Abstract: Restoration, when linked to the development of sustainable value chains, has the potential to tangibly benefit local stakeholders who therefore have a stake in its success and sustainability and promote bioeconomy. Linking restoration to marketable opportunities also facilitates the mobilization of private finance. The degree to which restoration initiatives have utilized these connections, or their level of success when they did it, is not well studied. This paper reviews experiences of integrating inclusive forest-based VCD in restoration initiatives with an aim to identify impacts, lessons learned, and good practices that could inform project development and implementation globally. The geographical focus of the paper is African drylands, Mesoamerican countries, and Small Island Developing States (SIDS). The key questions the paper attempts to answer are: what modalities are most used to link restoration to VCD? And do such links translate into investments and local actors' engagement? For the purpose of the analysis, a database is developed with a group of shortlisted projects that integrate both VCD and restoration activities. The projects are identified based on a set of selection criteria among databases of FAO, IUCN, UNEP and UNDP as well as of GEF, World Bank and GCF.

The results suggest that VCD generates income for smallholder farmers and small producers and thus giving them more resources and incentives to invest in restoration. Proximity to the markets, organizations of farmers and producers and strengthening of local support structures and institutions (e.g. NGOs, community organizations and government agencies) are the most common conditions to link VCD with restoration. To develop efficient linkages, these conditions need to be combined with a set of suitable modalities (e.g. improving access to markets and finance, and integration of small producers into the value chain) and tools (e.g. financial, technical and organizational capacity building, facilitation of partnership between small producers and primate companies and SMEs). Therefore, it can be concluded that the investments in VCD can support the restoration of forests and land given an optimal combination of conditions, modalities and tools are applied.

Assessment of factors influencing the adoption of e-commerce platforms by timber companies in Colombia

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Steven Bernal[1]
Sandra Rodríguez Piñeros[2], Liz Villarraga[1]
[1] Universidad Distrital Francisco José de Caldas
[2] Universidad Autonoma de Chihuahua

Abstract: The challenges for forestry companies in the electronic timber market have been increasing due to various factors that affect its adoption. It has been shown that for adopting electronic commerce, different Technological, Organizational, and Environmental (TOE) factors influence companies' decision-making. This study seeks to evaluate the factors influencing the adoption of electronic commerce platforms by timber companies in Colombia. The evaluation of TOE factors allows us to understand the behavior of companies regarding the adoption of technologies and, likewise, includes valuable information for different actors that are immersed in the chain of commercialization of timber, as well as for the leading economic organizations and institutions interested in strengthening the timber industry in Colombia. A survey of 216 companies registered in the Elija Madera Legal platform is undertaken to identify factors based on TOE. In order to evaluate the incidence of the factors, an electronic commerce adoption index (IACE) for each company will be estimated using a Principal Component Analysis where the factors that have a greater specific weight will be identified, meaning that they have greater relevance concerning the adoption of electronic commerce.

According to the specialized literature review, some of the main factors are relative advantage, the expectation of effort, communication (technological), technological readiness, technological integration, obstacle management, company certification (organizational), regulatory framework, inequality, informality, traceability (environment), which have been identified as those that have the most significant incidence in the adoption of electronic commerce for the forestry sector and on which it is pertinent to carry out the analysis.

These findings are expected to present significant implications on the link of timber commercialization at the global level; international treaties call for more sustainable timber trade; in this regard, identifying factors that influence the adoption of technology will help the development of policies and capacity building at the national and regional level.

EUROPEAN TRENDS IN INNOVATIVE ENGINEERED WOOD PRODUCTS AND SYSTEMS FOR THE CONSTRUCTION SECTOR

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Vanesa Baño[1]

Uwe Kies[1], Oliver Jancke[1], Javier García-Jaca[2]

[1] InnovaWood absl, Belgium

[2] Tecnalia, Spain

Abstract: Construction accounts for around 37% of global CO_2 emissions and it is the second largest EU industrial sector. The use of engineered wood products (EWP) in buildings is increasingly acknowledged as a major lever for decarbonisation of the construction sector and a contribution to sustainable forest management. The study, part of EU projects BASAJAUN and EUFORE, attempts an outlook on leading wood innovation trends and their role in the construction sector. Analysing the *European Organisation for Technical Assessment* (EOTA) database, a range of wood-based products were categorised as a) mature products, i.e. with CE marking complying with the *European Construction Products Regulation* according to harmonised standards, or b) innovative products, i.e. with CE marking via *European Technical Assessment* (ETA). ETA products since 2002 were analysed in *European Assessment Documents* (EAD) of the two *Product Areas* related to wood products (PA13 and PA14) and also from 34 other PA whose EADs include the term 'wood' or 'timber' in their titles, complemented by reviews of innovation topics observed in both literature, conferences and trade fairs. The results show an increase in certified innovative EWP since 2015, produced inside and outside Europe. They also highlight emerging types of technological innovations, such as novel products with enhanced properties regarding material efficiency and circularity, alternative wood species and advanced design and prefabrication systems. A main share observed relate to structural EWP and panels for use as slabs, roofs, or walls and their connections, thermal insulation products and building kits. Establishing innovative EWP on the market implies rethinking the way we design, manufacture and construct buildings. The emerging timber boom in multistorey buildings demands also novel timber engineering and constructive systems and components for more safety, comfort, health, resource efficiency and CO_2 neutrality. Many innovations originate from collaborations between wood manufacturers, engineers, building companies, research centres as well as architecture, design and digitalisation. Widespread national and European policy initiatives fostering building with wood, such as the New European Bauhaus, aim to create an enabling 'ecosystem' to facilitate exchange and co-creation across disciplines and domains, leading to a gradual mainstreaming of wood solutions in the construction sector.

Factors and criteria influencing financing decisions in wooden multi-storey construction

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Jaakko Jussila[1]
Katariina Heikkinen[1], Ritva Toivonen[1]
[1] Department of Forest Sciences, PO Box 27, 00014 University of Helsinki, Finland

Abstract: Wooden multi-storey construction (WMC) has experienced increasing interest in Finland during the past years. Wood is seen as an environmentally friendly and aesthetically pleasant alternative to dominant building materials. This research explores financial decision-making criteria affecting construction of multi-storey residential building from financiers' point of view. Specifically, 1) which factors and criteria the financiers consider while making investment decision on WMC projects, 2) how they assess risk and opportunities and 3) what is the role of sustainability in WMC.

The study relies on thematic interviews with professionals working in the field of financing and real estate investing, conducted between August and October 2022 to study how they assess risks and opportunities in WMC. The data consists of 10 interviews conducted to different types of financial organizations active in funding of construction projects.

Results imply that financiers emphasize traditional financial criteria (such as profitability and risk-return) over building materials and sustainability aspects. Alongside financial criteria, location and micro location, energy efficiency, apartment pre-marketing and maintenance costs of the building were identified as a criteria. Building material was not considered as significant factor as it is decided by the construction company and is part of the overall risk analysis of a project.

In general, construction phase was considered as the riskiest part of the project for the financiers. Specific risks associated with WMC was the construction company's capabilities for the project, their lack of references and unknown life cycle costs compared to concrete buildings. Good availability of the material, development opportunities for element construction to lower prices and ecological properties of wood were seen as opportunities for WMC.

Sustainability was seen as an important part of the financing decision; however, not all respondents found it as a part of the main financial criteria. In addition to organization's own sustainability goals, sustainability is guided by policies and regulation, including the EU taxonomy. To conclude financiers require more knowledge on long-term usage and cost experiences of WMC buildings.

Potential of Small Scale Tree growers in Plantation Development: Case of Nyandarua Tree Growers Association in Kenya

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Joram Kagombe[1]
Charles Nyanjui[2], Geoffrey Wanyama[2], Benjamin Karanja[3]
[1] Kenya Forestry Research Institute
[2] Forest Smallholders Producer Association of Kenya (FFSPAK)
[3] Forest Smallholders Producer Association of Kenya

Abstract: Kenya aspire to grow its tree cover to 30% by 2032 with 35% being contributed by commercial forestry. Private forest under small scale holders provide opportunity for forest growth. However they need to come together to do joint technical advisory services, value addition and marketing. The Farm Forestry Program with support of FAO have provided support to tree growers association to upscale commercial forestry with one being Tree Growers Association of Nyandarua (TGAN). This is a legally registered entity under the Societies Act with a membership of approximately 3,000 tree growers in Nyandarua County. It is a member of Farm Forest Smallholders Producer Association of Kenya (FFSPAK). To be able to trade members of TGAN formed a Cooperative society. All the activities that TGAN is engaged in are demand-driven. The demands are identified through a process of problem identification, project planning and project implementation facilitated by the Association in a participatory process. With support from FAO/FFF programme, TGAN implemented the tree census project in 2020 to support farmers undertake an on-farm tree inventory and develop a strategic business plan for sustainable production and marketing of timber products including wood fuel.The results from the census indicated that the net worth of the association is about 53million USD$ hence there is great potential in farm forestry.Eucalyptus constituted 48%, Cypress 44%, Pine 3% and other 6% of tree planted. By 2023, TGAN had 785 ha under trees and this is projected to increase to 1,578ha in 2,028 and 3.175 ha in 2033. Annual products offered projections by 2023 was 5022 tons of carbon, 6840 M^3 of sawlogs, 6840M^3 of firewood and 196,012 pcs of transmission poles. These figure will grow further through 30% tree cover strategy This shows that forestry under small scale tree growers have huge potential to increase forest cover and livelihood of participating farmers. Results recommend continuous capacity building in value addition and marketing and tapping into financial models that can support tree growing. Tree growing cooperative offers solution to small scale growers and should be upscaled in other Counties.

Potential to facilitate Large-scale Private Investment in UK Woodland Creation while accounting for local community preferences

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Wen Hao Low[1]
Nishad Kadam[1], **Eleanor Gardner**[1], Gregory Valatin[1]
[1] Forest Research

Abstract: To achieve its net zero and biodiversity targets, the UK Government has committed to increasing woodland cover. The Devolved Administrations have set targets for woodland cover to rise from 10% currently to 12% in England by 2060, and from 15% to 24% in Wales and 19% to 25% in Scotland by 2050. The overall UK target is to plant 30,000 ha of woodlands annually by 2025. UK woodland creation rates reached around this level in the late 1980s but have been lower in more recent years. In the year to March 2022, for example, 13,850 ha of new woodland was created.

It is estimated that at least a further £1.8 billion in investment will be required for woodland creation and management between 2022-2032 (roughly 2.5 times public spending committed as of 2021) for current targets to be met. A lack of available finance is not considered a principal barrier, but a lack of a pipeline of investment-ready projects at a suitable scale for large-scale investors is widely thought a significant barrier.

As part of the Nature for Climate Fund R&D project on ‘Economics of Woodland Creation’, this paper sets out to investigate innovative mechanisms to link different elements in the woodland creation investment chain to help overcome existing financial barriers to investment in tree planting. It explores how investment opportunities suitable for large scale investors that account for local community preferences could be created, as well as mechanisms to help overcome existing cash flow barriers faced by landowners in creating woodlands.

Approaches are investigated from both finance supply and demand perspectives. They include ways to foster economies of scale and reduce investor transaction costs through pooling information on project risks and returns, and potential use of blended finance to de-risk projects. Investment opportunities that help meet particular water-related challenges (e.g., improving water quality) and how they could be aggregated are explored. The exploration links with work by Forest Research on developing a UK Woodland Water Code designed to underpin a market for woodland water credits and increase private sector investment in woodland creation for its benefits to the water environment.

Role of Kenya Commercial Forestry Innovation Centre in Up-scaling offtake of commercial forestry in Kenya

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Joram Kagombe[1]
Jonah Kiprop[1], Anthony Macharia[2], Gilbert Busolo[1], Eric Wainaina[1]
[1] Kenya Forestry Research Institute
[2] Ministry of Environment Climate Change and Forestry

Abstract: The Commercial forestry sector in Kenya has witnessed tremendous growth over the past few decades occasioned by the Country's rapid population growth, economic growth, and urbanization. The growing demand has not been able to match the local supply of forestry products making Kenya a timber deficit country. Challenges that have impeded growth of commercial forestry include: competition from alternative land uses, inadequate technologies, lack of investment data, inadequate infrastructure development and rising population growth, lack of adequate information on tree growing and management operations, species site matching, valuation techniques, markets outlets and market specifications for the various products hinder the growth of the sector. A conference on Commercial forestry investment held in 2021 recommended establishment of a the Kenya Commercial Forestry Investment Centre (KCFIC) hosted KEFRI.. The key partners in supporting the centre include FAO and UNDP with strong private sector engagement.

This is a Centre for Commercial Forestry Investments, Innovations, Advisory and Linkages whose Objectives is to enhance adoption and promotion of commercial forestry in Kenya as a competitive land use option to diverse investors and landowners. The Vision is to make Commercial Forestry a competitive sector that contributes to economic growth with a Mission of enhancing commercial forestry investments in Kenya through providing a platform for generation of technologies and showcasing innovations. The Outputs of the centre include: Strengthening the role of private sector and international communities in the forestry industry; enhance co-financing for investment in commercial forestry to propel economic growth and environmental sustainability; Creation of opportunities to incentivize youth's participation in commercial forestry investment which include; digital technologies, capacity development and enable access to market and enabling policies;

The Centre's governance approach is multi-institution, multi sectoral approach where KEFRI plays a coordination role. An ICT based decision support system is in place and will be supported by technical officers who will provide additional information to entrepreneurs.Innovation centre will provide a game changer to investors in commercial forestry.The Centre has created a lot of interest from all stakeholders. The paper gives details of the centre and its role in upscaling commercial forestry in Kenya.

Unlocking finance for sustainable forest value chains: Bridging the gap between producers' needs and investors' requirements in East Africa

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Marco Boscolo[1]
Petri Lehtonen[1], Jhony Zapata[1], Sophie Grouwels[1], Phosiso Sola[2], Gordon Manu[1]
[1] Food and Agriculture Organization (FAO)
[2] World Agroforestry Centre (ICRAF)

Abstract: The East Africa region presents enormous opportunities to promote sustainable production and consumption of wood products. On the production side, for example, the Kenya Government has committed to plant 15 billion trees to achieve 30% of tree cover by 2032 (at an estimated cost of about USD 4.5 billion). On the processing side, improvements in sustainability and efficiency are being sought in the region, and especially in Uganda. On the end market side, various initiatives are underway to promote the use of wood-based products instead of more carbon intensive materials in sectors such as building and construction. The coordinated support to various segments of wood value chains, from wood production to processing to the development of markets for sustainable wood can have significant positive effects on the environment, biodiversity and development.

Yet, scaling up such value chains requires further investments, both public and private. Several obstacles prevent larger investments to reach forest value chains in general, and small forest and farm producers and SMEs in particular: the perception of forestry as a high-risk business, informal and fragmented value chains, unattractive investment conditions (e.g., weak governance, inadequate infrastructure, high transaction costs, lack of financial literacy in the sector), and limited capacity by SMEs and local market participants to attract and access finance (lack of bankable projects).

The paper provides a series of key findings and recommendations emerging from of a series of dialogues between forest producers, value chain stakeholders, government agencies, development agencies and financial service providers all aimed to unlock finance for smallholder producers in support of landscape restoration and sustainable production in Africa.

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

Advancing the science and application of forest farming in the Appalachian region of the United States

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

James Chamberlain[1]
John Munsell[2]
[1] USDA Forest Service, Forest Inventory and Analysis, USA
[2] Virginia Polytechnic Institute and State University, College of Natural Resources and Environment, USA

Abstract: Forest farming in North America has become a popular way for landowners to diversify income opportunities, improve management of forest resources, conserve biodiversity, and sustain tradition. People have been farming in forests for generations, but in the last several decades this agroforestry practice has evolved into a formally recognized means for reducing pressure on wild populations in the face of growing markets and satisfying consumers who demand traceable, sustainable, and high-quality woodland natural products. In particular, the Appalachian region is an iconic supplier of forest food and medicine. The region is 534,000 sq/km and traverses 13 eastern states largely dominated by deciduous forests. It hosts ancient mountains that are home to some of the most diverse mixed-mesophytic forests in the world and estimates suggest that close to 50% of woodland botanical species traded in the global market are endemic. We present the trajectory of forest farming in Appalachia over the last 20 years and discuss critical advances in science and application that support adoption. Results of field trials indicate that site selection and configuration are imperative for successful cultivation. Site preparation, protective measures, and soil amendments, as well as manipulation of the overstory canopy to change shade dynamics are recommended to enhance growth and productivity. Price-premium markets for forest farmed products are growing and aggregation often is necessary to ensure forest farmers have access. Federal, state, and private investments, as well as legislator support are fueling growth in application by way of drawing attention to the economic, environmental, and social benefits of forest farming and supporting establishment or expansion of farms using science, extension services, and coalition-building. Efforts in Appalachia have inspired development of forest farming coalitions in other regions of the US and efforts to establish a national forest farming association are underway.

Biological issues of simultaneous cultivation of large-diameter bole and high-yield cones of Pinus koraiensis

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

Hailong Shen[1]
Peng Zhang[1], Haibo Wu[1], Yu Wang[2], Yuhua Li[2], Dongsheng Yin[3]
[1] School of Forestry, Northeast Forestry University, Harbin 150040, China
[2] College of Life Sciences, Northeast Forestry University, Harbin 150040, China
[3] Research Institute of Forestry, Heilongjiang Academy of Forestry, Harbin 150081, China

Abstract: Ecosystem services (ES) of forests is growing rapidly at the global level, multi-functional Korean pine (*Pinus koraiensis*) is a dominant big arbor tree species in forest in the humid temperate region in East Asia, and its large-sized high-quality timber and nutritious pine nut production ES is in the global level, but there is little biological understanding of simultaneous cultivation of bole timber and nuts. Biological and technological issues of stand density regulation, tree top-pruning, fertilization and irrigation, photosynthesis patterns and the photosynthate allocation, hormone action and genomics were investigated. The main results: (1) Rational stand density such as 600 trees/ha at 40 years old and 350 trees/ha at 60 years old was both favorable to large-sized bole formation and high yield of cone in term of single tree and per unit area yield. (2) Top-pruning could promote bole radial increment and cone yield but the pruning height should be controlled properly for ensuring certain length of bole timber and succeeding top-pruning may need for the wide crown formation. (3) Fertilization and irrigation could increase the bole radial increment and cone yield at the same time. (4) Three years continue measurement on trees with long term rich fruiting and non-fruiting features shown that fruiting had no inhibition effect on growth ring increment, the fruiting trees obtained more strong photosynthetic capability and product more carbohydrates to support cone growth. (5) Needle and twig NSC on fruiting branches was significantly higher than that of non-fruiting branches, and carbon-13 labeling shown that the current photosynthates were transferred to fruiting branches and cones from non-fruiting branches. (6) The functional gene control trehalose 6-phosphoric acid that regulating the photosynthetic product allocation was found in the genome and showed higher expression in cones and fruiting branches. (7) Cytokinin might be more important role related to cone production. The above results implied that the cone production may not affect the bole timber production for Korean pine, and the source-sink relationship and its regulation mechanism might be the key biological issues for determined the biological mechanism of synergistic silviculture of timber and nuts.

Determining the feasibility of value chain development for non-timber forest products: insights from the Cerrado, Brazil

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

Kathrin Meinhold[1, 2]
Dietrich Darr[1, 2]
[1] Rhine-Waal University of Applied Sciences
[2] Sustainable Food Systems Research Centre

Abstract: The Cerrado region in Brazil features many indigenous species offering non-timber forest products (NTFPs), particular fruit trees and palm species. For a variety of these the commercial potential is considered high, including e.g. pequi (*Caryocar brasiliense*), baru (*Dipteyx alata*), or buriti (*Mauritia flexuosa*). Higher value processing of such NTFPs is a promising strategy to enhance smallholders' livelihoods and create incentives to sustainably manage the Cerrado forests, rather than making the area available for commercial agriculture. However, although some NTFPs of the Cerrado are already collected, processed and traded, these efforts often are on a small scale and only generate limited benefits for local populations. In order to make the use of NTFPs financially more rewarding to land users in the region, while simultaneously safeguarding their natural habitat, there is a need for research on how benefits to producers in these value chains can be improved. We aim to help aid the development of NTFP value chains in the Cerrado by applying a participatory, holistic research approach in collaboration with the relevant stakeholders active in the region such as cooperatives and enterprises and other value chain members involved in utilizing and processing priority NTFPs. As such, prevailing NTFP commercialisation in the Cerrado region will be assessed based on focus group discussions and interviews amongst value chain members in order to understand its current performance; relevant actors and product flows mapped in order to more deeply understand prevailing power dynamics in the Cerrado food system and current limitations for NTFP value addition; and prevailing laws, regulations, or advisory services affecting NTFP commercialisation assessed in order to determine the current feasibility of value chain development. This paper will present the initial results of the ongoing research.

Forest Fruits for Food Security: Identifying Uses & Socio-economic Significance of Selected Indigenous Fruit Tree Species in South Luzon, Philippines

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

Giorjia Mae Veran
Analyn Codilan[1], Eljohn Dulay[1], Bernadeth Balonga[2], Pastor Malabrigo Jr.[3], Cristino Tiburan Jr.[1], Marco Galang[1], Dennis Marvin Santiago[2]
[1] Institute of Renewable Natural Resources, College of Forestry and Natural Resources, University of the Philippines Los Baños, College, Laguna, Philippines
[2] Institute of Food Science and Technology, College of Agriculture and Food Science, University of the Philippines Los Baños, College, Laguna, Philippines
[3] Department of Forest Biological Sciences, College of Forestry and Natural Resources, University of the Philippines Los Baños, College, Laguna, Philippines

Abstract: The Philippines is home to a wide diversity of biological and cultural resources, including many indigenous fruit tree species (IFTS). Despite the potential of IFTS to contribute to the achievement of food security and alleviation of upland poverty, IFTS in the Philippines remain underutilized. This study, therefore, explored the uses and socio-economic importance of six (6) selected indigenous fruit trees (IFTS) namely, Kalumpit (*Terminalia microcarpa* Decne subsp. *microcarpa*), Bitongol (*Flacourtia rukam* Zoll & Moritzi), Tibig (*Ficus nota* (Blanco) Merr.), Libas (*Spondias pinnata* (Linn. F.) Kurz.), Binayuyu (*Antidesma ghaesembilla* (L.) Spreng), and Lipote (*Syzygium polycephaloides* (C.B.Rob.) Merr.) through structured and key informant interviews involving 270 respondents in Southern Luzon, Philippines. Tibig was the most cited IFTS in the region with a relative frequency of citation (RFC) of 80.6%, followed by Bitongol, Kalumpit, Lipote, Binayuyu, and Libas with RFC of 77.2%, 51.1%, 41.77%, 40.5%, and 29.5%, respectively. Three of the selected IFTS (Kalumpit, Lipote, and Bitongol) were also found to be socio-economically important in the region – these fruits were sold in the markets during their fruiting seasons and were sought after by the locals. Findings further reveal a range of uses for the IFTS, from dietary and medicinal to practical purposes. The most cited dietary use was the consumption of fruits as fresh, sweetened, or fermented treats. Some of the widely known medicinal purposes were the use of Tibig leaves as topical relief for headache and wounds, and the consumption of Binayuyu bark and leaf extracts to treat urinary-related illnesses. Although Tibig was the most cited IFTS, it has little to no use at all for the locals. Binayuyu and Lipote fruits were also recognized as a flavoring agent for alcoholic beverages (i.e., wine and nipa sap wine) while Libas foliage were acclaimed as a souring agent for local dishes. Results of the study strongly suggest that these IFTS, although underutilized, have a promising potential as valuable food and income sources. It emphasizes the need for further research, development, and national recognition of indigenous food resources in the Philippines.

