 1998. The share of wood fuels from energy balance of Estonia provided 10% in 1997. Now in the conditions of stabilised economy, the driving forces for the further progress are improvement of environmental conditions and solving the social problems of rural areas. According to the Long-term Development Plan for the Estonian Fuel and Energy Sector, the share of wood and peat is planned to increase in the energy balance to 13% by the year 2010. To reach the goal, such development should be supported by the legislation and reversing a tax policy, but the determinant factor is the sufficiency of biofuels resources and their more extensive use in future.

In the present study the supply-demand balance concerning the supply for raw material and the demand for wood fuel were analyzed. To calculate the quantities of wood fuel, the existing forestry inventory database was used. The results of the study can be considered preliminary, since the ownership reform in forestry has not been completed and it was complicated to get a comprehensive overview of all forest resources. For reliable results forecasted industrial consumption, environmental restrictions as well as technical and economic conditions, and possible use of wood fuels by various user categories were used. To find out distances between energy wood resources (forest stands and mechanical forest industry enterprises) and users, the co-ordinates were determined. The results of the calculation are visualized with GIS-software (MapInfo Professional 5.5). The data indicate that there are still remarkable resources of wood fuel, not used at the present moment.

Bioinsecticidal Properties of *Azadirachta excelsa*

Lean Teik Ng, PM Yuen, A Sivapragasam, WH Loke, Mohd Radzi Ahmad and Azizol Abdul Kadir
Forest Research Institute Malaysia, Kepong, 52109 Kuala Lumpur, Malaysia
Tel: (603) 6302352, FAX: (603) 6365793, Email: nglt@frim.gov.my

Azadirachta excelsa (commonly known as sentang in Malaysia), one of the two important congeneric species of neem (*Azadirachta indica*), is a little known tree found naturally in lowland forests of

Malaysia. Because of its multipurpose properties and fast-growing nature, the plant is currently a popular timber species and is intensively promoted by FRIM for large-scale commercial cultivation. The objective of present study was to examine the bioinsecticidal effects of sentang extracts on *Paliga damastesalis* (a teak pest), and *Plutella xylostella* and *Spodoptera litura* (vegetable pests).

The sentang leaf, bark and wood of tree age about 15 years old was obtained from FRIM's forest. The extraction was carried out by soaking the sentang samples in water or methanol for 24 hours. The aqueous extract was freeze-dried with a freeze-dryer whilst the methanol extract was first concentrated with a rotary evaporator and then subjected to vacuum drying. The dried sentang extracts, except the aqueous one which was dissolved in distilled water, were dissolved in methanol (1% v/v), dimethylsulfoxide (DMSO; 0.5% v/v) and diluted to the desired concentrations with distilled water. Tween 20 (0.5% v/v) was added in all sentang extract solutions as emulsifier. Leaf pieces treated only with methanol and emulsifier served as control. The antifeedant effect of various extracts was evaluated against 3rd instar larvae of *Paliga damastesalis* and *Plutella xylostella*, and 2nd instar larvae of *Spodoptera litura*. Aqueous and methanol extracts of leaf, bark and wood at concentrations 0.5, 1.0 and 2.0% (w/v) were used in this study.

Under no-choice condition, both aqueous and methanol extracts at concentrations of 0.5% or above produced significant ($p<0.05$) antifeedant activity on *Paliga damastesalis* and *Spodoptera litura*, with an inhibition of at least 50% when compared to control groups. However, a higher concentration, i.e. 2% of sentang extracts was required to inhibit the *Plutella xylostella* from feeding the leaves. A high mortality rate was found in all insects fed on treated leaves.

The present study demonstrated that both aqueous and methanol leaf, bark and wood extracts of sentang were active against a forest pest (*Paliga damastisalis*) and vegetable pests (i.e. *Plutella xylostella* and *Spodoptera litura*). However, *Plutella xylostella* seems to be less sensitive to the antifeedant activity of sentang extracts though many of them died at the end of 48 hr feeding. These findings suggested that sentang could be a potentially good source of botanical insecticides (e.g. as a growth inhibitor).

Air Freshener from *Manila elemi* (*Canarium ovatum*) oil

Irma I. Palanginan, Mildred M. Fidel
Forest Products Research & Development Institute,
4031 Laguna, Philippines
FAX: (63) (049) 536-3630, Email: Ma. Socorro R. Dizon [ying@fprdi.uplb.edu.ph]

A resin processing Company generates a waste by-product in a form of *Manila elemi* oil after processing *Manila elemi* from *Canarium* sp. Previous study confirmed that *Manila elemi* oil contains a very important essential oil called limonene. Limonene is utilized extensively as top note perfume component in fragrances where citrus odor is desirable. It is one of the most inexpensive perfume components but is not necessarily applied to cheap fragrances. The present study was conducted to establish optimum conditions of limonene extraction from *Manila elemi* oil and utilize limonene as component of air freshener.