Mediterranean stone pine production systems and the emerging bioeconomy in Chile

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

Veronica Loewe-Muñoz[1, 2]
Claudia Delard[1]
[1] Chilean Forest Institute (INFOR), Santiago, Chile
[2] Centro Nacional de Excelencia para la Industria de la Madera (CENAMAD), Pontificia Universidad Católica de Chile, Santiago, Chile.

Abstract: Stone pine (*Pinus pinea* L.) is a Mediterranean species whose edible seeds are a highly valued non-timber forest product with worldwide-unsatisfied demand. Cones are harvested mainly from natural forests, and cone or pine nut sales generate income and jobs. This study assessed the economic benefits of cultivating stone pine, an emerging crop in Chile, and its role in the transition towards a bioeconomy, due to the broad ecosystem services the species provide, along with socioeconomic benefits, allowing a value chain development. Primary and secondary data on costs, production, and income were collected, and an economic evaluation performed considering three management schemes (medium-intensity managed plantation, medium-intensity managed agroforestry system, and high-intensity managed plantation) under four production and price scenarios. The net present value was positive for all schemes under the most likely production and price scenario at 6% and 8% interest rate, with the high-intensity managed system being the most profitable; the medium-intensity managed agroforestry system was more profitable than the similarly managed plantation and easy to implement by landowners; it also had the highest financial resilience. The evaluation performed provide insights to better understand how stone pine cone and pine nut production can contribute to the bioeconomy development in Chile. Stone pine cropping under the three management schemes evaluated, showed attractive economic benefits; the high-intensity managed system proved the most profitable, with an NPV of up to US$6,400 per hectare. Stone pine cropping will provide local and export markets with high quality, high-value, healthy, and potentially equitably produced pine nuts to help meet the growing global demand. This emergent crop can contribute to transitioning towards a bioeconomy by favouring sustainable and inclusive rural development with economic (annual significant income generation), social (jobs creation, recreation) and environmental benefits (carbon sequestration, erosion control). Providing incentives and fostering stakeholder involvement to reach a critical production area and volumes, supported by science-based technological innovation, will facilitate the transition to a bioeconomy.

Sustainable deficit irrigation to enhance establishment of young, grafted plants of Pinus edulis, a potential nut-tree crop

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

Jacob Smith[1]

[4] Universidad Autónoma Chapingo, Texcoco, Mexico

Abstract: A growing number of consumers across the world want access to locally produced, healthy food, but also highly value sustainable food production, including the cultivation of low-water-use crops. Producing pine nuts from the regionally native, drought-tolerant two-needle pinyon pine (*Pinus edulis*), which currently is not cultivated, offers an opportunity to produce a sustainable, long-lived tree crop on tribal and non-tribal lands. We have developed a highly effective grafting protocol, using the side-wedge graft, for the propagation of superior pinyon genotypes, which we have collected from across its native range in the southwestern United States. Prior to widespread adoption of pinyon pine as a nut-tree crop, however, we need to determine the minimum amount of irrigation water needed to successfully establish young, grafted pinyon pines in typical orchard conditions in semi-arid environments. As such, we applied four irrigation treatments (50, 75, and 100% drip-irrigation plus a wick-based irrigation technique (Groasis Waterboxx)) to 1-year-old grafted pinyon pines (*Pinus edulis* scions on *Pinus edulis* seedling rootstocks) in orchard in central Utah, USA. We found that pinyons drip-irrigated at 75% the amount of the positive control had comparable growth rates with those in the control. However, those growing in the Waterboxxes exhibited similar end-of-season growth compared to those in the control treatment. Our research suggests that deficit-irrigating young, grafted pinyon pines leads to an appreciable amount of successful establishment. Future work needs to determine long-term establishment and growth of grafted pinyon pines under suboptimal conditions.

Sustainable forest management for progressive bioeconomies

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

[4] Chair of Forest Growth and Dendroecology, University of Freiburg, Germany

Abstract: Despite being essential to forest health and resilience, and supporting the food security, nutrition, and wellbeing of billions of people, non-timber forest products (NTFPs) have been largely overlooked within traditional forest management planning and implementation strategies. Historically, forest management has aimed at harnessing diverse and complex ecosystems with single-goal production models, evolving with changing demand for raw materials. As sustainable forest management moves towards modern and more inclusive models, an innovative paradigm is needed, in line with bioeconomy principles. The focus of this presentation is management of forest resources and derivative products that make up a forest-based bioeconomy. A bioeconomy ostensibly includes production, utilisation, conservation, and regeneration of biological resources, incorporating related knowledge, science, technology, and innovation, to provide sustainable solutions across all economic sectors. Transition to a forest-based bioeconomy depends on moving from "single-objective" management to multiple-objective sustainable forest management (SFM). Contemporary SFM principles recognise forests as more complex ecosystems, incorporating provisioning of food, water, materials, and cultural amenities; regulating effects of climate, floods, disease and water quality; and supporting services such as soil formation, photosynthesis, and nutrient cycling. SFM also considers the provisioning ecosystem services of goods other than wood, although it has not yet fully integrated the production and extraction of NTFPs. This presentation explores and integrates the concepts of forest management that consider NTFPs relative to the principles of a bioeconomy, focusing on possibilities and challenges that support or impede the integration of NTFPs into SFM. We examine relevant aspects of NTFPs that may be influenced by forest management and discuss how silvicultural and forest management practices can be adjusted for the sustainable production of multiple goods. Finally, we discuss challenges and factors that may encourage a transition to SFM including NTFPs within a functioning bioeconomy.

Utilizing Artificial Intelligence for Discrimination of Pollen in Taiwan Forests: A Preliminary Case Study of Dimocarpus longan and Litchi chinensis

Abstract: Bees play a critical role as pollinators in the ecological world, and bee honey is a significant global product. In recent years, Taiwan's forestry policies have actively promoted beekeeping in forested areas. Understanding the species composition of honey is crucial for determining bee preferences as food sources and assessing the botanical composition of honey. However, with the diverse range of plant species in Taiwan's forests, distinguishing between them becomes challenging. This study focuses on two popular varieties, *Dimocarpus longan* and *Litchi chinensis*, which are important economic trees in Taiwan and exhibit very similar pollen morphology. The primary objective is to investigate the dominant species ratio of *Dimocarpus longan* and *Litchi chinensis* in honey products, with the potential to expand the identification to other forest tree species.

To achieve this, pollen was extracted from flower buds of both species, and optical microscopy was employed for species identification. Subsequently, an AI technology utilizing the Mask R-CNN deep learning model was developed to train and identify pollen samples specifically from *Dimocarpus longan* and *Litchi chinensis*.

Our results indicate that after ten training cycles, the model exhibited significantly improved precision with a value of 0.94, while the recall rate was moderate at 0.50, indicating a higher type 2 error during the training process. The mean average precision (mAP) value achieved was 0.91. In comparison, three training cycles yielded lower precision (0.7), recall rate (0.44), and mAP (0.59). However, it is important to note certain limitations, including a limited dataset, uneven pollen sample sizes, and deformations during the preprocessing stage, which may have influenced the training and recognition capabilities of the model. Additionally, factors such as bubbles and impurities on pollen slides, as well as variations in focal lengths in the photos, could introduce errors in the model.

Future work will involve further calibration and expansion of the pollen species database to automate the identification process, particularly for species in forested areas. This approach will enable the determination of forest honey species composition and reduce the time and labor costs associated with manual identification.

Yield and quality of Ugni molinae fruits from natural forests, in response to silvicultural interventions to optimize its sustainable production

T2.25 Silviculture for food and medicine in a forest-based bioeconomy

Andrea Alvarez[1]
Marta García[1], Mauricio Aguilera[2], Oscar Larrain[2], Gerardo Valdebenito[1], Marco Hormazabal[1], Edison Garcia[2]
[1] Instituto Forestal INFOR, Sucre 2397, Ñuñoa, Santiago, Chile
[2] Instituto Forestal INFOR, Camino Coronel, San Pedro de La Paz, Concepción, Chile

Abstract: Murta (*Ugni molinae* Turcz), a native understory shrub that grows wildly in central and southern Chile, used by native people who attributed beneficial properties to its fruits and its leaves. It is the species fruit is an edible berry, which it is considered a super fruit due to its high level of secondary metabolites. Currently there is information about murta management focused on agricultural cultivation with little or no information on the state of conservation and sustainable management in native forest conditions.

In a stand of Roble-Raulí-Peumo, (*Nothofagus obliqua, Nothofagus alpina and Cryptocarya alba*) belonging to the Roble-Raulí-Coihue (*Nothofagus dombeyi*) forest type, subtype Degraded Forests, located in Biobío region, eastern slope of the Nahuelbuta Mountain Range, a study was established aimed at designing and evaluating methods of silvicultural management in native forest formations with the presence of *Ugni molinae*, with the objective of increasing yield and quality. The experimental trial involves 24 plots of 25 m2, with a factorial design in randomized blocks. Treatments were release cutting, increasing light on plants; thinning of murta and elimination of other competing shrub species; and pruning. In total eight treatments and three repetitions. Preliminary results indicate a superior fruit weight in the thinned plots without release, which presents significant differences with the plots without release or thinning. The size registers statistically significant higher values in the treatments without release, with thinning and pruning. Finally, fruits harvested in the control plots presented significantly lower weight and size. We conclude that optimal solar radiation favors the increase in the size and weight of the fruits of murta fruits, and that with the high level of thinning of plants of murta, and of all direct competing shrub species, in the coming years, a positive response of the remaining murta to the greater arrival of light, temperature and release of nutrients would affect fruit productivity.

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

BEYOND BLIGHT: SILVICULTURE AND POLICY CONSIDERATIONS FOR AMERICAN CHESTNUT RESTORATION

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Douglass Jacobs[1]
[1] Purdue University

Abstract: American chestnut (*Castanea dentata*) was functionally extirpated from eastern US forests by chestnut blight. As efforts to produce blight-resistant American chestnut germplasm advance, approaches to reintroduce chestnut throughout its former range are being developed. Over the past twenty years, I have collaborated with many colleagues to better understand how reintroduced chestnut may perform across the landscape. We have parameterized chestnut ecophysiology, responses to silviculture, seed dispersal and establishment, and carbon storage / decay; and then used these findings to conduct modeling experiments. We have published several key findings related to this work. First, American chestnut is very fast growing, competitive, relatively long-lived, and resistant to decay. Nevertheless, aggressive restoration efforts are needed to ensure that chestnut will become a significant and stable component of the forest within a century under current or future conditions (i.e., introduced pests, climate change). Additionally, despite its fast growing and long-lived nature, chestnut will produce only modest increases in carbon storage, mainly through slow decay of its wood. Second, analysis of non-structural carbohydrate (NSC) pools in different organs of American chestnut trees found that coarse roots were a remarkably important storage site, suggesting that chestnut may thrive under disturbance-based management. Third, the pathogen *Phytophthora cinnamomi*, which causes a root rot disease, generally reduced chestnut biomass on the landscape even when modeled using the highest levels of resistance to root rot infection that are incorporated into current breeding efforts. As root rot is expected to increase in virulence and migrate north in response to climate change, we suggest the need to further increase root rot resistance through biotechnology, as well as to target reintroduction to sites where root rot is not expected to be present well into the future. Finally, although remarkable progress has been made in developing blight-resistant chestnut, we suggest that successful reintroduction will ultimately depend on regulatory policy, informed by science and with public support.

Biodiversity in sweet chestnut forests: effects of coppicing and of the spread of black locust

Abstract: Sweet chestnut (*Castanea sativa* Mill.) dominated forests are commonly shaped and maintained by silvicultural practices. Coppice systems are frequently applied; however, in many European landscapes over-aged stands are developing because of the lack of silvicultural interventions. Furthermore, these forests are frequently considered a habitat type of community interest and it is a widely spread forest type in several Natura 2000 sites. This contribution builds on the results of a recent study (https://doi.org/10.1016/j.foreco.2023.120907) that compared the effects of different management regime intensities on sweet chestnut forests as well as on the differences with forests dominated by the invasive non-native tree black locust (*Robinia pseudoacacia* L.) in north-eastern Italy (Veneto region). The main results on plant composition, soil Ammonia-oxidising archaea abundance and stand structure was used to understand the implications of forest management as well as the spread of an invasive non-native tree. This discussion helps proposing conservation measures, mainly forest management indications, aiming at a good conservation condition for sweet chestnut (*Castanea sativa*) forests.

Blight-tolerant Darling™ transgenic American chestnuts

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Patrícia Fernandes[1]
William Powell[1], Andrew Newhouse[1]
[1] Department of Environmental Biology. State University of New York, College of Environmental Science and Forestry, 1 Forestry Drive, Syracuse, NY 13210, USA

Abstract: The American chestnut was once one of the most abundant trees in the eastern US. It was considered a keystone species for wildlife and provided significant economic benefits due to the delicious nuts it produced and valuable rot-resistant timber. The chestnut blight fungus, *Cryphonectria parasitica,* killed over 3 billion American chestnuts in the 20th century, leaving the species functionally extinct. We developed transgenic American chestnut trees called Darling™, with enhanced blight tolerance. This trait was achieved by inserting a single gene from wheat, oxalate oxidase (OxO), which encodes for an enzyme that detoxifies oxalic acid produced by the fungus, preventing necrosis of chestnut tissues that can lead to fatal cankers. This trait is inherited throughout generations (classical Mendelian inheritance) and has already been a valuable tool to rescue surviving remnant American chestnut trees. We are continuing these crosses with diverse wild-type trees for multiple generations to ultimately produce a resilient and diverse population suitable for restoration. Extensive research on Darling, their offspring and other OxO-expressing events has been ongoing for several years. Inoculations of seedlings and young trees have shown a substantial reduction of canker size and severity on the transgenic trees compared to the closely related non-transgenic controls. Multiple non-target studies (e.g., mycorrhizal colonization of roots, insect herbivory of leaves, and wood frog tadpoles feeding on leaf litter) and nutritional comparisons confirm that the transgenic and wild-type trees are essentially equivalent apart from blight tolerance. The comprehensive characterization of Darling trees and environmental tests were required for ongoing governmental regulatory review, which we expect to conclude this year, allowing the first public distribution of transgenic disease-tolerant chestnut trees. The tree's scientific path, project status, and regulatory updates will be discussed during this presentation.

Chestnut technique, physiology and legislation: an emblematic paradox. The Amiata experience

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Mirko Benanchi[1]
Piergiuseppe Montini[1]
[1] Unione dei Comuni Amiata Val d'Orcia

Abstract: The origin of stand coppice in forestry, as we understand it and study it nowadays, has very deep and varied roots, often influenced by the rural habits of the territory [Zanzi Sulli and Di Pasquale 1993]. To the classic objectives that can be found in all the basic forestry texts it is in fact necessary to add the multiple possibilities motivations that were widespread in the Apennine environment.

This reasoning is difficult to apply to the Amiata chestnut groves, in fact these statements find little foundation in an environment as peculiar as it is replicable. Since the past centuries, the people of Amiata were accustomed to grafting, and therefore cultivating chestnuts, with the many local varieties selected over time to satisfy their own uses. Therefore, since the past, fruit chestnut groves were clearly distinguished from those aimed at wood production, all woods that were in the courtyard of small inhabited areas in which squeegees and carpenters alternated.

Going even further into the silvicultural peculiarities of chestnut, and more precisely into its biological characteristics, we realize even more that the concept of stand coppice in this specie groves leaves room for many perplexities. The production of chestnuts for the rejuvenation of the stumps is very little required since it shows surprising longevity of these apparatuses, and for this requirement the seed production that the suckers guarantee from the very first years following the utilization. The site conditions and the objective fertility of the local soils guarantee maximum vigor of the young shoots. Research conducted in the municipality of Abbadia S.S. (SI) show that in simple coppices (without the release of stand) the re-explosion and the state of health of the young shoots is at least as good as that observed in the stand coppice. Thus the experience and the state of the forest of this surprising species suggests a radical re-evaluation of the Italian legislation that governs it, as happens moreover in many European countries where they have (for some time) become aware of the disadvantages due to the release of stand in chestnut coppices (Switzerland, France, Spain, Portugal).

Continued Chestnut Biotechnology Development at SUNY-ESF

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Erik Carlson[1]
William Powell[1], Andrew Newhouse[1]
[1] State University of New York, College of Environmental Science and Forestry

Abstract: Our research team at SUNY-ESF in Syracuse, NY, USA has developed an innovative biotechnology pipeline for the American chestnut (*Castanea dentata*) . Transgenic lines such as Darling 58 contain an oxalate oxidase (OxO) gene from wheat, which enhances tolerance to the necrotrophic blight pathogen *Cryphonectria parasitica*. These have undergone rigorous safety reviews to attain required US government regulatory approvals, which are anticipated this year. However, research toward improved disease resistance in American chestnut will not end with regulatory approval of Darling 58. New transgenic lines are currently in development for enhanced and refined resistance to *C. parasitica,* as well as *Phytophthora cinnamomi*, the causal pathogen of root rot disease in chestnut. The 'DarWin' chestnut line contains the same OxO gene as Darling 58, but with expression controlled under a pathogen-inducible promoter from poplar instead of a constitutive promoter. A putative *Phytophthora* resistance gene from Japanese chestnut is also being assessed in American chestnut lines, which could enable restoration to the Southern portion of the American chestnut range. In addition, RNAi Host Induced Gene Silencing (HIGS) is being researched as an additional source of resistance to both *C. parasitica* and *P. cinnamomi*, and possibly others pests and pathogens as well. Continued improvement in American chestnut genetics and resistance to multiple diseases will be critical for success of future restored populations.

Coppices are not the same anymore: evolution of the radial increment in young chestnut coppices

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Enrico Marcolin[1]
Marco Conedera[2], Mark Bertogliati[2], Mario Pividori[1], Maria Chiara Manetti[3]
[1] University of Padova, TESAF Department, Legnaro, Italy
[2] WSL Swiss Federal Research Institute, Insubric Ecosystems Research Group, Cadenazzo, Switzerland
[3] CREA Research Centre for Forestry and Wood, Arezzo, Italy

Abstract: We evaluated the radial increment in the young stage (up to 10 years old) of dominant sprouts in chestnut (*Castanea sativa*) stands coppiced in two different epochs (before 1980 and between 1990 and 2000) but before the arrival of the Asian chestnut gallwasp (*Dryocosmus kuriphilus*). The study sites were located in in Ticino (Switzerland), Veneto, Piedmont, and Tuscany (Italy). The analyzed data highlighted a significant higher increment rate in shoots from post-1990 coppicing. Possible explanatory factors are the management techniques, the increasing temperatures, the atmospheric CO2 enrichment and the increased soil nitrification due to the anthropogenic-induced N-depositions.

Conversely, in sites located at the edges of the climatic optimum for the chestnut tree, frequent summer droughts observed from 2003 on seem to have caused a decline in the woody increments of the species.

Development of blight-tolerant Castanea ozarkensis

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Patrícia Fernandes[1]
Hannah Pilkey[1], William Powell[1], Andrew Newhouse[1]
[1] Department of Environmental Biology. State University of New York, College of Environmental Science and Forestry, 1 Forestry Drive, Syracuse, NY 13210, USA

Abstract: We have engineered transgenic American chestnuts to express oxalate oxidase (OxO), which counters the main virulence factor produced by the chestnut blight fungus, *Cryphonectria parasitica.* These blight-tolerant trees have been extensively studied and are currently under governmental regulatory review. The present work focuses on applying the knowledge used to develop the transgenic American chestnuts to the Ozark chinquapin, a closely related North American species also severely impacted by chestnut blight. *C. parasitica* reached the Ozark chinquapin native range (U.S. Interior Highlands) after 1950, killing mature trees that used to reach up to 20 m tall. Their population substantially decreased, and currently surviving individuals are heavily suppressed subcanopy trees or grow as small resprouting bushes. We are using two biotechnological approaches to develop blight-tolerant Ozark chinquapins: a backcross breeding program with transgenic American chestnuts and direct genetic transformation of Ozark chinquapin. Pollen from the transgenic American chestnuts is being used as source of blight tolerance to introgress the OxO gene into Ozark chinquapin mother trees. Transgene inheritance has been confirmed in F1 hybrids, which are currently under high-light treatments to induce pollen production, which is typically achievable in less than a year. This transgenic hybrid pollen will be backcrossed to full Ozark chinquapin mother trees to start the process of recovering the species' phenotype. We are also performing genetic transformations of Ozark chinquapin somatic embryos using the American chestnut's *Agrobacterium*-mediated transformation protocol. We first confirmed this technique by transforming Ozark chinquapin somatic embryos with a reporter gene, and subsequently obtained multiple transformed events with OxO and other candidate genes for blight resistance (e.g. laccase from *C. mollissima*). These results show great promise for meeting the challenge of developing a blight-tolerant Ozark chinquapin and potentially addressing related threats in other species.

Integrating Diversity, Ramping Up Capacity, and Transforming Nursery Capacity for Threatened Native Tree Species Restoration

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

John Scrivani[1, 2, 3]
Sara Fern Fitzsimmons[1, 4], Jared Westbrook[1], Stephen Hoy[1, 4], Michael French[5]
[1] The American Chestnut Foundation
[2] Virginia Department of Forestry
[3] Richmond University
[4] The Pennsylvania State University
[5] Green Forests Work

Abstract: As wildfires ravage forested landscapes, native species' habitats are being altered and constricted due to climate change, and non-native pests and pathogens extirpate native tree species from their range, the need for tree seedlings is estimated to be double the current capacity across the US. The American chestnut was one of the first native tree species in the United States extirpated due to the importation of non-native pathogens, taking place sometime in the years between 1850 – 1950. Since that time, globalization and trade have introduced a multitude of new pests, pathogens, and invasive vegetation which threaten the sustainability of US forested ecosystems.

While the American chestnut was one of the first to become functionally extinct in its native range, it is also poised to be one of the first to be restored. Over the past 40 years, The American Chestnut Foundation (TACF), working with hundreds of partners, stands ready to deploy a diversified population of disease-resistant American chestnuts. In order to restore a species across millions of acres, millions of tree seedlings will be needed. Tree planting, especially that with hardwood trees, is expensive and laborious. Forest landowners will need access to high quality and low-cost tree seedlings, not only of American chestnut, but other native tree species which can facilitate large-scale ecosystem sustainability.

This decades-long project will involve hundreds of private landowners, academic institutions, federal and state agencies, and NGOs. The work ahead relies on timely installation and implementation of seed orchards and which exponentially ramp up seed production for the subsequent distribution of tree seedlings to be planted across the eastern United States.

Mid-last century, many states had multiple agency tree seedling nurseries; most of those have been mothballed or entirely closed. Working with limited budgets, aging infrastructure, and limited personnel, these state nurseries need infusions of funding to be able to meet increased capacity goals. Using the American chestnut as a test case for introduction of a new species into nursery production pipelines, TACF seeks to re-invigorate the use of seed orchards and to install new processes and efficiencies in private and state agency nursery seedling production.

Micro-collective approach to establish a mixed forest with Castanea sativa and Quercus petraea after two years from plantation

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Barbara Mariotti[1]
Alberto Maltoni[1], Gianluigi Mazza[2], Pietro Castellucci[1], Maria Chiara Manetti[2]
[1] Department of Agriculture, Food, Environment, and Forestry (DAGRI), University of Florence, Via San Bonaventura 13, 50145 Florence, Italy
[2] CREA Council for Agricultural Research and Economics, CREA-FL Research Centre for Forestry and Wood, Viale Santa Margherita 80, 52100 Arezzo, Italy

Abstract: We present the preliminary findings of a forest restoration project involving micro-collectives of a mixed plantation comprising European chestnut (*Castanea sativa* Mill.) and sessile oak (*Quercus petraea* Matt. Liebl.), replacing a degraded pure stand of exotic Pinus strobus L. The indigenous species, better adapted to the site compared to pine, can offer improved climate change mitigation, enhanced biodiversity, and increased economic value through wood and non-wood products. The study site, located in Tuscany, Italy, provides favorable soil and climatic conditions for both species, with chestnut particularly well-suited.

The micro-collectives were designed to emulate a natural and irregular distribution pattern, with five 1-year-old chestnut seedlings as the primary species and oak as the secondary species, spaced 10 meters apart. Planting took place in early spring 2022. Approximately half of the area was fenced to protect against wildlife damage and browsing. Chestnut seedlings were sourced from three local stands with varying altitudes and exposures. Our research aimed to address three key questions: a) Is the micro-collective approach more effective than natural regeneration? b) What is the influence of wildlife on the regeneration process? c) How do provenance and seedling size affect chestnut field performance?

Destructive analysis was conducted on nursery seedlings from each provenance to assess their morphological characteristics and their relation to field performance. Field monitoring encompassed the assessment of survival, growth, stem structure, viability, and phytosanitary conditions of all planted seedlings, both within and outside the fenced area. Additionally, 30 subplots with a 2-meter radius were established to evaluate natural regeneration capacity in the presence or absence of wildlife.

Initial results from the first two years of monitoring indicate higher survival rates in chestnut compared to oak within the micro-collectives. Indigenous species from surrounding stands displayed encouraging levels of natural regeneration. The impact of fencing and the influence of climatic patterns on the observed outcomes are also presented.

These findings contribute to our understanding of early-stage dynamics in mixed plantations and highlight the challenges and opportunities associated with introducing diverse tree species in reforestation initiatives.

More than trees: how fungal community ecology can inform and improve success of Castanea outplanting performance and disease outcomes

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Shawn Brown[1]
Richard Baird[2], Ryan Williams[2], Scott Schlarbaum[3], Stacy Clark[4]
[1] University of Memphis, Department of Biological Sciences
[2] Mississippi State University, BCH-EPP
[3] The University of Tennessee, Department of Forestry, Wildlife, and Fisheries
[4] USDA Forest Service, Southern Research Station

Abstract: American chestnut (*Castanea dentata*) is a historically important species in the eastern United States that has become functionally extinct due to major pathogen stressors, including the causal agent of chestnut blight (*Cryphonectria parasitica*). Backcross hybrids of American chestnut have been developed with the goal of increasing disease resistance for reforestation efforts. Further, outplanting success may be affected when co-planting with naturally co-occurring Fagaceae trees such as white oak (*Quercus alba*). Here, we explore the role fungal community ecology can play in improving success of reforestation efforts and informing future management options. Outplanting of American chestnut, Chinese Chestnut (*C. mollissima*), five families of third generation backcross hybrids and white oak was established in southern North Carolina (USA). Soils were collected at time of planting and at 3- and 6-years post planting. Secondary roots and leaves were collected at year 6 to examine rhizosphere and root and leave endophytic communities. Additionally, metabolites from chestnut leaves at year 6 were queried using nuclear magnetic resonance (NMR) to explore functional differences between plant families and as associated with foliar fungal communities. We find that soil fungal communities associated with chestnuts and oaks shift in similar ways over the first three years of plant growth and that key fungal taxa might be able to be used to predict tree performance and/or chestnut blight occurrence. We also provide strong evidence of shared ectomycorrhizal communities across Fagaceae species, and persistent nursery-bed fungal taxa that may play an unappreciated role in plant performance. Ongoing work is expected to demonstrate chestnut family differences in 6-year rhizospheric soils and endophytes, particularly with pathogens. We also expect to see broad metabolic profile differences among chestnut families and to identify key metabolite groups associated with foliar fungi. Taken together, these analyses demonstrate the utility of integrating fungal ecology into chestnut reforestation efforts as an additional tool to inform silvicultural decisions and to improve plant performance.

Multifunctionality of chestnut coppices and future prospects in timber production and ecosystem services.

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Maria Chiara Manetti[1]
Marco Conedera[2], Mario Pividori[3], **Enrico Marcolin**[3]
[1] CREA Research Centre for Forestry and Wood, Arezzo, Italy
[2] WSL Swiss Federal Research Institute, Insubric Ecosystems Research Group, Cadenazzo, Switzerland
[3] University of Padova, TESAF Department, Legnaro, Italy

Abstract: The chestnut coppice management has been perpetuated for millennia thanks to the unlimited resprouting capacity of the stool, which results in a high number of fast-growing shoots. In Europe, first written historical evidence of applying a coppice management to the sweet chestnut (*Castanea sativa*) date back to Theophrastus (~370 B.C.–287 B.C.). The widespread diffusion of *C. sativa* for wood production, well beyond its natural range, has pushed the diffusion in Europe up to the current 1.78 million hectares of which 79% is managed as coppice.

Over time, the biological and economic sustainability of the chestnut coppice have been usefully included into the traditional small farm management, since a wide range of wood assortments can be obtained (poles, beams, sawn wood, wood-based panels, tannins, biomass for energy) in monospecific, coeval, and even-structured forest stands.

Regular coppice management of chestnut carried out on small plots has always represented a guarantee both in terms of production continuity and ecosystem services (biodiversity conservation, landscape structuring and protection against natural hazards).

However, in the last century, profound economic and social changes have caused a general abandonment of the coppice management with the consequent loss of ecosystem products and services, including the replacement of the chestnut with other tree species.

Recently, there has been a renewed interest in chestnut coppice products and services such as sustainability of timber but also non-timber products, ecological function and biodiversity, slope protection, carbon sequestration and educational and tourist recreational activities.

Where possible (sites with good fertility, reduced presence of aggressive pathogens), the main practice proposed in chestnut coppices is the extension of the rotation time accompanied by the application of adequate silvicultural practices. In this way, larger quality assortments can be obtained with additionally benefits for the diversity of the vascular flora, the stand stability and for the general vulnerability of the chestnut forest to fire. This results in social benefits for local communities (employment, reduction of timber imports).

In this perspective, innovative silvicultural systems (e.g., tree-oriented silviculture) have been introduced recently, while others have been implemented for improving the tradition of coppice management options (e.g., stand-silviculture).

Naturalized sweet chestnut (Castanea sativa Mill.) in the rural landscape

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Veronica Loewe-Muñoz[1, 2]
[1] Chilean Forest Institute (INFOR), Santiago, Chile
[2] Centro Nacional de Excelencia para la Industria de la Madera (CENAMAD), Pontificia Universidad Católica de Chile, Santiago, Chile

Abstract: Sweet chestnut is widely naturalized in allochthonous environments, derived from the long history of cultivation of this tree for chestnut production, that have been traded since Roman times with relevant socioeconomic benefits. Furthermore, a wide range of timber products is also valuable. The species characteristics allow for different management options (coppicing, high-forests, mixed plantations, agroforestry), depending on environmental, economic and/or social conditions. The species was introduced outside its native range in South America (mostly in Argentina, Chile and Uruguay), Australia and New Zealand as early as the 19-century for nut and timber production. Management of the species is appealing to small and medium-size landowners because since it may provide yearly chestnuts along with timber at the end of the rotation. In Chile, *C. sativa* is considered naturalized, and it has been planted both in pure and mixed plantations with conifers and broadleaves. Furthermore, ring shake, a timber defect causing important economic losses in the species native range, is not present in Chile. An inventory of plantations was performed, recording tree growth variables and plantation characteristics. The presentation includes information on tree growth and management schemes in naturalized environments, explores the expected impact of climate change on the species performance, and presents possible tools to deal with these challenges, including genetic breeding, assisted migration and management adjustments to foster its adaptation.

Optimizing American Chestnut Restoration Efforts Through Habitat Suitability Modeling

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Segun M. Adeyemo[1]
Joshua J. Granger[1]
[1] Department of Forestry, Mississippi State University, P.O. Box 9691, MS 39762, United States

Abstract: American chestnut (AMC) (*Castanea dentata*), a once widely abundant tree species in the eastern US has functionally been lost from much of its natural range due to the introduced fungal pathogen, *Cryphonectria parasitica*. Restoration efforts have since focused largely on the development of disease-resistant chestnuts, while the restoration strategic plan has little or no information on the effect of changing climate on suitable habitats as well as changes in this species' range over the last century. Our research centers on utilizing improved models to forecast appropriate habitats in the eastern United States, predict changes in habitat ranges, and identify factors influencing the habitat suitability of the AMC within the region. The aim is to support the ongoing restoration efforts of AMC by employing an ensemble model that combines different species distribution modeling (SDM) methods. Additionally, our study extends the predictions until 2100 to account for the impact of climate change. We gathered 1,806 occurrence records from various sources, including the United States Department of Agriculture (USDA) Forest Service, iNaturalist, and TreeSnap. The application of SDM techniques yielded highly accurate models with true skill statistics (TSS) and Area-Under-the-Curve (AUC) values exceeding 0.8 and 0.90, respectively, which were assembled. A comparison between the historically suitable habitat of AMC and the present habitat suitability prediction in the US revealed a significant decline in suitable habitat. The primary variables influencing the distribution of the American chestnut in the US were identified as the mean temperature of the warmest quarter, precipitation seasonality, and temperature seasonality. The future projection indicates a potential reduction of up to 61.1% and 100.0% in suitable habitats by the end of the century under high emissions as well as stable and high precipitation conditions, respectively, with a northeast range shift spanning approximately 43.2 and 476.9 km which translates to 4.3 and 47.7 km per year. It is crucial to model the habitat suitability of the AMC for a successful restoration program, and these findings underscore the importance of increased conservation efforts and the utilization of southern genotypes.

Promoting species diversity: understanding Sweet chestnut within regeneration of Scots pine stands

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Maria Sameiro Patrício[1]
Luís Nunes[1]
[1] Centro de Investigação de Montanha (CIMO), Instituto Politécnico de Bragança, Campus de Santa Apolónia, 5300-253 Bragança, Portugal; Laboratório Associado para a Sustentabilidade e Tecnologia em Regiões de Montanha (SusTEC), Instituto Politécnico de Bragança, Campus de Santa Apolónia, 5300-253 Bragança, Portugal

Abstract: Pine forests show a natural gradual transition to mixed plantations where, with the progression of ecological succession, hardwoods such as Sweet chestnut (*Castanea sativa* Mill.) and oaks begin to progressively settle. However, the persistence of chestnut in conifer stands remains poorly studied and appears to be strongly influenced by the surrounding areas where the species is cultivated and light availability. In this case study conducted in Serra da Nogueira, Portugal, which is characterized by a mosaic of habitats resulting from mountain agriculture, including extensive Pyrenean oak forests and stands of other hardwoods and conifers, such as Scots pine (Pinus sylvestris L.), it was observed that chestnut persisted in the natural regeneration of these stands primarily due to the presence of nearby chestnut forests and agroforestry stands. The presence of advanced regeneration in the understory of Scots pine stands suggests that chestnut can persist in the natural regeneration dynamics, leading to the formation of mixed stands more resilient and biodiverse. Therefore, the regeneration status of two Scots pine stands covering a 12-hectare area in Serra da Nogueira (41°45'34"N, 6°54'53"W, altitude 980 m) was assessed. A systematic sampling approach was applied. A semi-permanent circular plot device was installed, following a concentric system with a fixed radius. Natural regeneration ($d<10$ cm) was divided into two height strata: up to 2 m and > 2 m. Concentric circular plots of 100 and 200 m^2 were used to study each height stratum. Abundance and diversity were evaluated using modified Shannon and Simpson indices, the inverse of the Berger-Parker index, and species richness. Generalized linear models (GLM) and generalized additive models (GAM) were employed to explore the influence of potential explanatory variables related to stand structure, crown cover, and degree of shrub cover (SC) on the abundance of the main species contributing to natural regeneration. The results indicate that basal area (G) significantly affects the abundance of natural regeneration. Additionally, it was found that the percentage of SC also had an influence. Basal areas close to 40 $m^2\ ha^{-1}$ promote the regeneration of Scots pine while lower G favors the establishment of hardwoods, particularly chestnut.

Synergies between the American and Sweet chestnuts could impact the rural bioeconomy

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Stacy Clark[1]
Enrico Marcolin[2], Maria Sameiro Patrício[3], Verónica Loewe-Muñoz[4]
[1] USDA Forest Service, Southern Research Station, United States
[2] University of Padova, Department of Land, Environment, Agriculture and Forestry (TESAF), Italy

[4] Chilean Forest Institute (INFOR) and Centro Nacional de Excelencia para la Industria de la Madera (CENAMAD), Chile

Abstract: Sweet chestnut (*Castanea sativa*) and American chestnut (*C. dentata*) have been explicitly linked to historical and contemporary cultures and have played important roles in rural bioeconomies. These species also have been important for enhancing ecological services, such as mast production, soil stabilization, and high water use efficiency. Threats to these species are unprecedented and additive, including global climate change, nonnative pests and pathogens, land use changes, and lack of scientific knowledge and technologies. We will provide a synthesis of traditional and novel silvicultural systems for chestnut, focusing on timber and non-timber forest products that enhance the forest bioeconomy. Sweet and American chestnuts require divergent management strategies to sustain their conservation values, and both species require active forest management to maintain or restore populations in native or naturalized habitats. Even-aged regeneration systems are the preferred silvicultural practice for both species. Coppicing is commonly implemented for sweet chestnut and provides a potential future strategy for American chestnut once disease-resistant material is available. *Cryphonectria parasitica* causes chestnut blight and may limit long-rotation timber production of American chestnut making coppice systems more attractive for managers. High forests of sweet chestnuts are managed primarily for timber production in single or mixed species plantations and naturalized stands, although ecosystem services are being increasingly considered in value estimations for this species. American chestnut will probably be reintroduced to achieve ecological restoration goals that can be considered in determining values to the bioeconomy. Traditional and emerging markets for sweet chestnut, such as biomass or carbon, may help inform future opportunities around American chestnut, particularly for tribal and rural communities. Climate change and other threats call for synergistic partnerships and knowledge sharing to maintain or restore sweet and American chestnuts as part of the global ecosystem.

The Management of Agroforestry for Japanese Chestnut (Castanea crenata) in Taiwan.

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Ming-Yuan Huang[1]
Wei-Chun Chao[1], Yue Ken Liao[1]
[1] Department of Forestry and Natural Resources, National Chiayi University, Taiwan

Abstract: Japanese chestnut (*Castanea crenata* Sieb. & Zucc.) was introduced into Taiwan in 1910 for the purpose of harvesting its edible nuts. However, due to the difficulties in cultivation and the influence of the local warmer climate, Japanese chestnut grows slowly in Taiwan. Currently, the primary chestnut orchard covers about 25 hectares in Jhongpu Township, Chiayi County.

This study addresses two major issues. Firstly, the research applied in-depth interviews to conduct 6 landowners in 2018. We collected their management information and experience regarding orchard maintenance operations, harvesting practices, production status, and the challenges of management. At the same time, agricultural statistics data from 1997 to 2021 were also collected and analyzed the trends in annual yield and marketing status of the chestnuts in Taiwan. The results showed that chestnuts are vulnerable to the Formosan rock-monkey (*Macaca cyclopis*). Additionally, the cost of labor and process equipment is high, and the harvest period coincides with the typhoon season, making nuts production unstable and susceptible to damage from natural disasters or climate variations.

With regard to the second issue of the study, the research team aims to develop an agroforestry management model by integrating beekeeping businesses into the orchard operations. Starting in 2020, beehives were placed in the designated area to collect chestnut honey. The blooming season of Japanese chestnut typically occurs from late of April to mid-May. Based on the harvest data from 2020 to 2022, the average honey yield per beehive is about 1060±597g. However, the yield varies significantly due to fluctuations in rainfall and temperature. This research will continue to collect Japanese chestnut honey and expect to establish an agroforestry model. It is not only to increase the benefit for landowners but also to provide valuable information to landowners and management agencies, enhancing their recognition of the value of the ecosystem services provided by bee populations.

The potentials of chestnut forests for supporting a forest-based bioeconomy

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

[2] TESAF Department - University of Padova

Abstract: Chestnut forests are multifunctional ecosystems. They can be managed under different management approaches (coppice, coppice with standards, highforests) and rotation periods for one specialized product or, more frequently, for a set of different ones: biomass for energy, biomass for tanning and other chemicals, small poles, transmission poles, construction wood, high quality timber for the construction sector (also through Engineered Wood Products) or for the furniture one. Additional marketable products from chestnut forests include nuts (with some valuable varieties like "*maroni*"), honey, and the collection of wild forest products, like mushrooms, which might be associated to recreational and cultural activities with relevant social impacts in local rural economies. Finally, chestnut forests are able to provide non-priced ecosystem services like carbon sequestration (including in durable wood products), such as biodiversity protection and water-cycle regulation for erosion control. For some of these services, such as carbon and biodiversity, new voluntary markets are likely be created based on credit systems or on donations associated to environmental claims made by sponsoring organizations.

This paper will discuss the financial and economic benefits related to various investments in chestnut forests through traditional indicators like the Net Present Value, Internal Rate of Investments and Land Expectation value. The research targets Piedmont Region (NW Italy) as a case study area. This is a region where chestnut forests traditionally play a relevant role in the local economy and for the quality of the landscape (with associated positive impacts on tourism). The region has some elements of relevant interest in the value chain organization: chestnut orchards for the production of nuts (some of them of certified origin) and derived products (like the *marron glacé*), chestnut wood for the chemical industry (Silvateam, one of world's largest producer of tannin and other chemicals, is based in Piedmont), poles (both in vineyards producing Piedmont famous wines and for communication poles, under the new ideas connected to bioeconomy), timber for the building and the furniture sectors. The above-mentioned financial indicators associated to these activities will be integrated by estimated values for non-market services that have been recently subject to payment mechanisms in the area.

Unlocking the Potential of Sweet Chestnut Stands: Sustainable Management, Carbon Sequestration and Revenue Generation

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Maria Sameiro Patrício[1]
Luís Nunes[1]
[1] Centro de Investigação de Montanha (CIMO), Instituto Politécnico de Bragança, Campus de Santa Apolónia, 5300-253 Bragança, Portugal; Laboratório Associado para a Sustentabilidade e Tecnologia em Regiões de Montanha (SusTEC), Instituto Politécnico de Bragança, Campus de Santa Apolónia, 5300-253 Bragança, Portugal

Abstract: The sweet chestnut (Castanea sativa Mill.), a species common in European forest ecosystems, provides numerous ecosystem services including landscape diversity, supporting biodiversity and enhance resilience to forest wildfires in Mediterranean regions. While climate change poses challenges to this species, it also presents opportunities to leverage its ecosystem services that have been overlooked in the potential incomes on chestnut management. Carbon sequestration is one such service that can revitalize chestnut areas. By exploring carbon storage as a passive income stream, profitability in chestnut areas can be enhanced beyond traditional revenue sources like timber and nuts. A comparative analysis is carried out to assess the potential of carbon sequestration in diverse cultural systems of chestnut stands during the juvenile phase (up to 24 years). The analysis is based on data of field permanent plots used to estimate biomass and carbon levels. The estimation of carbon value is based on EU Carbon Permits. To effectively mitigate greenhouse gas emissions, it is crucial to strike a balance between carbon sequestration and the duration of carbon retention in wood products. By emphasizing the production of high-quality wood and incorporating it into long-lived products, significant environmental benefits can be achieved by storing carbon outside the atmosphere for extended periods of time. Furthermore, the silviculture practices related to this innovative approach are also discussed. By transferring the significant value of Carbon Permits for carbon ecosystem services, we can demonstrate the potential impact of carbon sequestration as a compelling factor for revitalizing the chestnut forests. The most carbon-sequestering chestnut forest areas are productive sites, including high forest stands and coppices. These areas exhibit an average annual CO_2 sequestration ranging from 12.7 to 13.6 Mg ha^{-1} $year^{-1}$ over a period of 23-24 years, with carbon values exceeding €900.00 per hectare per year and possibly reaching €1,150.00 per hectare per year. When combined with the quality and durability of wood products and the opportunity to substitute alternative materials like plastics and steel in construction, the environmental and economic benefits become even more pronounced. This presentation highlights the potential of chestnut in mitigating climate change, generating revenue and fostering sustainability.

What new frontiers for the socio-economic revival of the Italian chestnut sector?

T2.26 Silviculture for the Bioeconomy and Ecosystem Services in Castanea Forests

Stefano Bruzzese[1]
Simone Blanc[1], **Silvia Novelli**[1], Filippo Brun[1]
[1] University of Turin, Department of Agricultural, Forest and Food Sciences, Largo Paolo Braccini, 2, Grugliasco, 10095, Italy

Abstract: Natural resource governance cannot disregard participatory decision-making processes including different stakeholders, both public and private, and citizens. In this work, an attempt was made to actively involve at a regional scale the various stakeholders related to the chestnut wood resource. The aim is to investigate what factors should be involved to revitalise and valorise a resource that has strongly characterised European mountains. The same resource that today, at least in Italy, is now subject to abandonment or sub-management, apart from the market niches of the fruit and tannin production chains. The A'WOT methodology used is part of the multi-criteria analysis family and consists of the qualitative SWOT method combined with the quantitative analytic hierarchy process (AHP) method. Starting from a SWOT analysis, 20 factors - 6 for strengths and weaknesses and 4 for opportunities and threats, respectively - were selected to create the pairwise comparison questionnaire required for the AHP. The sampling technique used was the snowball technique, and the questionnaire was administered in two different periods, between 2021 and 2022, involving 36 chestnut resource experts. A total of 20 were collected and validated (55% response rate). The results showed a strong propensity of respondents to leverage factors external to the resource, for which they have no control, as opposed to internal factors that they could manage. Specifically, the opportunity to increase awareness of the role and importance of ecosystem services, the implementation of projects targeting the chestnut tree, and the need to reduce and reverse the trend of depopulation of mountainous areas appear to be the priority factors on which to act. The results of the work point to the potential for expansion and replicability of our analysis to larger spatial scales, while also highlighting some limitations that future studies should address, such as the inherent limits of AHP depending on the objective and the need, therefore, to combine it with other multi-criteria analysis techniques and the need to stimulate stakeholders motivation to participate in such decision-making processes from the outset, otherwise there is a risk of poor adherence.

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

A comprehensive analysis of the most relevant uptake factors for agroforestry systems

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Sabine Reinecke[1]
Fernando Esteban Montero de Oliveira[1]
[1] University of Freiburg, Chair of Silviculture, Forestry and Rural Development

Abstract: Agroforestry systems (AFS) offer various socio-economic and ecological benefits but can hardly outcompete monocultural approaches in practice. Despite their key role for climate change mitigation, and adaptation, AFS adoption, diffusion, and scaling have not kept pace with the urgency of the global problems they may help address. AFS are even disappearing in the European Union mainly due to agricultural intensification and unfavorable policies. Although the literature on AFS adoption is rich and extensive, it remains somewhat scattered, disciplinarily siloed and therefore inconclusive as to fully understand exactly when, why, how, and by whom AFS are taken up in practice. For instance, several studies put emphasis on farmers' agency, while others highlight mainly environmental constraints or structural issues including market access and policy frameworks. Overall, many existing studies remain conceptually limited within their specific disciplines, or disproportionately focus only on specific regions, like Asia and Africa, undermining to gain a more complete understanding of technology appropriation at scale. To address the pertaining knowledge derangement, we conducted a configurative review of AFS adoption arguments from different disciplines and world regions, aiming at understanding and ordering the key factors behind what makes AFS desirable, practicable, and applicable in different contexts. Our narrative and iterative approach to synthesizing the state of knowledge goes well beyond classical meta-analytical approaches to literature review. Our reflexive configurative review explicitly draws on expert and stakeholder perspectives as well as empirical case studies when collecting and re-organizing the key conceptual arguments and supportive evidence on AFS adoption from various disciplines and research traditions. This way our configurative approach helps to identify and differentiate broader narratives and their shared, but also contradictory, arguments, while embracing the complexity and diversity in the AFS adoption literature. When exposing and mapping out the diversity and tensions among different traditions, our review contributes to gaining a more holistic but likewise less tendentious picture of the problem that offers a nuanced knowledge basis for decision-making in policy and practice.

Agroforestry across geographies: seeking "Options by context" that work

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Fernando Esteban Montero-de-Oliveira[1]
Sabine Reinecke[1], Sebastian Mayr[1]
[1] Freiburg University, Faculty for Environment and Natural Resources, Institute of Forest Sciences

Abstract: Agroforestry systems (AFS) summarize a collective of land-uses, combining forest and agricultural species, providing long-term economic and ecological benefits. They offer a timely and readily available approach to addressing climate change, ensuring food security, and promoting sustainable rural development in much more (land) efficient ways than intensive monoculture farming. However, policies and rural development programs prioritize and promote supposedly economically more viable monoculture approaches to agricultural commodity production, limiting the spread of more integrated systems. Despite limited policy support, innovative AFS approaches have emerged and, at least at small scales and in niches, demonstrated ecological, social and economic benefits. Apparently. the process of technology uptake in agriculture is far more complex and nonlinear and rests in more factors than just supportive policies. Better understanding what makes farmers adopt a niche technology – against all odds – can therefore be highly authoritative for designing better policies for widespread adoption. Existing theories and single-focused approaches of what determines AFS adoption often fall short of providing a comprehensive and holistic understanding of when and why smallholders (or farmers more generally) adopt (or not) agroforestry within their distinct situations. To capture the heterogeneity of farmers' responses across different geographical contexts, this study employs the "Options by Context" conceptual framework. Integrating the theory of affordance and the innovation system, the framework helps us getting a more comprehensive understanding of the socio-economic, political, and household contexts, in which AFS interventions emerge, resist, adapt, or transform. Data from two distinct case studies (Eastern Amazon in Brazil and Upper Rhine region across Germany, France and Switzerland) help us empirically substantiate and ground-truth the varied driving forces behind technology appropriation (i.e., adoption, non-adoption, mal-adaptation, diffusion) at farm level in different contexts. By delving into diverse contexts, in which AFS adoption occurs, we seek to get a more complete understanding of the complex decision-making processes and of what exactly motivates (or not) farmers to adopt AFS vis-à-vis specific contextual factors, like subsidies or legal frameworks. This way the paper provides key insights needed for re-designing those very context-specific policies in a way that they may promote rather than hinder widespread AFS adoption.

Agroforestry as a climate-resilient development path

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

[3] West Africa Science Service Centre on Climate Change and Adapted Land Use (WASCAL) Graduate Research Program on Climate Change and Biodiversity, Université Félix Houphouët-Boigny, Abidjan, Côte d'Ivoire.
[4] World Agroforestry Centre, P O Box 30677, Nairobi, Kenya

Abstract: In most parts of Africa, Asia and tropical America, agroforestry is not new. There are traditional agroforestry practices spanning centuries. Examples include the Moringa-based agroforestry system in Ethiopia, the parkland systems of the Sahel, the Gedo home garden cultural landscapes in Ethiopia, coffee agroforestry systems, *Faidherbia albida*-based cropping system in Malawi, , rotational woodlots in Kenya, multistory home gardens in Mt. Kilimanjaro, cocoa systems in Cameroon, Cocoa agroforestry sysetems inCôte d'Ivoire and farmer-managed natural regeneration in the Sahel. Agroforestry is also gaining ground in the global North.

As a result of their diversity, agroforestry systems are more resilient to environmental shocks and the effects of climate change than conventional agriculture. Trees serve as safety nets in times of emergency such as natural disasters (e.g., floods and droughts). Trees substantially cool cities. Agroforestry provides a range of other benefits – food and nutrition security, improved health and well-being, and livelihoods. In addition, homestead agroforestry empowers women and youth. Agroforestry connects habitats and provides corridors for vulnerable species. Depending on the system and local conditions, agroforestry can enhance biodiversity, restore wildlife habitats, it guarantees the balance of ecosystems.

Despite its multiple benefits, the adoption of agroforestry has not been widespread in many parts of Africa. Nevertheless, some general principles for their wider adoption, from lessons learned so far, in Africa and research needs to better understand the challenges and opportunities at the local and global level will be presented and discussed.

Agroforestry as a Resilient Land Use Strategy in Central Asia: Exploring Sustainable Management of Apricot Orchards in Kyrgyzstan

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Philip Schierning
Malte Finn Hauke Oetker[1], Florian Wichern[1], Jens Gebauer[2]
[1] Soil Science and Plant Nutrition, Faculty of Life Sciences, Rhine-Waal University of Applied Sciences, Germany
[2] Sustainable Agricultural Production Systems, Faculty of Life Sciences, Rhine-Waal University of Applied Sciences, Germany

Abstract: Central Asia, a region highly vulnerable to climate change impacts, presents an urgent need for adaptive land practices. This study focuses on the existing sustainable management of apricot orchards in the arid Kyrgyz border region of Batken, combining trees with crops, specifically alfalfa, to address these challenges. Agroforestry systems offer a promising solution by integrating ecological resilience with agricultural productivity. Understanding the management principles and carbon cycling within such systems is essential for achieving sustainable livelihoods and a healthy environment.

By evaluating the interactions between apricot trees and alfalfa crops, considering site-specific characteristics, we aim to identify resilient practices of withstanding climate change while conserving biodiversity, soil health, and water resources. Additionally, we investigate the carbon cycle within the agroforestry system to assess its contribution to climate change mitigation and the potential for carbon sequestration.

Our findings emphasize the role of agroforestry as an effective climate change adaptation strategy in Central Asia, specifically in the context of apricot orchards integrated with arable crops. These systems not only enhance ecosystem services but also maintain agricultural production, provide economic opportunities, supporting rural employment from nursery management to product processing and marketing. By sharing design and management principles, innovative technologies, and local insights, we can maximize the full potential of agroforestry systems and contribute to a more sustainable future.

Agroforestry systems and their function as islands of biodiversity in human dominated environments

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

[4] Bioren Systems, 16 Andrew Circle, Hampden, MA 01036, U.S.A.

Abstract: Given their ability to harmonize productivity with environmental functions, agroforestry systems (AFS) are an important strategy for conservation within human managed landscapes. AFS are heterogeneous in their design, management, and species composition, with consequences for their restoration, conservation, and productivity functions. AFS can function as biodiversity islands (BI) or areas of land with greater diversity than surrounding areas, where plant and animal species can thrive without major interference from human activity. More complex multistrata AFS such as many indigenous land use systems, homegardens, successional agroforestry and intensive silvopastoral systems hold higher conservation values than more simplified AFS and may constitute BIs themselves. Other less complex AFS may be part of a BI, or form part of a buffer zone of different categories of protected areas. In all cases, the inclusion of AFS within a human dominated landscape provides greater biodiversity than conventional agriculture or degraded areas. However, the positive role of AFS on biodiversity should not justify land use change from natural forest. Rather, AFS can be integrated into landscapes already dedicated to agriculture, afforestation, and other productive land uses.

This presentation provides an overview of the various ecological, social, and economic benefits of the main types of AFS and their applications as and within BI, expanding on their role in providing critical ecosystem services. Moreover, it discusses the use of incentives such as Payments for Ecosystem Services (PES), credits, international funding and government programs to support and promote AFS, safeguarding the contributions they provide to landscape biodiversity and rural communities. Finally, the role of government initiatives in supporting agroecological transitions from conventional agriculture is described, with updates from the USA and Latin America. These programs support the role of AFS and climate-smart agroecology over conventional agriculture, reinforcing the contributions of AFS to the consecution of the Sustainable Development Goals (SDG) and the conservation of biodiversity in agricultural landscapes.

Assessing Environmental Impacts and Carbon Stocks in Temperate Agroforestry Systems with Sheep and Cattle: A Systematic Map

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Gillian Petrokofsky[1, 2]
Leo Petrokofsky[1], William J Harvey[1, 2], Matthew Jordon[2, 3]
[1] Oxford Systematic Reviews
[2] University of Oxford
[3] Regenerate Outcomes

Abstract: The escalating challenges of climate change and biodiversity loss necessitate innovative approaches in agricultural land management, specifically, in temperate ruminant livestock farming. Current farming practices contribute to greenhouse gas emissions (GHGEs), air pollution, increased flood hazard, reduced water quality, and enhanced soil erosion. This study presents a systematic map exploring the potential of agroforestry - the re-integration of trees and farming systems - as a strategy to alleviate these environmental impacts, while maintaining productivity and economic viability. Building upon an existing systematic map, this systematic evidence map focuses specifically on the environmental impacts and carbon stocks in temperate agroforestry systems with sheep and cattle. This evidence map follows best practice guidance to search for, select, and synthesise pertinent studies on the environmental impacts and carbon stock implications of integrating trees into temperate ruminant production systems. An interactive online map is presented, which is free to use and encompasses multiple filters based on topics and time slices. Links are provided to the included studies (full-text if open access, or bibliographic information only, where articles are in journals requiring subscriptions). The systematic evidence map of relevant studies offers a valuable tool to guide decision-making by land managers, academics, and policymakers across temperate regions, highlighting knowledge gaps and potential areas for future research.

Certified community forestry in endemic Boswellia species conservation - case study from Socotra Island

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Petr Madera[1]
Petr Vahalík[1], Kay Van Damme[1, 2], Salem Hamdiah[1, 3], Fabio Attorre[4], Dario La Montagna[4]
[1] Mendel University in Brno
[2] Ghent University
[3] University of Ljubljana
[4] Sapienza University in Roma

Abstract: Globally, frankincense trees (Burseraceae: *Boswellia*) are increasingly under threat due to habitat deterioration, climate impacts and the olibanum trade. Despite harbouring nearly half of the species in the genus, up-to-date insights are lacking for the insular frankincense trees of the Socotra Archipelago UNESCO World Heritage Site (Yemen). We present an overview of key conservation data for all eleven endemic *Boswellia* taxa occurring in the Socotra Archipelago. We discuss the current distribution in detail and evaluate threats based on new on-the-ground surveys in 2020-2022. Our field data support that the Socotran frankincense trees are endangered by fragmentation and overgrazing resulting in a lack of natural regeneration, in combination with effects of climate change some species´ populations are near to extinction. We suggest the certified community agroforestry silvo-pastoral system to manage the woodlands with Boswellia spp. populations in sustainable way. Involvement of local communities in Boswellia trees conservation is only possible way how to save these unique trees from extinction.

Chlorophyll Content of nine selected Crops at Different Temperature and Light conditions

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Wrojay Bardee Potter, Jr.[1]
[1] Department of Plant and Soil Sciences, Cuttington University

Abstract: Shifting cultivation is still a major form of agriculture pracictice in Liberia, which is a concern for forest conservation in Liberia and way to increase production for smallholder farmers. Understanding the role played by temperature and light intensity on chlorophyll content of plants remains a minor priority for farmers and many researchers in Liberia that could help reducesd the need for shifting cultivation. A lab experiment was conducted in the Plant and Soil Science Laboratory of the Department of Plant and Soil Science (PSS) on nine selected crops of different taxonomical classes, crop type, growth type, temperature and light requirements grown in the Upper Highland Tropical Forest Agro-Ecological Zone (UHTF AEZ) of the Suakoko District, Bong County from November 2022-March 2023. The aim of this study was to assess the effect of temperature and light intensity on chlorophyll content of the selected crops at CASD. Results of the study show that among all the nine crops, pepper has the most significant chlorophyll content while corn recorded the least chlorophyll content. Temperature and light intensity have significant effect on Chlorophyll content and growth and development of plant. Results of the study also show that chlorophyll contents were higher in higher temperature and light conditions with corresponding higher yields. The null hypothesis of the study was therefore rejected while the alternative hypothesis was accepted as temperature and light intensity had significant effect on Chlorophyll content and plant growth and development.

Complex agroforestry systems for promoted ecosystem services

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Eva-Maria L. Minarsch[1]
Andreas Gattinger[1], Philipp Weckenbrock[1]
[1] Chair of Organic Farming with Focus on Sustainable Soil use, Justus-Liebig-University Giessen, Germany

Abstract: Soil erosion, droughts, nutrient leaching, and biodiversity loss pose significant challenges for agriculture. Agroforestry systems, integrating woody plants into agricultural land, offer potential solutions. These systems have been found to positively influence microclimate, soil erosion, water availability, and biodiversity. By using multiple tree species on the same land, ecosystem services like biodiversity and carbon sequestration can be further enhanced. However, there is a lack of practical examples and research on agroforestry systems in temperate regions.

At Gladbacherhof, a teaching and experimental farm of the Justus-Liebig-University Gießen in Germany, three alley cropping systems were established to reduce erosion on arable land and provide shade for pasture animals. These systems cover around 15 hectares and comprise different tree strip planting schemes. The tree strips, 3-4 meters wide, alternate with 18-meter-wide arable strips. The tree use types include fruit, valuable timber, and biomass trees organized in simple and complex tree strip planting schemes. Simple strips consist of a single tree use type, based on well-known agroforestry systems like orchard, short-rotation coppice, and valuable timber. Complex strips combine multiple tree use types, aiming for a multi-layered structure with high-pruned valuable timber trees, apple trees, and elderberry shrubs. Biomass trees in the complex strips are removed and serve as mulch after the initial years, following the concept of successional agroforestry.

These long-term field trials at Gladbacherhof serve as practical examples for land managers and others. The accompanying scientific research focuses on management factors, ecological services (including soil fertility, water availability and biodiversity), and developing recommendations for agricultural subsidies. This contribution presents the design, research, experiences in planning and maintenance, and initial results on ecosystem services.

Does Shade Impact Coffee Yield, Tree Trunk, and Soil Moisture on Coffea canephora Plantations in Mondulkiri, Cambodia?

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Lenka Ehrenbergerová[1]
Marie Klimková[1], Yessika Garcia Cano[1], Hana Habrová[1], Samuel Lvončík[1], Daniel Volařík[1], Warbota Khum[2], Petr Němec[1], Soben Kim[2], Petr Maděra[1]
[1] Mendel University in Brno, Zemědělská 1, Brno 61 300, Czech Republic
[2] Royal University of Agriculture, Cambodia

Abstract: Coffee crops are highly sensitive to climate change, whereas robusta is more adaptable than arabica and able to thrive in warmer and lower land conditions. For these reasons, knowledge of the impact of shading on the yield of robusta coffee is extremely important as decreasing yield is one of the reasons why farmers do not grow coffee within the agroforestry system. The necessity to determine the effects of shade on the yield of *Coffea canephora* and on the soil water availability is obvious. Three coffee plantations in the province of Mondulkiri, were selected to evaluate the effect of shade on *Coffea canephora* yields, coffee trunk changes, and soil moisture. Shade-grown coffee has the same yields in terms of coffee bean weight or size, the total weight of coffee fruits per coffee shrub and the total weight of 100 fruits (fresh and dry) as coffee grown without shading. Additionally, fruit ripeness was not influenced by shade in terms of variability neither in terms of delay in ripening. Soil moisture was higher throughout shaded sites. These results show that the plants were not affected by the lower soil moisture in sunny sites or higher soil moisture in shaded sites, which may indicate that competition for water did not occur between coffee tree and shade tree roots in the studied plantations. In our study, in the morning the trunk of the coffee tree shrinks and, after 12 p.m., it grows again. The changes in coffee trunk diameter are visibly connected (especially in the dry season) with the curves of air humidity and temperature on studied localities. These daily changes were more pronounced on sunny sites. Our findings indicate that planting robusta coffee in agroforestry systems will not cause losses in yield for individual coffee plants. Considering the ecological attributes and ecosystem service benefits of agroforestry, such as increased biodiversity and landscape diversity, providing soil protection, increasing the carbon stock, and providing sources of fuel wood and construction material, we suggest maintaining and planting *Coffea canephora* in agroforestry shade-based systems, as coffee producers transition away from monoculture plantations.

Enhancing landscape connectivity through agroforests: The case of Gedeo's agroforests in Ethiopia

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Hafte Mebrahten Tesfay[1]
Mesele Negash[2]
[1] Department of Forest Biodiversity and Nature Conservation, Federal Research and Training Centre for Forests, Natural Hazards and Landscape, Seckendorff-Gudent-Weg 8, A-1131 Vienna, Austria
[2] Department of Agroforestry, Wondogenet College of Forestry and Natural Resources, Hawassa University, Shashemene P.O. Box 128, Ethiopia.

Abstract: *The Gedeo agroforested cultural landscape in Ethiopia is recognized as a leading example of sustainable agroforestry practices. It mimics and resembles with natural forest. The agroforest is characterized by vertically and horizontally diverse composition, structure, and functionality, which contribute to on-farm conservation, environmental well-being, and livelihood support systems. Numerous studies have highlighted the positive impacts of agroforests in the landscape on circa situm biodiversity conservation, implicating conservation of biodiversity through utilization. The agroforest provides additional habitats for species that are sensitive to disturbance, conserve gene pools of native tree species, enhance microbial, avian, and faunal diversities. They also act as a buffer against forest degradation and deforestation in the surrounding natural habitat, while connecting fragmented habitats for floral and faunal species through the creation of corridors and stepping stones. Agroforests in the Gedeo landscape serve as important havens for preserving high levels of diversity. The smallholder agroforests play a crucial role in conserving tropical woody plant species as circa situm reservoirs of biodiversity in agricultural environments. Previous studies have shown that with a diverse species composition the agroforest contributes significantly to biomass and carbon storage, which in turn helps mitigate climate change. For the Gedeo people, agroforestry is not just a supplementary livelihood activity but a mainstay. Therefore the Gedeo agroforests have a great role in enhancing the landscape connectivity and hence, contributing to the integrity and sustainability of the system. However, the Gedeo agroforests face challenges such as land degradation, land fragmentation, emergency of lucrative monocropping cash crops, climate change, and limited market access, as well as lack of financial resources, and insufficient technical knowledge and training*.

Key words: Agroforest, landscape connectivity, circa situm conservation, Gedeo landscape

Evaluating Melientha suavis Agroforestry Systems for Climate Resilience

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Wirongrong Duangjai
Nittaya Mianmit[1], Narinthon Chumwong[1], Phruet Racharak[1]
[1] Kasetsart University

Abstract: Evaluating *Melientha suavis* Agroforestry Systems for Climate Resilience

Agroforestry, the practice of integrating trees with crops, is beneficial for farmers due to its multifaceted returns. This study focuses on *Melientha suavis*, a Thai tree crop known for its edible shoots, as the main element in an agroforestry system. Intercropping M. *suavis* with various companion tree species not only fosters suitable microclimatic conditions for M. *suavis* shoot production but also offers additional income through fruit or timber, promotes soil conservation, and unlocks the potential for financial gains from carbon credits. The study compared two M. *suavis* agroforestry systems in terms of productivity, carbon sequestration potential, and co-benefits, particularly when intercropped with fruit trees and native timber trees. Data were collected through on-field measurements of M. *suavis* and companion trees across six farms over three seasons, complemented by farmer interviews. The variables measured included productivity, carbon storage, microclimate, and soil conditions, with farmer interviews used to understand farm management practices and socio-economic benefits. Our findings show that farm microclimate variations significantly impact the growth of M. *suavis* and its associated tree species. Native timber trees were found to optimize microclimate and soil conditions, thereby improving M. *suavis* productivity. The system that saw M. *suavis* intercropped with fruit trees demonstrated the highest carbon storage—29.17 tCO_2/rai over 24 years, but this was offset by high input requirements and unstable market prices. In contrast, M. *suavis* intercropped with various timber tree species showed lower carbon storage (21.02 tCO_2/rai over 22 years). However, due to its more stable income and market conditions, this system presents a viable alternative. In light of increasing drought risks, the study concludes that agroforestry practices - especially those involving the cultivation of M. *suavis* - can enhance climate resilience and contribute to sustainable carbon sequestration efforts.

Impacts of Climate Changes and Adaptation Measures of Local People in Central Highlands of Viet Nam

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Tran Nghi[1]
[1] Tropenbos Viet Nam

Abstract: Central Highlands is located in the central part of Viet Nam where is the home of difference ethnic minorities groups and have a lot of traditional customs on the agriculture production and society. This is also famous for many perennial crops which contribute to local and national economy and generate income for local communities. There are several major crops including Coffee, black Pepper and Rubber, cultivated in the Central Highlands. These crops have contributed to the economic development of the region but have also created problems and challenges for local communities and authorities as well, including (add challenges – conflict over land? Land degradation?).

In recent years, the impact of climate change is becoming clear in the region: There are more and stronger rains in the rainy season, which cause a lot of landslides and flooding. On the other hand, the longer dry season and stronger winds lead to water scarcity, which has an impact on crop irrigation and has caused more and bigger forest fires.

In response to these changes, local communities have started to apply different measures for adapting to the changes in weather and its impacts. This includes: planting more multipurpose trees (for shade, timber and non-timber products) in the coffee plantation, with the aim to reduce water evaporation under strong sun light, and avoid the soil erosion. Tropenbos Vietnam, through its Green Livelihoods Alliance Programme, has supported in capacity building of farmer associations and communities in these agroforestry practices, and supported the development of demonstration models. We have also organised exchange visits, for farmers from different parts of the landscape to learn from each other, and facilitated the local government in the development of new policies for climate change adaptation.

The presentation will not only address the technical solutions but also talk about the governance and monitoring aspects in the climate change adaptation process in the landscape

Integrated approaches for food, energy and environment: lessons from Asia, Africa and Europe

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Himlal Baral[1]
Dietmar Stoian[1], Mary Njenga[1], Christopher Martius[1]
[1] Center for International Forestry Research and World Agroforestry (CIFOR-ICRAF)

Abstract: The demand for woody biomass for energy and biomaterial is increasing rapidly in line with the rise in global populations and changing consumption patterns for sustainable resources. Central to meeting this demand is answering the question of how woody biomass and biofuel production and use can be reconciled with food production, biodiversity protection, climate-change resilience and mitigation, and inclusive prosperity for local communities. In many cases, policy and development interventions tend to address these issues in isolation whereas they are interconnected.

CIFOR-ICRAF and partners propose — and are demonstrating — integrated approaches to food and energy security that focus on bioeconomy opportunities and are based on agroecological principles. Such opportunities are identified with a view of value chains for diverse bioeconomic products, such as food crops, woody biomass for energy, and non-timber forest products. In terms of agroecological principles, emphasis is on measures to increase soil fertility and the diversity of plant and animal species and on improving control of pests and diseases, management of water and promotion of a combination of multi-structured land uses.

This talk highlights such approaches with examples from across diverse geographies and settings. In Southeast Asia, integrated approaches to climate-smart agroforestry produce a variety of food, energy and biomaterial while restoring degraded landscapes. In Sub-Saharan Africa, a balanced agroforestry approach considers demand and supply dynamics in wood-energy value chains, food production, recovery of waste bioresources for energy, and the use of improved kilns and stoves, with a significant impact on improving smallholders' livelihoods and reducing pressure on forests. In the Western Balkans, the combination of short-rotation plantations of fast-growing tree species (willow, poplar), agroforestry borders and permanent tree areas enhances energy security, income generation and biodiversity in landscapes otherwise dominated by the production of wheat, maize and sunflowers while at the same time contributing to the urgently needed energy transition away from coal.

Our findings indicate integrated approaches to bioeconomy based on agroecological principles are an often-overlooked pathway to producing healthy foods, providing sustainable energy, reducing greenhouse gas emissions, creating equitable jobs and prosperity, and conserving biodiversity at global scale.

Minimum support price of farm-grown wood: How relevant will it be?

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Dinesh Kumar[1]
[1] ICFRE-Forest Research Institute, Dehradun, India

Abstract: Agroforestry is widely recognised as a tool to increase farm productivity and diversify income sources of farmers while providing various environmental services. Agroforestry is an age-old practice which has traditionally been used by farmers to meet their domestic requirements. It has been considerably refined through research during the last four decades and is now being adopted by farmers on commercial lines with a more conscious selection of species and intensive management. Agroforestry has been supported by the government through need-based policy changes during this journey. As the prices of agricultural produce vary frequently, fluctuations are witnessed in prices of wood as well. The fluctuation is quite marked in prices of *Populus deltoides* wood.

The government of India provides minimum support price (MSP) to many agricultural crops. MSP is fixed by the government of India and markets operated by the government are encouraged to buy produce at or above the MSP. MSP is usually fixed around one-and-a-half times the cost of production incurred by the farmers. The MSP is announced in the beginning of the sowing season of crops and protects the farmers in case of excessive fall in price during bumper production years. Crops which receive a more steep increase in MSP at the beginning of a sowing season are able to attract more growers during that season. This intervention helps the government indirectly regulate the extent of area under different crops.

Trees are long-gestation crops and it is not possible foresee the price scenario at time of harvest. They are subject to longer period of uncertainties on account of changing weather, pests and diseases. An assurance about minimum price would go a long way in encouraging the farmers about threshold price in the market. Farmers have been demanding a system of providing MSP for farm-grown wood for long time, especially for poplars. A critical analysis has been done by the author which showed that MSP would not be able to solve the problem for growers of poplar and possibly other species too.

Potential of agroforestry as win-win solution to enhance livelihood and biodiversity of the degraded Sal forest in Bangladesh

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Kazi Kamrul Islam[1]
Noriko Sato[2], Takahiro Fujiwara[2], Kimihiko Hyakumura[3]
[1] Department of Agroforestry, Bangladesh Agricultural University, Mymensingh-2202, Bangladesh
[2] Forest Policy Laboratory, Kyushu University, Fukuoka, 819-0385, Japan
[3] Institute of Tropical Agriculture, Kyushu University, Fukuoka,819-0385, Japan

Abstract: Agroforestry in the degraded forestland has gained enormous attention from traditional to people-oriented forest management approaches in Bangladesh. Various types of tree-crop combinations of agroforestry practices in the degraded forestland support the basic needs, increase species richness and alleviate the poverty of millions of small-scale farmers. Thus, the study tried to identify the impacts of agroforestry practices on the livelihood improvement of forest-dependent people and biodiversity conservation of Sal forests in Bangladesh. The study was conducted in the Madhupur Sal forest of Bangladesh, which is considered an economically and ecologically important moist deciduous Sal (*Shorea robusta*) forest in Bangladesh. The study used mixed-methods data collection techniques such as interviews with 100 farmers for livelihood analysis and quadrat (20m × 20m) sampling techniques for biodiversity measurements from 2020 to 2022. The results found that the most common features of the agroforestry practices were the contribution of financial income and improvements to the physical and natural assets of the forest dependent farmers. Farmer training programs were sufficiently developed to increase 82% of farmers' capacity on how to cultivate profitable tree-crop based agroforestry practices on their farms; however, their social asset development faced some constraints and difficulties. At the same time, agroforestry practices restored 34 plant species to the depleted Sal forest. The fast-growing tree species, mainly *Acacia spp*., in association with pineapple, ginger, aroid and turmeric crops, were the most dominant species in the degraded Madhupur Sal forest. The study also revealed that agroforestry serves as a wildlife corridor and attracts birds for breeding and feeding. Despite its limitations on the development of farmers' social assets, agroforestry is a viable land-use practice to improve farmers livelihoods and biodiversity conservation in degraded Sal forest in Bangladesh. Therefore, the study recommended implementing high yielding agroforestry models under the direct patronage of the local government and involving all stakeholders in a more sustainable way.

Sustainable Agro-forestry Practices for Climate Adaptation and Mitigation: A case study of Kerala

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Annie Biju[1]
Vaisakhy Prem Chand[1], Swathi S[1]
[1] Forest Research Institute, Dehradun

Abstract: Agroforestry shows promise for co-delivery of adaptation to and mitigation of climate change. Agrisilvicultural, silvopastoral, and agrosilvopastoral systems constitute the dominant agroforestry types of Kerala. Examples are numerous: tropical homegardens, plantation crop - food crop combinations, jackfruit tree and palm-based food production systems, integrated agriculture-aquaculture systems—agrosilvofishery systems, small holder livestock production systems and so on. Home gardens are physiognomically similar to evergreen forests because they are composed of a variety of different trees and plants and are arranged in a multi-tiered, intimately interconnected pattern. Dominant trees include the coconut (*Cocos nucifera*), arecanut (*Areca catechu*), and para-rubber (*Hevea brasiliensis*); in addition to a large number of multipurpose trees (MPTs), including mango (*Mangifera indica*), jack (*Artocarpus heterophyllus*), teak (*Tectona grandis*), cashew (*Anacardium occidentale*). In this present paper, we focus on the prevalent agroforestry practices and commodities as well as its significant social, economical and environmental benefits to the society. We also discuss in detail social and technical barriers that limit the implementation of adaptation and mitigation practices in agroforestry. We will propose comprehensive alternative solutions to agroforestry and consider rational and sound changes for regulations and encourage farmer adoption. We will come to the conclusion that agroforestry is one of the finest land-use techniques for promoting food security while also reducing environmental deterioration in the case of state of Kerala, India.

Unleashing Payments for Ecosystem Services applied to agroforestry: state of research and policy implications

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

Sebastian Mayr[1]
Sabine Reinecke[1], Fernando Esteban Montero-de-Oliveira[1], Benno Pokorny[1]
[1] University of Freiburg, Faculty of Environment and Natural Resources, Institute of Forest Sciences

Abstract: Both Payments for ecosystem services (PES) and agroforestry have been increasingly attracting the attention of policy-makers and scholars alike, which has led to an increasing amount of literature in these research fields. Accordingly, syntheses on the state-of-art and performance of those payments have been performed both cross-sectoral and sector-specific, such as for water services or forest-related services. However, no such synthesis has been performed yet on payments for ecosystem services applied to agroforestry or, broadly spoken, to trees and carbon removals in agriculture. Therefore, this synthesis aims to provide an overview of the current state of research on this topic including policy implications. We examine a wide range of relevant literature from various disciplines, including environmental science, economics and policy analysis. We identify payment types, explores the effectiveness of payment schemes in achieving carbon sequestration and other environmental objectives and identify factors explaining the effectiveness of those schemes. The review also discusses key policy considerations for designing and implementing effective payment schemes such as the role of public-private partnerships and monitoring and verification mechanisms. Overall, the review highlights the potential for payments for ecosystem services and carbon removal to contribute to sustainable agricultural development and climate change mitigation, and identifies key areas for future research and policy development.

Valuing under-utilized green manure of available agroforestry species: Potential organic input sources in humid highland and semi-arid areas

T2.27 SMART (Sustainable Modern Acceptable Resilient Technological) Agroforestry Practices for Sustainable Livelihood and healthy environment

VESTINE MUKAMPARIRWA[1]

[3] University of Rwanda, Department of Forestryand Nature Conservation, Rwanda

Abstract: In Rwanda, land degradation is a major challenge threatening food production, and soil and water conservation measures are insufficient. Building the resilience of food systems requires urgent action to prevent and reverse land degradation and restore soil health. Green manure from agroforestry trees can increase soil nutrient inputs via litter decomposition and hence contribute to replenishing soil fertility and enhancing food security. Even though agroforestry is widely promoted in Rwanda, native agroforestry tree species are undervalued and under-utilized as potential sources of nutrients. The aim of this study was to investigate litter decomposition rates and nutrient release patterns from six agroforestry tree species grouped into three categories: Exotic N-fixing species (*Alnus acuminata* and *Calliandra calothyrsus*), farmer-preferred species (*Eucalyptus globulus* and *Grevillea robusta*) and native species (*Markhamia lutea* and *Croton megalocarpus*). We conducted a litterbag field experiment in two regions of Rwanda during the wet and dry seasons. Changes in litter mass loss and chemical composition (C, N, P, K, lignin and polyphenol) were determined. Our results highlight the importance of revisiting native and exotic N-fixing tree species that deliver higher green manure quality than the most prevalent agroforestry tree species. While native species have been largely overlooked in agroforestry, our findings show they offer great potential as sources of high-quality green manure. We hope these results will contribute to guiding ongoing tree-based restoration efforts in Rwanda and across the region for enhanced food security and biodiversity.

Key-words: Green manure, leaf litter decomposition, soil fertility, tree-based restoration, agroforestry.

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Assessing the sustainability of harvesting practices in the southeastern US to meet European renewable energy goals: a review

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

[3] Virginia Tech, Forest Resource and Environmental Conservation, USA

Abstract: The transition towards renewable energy sources over the last decade has generated a surge in demand for sustainable alternatives, notably woody biomass. In Europe, this demand is driven by the creation of legislation, such as the Renewable Energy Directive passed by the European Union (EU) member states, which determines biomass utilization and practices. As a result of the heightened demand, biomass production in the southeastern United States (US) has expanded, giving rise to concerns regarding the intensified removal of residual material, distribution and spatial allocation of residues, and potential ramifications for site nutrients, erosion rates, and water quality. Due to the relatively recent market developments, there is limited literature evaluating biomass market effects on forest management practices and site sustainability. With the continued growth and utilization of woody material as a source of bioenergy it is important to further our understanding of wood pellet harvesting practices and evaluate the sustainability of accelerated removal of forest residuals. Therefore, the primary objective of this study was to evaluate the status of knowledge related to biomass harvesting in order to provide a baseline for future policy, practice, and implementation. Environmental, social, and governance impacts from biomass harvesting practices were categorized to gauge a full scope of sustainable harvest practices. Three key themes were outlined: international bioenergy demand interactions, public perception, and harvest characteristics. Our survey of existing literature revealed that there is a lack of research evaluating residual retention across the southeastern US. There are minimal field studies assessing biomass harvesting, and effectively no studies assessing wood pellet operations. These markets are growing at an expedited rate, and it is important to characterize these operations to better understand regional resource utilization, changes in forested land allocation, and the quality of post-harvest features.

Biomass expansion factors for commercial and restoration forest plantations in Brazil: developing specific factors for tropical regions

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Abstract: Carbon sequestration by forest plantations, for commercial or restoration purposes, is a nature-based solution to mitigate the impacts of climate change. One of the methodologies suggested by IPCC to quantify carbon sequestration in biomass by forest plantations is to use biomass expansion factors. These factors derive aboveground (BEF) and belowground biomass (R) and carbon information from merchantable bole volume, based on regular inventory of diameter at breast height (DBH) and total height measurements. Currently, most of the IPCC default BEF and R values are based on data from studies in the northern hemisphere and might not be accurately applied to forest plantations in Brazil. Few studies have been carried out to determine BEF and R factors for Brazilian forest plantations due to the high cost of sampling. Therefore, we integrated a dataset of thousands of destructively sampled trees under field conditions, from *Eucalyptus*, *Pinus* and Brazilian native tree species at contrasting climatic regions and at different stocking and ages over the rotation.

The objectives were to calculate the BEF and R for Brazilian forest plantations and compare those with the factors suggested by IPCC to explore the potential impacts on carbon sequestration calculations for Brazilian forest plantations.

The average values of R in our dataset were higher than those proposed by the IPCC for *Eucalyptus*, *Pinus* and native trees. However, some BEF factors were lower than IPCC values. Despite these average numbers, the distribution range of these factors was large and responsive to climate, stocking and age of the trees.

These results suggest that there are significant differences between Brazilian BEF and R factors and IPCC recommendations and instead of focusing only on average numbers, using other statistical

metrics that explore the distribution of values would be important. Additionally, understanding the relation of BEF and R to climate, soils and age is key to better represent carbon sequestration in living biomass of commercial and restoration forest plantations in Brazil.

Early stand management using an unmanned aerial vehicle to locate trees and measure survival, height, and competing vegetation

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Timothy Albaugh[1]
Francisco Flores[2], Zach Grover[3], David Carter[1], Rachel Cook[4], Otávio Campoe[5], Rafael Rubilar[6]

[6] Universidad de Concepción

Abstract: At an operational scale, early stand management presents difficulties given the large areas under management and limited resources to manage that area. Early survival data is typically generated from a few small plots and, consequently, may not adequately capture survival in the entire stand. Similarly, assessments of competing vegetation will also represent smaller areas with in a stand. Unmanned aerial vehicles (UAV) can be used to generate survival and competing vegetation coverage for the entire stand or a larger sample than normally captured with ground measurements. Additionally, three-dimensional point clouds derived from UAV photographs permit height estimation. We tested a system to locate and measure individual trees in a pine plantation using an UAV to fly over the area while taking multiple photographs on a rectangular grid pattern. Flights were planned and managed using readily available applications (i.e. PIX4D, Drone Deploy Flight) to fly a DJI Phantom 4 with a 12.4 megapixel camera. Images were processed using WebODM to generate a point cloud. We tested different UAV flying altitudes and identified the optimum flying altitude (66 m), which produced the best height estimates with a reasonable flight time for trees 0.4 to 5.0 m tall. UAV height measurements were well correlated with field measurements. UAV tree locations were well matched with locations acquired using a sub centimeter global positioning system. We determined competing vegetation coverage area and height from the same flight used for the tree location and measurements. Flight time for a four hectare stand was ~25 minutes. Post flight processing to generate point clouds, orthophotos, and digital surface and terrain models was automated and only required image uploading. Additional metrics could be extracted from the data including crown size (estimating leaf area index), growth over time with repeated flights, and identification of underperforming areas within a stand that may require additional treatment. The combination of precise geolocation and the ability to generate metrics of tree size, location, and competing vegetation presence, provides an opportunity to characterize stand establishment performance, and the possibility of creating a system based on multidimensional spatially explicit records to help explain future stand performance.

Economic analysis of mixed forest plantations in the Southeastern US

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Jonas Moller[1]
Andres Susaeta[2], Ajay Sharma[3], Peter Deegen[1]
[1] TU Dresden
[2] Oregon State University
[3] Auburn University

Abstract: The importance of forest plantations has increased rapidly in recent decades. Although they occupy 3% of the world's forest area forest plantations supply 33% of the global roundwood output. Due to their high profitability easy management, and straightforward ecological relationships, most plantations are managed as pure forest stands. However, a growing number of researchers have indicated the disadvantages of this type of stand structure maintained for the production of timber only. They suggest that pure forest plantations are particularly susceptible to insect outbreaks, pests and forest fires, provide low levels of biodiversity and reduce the range of ecosystem services provided.

Study of mixed forest plantations is necessary to improve the sustainability of forestry, under the assumption that mixed forest plantations are more productive, reduce natural risks, positively impact biodiversity and provide additional ecosystem services in a better way than pure plantations. Obviously, a gap exists between the pure forest plantation management applied in practice and the desired introduction of mixed forest plantations. The aim behind the research presented in this paper is to address some of this gap. The focus of this paper is on the economic analysis of the profitability of mixed forest plantations in the southeastern US.

We compared the economic performance, in terms of land expectation value (LEV), of loblolly pine mixed in various ratios with either white oak or sweetgum, the two commercially important hardwood species of the southeastern United States. The reference for comparison were pure stands with 100% loblolly pine. When considering only timber production, our finding that mixed plantations of loblolly pine and hardwoods are more profitable than pure loblolly pine plantations. The optimal mixture consisted of 1500 trees per hectare at a ratio 75% loblolly pine and 25% sweetgum. The density effect between the loblolly pine trees within the mixed plantation of loblolly pines and sweetgums was the main factor driving the higher profitability of mixed plantations in comparison to the pure plantations. With payments for carbon credits, the most profitable mixture consisted of 2000 trees per hectare in stands consisting of 75% to 100% hardwoods.

Evaluating Pinus taeda L. crown morphology development and its impact upon stem volume through UAV laser scanning derived datasets

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Matthew Sumnall[1]

[4] Universidad de Concepción

Abstract: Individual tree growth is associated with the size, shape and efficiency of its crown, which represents an expression of resource acquisition. Many existing tree crown models are based on simple symmetric three-dimensional shapes, which often do not accurately represent crown shape. Remote sensing data could overcome this limitation and provide information over large areas. We used high-pulse density airborne laser scanning (ALS), from unoccupied aerial vehicles, to classify individual tree crowns (ITC) for two dates (four years apart) in loblolly pine (*Pinus taeda*) forest. The study included six genotypes, each exhibiting different crown architecture, comprising 1337 trees. We classified potions of the pointcloud for each ITC as part of the tree stem to represent tree center. We approximated 3D ITC exterior using a 3D alphashape. The horizontal distance of the alphashape exterior from the stem at multiple heights was calculated, and the largest distance assessed using circular statistics. The genotypes exhibited significant ($p < 0.05$) preferred direction and difference between the two dates. We used mixed-effect-models (MEM) to evaluate the effects of genotype and 3D alphashape, as represented by the orientation patch count rotated (OPCR) index on stem volume growth. ITC OPCR was significantly related to stem growth. Significant interactions between OPCR and genotype were observed. The effect of direction of ITC crown volume growth in a horizontal direction was evaluated by calculating 3D ITC change in 45° segments from stem center using MEM. Significant main effects and interactions were observed among volume, direction and genotype. Our results provide evidence that ALS can evaluate change within ITCs. This includes determining if there is any preferred direction of expansion and the responsiveness of specific genotypes in utilizing available growing space. Accounting for within tree variability and available 3D growth space could improve our estimates of tree growth over large areas.

Modeling dominant height with USGS 3DEP LiDAR to determine site index in even-aged loblolly pine (Pinus taeda L.) plantations in the southeastern US

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Vicent Agustí Ribas Costa[1, 2]
Aitor Gastón González[1], Rachel Cook[2]
[1] ECOGESFOR Research Group, Departamento de Sistemas y Recursos Naturales, ETSI Montes, Forestal y del Medio Natural, Universidad Politécnica de Madrid, José Antonio Novais 10, 28040 Madrid, Spain
[2] Department of Forestry & Environmental Resources, NC State University, Raleigh, NC 27695, USA

Abstract: Accurate quantification and mapping of forest productivity are critical to understanding and managing forest ecosystems. LiDAR- or photogrammetry-derived point clouds have been used to obtain reliable estimates of canopy heights, yet most of the models rely on expensive data acquisitions. In this context, the use of publicly available data would provide invaluable information for managers and policymakers. We developed models of dominant height using United States Geological Survey (USGS) free LiDAR data with the goal to map site index across loblolly pine (*Pinus taeda* L.) plantations in the southeastern US. We used the 2017 – 2020 national USGS 3D Elevation Program LiDAR acquisitions and explored how different height percentiles, grid output resolutions, time difference between LiDAR acquisitions and ground measurements, tree size, and dominant height definition affected the proposed model. We built the model using 1,301 ground plots from timber industry inventories. The final regression model was constructed with the 95th percentile of the height distribution of the first returns above ground and had a high accuracy in dominant height estimation (R2 = 0.88; RMSE = 1.55 m; RRMSE = 7.65%) at a 20-m pixel basis, yet all the percentile-resolution combinations were found acceptable. Little evidence of effect was found due to time difference when the flight was less than 4 months in advance or after the ground measurement, and it was also found independent of pulse density when this variable was lower than 9.5 pulses m^{-2}. Finally, we assessed the error propagation when translating dominant height to site index, in two commonly used site index models, and found a relative RMSE lower than 10% in both. We found that USGS LiDAR acquisitions can be reliably used to map dominant height as a proxy for forest productivity, adding value to a tool proven widely applicable in time and space. That offers a great opportunity for stakeholders in different fields to use.

Modeling Wood Product Carbon Flows in Southern U.S. Pine Plantations: Implications for Carbon Storage

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Sarah J. Puls[1]
Rachel L. Cook[1], Justin S. Baker[1], Andrew Trlica[1], James L. Rakestraw[2]
[1] NC State University, Department of Forestry and Environmental Resources, United Sates
[2] International Paper in Georgia, USA

Abstract: Wood products continue to store carbon sequestered in forests after harvest and therefore play an important role in the total carbon storage associated with the forest sector. Trade-offs between carbon sequestration/storage in wood product pools and managed forest systems exist, and in order for forest sector carbon modeling to be meaningful, it must link wood product carbon with the specific forest system from which the products originate and have the ability to incorporate *in situ* and *ex situ* carbon synchronously over time. This study uses elements of a life cycle assessment approach, tracing carbon from US southern pine timber harvests to emission, to create a decision support tool that practitioners can use to inform policy design around land- and bioproduct-based mitigation strategies. We estimate that wood products from annual loblolly and shortleaf pine timber harvests across the southern US store 29.7 MtC in the year they enter the market, and 11.4 MtC remain stored after 120 years. We estimate fossil fuel emissions from the procurement, transportation, and manufacturing of these wood products to be 43.3 $MtCO_2e$ $year^{-1}$. We found that composite logs, used to manufacture oriented strand board (OSB), were the most efficient log type for storing carbon, storing around 1.8 times as much carbon as saw logs per tonne of log over 120 years. Results from our analysis suggest that adjusting rotation length based on individual site productivity, reducing methane emissions from landfills, and extending the storage of carbon in key products, such as corrugated boxes, through longer lifespans, higher recycling rates, and less landfill decomposition could result in significant carbon gains. Our results also highlight the benefits of high site productivity to store more carbon in both *in situ* and *ex situ* pools and suggest that shorter rotations could be used to optimize carbon storage on sites when productivity is high.

Precision thinning: Using light detection and ranging to inform row removal selection

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

[2] Federal University of Lavras, Brazil
[3] North Carolina State University, USA
[4] Universidad de Concepcion, Chile

Abstract: Remote sensing technologies are facilitating sub-stand treatments in forests. Near-complete inventory data from LiDAR in loblolly pine (*Pinus taeda* L.) plantations facilitated a case study testing the effect of selecting removal rows in a mechanical thinning operation. Two treatments were implemented on the 64-row, 3.5-hectare study area. One 32-row block used a fourth-row removal scenario which removed the least amount of volume while the other 32-row block used a scenario which removed the most volume. Such deliberate selection of take-rows resulted in a significantly greater volume removed in take-rows and a greater removal of stems ≥ 25 cm in diameter across the high volume removal treatment. Post-thinning LiDAR data were capable of being matched with pre-thinning LiDAR data indicating that monitoring of operator-select removals is possible as is estimating localized thinning effects on individual tree growth post-thinning.

Site-specific silvicultural practices enhance productivity of pine plantations in Brazil

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

[6] Envu, Brazil

Abstract: Pine plantations in Brazil cover approximately 2 million hectares, mainly in the southern part of the country, in a subtropical climate. Currently the average productivity is reaching 30 m^3 ha^{-1} $year^{-1}$, after decades of investment in research and optimization of field operations. Despite the high productivity, there is room for improvement by adjustments of silvicultural practices to site-specific conditions. The variability in climatic and edaphic characteristics of the planting region requires specific recommendation of silvicultural practices, focusing on optimal soil management, demand for fertilization, frequency and intensity of competing vegetation control, and stocking for specific genotypes.

This study is an integration of three experiments with trials in five locations covering different varieties of pine at different planting spacings, under contrasting levels of soil preparation, competing vegetation control and fertilization. To evaluate the effects of these silvicultural practices, survival, growth, and carbon stocks were frequently measured from planting up to 10 years of age, depending on the trial design and objectives.

Differences in pine varieties resulted in significant differences in productivity, up to 20% within the site, and they respond disproportionately to changes in stocking according to their level of improvement. Overall, more intensive silviculture increased productivity across sites. Competing vegetation control was the most important factor for all sites, and soil preparation was only significant on sites with higher soil clay content. Fertilization seemed to be significant during early years, with marginal (or inexistent) gains over the years.

Pine plantations in Brazil demand site-specific silvicultural recommendations to maximize gains in wood productivity. General silvicultural practices recommendation should be avoided. This network of trials will be monitored for a full rotation (~14 years in Brazil) to evaluate the long-term effects of applying intensive silviculture to pine plantations in Brazil.

Soil Classification for Loblolly Pine (Pinus taeda L.) Productivity and Management

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Abstract: Forest productivity and response to silvicultural treatments are dependent on inherent site resource availability and limitations. As trees have deeper rooting profiles than agronomic crops, evaluating the impacts of soils, geology, and physiographic province on forest productivity can help guide silvicultural management decisions in southern pine plantations. In this study, we use a series of "Regionwide" trials that go back decades to assess the variable importance of the new Forest Productivity Cooperative forest soils classification system that includes texture, depth to increase in clay content, drainage class, soil modifiers, geologic formations, and physiographic province on site index and fertilizer response. We also included variables such as climate and year of plantation establishment. We then used a remotely sensed layer that identifies managed loblolly pine across the southeast (approximately 14 million ha within its native range). The variable importance results from random forest modeling showed geology to be one of the top-ranking variables to explain site productivity. Plantation year was the most important variable, showing an increase of 16 cm per year since 1970. Because the Regionwide trial soils represent 72 out of over 10,000 unique soil site codes and approximately one million ha or about 7% of all soils identified as supporting management loblolly pine, we created a predictive model to extrapolate site productivity results outside of the unique soil & geologic conditions empirically represented. This model will be improved by additional observations across more soils. Overall, this system will allow managers to assess their current site productivity and assess the likelihood of fertilization response due to inherent site resources.

The Genetics-Genomics, Management-Modelling, Protection-Products experimental network: opportunities for gains in Eucalyptus productivity in Brazil

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Jose Stape[1]
Clayton Alvares[1, 2], Everton Soliman[2], Italo Cegatta[2], Leandro Siqueira[2]
[1] Sao Paulo State University (UNESP), Brazil
[2] Suzano, Brazil

Abstract: The Genetics-Genomics, Management-Modelling, Protection-Products (G2M2P2) experimental network consists of 71 experiments of five themes (C = clonal-protection, P = soil preparation, N = nutrition, E = spacing and M = weed -competition) installed in 2016-2017 in 18 places of edaphoclimatic representativeness of Suzano SA.

In the “C” tests, a total of 200 clones were tested, evaluating the incidence of pests and diseases. For the “P” tests, minimal to intensive preparations were used to verify the influence on growth. In the “N” tests, the omission of nutrients was used to map the deficiencies that still occur in soils under silviculture. In trials “E”, densities of 600 to 2,500 arv/ha were used to assess survival, growth and impact on harvest. For the “M” trials, the effects of weed communities and the period of interference-coexistence were evaluated.

The six years-old rotation results show that an experimental network that samples different climates and soils is essential to understand the different “non-linear” behaviors of Eucalyptus clones. It also shows that the correct clonal deployment can provide productivity gains for Brazil, as long as pest and disease monitoring is active.

For site preparation, fertilization, spacing and weed recommendations, there are possibilities for optimizing the use of machines and fertilizers and herbicides.

In summary, the G2M2P2 network is capable and crucial to better calibrate hybrid production - ecophysiological models for eucalyptus cultivation incorporating site-specific constraints.

The role of ectomycorrhizal fungi in the long-term management of Pinus taeda phosphorus fertility in intensive silviculture

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Benjamin Rose[1]
David Carter[2], Brian Strahm[2], Kevin Garcia[3], Rachel Cook[1]
[1] North Carolina State University, Department of Forestry and Natural Resources, USA
[2] Virginia Tech, Department of Forest Resources and Environmental Conservation, USA
[3] North Carolina State University, Department of Crop and Soil Sciences, USA

Abstract: Loblolly pine (*Pinus taeda* L.) is one of the most intensively managed tree species for timber production globally, especially in the southeastern United States. Phosphorus (P) fertilization has been shown to improve productivity and can lead to growth responses of 20 years or more, but little is known about the carryover effect of P fertilization from one rotation to the next. Long-term P availability depends on complex interactions among abiotic and biotic factors. Ectomycorrhizal (ECM) fungi are perhaps the most important biotic factor influencing pine nutrient acquisition, as they provide nutrients and water to roots in exchange for sugars from tree photosynthesis. ECM fungi mycelial scavenging can produce enzymes and organic acids that facilitate mobilization and uptake of fixed soil P from organic, mineral, and surface-sorbed sources. Fungal community composition has been shown to respond to additions of P fertilizer, but the long-term effects on the composition of ECM communities in subsequent plantings is poorly understood. A long-term, regionwide experiment is being conducted on sites that were fertilized with increasing P rates during the previous rotation, and with or without P additions in the current rotation. ECM fungal community composition following harvest and re-planting are examined by DNA extraction from rhizosphere soil and buried P-baited mesh ingrowth bags that capture fungal hyphae beyond the root zone. Preliminary results show ECM community structure responses to P fertilization and soil type, and dominant ECM species were identified as possible biological indicators of P fertility. To further understand the role of ECM communities in pine P nutrition, field observations are being coupled with analogous laboratory experiments that utilize culturable fungi and field soil in multi-compartment systems to assess the capacity of important loblolly-associated ECM fungal symbionts to transport P to pine roots from various labile and non-labile P sources. This research aims to provide a more robust understanding of the role of ECM fungi in long-term P-cycling processes in intensively managed pine plantations and determine the suitability of ECM fungal community assays as indicators that may improve predictive models to optimize P fertilizer use in loblolly pine production.

Tropical Eucalyptus plantations yields depends on topographic features that influences water availability on sandstone derived landscapes

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Jose Stape[1]
Clayton Alvares[1, 2]
[1] Sao Paulo State University (UNESP), Brazil
[2] Suzano, Brazil

Abstract: Eucalyptus growth driver has been deeply studied and associated with species/clones, soil type, fertilization regime, spacing, weed control, temperature, and rainfall over the years. In parallel a lot of effort has been carried out to understand eucalypt root system, and at spot trials, proved to be important to fully describe Eucalyptus growth in deep profile soils (Oxisols and Quartzpsaments) and its relationship on with the traditional tropical monsoon climate in Brazil, Australia, and South Africa.

Based on that review and in broad field mortality observation we hypothesized that the water table depth (WTD) and root dynamics would play a strong role in tree growth. In this study an extensive spatial (270 km x 270 km range) and temporal scale inventory network was put together and related with a water table algorithm based on most recent geo-information data available in a 30 m x 30 m resolution for the forestry part of the Brazilian state of Mato Grosso do Sul. We used the HAND terrain descriptor (Height Above Nearest Drainage) as a surrogate for the WTD on the watershed scale. Approximately 113,000 plots of the permanent forest inventory of Suzano's commercial Eucalyptus plantations, spread over dozens of thousands of hectares for the last 10 years, were made available for this study. The forest dataset included planted stands from 2005 to 2018 and tree measurements from 2008 to 2021.

Our study identifies physiography (position in the local relief) as the factor that controls the availability of water, and indirectly nutrients, to the Eucalyptus forests on sandstone derived landscapes in the Mato Grosso do Sul. The results obtained will allow the classification of the region into physiographic zones, which explain productivity by the effect of local drainage and water deficit, opening opportunities for clonal adequacy, management, operational activities, increasing tree survival and the productivity. Genetic and silvicultural prescriptions as variety and spacing recommendations have already been implemented, and further ones as fertilization rates, weed control and site preparation and conservation are being considered.

Using Spectral Vegetation Indices to estimate mid-term responses to soil preparation intensity and weed control timing for Pinus radiata plantations

T2.28 Strategies and challenges for improving commercial forest plantations productivity and sustainability in North and South America

Abstract: Leaf area index (LAI) is a key parameter in forestry research due to its association with many ecological processes such as photosynthesis, evapotranspiration, carbon sequestration and growth of forest stands. Given this, the use of remote sensing in the study of forest productivity has been of great importance due to the relationship between spectral vegetation indices (SVI) with LAI and its potential to monitor forest management. Silvicultural treatments, such as soil preparation and weed control, are key to improve commercial forest stands and the use of remote sensing provides an excellent tool to estimate responses to treatments. Our objective was to quantify the effects of soil preparation intensity and weed control on young radiata pine plantation growth and model these effects on stand productivity using SVI. The investigation utilized two field trials established with a split-plot design examining cultivation treatments as main plots (shovel, subsoiling to 80 cm, disking to 30 cm depth) and weed control as subplots (none, pre+post 2 years after planting, and only post 2 years after planting). Trees were planted in 2013 and measured in diameter and height annually. Sentinel-2 images were acquired (converting digital numbers to radiance and then to reflectance) to estimate SVIs. At both sites, nine years after establishment, soil preparation treatments with weed control applied pre+post planting showed the best accumulated volume, with responses ranging from 83 to 85 $m^3 ha^{-1}$ over no weed control for both sites. Volume responses to soil preparation did not show differences between disking and subsoiling ($p>0.05$), but they did show differences compared to shovel only. A significant correlation was observed ($p<0.001$, with $r^2=0.77$ to 0.79) between the current annual increment (CAI) and the simple ratio (SR, the ratio between the spectral NIR and Red bands). At both sites, a linear model between CAI with SR showed weed control pre+post planting had a higher slope than no weed control or only post-planting weed control.

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Development of smallholder teak plantations in Vietnam

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Dong Lam Tran[1]
Trieu Thinh Dang[1]
[1] Vietnamese Academy of Forest Sciences

Abstract: Teak has been introduced to Vietnam in the early 20th century. Although it performed well adapted to a wide range of climatic conditions in Vietnam with a yield of 7-16 m^3/ha/year for 20-25 years rotation, its extent of areas is still very limited in comparison with about 2.5 million hectares of *Acacia* and *Eucalyptus*. In Vietnam, about 70% of the plantation lands are owned by the households and the major constraint for teak development is that the rotation length is about four times that of acacia (4-7 years), even though the economic return from Teak (converted to annual basis) is much higher than Acacia. The ITTO Teak in Mekong Project (PP-A/54-331) implemented during 2019-2022 has supported Vietnam teak planting households in several communities in capacity building, selection of quality seed sources, development of silviculture demonstration plots, and identification of teak value chain, those initially support the smallholders in development and sustainable management of the teak plantation.

The demand for high-quality timber including teak in Vietnam for the furniture industry has been increasing steadily during the last 15 years, mainly for export with exporting value increased 15% annually to reach 15.7 billion USD in 2022. Teak promises to be a valuable and suitable tree species for the large-dimension timber plantation regime in Vietnam, which is recently encouraged by the government. Finding solutions for smallholders to invest in long-rotation plantations, particularly for teak, is crucial. Recommendations from findings in the ITTO Teak in Mekong project, including (1) boosting teak growth by improvement of germplasm and silviculture technology, (2) diversifying income regime based on teak-based agroforestry, (3) improvement of the value chain and marketing, (4) promotion of linkage between wood processing company and teak smallholders for sustainable material supply chain, and (5) micro-finance mechanism for long-term investment, are promising solutions. This presentation will discuss those issues with the aim to support smallholder teak plantations in Vietnam and the livelihood enhancement of the people employed in the sustainable teakwood industry sector.

Effect of Topographic Conditions on Teak Heartwood Quality in Mountainous Area

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Abstract: Teak is a globally commercial hardwood tree species. Teakwood exhibits a high timber quality, owing to unique properties such as lightness with strength, stability, durability, malleability, resistance to termites and fungi, and high adaptability to environmental variations. Hence, it is widely used to build outdoor and indoor furniture, ships, decorative veneers, paneling, doors, and windows. High-quality teakwood has been obtained from tree dimension, wood quality (e.g., heartwood content, wood properties, wood characteristics, and defects). The heartwood factor is a crucial component that alters to log yield, grading, and price, directly affecting wooden productivity and profitability. In Lao PDR, there is little research on teakwood quality. Despite this, wood quality is vital for the Lao wood industry sector. This study has specific criteria, according to commenced harvest year of ≥ 10 years along with optimum site elevation of <900 m.a.s.l and without evidence of damage in heartwood. Forty-nine sample plots in total were selected from target plantations, having 147 short log samples obtained from the felled tree (three trees per plot) using for heartwood quality assessment. This study found that the heartwood content of the basal area mainly increases with tree size. However, it had slightly affected by topographic conditions. Heartwood content of commercial volume increases with tree age, having a greater proportion in the middle to upper slope. Lower tangential shrinkage and radial shrinkage with higher basic density mean better wood properties. Therefore, the analysis results suggest that teak's heartwood properties; basic density and tangential shrinkage have an increasing quality with tree age, slope gradient, and elevation, while radial shrinkage showed a good value with larger stem diameter at gentle concave slope along where an area of lower elevation, while tangential shrinkage had a better value at steep land where an area of higher elevation might be affected by soil condition factors. Teak heartwood color; L^* has a darker color associated with the southwest-facing gentle slope in lower elevation. The redder color showed a relationship with the southeast-facing straight slope, while yellow has a higher value at lower stand density whereas southwest facing slope in lower elevation.

Global Teak Resources and Market Assessment 2023

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Sandeep S[1]
Walter Kollert[2]
[1] Scientist & TEAKNET Coordinator, Kerala Forest Research Institute, Peechi, Kerala, India
[2] Waka Forest Investment Services AG, Brazil and Switzerland

Abstract: Teak (*Tectona grandis*) is one of the most valuable tropical hardwoods of the world and is grown in nearly 70 tropical countries. Besides timber, teak is also considered an important livelihood option for dependent communities in the tropical region. Myanmar, India and Indonesia hold more than 75% of the world's teak planted area. The global teak 'heavyweights' namely India, Myanmar and Indonesia have teak planted areas of 1.667 million ha (38% of total teak planted area globally), 1.269 million ha (29% of total teak planted area globally) and 0.39 million ha (9% of total teak planted area globally). Since 1990's, teak plantations had expanded rapidly in Africa with large tracts of land in Benin, Côte d'Ivoire, Ghana, Nigeria, and Tanzania. Realizing the potential of teak in the international market, commercial teak plantations were established in the South and Central American countries like Brazil, Columbia, Costa Rica, Ecuador, El Salvador, Guatemala, Nicaragua and Panama. However, reports show that the timber output from planted teak forests in West Africa would have declined in recent years due exhaustive felling and non - replanting of old plantations. A comprehensive outlook on the teak sector was published by FAO in 2010 in its global assessment of teak resources and estimated planted teak forests from 38 countries at 4.35 million ha. However, there has been no attempt to assess the changes in the global teak resources and trade since this study in 2010. Hence, there exists a huge data gap in the status of these resources and trade. The Teak Resources and Market Assessment 2022, a joint project by TEAKNET, IUFRO and FAO, fills this data gap and presents a detailed assessment the world's teak resource, its distribution at country, regional and global levels, ownership ship status of the plantations, productivity aspects, trade and major markets and the ways in which these teak sectors have changed over the years.

Heartwood production and density of 22-year-old teakwood from fast-growth plantations: a comparative study across three locations in Brazil

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Bárbara Luísa Corradi Pereira[1]
Jackeline Eliada Cichoski da Silva[1], Leandro Vinícius Carbonato de Souza[1], Tielis Lucas Bianchini Azevedo[1], Aylson Costa Oliveira[1], Gabriel de Assis Pereira[2], **Mario Tommasiello Filho**[2]
[1] Federal University of Mato Grosso
[2] Luiz de Queiroz College of Agriculture/ University of São Paulo

Abstract: In Brazil, there are approximately 100,000 hectares of teak plantations, with 65% of them located in the state of Mato Grosso, which has an extensive territorial area and diverse soil and climate conditions. These plantations are typically established by private investors and managed with short rotations, with the final harvest taking place between 20 and 25 years. The objective of this study was to compare the diameter, heartwood percentage in the first commercial log, and radial apparent density of 22-year-old trees from three planting locations. The plantations are situated in Santo Antônio do Leverger (L1), Nova Maringá (L2), and Alta Floresta (L3) in Mato Grosso, Brazil. The average temperature varies from 26 to 27°C, and the annual rainfall is 1360 mm (L1), 1700 mm (L2), and 2250 mm (L3). Five trees were sampled from each location, and a disk was taken at a height of 2.3 m (end of the first commercial log) to determine the total diameter, heartwood diameter, and apparent density in the heartwood, transition, and sapwood regions. The average total diameter was 22.35 cm (L1), 32.10 cm (L2), and 28.91 cm (L3). The heartwood diameter followed the same trend as the total diameter, with average values of 17.64 cm (L1), 25.34 cm (L2), and 21.86 cm (L3). The heartwood percentages were above 50%, from 57% (L1) to 62% (L2 and L3). For L1 and L2, the average apparent density (at 12% moisture content) was 608 kg/cm³ and increased from pith to bark. In L3, where the wood density was higher at 643 kg/cm³, the sapwood presented a lower average density compared to the heartwood. Teakwood from these fast-growth plantations is classified as medium density. While there was no observed relationship between growth and wood density, the planting location does affect both the growth of teak trees and the properties of the wood. It should be emphasized that wood from fast-growth plantations has potential for common uses of teak wood. However, further in-depth studies on the characteristics of teakwood from the final harvest in fast-growth plantations are necessary to fully explore its potential and better understand its properties.

Intensely managed teak plantations – Quality of teakwood & common grading rules for teak logs

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Praveen Angusamy[1]
Chandrasekaran Bala[2]
[1] Forest Development Corporation of Maharashtra (FDCM) Ltd.
[2] State Forest Department of Maharashtra

Abstract: Teak is a valuable species, predominant in the Central India especially in the state of Maharashtra. The Forest Development Corporation of Maharashtra (FDCM) focuses on intensely managing the teak plantations which are raised by clearing the irregular forests & converting them into a uniform system with supplemental artificial regeneration of genetically superior stock. This is a form of clear felling system but leaving out 20 trees per ha which are middle aged fruit bearing trees and 20 trees/ha which are superior miscellaneous species which are teak associates.

The intensely managed teak plantations begin from the nursery practice of soil & fertility analysis, green manure (sun hemp) supplements in bed preparation. The planting stock management includes weeding, culling, application of fertilizer, sprinkler irrigation, pest management (from white grub attack). This is followed by preparation of teak stumps which are uprooted just at the beginning of first showers in monsoon season. Once the plantation is in place , the casuality replacement of inferior/dead/diseased growths are replaced with root trainers which are raised in potting media which consists of neem cake, borax powder, posphates and sulphates. This is complimented with vermi compost as a means to minimize the impact of chemical fertilzers and to reverse its effects on soil.

Once the plantation is established, silvicultural thinning (growing stock manipulation) ensures that there is no overstocked plantation which affects the reproduction of teak, since it is a heavy light demander. This regulates the distribution of growing space for the advantage of the existing crop. The thinning cycle starts from the 10th year and is carried out every 5 years till the final felling in the 80th year.

The timber extracted during the thinning process as well as final felling is graded once it is transported to the sales depot. The grading rules depend on the length, girth, bends, buttresses, surface cracks, splits & shakes, twists, hollows & rots, knots, wound and taper. The grading rules standardization is important interms of bringing uniformity in measuring units & volume of log dimensions especially in timber exports.

Keywords
Supplemental artificial regeneration of genetically superior stock, planting stock management, silvicultural thinning, grading rules.

On-farm thinning trials in smallholder woodlots of teak: intensive early thinning improves productivity

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Mark Dieters[1]
Outhai Soukky[2]
[1] The University of Queensland, School of Agriculture and Food Sciences, Brisbane, Australia
[2] Lao PDR

Abstract: Teak woodlots in northern Lao PDR are a dominant component of the landscape in many districts of Luang Prabang Province. Smallholder famers planted teak into their upland crops, which after usually 2 years of cropping, were allowed to continue to grow with limited management until such time as some trees had achieved the minimum merchantable size and the owners required cash to meet household needs (e.g. schooling, medical, wedding or other expenses). Initial stocking rates were typically much greater than 1100 t/ha (e.g. 3 x 3 m), sometimes exceeding 3000 t/ha. Smallholder valued their woodlots based on the number of trees on the plot, and viewed 'thinning' only as thinning from above where the best/largest (i.e. dominant) trees are sold for cash usually to middle men acting for a sawmill. Extract is usually manual, with 2 or 3 men carrying short logs (2.3 m) to the roadside; however, while elephants can be used to extract larger logs, extraction methods and woodlot location do limit maximum log size. The results of thinning trials established in collaboration with a network of smallholders, as part of a series of ACIAR projects in Luang Prabang Province of northern Lao PDR commencing in 2009, are described. Due to the relatively small size of teak woodlots in northern Laos, and variability of the terrain, only two plots were established in each woodlot: a thinned plot and an un-thinned control plot. Initially, farmers were reluctant to be involved in the project, and so woodlots of disparate age were recruited into the trail, and thinning intensities were relatively low. In a second phase of the ACIAR project, new thinning trials were established within target age of 5-9 years and selected trial sites were retained, and thinning regimes involving removal of approximately one half of the trees (equating around one third of the standing basal area) were implemented. Trials were measured annually through to 2019 when the project ended. This network of thinning trials can continue to provide valuable long-term information on the growth and productivity of teak in north Laos.

Promoting Legal and Sustainable Supply Chains for Sustainable Global Teak Markets

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

HWANOK MA[1]
Tetra Yanuariadi[1], Yongyut Trisurat[2], P.K. Thulasidas[3]
[1] International Tropical Timber Organization, Japan
[2] Kasetsart University, Faculty of Forestry, Thailand
[3] TEAKNET, Kerala, India

Abstract: The global teak market faces challenges in establishing transparent and sustainable supply chains due to the complex nature of roundwood products and the need to verify the legality of raw materials. Industrialized countries have implemented regulations to prevent the import of timber from unknown sources, requiring importers to demonstrate the legality of their supplies through due diligence (e.g. the Lacey Act, USA; the EU-FLEGT Timber Regulation; the Japanese Clean Wood Act, the Australian Illegal Logging Prohibition Act). India stands as a key player in the global teak trade, consuming nearly 95 percent of teak wood from teak plantations in three tropical regions. While a niche market for luxury yachts also exists, the bulk of the teak wood is used to support India's economy, provide employment opportunities, and cater to the demands of discerning Indian consumers. To address the challenge of illegal logging, it is imperative to establish cost-effective certification systems that facilitate the production of legal teak wood. By implementing such measures, the origin and legality of teak supply chains can be ensured, mitigating the risks associated with trading in illegal wood. Sustainability in teak production is crucial for the long-term viability of this valuable resource. Establishing and managing teak plantations using environmentally responsible forest management practices are key. Encouraging certification schemes and standards incentivizes sustainable teak production and provides assurance to consumers regarding the origin and sustainable management of teak products. Fostering collaboration among stakeholders is vital for building sustainable teak supply chains. Engaging with local communities, indigenous groups, governments, and industry actors is essential to address social issues and ensure the inclusion of diverse perspectives. Robust monitoring systems, sustainable management practices, and transparent communication channels can facilitate cooperation and contribute to the establishment of sustainable global teak trade.

Reducing initial stocking rates in smallholder teak woodlots: results of a Nelder wheel experiment in Northern Lao PDR after 15 growing seasons

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Mark Dieters[1]
Outhai Soukkhy[2]
[1] The University of Queensland, School of Agriculture and Food Science, Brisbane Australia
[2] Northern Agriculture and Forestry College, Ministry of Agriculture and Forestry, Luang Prabang Province, Lao PDR

Abstract: Teak has been planted in the upland areas of northern Laos for more that 50 years, resulting in an estimated 15,000 ha of teak, established as a patchwork of small woodlots distributed across the landscape. There were varying reasons underpinning the adoption of teak planting by smallholder famers in northern Lao PDR, from securing land tenure, to providing a mechanism for long-term investment (i.e., a green bank). Typically, teak woodlots were established at high initial stocking rates, and were then thinned by progressively removing the largest trees once they obtain a marketable size. This strategy has returned significant benefits to households that have retained ownership of their woodlots until maturity. However, the timeframes are long (often 15 or more years to first harvest) and repeated thinning from above results in a residual stand dominated by poorly formed, suppressed trees that grow very slowly, with limited value. Here we present the results of a Nelder Wheel experiment planted in 2008 under an ACIAR project and remeasured after 15 growing seasons during 2023. The results demonstrate the potential for teak to be grown under shorter rotations, by either planting at around 625 t/ha or adopting early pre-commercial thinning to reduce stocking levels to 500-600 t/ha. This approach can allow intercropping with the developing teak for longer periods, greatly increase diameter increments, thereby reducing time to first commercial harvest and increasing profitability. Woodlots can then be commercially thinned (from below) at 12-15 years of age, or potentially clear-cut at 15 years, and the coppice managed to regenerate the woodlot, providing long-term, sustainable timber production, with limited management requirements.

STRENGTHENING SMALLHOLDER COMMUNITY-BASED TEAK PLANTATIONS IN THAILAND

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

[3] TEAKNET, Kerala, India

Abstract: Thailand's 20-year National Strategy (2018-2037) targeted at increasing the forest cover up to 40% of the country's land area. In addition, the National Forest Strategy and Action Plan for Extension of Integrated Economic Trees aims at increasing economic plantations of 4.1 million ha to meet future wood demand and the economic forests of 15% out of 40% target by motivating people to plant more trees for economic benefits. Teak (*Tectona grandis*) is promoted as one of the top priority species for plantations, which was exempted from the list of restricted species and recognized as commercial timber species in the amended Forest Act of 2019. Although teak plantations were established more than 100 years ago and the first world teak orchard was initiated in Thailand in 1965, most of the existing teak plantations are of poor quality and from unknown genetic origin. Furthermore, teak smallholders lack of sustainable financing mechanisms and gain limited short- and medium terms income from the plantations. The ITTO Teak Project Phase I "Enhancing Conservation and Sustainable Management of Teak Forests and Legal and Sustainable Wood Supply Chains in the Greater Mekong Sub-region was implemented during 2019-2022 by ITTO with the participation of five countries, namely Cambodia, Lao PDR, Myanmar, Thailand and Vietnam as well as with the support of the Kasetsart University of Thailand. Although the COVID-19 pandemic caused disruptions in the global trade of tropical timber products, significant achievements could be made. Trainees became trainers to share knowledge with their colleagues. Fourteen demonstration plots were established in the five participating countries to support community-based smallholder teak forests. Plus trees were identified, and several clonal tests and seed production areas were established. Subsequently, good quality seedlings were distributed to teak smallholders. These outputs are bridging to project phase II. This presentation will focus on the strategies to strengthen smallholder community-based teak plantations in the Mekong and other countries in the tropics. In addition, support for the livelihood enhancement of the people employed in the sustainable teakwood industry sector will be discussed.

Keywords: smallholder teak, demonstration plots, plus trees, sustainable teakwood industry, *Tectona grandis*

Sustainable Development of the Global Teak Sector: Adapting to Future Markets and Environments

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Sreelakshmy MP[1]
[1] TEAKNET Secretariat, Kerala Forest Research Institute, Peechi, Kerala, India

Abstract: Teak has a world-wide reputation as high-quality tropical timber. In recent years, teak has attracted the commercial interest of investors and small land holders, especially, in developing short rotation teak plantations across the globe. The rapid expansion of planted teak forests risks compromising the excellent reputation of naturally-grown teakwood in the global markets due to the wide discrepancy of wood quality in plantation grown timber. The reduction in wood quality has a significant impact on the timber prices. This is aggravated by the absence of an approved international market intelligence, log grading rule or pricing mechanism. Recent years have also brought to the fore a plethora of challenges in the teak sector such as climate change induced growth constraints, erosion of the gene pool, emergence of new pests and diseases, difficulties in maintaining legal supply chains and disruptions in the markets through the COVID -19 pandemic. Though research and development has produced important results in recent years in all aspects of teak farming and markets, there exist serious gaps in knowledge management and dissemination to the stakeholders, as well as professional networking among the teak growing regions. Properly managed planted teak forests can produce financial benefits and offer opportunities to support the global environmental initiatives on Forest Landscape Restoration, carbon sequestration and livelihood enhancement of rural communities. Teak growers must ensure the proper management of planted teak forests using best forestry practices by producing highest possible quality wood. This includes proper species-site matching, using good genetic planting material, employing optimal rotation cycles and appropriate silvicultural techniques.

Sustainable teak harvesting and regeneration practices: Pivotal in attaining the economic, social and environmental gains

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

CHANDRASEKARAN BALA[1]
GINNI SINGH[2], PRAVEEN ANGUSAMY[3]
[1] Deputy Conservator of Forests, Amravati Forest Division, Forest Department, Maharashtra, India
[2] Deputy Conservator of Forests, Melghat Forest Division, Forest Department, Maharashtra, India
[3] Forest Development Corporation of Maharashtra (FDCM) Limited

Abstract: The teak forest which is spread over the eastern Vidarbha landscape in Maharashtra are renowned for producing superior quality teakwood with distinguished color, natural durability and mechanical properties. The teakwood is harvested, following the principle of 'Critical Crop Girth'- a concept which has been scientifically established on the basis of systematic studies on mean annual increment in the crop stand. The Critical Crop Girth is unique for every site quality and crop composition. This assures the maintenance of stock density in the forest at levels which will produce optimum productivity with desirable traits.

The management of teak forests through scientific harvesting principles followed by regeneration with genetically superior teak seedlings ensures continuous timber supply to meet the growing demand in the market. Certified seeds from Candidate plus Trees (CPT) are used to raise high quality teak saplings for artificial regeneration in the felled areas to ensure viable teak stand. In addition, systematic grading rules for harvested teak logs are established in consonance with market requirements to obtain best price. The system of grading is an age-old practice and the grade chart varies from Grade 1 to Grade 6 (superior to inferior). The logging as per the market needs and introduction of e-auction creates a demand driven competitive environment, fetching best prices.

Sustainable management of teak forests through scientific harvesting methods followed by artificial regeneration eventually leads to continued supply of teak for export and domestic markets and also delivers a range of environmental and social benefits thereby leading to community transformations by providing employment opportunities to local populace, forest landscape restoration with increased carbon sequestration.

Keywords: Candidate Plus Trees (CPT), critical crop girth, Grade chart.

Teak plantations in mixture with native species in tropical Latin America: growth, management, economics and carbon sequestration

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Arne Pinnschmidt[1]
Rasoul Yousefpour[1, 2], Anja Nölte[1], Marc Hanewinkel[1]
[1] Chair of Forestry Economics and Forest Planning, University of Freiburg, Tennenbacherstr. 4, 79106 Freiburg, Germany
[2] Institute of Forestry and Conservation, John Daniels Faculty of Architecture, Landscape, and Design, University of Toronto, 33 Willcocks Street, Toronto, ON M5S 3B3, Canada

Abstract: Teak is the dominating tree species in plantation forestry of many tropical Latin American countries, e.g. Costa Rica and Panama. Timber production and economic return are usually the main objectives in teak plantation forestry, but there is globally a growing interest in biodiversity protection and carbon sequestration. Mixing teak with native species has been suggested a promising strategy to increase the plantation's value for biodiversity protection while maintaining high economic return. Additionally, due to higher productivity, mixed-species reforestations have been suggested for carbon plantings. Here, we show how mixed species plantations of teak and natives perform in terms of growth, economic return and carbon sequestration under optimal forest management. We analyzed this by calibrating the mixture version of the process-based forest growth model *3-PG* (*3PGmix*) for four Neotropical native species and teak. We then coupled the forest growth model with a detailed economic model and using a simulation-optimization approach, we compared the economic and carbon sequestration performance of commercial mixed-species stands and monocultures in Costa Rica. Mixed species plantations showed good growth and economic performance (~ 3000 – 4000 USD/ha at 8 % discount rate). The best mixed species plantations outperformed conventional teak monoculture plantations with regard to carbon sequestration and economic return. Carbon storage and economic advantages of mixed species plantations increased with increasing carbon prices. The results suggest that mixed species plantations can be a competitive alternative to monocultures, especially if uncertainties are high, such as species-specific site suitability or when considering climate change scenarios.

The future is genomic: rapid clone selection for teak productivity and value

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Andrew Callister[1]
Olman Murillo[2], Jose Pablo Jiménez[3]
[1] Treehouse Forest Research, Check, Virginia, USA
[2] School of Forest Engineering, Instituto Tecnológico de Costa Rica
[3] Escuela de Ciencias Naturales y Exactas, Instituto Tecnológico de Costa Rica

Abstract: Teak is integral to countless tropical landscapes, contributing to society as a high-value commercial timber crop and a key component of smallholders' livelihoods. Genetic improvement has great potential to increase the value of teak in such diverse systems, especially by deployment of well selected clones. Genomic prediction is now a well-tested technology for rapid evaluation of untested clones and revealing unknown relationships. Therefore, we aimed to develop genomic resources suitable for predictive modeling in teak. We demonstrate the approach using a small set of clones.

GENFORES is a Costa Rican based tree improvement cooperative with active breeding programs in 6 Latin American countries. This genomic project started in 2019 with cooperation of North Carolina State University. Thirty-three elite teak genotypes from 9 independent breeding programs were sequenced using a reduced representation approach. This resulted in 10,812 polymorphic SNP markers with MAF>0.05 and 93% realized accuracy. Of the genotyped clones, 26 were accompanied by their genetic ranking values from field tests of DBH, commercial volume, wood specific gravity, heartwood percentage, heartwood color, and stem quality (form). Genomic information revealed previously unknown relationships amongst 18 of the clones, consistent with 7 small full-sib families. Bayes ridge regression (BRR) was found to be superior to Bayes A, B, C, or Lasso prediction models. Leave-one-out cross-validation of BRR models resulted in predictive ability of 0.66 for DBH, 0.60 for volume, 0.59 for specific gravity, and 0.40 each for heartwood percentage and stem quality. A genome-wide association study discovered 7 significant SNP markers for DBH, 8 each for Volume and Specific Gravity, 4 for Stem Quality, and 5 for Heartwood Color. These results compare favorably with published reports from other tree species. We conclude that genomic prediction for early clone selection in teak is a feasible and highly valuable approach.

Future work will focus on increasing the number of genotyped clones and test environments, and the functional annotation of significant markers. We expect that genomic evaluation will become standard in advanced teak improvement programs, particularly for pedigree reconstruction, rapid prediction for untested clones, and genetic connection of separate breeding populations.

Thinning of Teak Forests – A key to a productive , sustainable and profitable forest

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Praveen Angusamy[1]
Chandrasekaran Bala[2]
[1] Forest Development Corporation of Maharashtra (FDCM) Ltd.
[2] State Forest Department of Maharashtra

Abstract: Teak is a valuable species, predominant in the Central Indian forests especially in the state of Maharashtra. The Forest Development Corporation of Maharashtra(FDCM) focuses on making the teak forests/plantations of Maharashtra a productive, sustainable & thereby a profitable forest through periodic silvicultural thinning (growing stock manipulation), thereby ensuring that there is no overstocked forest which affects the reproduction of teak, since it is a heavy light demander. The idea is to maintain the growing stock per hectare at such levels which produces optimum annual increment in volume and the annual increment so produced is deposited on the main stem of the selected individuals. This regulates the distribution of growing space for the advantage of the existing crop.

India is a country of rich heritage in terms of forest conservation & known for having strict forest legislations. This makes plantations of valuable timber all the more important & relevant to meet the ever increasing demand of solid wood like teakwood. The first thinning in teak plantation is carried out in the 10th year only (Rotation of Teak crop is fixed at 80years). Prior to first thinning, only silvicultural operations like cleaning, singling, tending etc are carried out. Thinning at regular intervals ensures sustained yield of teak growing stock.This facilitaties teakwook supplychains and trade in perpetuity to meet the demand of teakwood.

This scientific intervention helps in increasing the total yield, redistribution of growing space to the advantage of teak , engaging the local people & tribals in meaningful employment, reduces fire incidences, increases the mobility of wild fauna, increases biodiversity of the forest (by retaining the fruit tress, mahua, tendu etc). The sustainably extracted timber by FDCM, through online auction fetches best market prices , generating revenue for the government as well as the employees (incentives). Most importantly, the FDCM increases the annual increment of the growing stock & accrual of timber thereby increasing the biomass, carbon sink & sequestration , a step towards a sustainable world.

Keywords:

Teak, productive, thinning, growing stock manipulation, light demander, meaningful employment, mobility of wild fauna, biodiversity, carbon sink & sequestration, sustainable.

Trends of trade and market access of tropical timber and timber products

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Tetra Yanuariadi[1]
[1] International Tropical Timber Organization (ITTO)

Abstract: Competitiveness of tropical hardwoods is in continuing loss compared to wood products produced in temperate forests. In the current situation, the availability and quality of large-diameter tropical hardwood logs of primary wood species are declining. Changes in the global trading environment for tropical timbers, including teak, are occurring at a rapid pace. This requires a longer-term view to enable tropical timber industry policy decisions to be effective. Degraded forests have a reduced capacity to supply local, national and global markets with essential forest products. Yet demand for harvested timber and other products are increasing. Demand for tropical primary and secondary wood products is a derived demand, driven by residential, non-residential and public construction activity and by consumer wealth and spending. Global housing and construction trends are therefore important indicators of tropical wood products demand. Commodities produced in tropical countries are not always viewed in a positive light as they are associated with deforestation, forest degradation, illegality, etc. Increasing degraded forests have reduced their capacity to supply local, national and global market with essential forest products. The COVID-19 crisis has affected tropical timber and timber product trade and amplified the economic slow down in its both producer and consumer countries. Tropical timber producer countries need to regularly assess the situation of competitiveness of their products in international markets to ensure continued maintenance of production and trade of sustainably managed tropical timber products. Ensuring sustainable tropical timber trade requires optimizing the utilization and improving productivity of production forests, which will, in turn, benefit conservation and protected forests, in terms of reducing pressures and disturbances. A key requirement of sustainability is compliance with all relevant legal frameworks.

X-ray densitometry and tree-rings applied in growth reconstruction of Tectona grandis

T2.29 Strengthening Teak Forest Management for Sustainable Teakwood Supply Chains and Trade

Gabriel Assis-Pereira[1]
Francisco Marques de Figueiredo[1], Júlia Lôbo Ribeiro Anciotti Gil[1], Vanderlei Benedetti[1], Geraldo Bortoletto Junior[1], **Mário Tomazello-Filho**[1]
[1] Laboratório de Anatomia e Identificação de Madeiras, Departamento de Ciências Florestais, EscolaSuperior de Agricultura "Luiz de Queiroz", Universidade de São Paulo, Brasil

Abstract: In view of the increase in the global demand for wood, it is necessary to know the dynamics of growth, productivity and wood quality in short and medium cycle forests in different environmental conditions. Thus, our objective was the reconstruction in diameter and height of planted forests of the Tectona grandis species in four locations in Brazil, Porto Esperidião – MT (L1), Glória D'Oeste – MT (L2), Rosário D'Oeste – MT (L3) and Angatuba – SP (L4), in addition to the analysis of the microdensity profile in the pith-bark direction. For this, disks were collected from five trees in each location and at different heights of the stem (every 1.30 meters in height). The forests were 9 to 18 years old, and the growth rings were measured in the different disks and the height was reconstructed through trunk analysis. The Faxitron X-Ray equipment was used to determine the apparent density (12%). In L1 at 14 years old, the trees had an average diameter of 24.88cm and 15.66m in height. In L2 and L4, both 9-year-old plantations, the diameters were 18.32cm and 21.39cm, and the heights were 13.50m and 6.75m, respectively. In L3, the longest planting (18 years), the diameter reached 33.25 cm and height 15.39 m. With dendrochronological analyses, it was possible to carry out the annual reconstruction both in diameter and in height. The apparent microdensity profile data point to an increasing trend in the base-to-top direction, on average the values were 0.65, 0.68, 0.68 and 0.63 (L1, L2, L3 and L4, respectively), being that the values are related to implantation variables, management, age of the trees and edafo-climatic characteristics. Information on growth and wood properties are basic for assessing the forest suitability of the site, as well as for defining silvicultural techniques, planning, forecasting the wood stock and estimating carbon sequestration in forest formations.

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

2016

Battery-powered chainsaws in forest operations: a sustainability assessment with a special focus on ergonomics

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Andrea Laschi[1]
Francesco Neri[2], Elena Marra[2, 3], Cristiano Foderi[2], Fabio Fabiano[2], Niccolò Frassinelli[2], Enrico Marchi[2]
[1] Department of Agriculture, Food and Forestry (SAAF) - University of Palermo, Italy
[2] Department of Agriculture, Food, Environment and Forestry (DAGRI) - University of Florence, Italy
[3] Institute of Research on Terrestrial Ecosystems (IRET), National Research Council of Italy (CNR), Italy

Abstract: The use of chainsaws in forest operations is still largely widespread. In fact, the use of this tool, in comparison with big machines, guarantees some pros related with reduced costs, good efficiency and versatility. Operating within the Sustainable Forest Operations should guarantee environmentally friendly, convenient, high-quality and fair productions. In this context, the use of chainsaws may be critical in terms of health and safety of forest operators, being the use of this tool very dangerous, as the direct or indirect cause of many accidents and the cause of several work-related diseases. Moreover, it has a limited but evident role in greenhouse gases emission. In this context, a forest operator with chainsaw is subject to exhaust fumes, noise, and vibrations exposure. In the last years, thanks to a rapid evolution of battery technology, new generations of chainsaws are available on the market. These battery chainsaws are professional tools with declared power and performances comparable with the modern petrol-powered chainsaws, but with many advantages in terms of emissions; no exhaust fumes and reduced noise and vibrations. For this reason, the use of battery chainsaws in forest operations instead of petrol ones would be a good solution to reduce the risks in terms of health and safety. The aim of this work is to show the results of several studies aimed at understanding the differences between petrol and battery chainsaws in terms of performance, i.e. productivity and noise and vibrations emission, assessing also the differences in logistics needed by the two types of chainsaw. These evaluations have been carried out during real forest operations and on different wood species. The results showed very good performance of battery chainsaw, but also some critical points that does not allow its current use in real forest operations. In particular, considering that battery duration is almost the same of a full tank in petrol-chainsaw, recharging process in forestry is a key-task to be solved. In conclusion, the use of battery chainsaws in forest operation has a very high positive potential especially in terms of risks reduction, but it needs further technological developments to be really implemented.

Birch among forestry measures to adapt to climate change

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Jimmy Johansson[1]
Rikard Jakobsson[1], Ljusk-Ola Eriksson[1]
[1] Linnaeus University, Department of Forestry and Wood Technology

Abstract: Authorities and actors in the Swedish forest sector advocate an increase in management of broad-lead tree species. Increased abundance of broad-leaved tree species would benefit biological diversity as well as adaptation to climate change. The major broad-leaved tree species in Sweden is birch, with 10% of the standing volume. The dominating use of birch is in pulp production and for energy purposes. For forest owners they represent low-value products and from a climate perspective they are products with short life and thereby short carbon storage time. Instead, sawn wood would benefit forest owners and the climate. However, the production of sawn birch is in Sweden on a very low level, only 2-3% of the annually felled volume of birch is processed in sawmills compared to more than 50% of the softwood volume.

The study investigates the potential for the sawmill industry in southern Sweden to extract and process birch. Current silviculture as well as silvicultural methods promoting birch are studied. The quality of trees for sawmilling is a critical parameter; data from new trials are used to illuminate this aspect. To explore the conditions that need to be fulfilled from a supply and demand perspective to increase the share of birch processed in sawmills, the forest sector model (FSM), SweFor, is used. The FSM contains a forest module (forest management options and simulation of forest owner behaviour), industry process models (transformation of logs and residues to outputs including costs), and market demand for semi-finished forest products. Results show what combinations of tree quality requirements and sawmill technology will yield adequate volumes for a viable industry. Since quality and volume is dependent on silviculture, this will also show what will be required in terms of forest management. The dependence of birch sawmilling on demand for other uses is demonstrated.

Challenges and Opportunities in Forest Operations: Case study from South Africa

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Muedanyi Ramantswana[1]
Junior Khoza[1], Francois Oberholzer[2]
[1] Nelson Mandela University, Natural Resource Science and Management Cluster, George, South Africa
[2] Forestry South Africa, Pietermaritzburg, South Africa

Abstract: The global industrial roundwood production in 2021 was just over 2 billion m^3. 4% of the total volume came from Africa with South Africa producing around 16 million m^3. Forest operations is an integral part of the timber product value chain, supporting livelihoods of people through employment, energy production, value addition and enabling food security. However, the sustainability of forest management activities in forest operations is dependent on managing risks and exploring opportunities within various forestry environments. The aim of this study is to highlight the key difficulties and opportunities in forest operations by focusing on South Africa as a case study.

Forest operations in South Africa are currently facing several challenges which are inhibiting the industry's growth. Forest operations are dependent on a large proportion of unskilled labour to meet timber volume production requirements. Labour intensive operations pose a challenge because of increasing labour costs, significant risks to health and safety, high labour turnover and anticipated labour shortages. The poor governance of state-owned entities over several years has led to the deterioration of rail infrastructure used to efficiently transport timber to the markets, a surge in criminal activities (e.g., theft of harvesting equipment, timber and materials like fuel) and a lack of reliable energy supply to various timber processing facilities has led to significant decreases in volumes produced and increased costs.

Existing opportunities in forest operations include the adoption of technologies to optimally harvest and recover timber in high-risk and difficult conditions where manual labour is not suited (e.g. integrating traction and cable assist technologies). The deregulation of the logistics industry by creating opportunities for privatisation of rail transport services will encourage more efficient, reliable and cost-effective rail systems to operate. Furthermore, road timber transportation can be optimised by using more advanced performance-based standard (PBS) trucks which carry larger payloads (e.g., 30.5 m long trucks; payload = 79 tonnes), reducing delivered cost, total vehicles, road damage, accidents and CO^2 emissions. The collection, processing and transport of biomass material (residues) presents an opportunity for renewable energy generation thereby reducing the dependence on non-renewables, generating employment, and revitalizing rural economies.

Compatibility of an increased machine operating trail distance with SFO

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Ferréol Berendt[1]
Maximilian Jakob[1], Tobias Cremer[1]
[1] Eberswalde University for Sustainable Development, Department of Forest Utilization and Timber Markets

Abstract: More and more German forest owners, especially state forestry departments, increase the distance between machine operating trails from 20 to 40 or more meters, which is in accordance to the current German Forest Stewardship Council-certification standard. Inevitably, with the current forestry machine equipment (e.g. 10 m boom reach of harvesters), this increase in distance leads to a machine operating trail system with midfields. Still, increasing the distance between the machine operating trails is fully in line with Sustainable Development Goals (SDG) 12, 13 and 15 as more productive forest area is available and, hence more carbon can be stored in both forests (soil and biomass) and in timber products.

In response to this, the mechanized forestry equipment and/or the forest operation systems need to be adapted. An example of adapted forestry equipment is an increase in harvester size, resulting in 18 m operational boom reach. An example for an adapted forest operation system is motor-manual felling and mechanized winching of the midfield tress to the machine operating trail with subsequent mechanized processing. Our research is about the impacts of equipment and operation system adapted to an increase of machine operating trail distance on the main pillars of the Sustainable Forest Operations (SFO) concept: Environment, Economics, Ergonomics, People & Society and Quality Optimization.

The results of this research provide decision support for practitioners in accordance to the pillars of the SFO concept. Work metabolism related strain using spiroergometry (Ergonomics), productivities and costs using time studies (Economics), environmental impacts using life cycle assessments (Environment), residual stand damage (Quality Optimization) and work safety as well as available (wo)manpower (People & Society) were analyzed.

As a result, adapted equipment or operation systems seems to be more in line with SDG's compared to fully mechanized systems with 20m spacings (reference) because of increased carbon stocks (SDG 13 & 15), higher timber production (SDG 12 & 13) and a higher recreational value (SDG 15). However, the analyzed forest operations systems showed weaknesses compared to the reference as well, such as lower work safety or higher cost.

Criteria for assessing the sustainability of forest operations - a systematic review

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Julian Grünberg[1]
Mohammad Reza Ghaffariyan[2], Meghdad Jourgholami[3], Eric R. Labelle[4], Nopparat Kaakkurivaara[5], Renato Cesar Gonçalves Robert[6], **Martin Kühmaier**[1]

Abstract: The comprehensive assessment of forest operations through the consideration of the three pillars of sustainability (Economic, Social and Environmental) has not received much attention. The use of criteria and indicators can significantly improve impact assessment. Therefore, the objective of this contribution was to analyze the most commonly used criteria and indicators for each dimension of sustainability in timber and fuelwood harvesting over the last six years. It is intended to provide an overview of these criteria for different harvesting machines, geographical areas, slope classes, time periods, types of research, and silvicultural treatments. Another important aspect was to analyze how these criteria are connected to the UN Sustainable Development Goals (SDGs) and targets.

The environmental pillar (46%) was the most studied, followed by the economic pillar (38%). However, productivity was the most investigated criterion. On the one hand, productivity is linked to the environmental and social pillars, as it is related to the level of greenhouse gas emissions, energy consumption and the employment rate. However, productivity is mainly used as a criterion of financial interest, as it is most often studied in combination with costs. In addition to productivity (15%), the most frequently examined criteria were costs (10%), soil nutrients (9.5%), and soil compaction (9%). The social dimension was the least studied with 16%. This may be due to a more complex understanding and lack of knowledge of social sustainability issues in this area. Seven SDG targets have been identified to have a connection to the criteria of sustainable forest operations, whereas the most important are 8.2 (45% of all investigated studies), 15.2 (41%), 8.8 (19%), 3.4 (18%), and 12.2 (8%).

Sustainability is achieved when all three dimensions of sustainability are balanced. The results of a review of scientific publications of the last six years showed an imbalance, with economic and environmental aspects being weighted more heavily than social aspects. Balancing all three dimensions normally require an assessment of trade-offs This contribution provides a comprehensive summary of the criteria that have been studied to date and can be used as a checklist and guideline for future sustainability assessments of forest operations.

Developing and testing sensor systems for the detection of people in danger zones of forest work

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Ferdinand Hönigsberger[1]
Christoph Gollob[2], Karl Stampfer[1]
[1] Institute of Forest Engineering, Department of Forest and Soil Sciences, University of Natural Resources and Life Sciences, Vienna, Peter Jordanstrasse 82, 1190 Vienna Austria
[2] Institute of Forest Growth, Department of Forest and Soil Sciences, University of Natural Resources and Life Sciences, Vienna, Peter Jordanstrasse 82, 1190 Vienna, Austria

Abstract: Few workplaces pose as great a challenge as the forest. Demanding terrain and harsh environmental conditions coupled with a multitude of hazards result in a high level of occupational accidents. Especially the large danger zones are highly problematic. They must be monitored by the forestry worker throughout the process in order to not endanger people. However, especially in difficult terrain covered with trees and bushes, this is often almost impossible. For this reason, smart sensor systems are needed to support forestry workers and protect other people involved in the work as well as forest visitors. To protect this wide spectrum of individuals the aim of this study is to use technologies that can use tags as well as devices most individuals already carry with them – smartphones. After a literature research the two most promising technologies Ultra Wideband (UWB) and Bluetooth (BLE) were selected for the prototype development. A field test was conducted in steep and hilly terrain, monitoring typical danger zones of 30, 50, 70 and 90 m.

Evaluated by reference measurements of all tested distances the **UWB** system showed, with a mean deviation of -0.44 m and a RMSE of 1.52 m, accuracy and precision which are more than sufficient for the use in forestry. The detection performance for the 30 m (mean detection distance: 28.4 m RMSE: 3.56 m) and 50 m (mean detection distance: 43.9 m RMSE: 7.92 m) danger zones showed, that the system is suited for the use in motor manual timber harvesting. Even though the implementation of smartphones into the system was possible, the required performance wasn´t achieved. However, due to the rapid development of UWB technology in the smartphone sector, we expect a continuing improvement. The current **BLE** prototype only allowed a presence detection, but monitored, with a mean detection distance of 83.66 m (sd: 13.26 m), larger danger zones. Also, the implementation of smartphones was possible when using BLE.

Particularly the UWB system consisting of a sensor and several tags showed promising results and is therefore tested, as a second step, during forestry work to assess detection performance, practical applicability and limitations.

Effects of passive exoskeletons for the lower back on forest workers conducting two different planting procedures

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Marius Kopetzky[1]
Henrik Brokmeier[1], Dirk Jaeger[1]
[1] Department of Forest Work Science and Engineering, University of Goettingen, Goettingen, Germany

Abstract: Forest work is physically demanding and can lead to joint and intervertebral disc problems. Manual planting methods, which involve repetitive tasks with monotonous bending movements, particularly strain the lower back. With significant deforestation caused by wind throw, drought, and bark beetle infestations in Germany since 2018, reforestation will be a crucial task in the coming decade, involving a significant degree of manual planting. The use of passive exoskeletons for lower back support has shown to reduce muscle activity in the erector spinae by up to 75 %, depending on the design of the exoskeleton and the specific task and could therefore be a device to reduce strain on the lower back during manual planting tasks. However, these exoskeletons were designed and tested for industrial work tasks like lifting and carrying heavy loads, which rely on a limited set of simple movement patterns in a clean and level work environment. In order to investigate the effects of a passive exoskeleton on forest workers during different planting procedures, field studies were conducted under typical conditions in forestry.

The studies involved two forest workers, one using a hollow spade on even terrain and another one using a Harzian plant hoe on steep slopes. Each planting method was executed for three days in eight to twelve sessions of at least 45 minutes duration, plus half a day for several electromyographic (EMG) and motion capture measurements. For half of the measuring sessions the forest workers were equipped with the individually fitted passive exoskeleton PAEXO Back, manufactured by Ottobock, to provide back support. The effect of the exoskeleton on productivity was measured through a time study, while motion capturing techniques were employed to examine changes in movement patterns resulting from restricted mobility. Additionally, EMG measurements were conducted to assess muscle activity in the supported muscles throughout the planting. In parallel, a spiroergometric device was utilized to measure whole body strain by analysing breathing gas, volume, and rate, complemented by heart rate measurement using a chest belt.

Final results will be presented at the conference.

Ergonomic assessment of motor-manual forest operations: a comparison among different work complexity conditions

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Francesco Sforza[1]
Francesco Zanotto[2], Tiziana Stangoni[3], Stefano Grigolato[2]
[1] Bern University of Applied Science
[2] University of Padova
[3] Istruttori Forestali Lombardi

Abstract: Motor-manual tree felling is still a widely adopted harvesting system in Europe, especially in difficult terrain where the deployment of modern harvesting machinery is limited. Motor-manual operations are exhausting, ergonomically adverse and tend to expose forest workers to potentially critical working conditions. Furthermore, an increased occurrence of hazardous situations, as well as a worsening of ergonomic and safety conditions, may be observed in the next future due to the increasing frequency of more complex work circumstances, such as salvage logging operations in steep terrain. Few studies investigate the relationship between the ergonomic conditions of forest operators and the complexity of the worksites. The following study aimed to assess the physiological workload and risk of work-related musculoskeletal disorders (WMSDs) of operators carrying out motor-manual tree felling and processing in different working conditions. 17 workers were heart rate monitored in tandem with a time study to analyse the workload experienced per productive working task. In addition, short videoclips were realized with action camera to capture the workers motions during felling and processing operations. Workload analysis was following developed by applying the relative heart rate at work (%HRR), ratio of working heart rate to resting heart rate (HRw/HRr) and 50% level of heart rate reserve (50% Level) indices, respectively. The risk of musculoskeletal disorders was evaluated through the procedure proposed by the Owako Working Posture Analysis System (OWAS). Heart rate was deeply explored to investigate the relationship among forest operator's workload and working conditions according to four complexity categories of the workplace.

Our results showed that regardless of working conditions, forest workers tend to assume higher risk postures while performing tree felling operation (RI = 195.4) compared to tree processing task (RI = 165.8). Conversely, the physiological workload analysis revealed that severe working conditions lead to a substantial increase in the workload of forest workers, such as in salvage logging operations carried out in steep terrain ($p = 9.18e-07$). Moreover, an increasing of potential risk situations and hazard events was observed for salvage logging worksites rather than ordinary harvesting activity.

Forest value chain resilience from a local perspective in five European countries: analysis of co-drivers and predictors

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Abstract: Climate change has severe environmental, social, and economic consequences on forests and the related forest value chain (FVC). One adaptation avenue relies on increasing the resilience of the forest systems. To ensure a stable supply of timber and products, forests and their value chains must be managed in a climate-adapted, sustainable, and carbon-neutral manner. However, the information about how to boost forest system adaptation capacities and deal with FVC irregularities resulting from disturbances and stressors is limited. Hence its operationalization is needed. Based on the Operational Resilience Framework (ORF) developed within the RESONATE project, this study aimed to identify and analyze the associations between predictors and co-drivers that affect forest value chain resilience from a local perspective in five European countries (Czechia, Germany, Croatia, Finland and Spain). The data on forest harvesting technologies, logistics, and forest stand-specific variables related to the timber supply was evaluated on an enterprise scale over 20 years (2001-2021). Our analysis indicated that larger forest holdings could offset disturbance effects to a certain extent and demonstrate more resilience by having more control over the value chain, such as managing their own sawmill or having more networking partners. Moreover, the results suggested that the efficiency of harvesting operations might improve resilience on a local level. Depending on their local suitability, the tree species used also influenced the resilience of the value chain through increased resilience of forests to disturbances.

Improving Forestry Supply Chain Resilience by Ensuring Steady Supply for Wood Processors

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Robert Radics[1]
Muhammad Umar[1]
[1] Lincoln University, Lincoln, New Zealand

Abstract: New Zealand is the largest softwood log exporter in the world, and its' sawmills productivity is excellent, but the domestic wood processing and added value are not increasing; contrarily, middle-size sawmills are closing due to supply uncertainty. Volatile log prices and short-term supply contracts erode job security and investors' confidence. At the same time, the unprocessed logs' export causes an unnecessary environmental burden due to the transported waste (water in logs and bark) and overseas transport fumigation requirements (CFC gases are used in the process). Log quality is also deteriorating while the wood is prepared for transportation due to blue stain fungi. Therefore, onshoring processing reduces negative environmental impacts, improves social and economic outcomes, and prevents log quality issues. Authors consulted with the literature, stakeholders and experts to identify potential solutions to ensure a steady wood supply that benefits growers, processors and society. Improvement opportunities were identified (compulsory registration of wood traders and consultants, long-term contracts with price adjustment formulas, cooperatives, business model changes, etc.). The potential solutions were investigated in detail by using a regional supply case study (Steady Northland Wood Supply), using three sawmills' 20 years of historical supply and sales data, and by stochastic models. The potential impacts on the economy, environment, jobs, and other effects were identified and discussed by stakeholder groups. The research triggered a new forest and wood industry legislation and contributed to New Zealand's Wood Industry Transformation Plan. Beyond the original research, the authors report the progress in implementation and compare the outcomes to the planned.

[1] Scion (New Zealand Forest Research Institute Limited), Christchurch, New Zealand
[2] School of Forestry, University of Canterbury, Christchurch, New Zealand
[3] Forest Growers Research, Rotorua New Zealand

Abstract: New Zealand is experiencing an increased public concern around how forests are managed, particularly regarding the suitability of plantation harvesting and roading operations in light of extreme weather events, with the need to afforest land for carbon sequestration and future timber production. Forest operations that are future-focussed require innovative responses to regulatory changes, community and market pressure, and societal scrutiny. In 2020, an online survey outlined perceptions of the New Zealand public towards three elements of forestry operations – harvesting on steep slopes; species change in plantations; and the use of chemical sprays for forest establishment and pest management. These highlighted an increased level of perceived societal risk particularly for steep slope harvesting, which was regionally concentrated, and effects the level of trust in the forest industry and its social licence.

Through incorporating technology adoption with a care for the environment, forest workers and the surrounding communities, more sustainable and integrated forest operations can be conducted. A targeted research programme “Te Mahi Ngahere i te Ao Hurihuri – Forestry Work in the Modern Age” has three major aims: to create value, improve profitability and enhance sustainability across the forestry value chain through automation. It aims to do this by exploring a new integrated forestry value chain from harvest to market, incorporating new technologies that will promote both industry and Government interests.

This presentation will outline the New Zealand context for improvements needed in forest operations, highlighting both public perceptions towards forest operations, and how new technologies are assisting the forest industry to meet Sustainable Development Goals. We highlight public attitudes towards harvesting, forest health and visual amenity, while introducing crosscutting science undertaken to address and improve operational management of forests. Particular emphasis will look at newer harvesting and roading technologies and the systems being investigated that seek to overcome steep slope forestry risks from environmental, economic, ergonomic and workforce perspectives.

Perspective on improving road networks including public roads through forested areas in Japan for sustainable forest management and wood supply chain

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

[6] Forestry and Forest Products Research Institute, Japan

Abstract: The mature stock of plantation forests planted in the 1950s to 1970s has reached the age for final harvesting in Japan. The relatively low current price of logs compared to that of the plantation age requires an improvement in the logistics of the wood supply chain. Recently, with regard to the situation, the Japanese forest road standard has been renovated to include 20-ton class semitrailers in the design vehicles in addition to 10-ton class log trucks and 4-ton class trucks. However, it is said that there are a number of public roads in steep mountainous forest areas in Japan that can only accommodate trucks with a lower load capacity. To confirm this situation, we investigated the suitability of six routes for access by 10-ton class logging trucks in a rural forest management area in Kochi Prefecture, which is located in the southeastern part of Japan and has steep mountainous forest areas. The width of the roads, measured in the field, was compared with images recorded on a drive recorder. The radii of road curves were estimated using interpolation algorithms available in a geographic information system (GIS) application. The required road widening was calculated as the difference between the actual road width and the width of the Type II Class 2 forest road (3.0 m), plus the amount of widening required for the curve radius. One of the existing routes, which was found to be unsuitable for 10-ton class trucks, was found to require significantly less road width expansion, indicating that it was originally designed for lighter 4-ton class vehicles. The other routes surveyed, including a specially constructed forest road and a forest road upgraded to a prefectural road, were found to be sufficiently wide to accommodate 10-ton trucks, although some sections were significantly narrow in residential areas. Based on the results, several options for improving the road network, including public roads over forested areas in Japan, are suggested for sustainable forest management and wood supply chain.

Pulled Three Ways: The Trilemma of Sustainable Northern Forest Operations

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Lars Högbom[1]
Dalia Abbas[2], Martyn Futter[3], Mika Mustonen[4]

[3] Swedish University of Agricultural Science, Department of Aquatic Sciences and Assessment
[4] Natural Resources Institute Finland

Abstract: Forestry in the Nordic Baltic region and elsewhere faces a 'trilemma' of societal demands. Forest management and forest operations are expected to (i) increase wood production to substitute raw fossil materials, (ii) increase forest carbon sequestration and storage capacity, and (iii) improve forest biodiversity and other ecosystem services.

In this presentation, we approach the trilemma with a focus on how it can be visualized through the lens of the UN Sustainable Development Goals (SDGs). Balancing trilemma goals can have both positive and negative effects on sustainability. Increasing wood production can contribute to achieving SDGs 9 (industry, innovation and infrastructure); 11 (sustainable cities and communities);12 (responsible consumption and production) and 15 (life on land) while increasing forest carbon sequestration and storage helps to meet SDG 13 (climate action). However, actions which increase wood production and forest carbon storage must be met with caution, since they can have adverse effects on achieving SDG 14 (life below water) through negative impacts on biodiversity and other ecosystem services, especially those related to clean water and SDG 6 (clean water and sanitation).

Successful, and sustainable, forest operations and management must not only meet the needs of the forest sector but must support sustainable societies. To be successful we need somehow to balance between these different goals and acknowledge that they sometimes counteract each other. By framing the trilemma in an SDG context, we can build a dialogue based upon an existing and relatively accepted global framework, and its connection with society. However, it is critical to emphasize that there is an intrinsic "conflict of interest" within the SDGs themselves to achieve sustainability. Achieving one goal, without considering other goals, may not constitute sustainability of all goals on the agenda.

Theory-of-Change Development for Chainsaw Operators' Safety Improvement from Natural Forests in Indonesia

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Hermudananto Hermudananto

Abstract: Tree felling with chainsaws is a dangerous occupation rendered even more so when workers do not utilize the recommended personal protective equipment (PPE). Despite regulations in Indonesia that require fellers to use PPEs, workers often do not comply, even in forests certified for sustainable forest management standards. This study analyses the impediments to using PPEs (i.e., safety boots, felling chaps, reflective vests, gloves, helmets, and eye and ear protection) and develops a Theory-of-Change (ToC) to improve worker safety. I observed a total of 11 Indonesian natural forest management units (10 in Kalimantan and 1 in Papua) in 2020-2022 to interview chainsaw operators and discuss with supervisors and forest managers related to PPE use. At least five potential interventions were revealed that could be adopted from the most to the least recommended. Frequent supervisor control to monitor chainsaw operators is the most recommended way to remind workers to use appropriate PPE during work. Not necessarily a formal command from top to bottom, but casual talks during leisure time in the forest camp might be worked. Another least popular option is a monetary incentive or award to the workers. However, its intervention might not be performed for some types of PPE, such as ear protection. Workers claimed that wearing that PPE risks their lives because they can't hear when a tree falls during harvesting. For the success of proposed ToC implementation, all possible assumptions, indicators, and metrics that were captured should be implemented for each ToC stage, including short- or long-term outcomes and final impacts. Worker safety improvement is not only about compliance against regulations or standards but rather a development of a good safety culture.

Work-related injury and chronic health issues among logging workers in the northeast United States

T2.30 Sustainable Forest Operations (SFO): Challenges and opportunities towards a resilient wood supply chain and worker's well-being

Erika Scott[1]

[2] Bassett Research Institute, Bassett Medical Center, Cooperstown, NY, USA

Abstract: Introduction: Despite dramatic improvements in safety and mechanization, logging remains one of the most dangerous industries in the United States. The purpose of this research was to explore injury trends and health issues among Maine logging workers.

Methods: Loggers participated in seven quarterly surveys and a one-time physical health assessment. Data exported from REDCap into SAS 9.4, Excel, and NVivo. We compared endpoints between the sub-group who completed a health screening versus those who did not using the Wilcoxon rank-sum test. Comparisons between groups with more than two levels were made using one-way analysis of variance (ANOVA) or the Kruskal-Wallis ANOVA. Categorical variables, such as gender, were compared using chi-square or Fisher's exact test, as dictated by assumptions. Time to injury was modeled using two different approaches: 1) time to the occurrence of first injury modeled by proportional hazard regression and 2) an intensity model for injury frequency. Two research team members also analyzed qualitative data using a content analysis approach.

Results: During the study, 204 injuries were reported. Of the 154 participants, 93 (60.4%) reported musculoskeletal pain on at least one survey. The majority of injuries were traumatic, including fractures, sprains, and strains. Lack of health insurance was found to be related to increased risk of first injury [HR=1.41, 95% CI=0.97-2.04, p=.069]. Health assessments were completed for 75 loggers. Nearly half of those screened (45.9%) had blood pressure at the level of stage II hypertension. Seeking medical attention for injury was not a priority for this cohort, and narratives revealed a trend for self-assessment.

Discussion: We found that loggers still experience serious, and sometimes disabling, injuries associated with their work. In addition, chronic health issues such as hypertension is a concern for for this cohort. The most frequent injuries were due to slips, trips, and falls along with contact with logging equipment and trees/logs. Entrenched values that prioritized independence, traditional masculinity, and financial considerations were consistently cited as a barrier to adequate care.

Conclusion: There is a continued need to address occupational health and safety in the logging industry.

[5] Center for International Forestry Research and World Agroforestry (CIFOR-ICRAF), Derrière Usine Bastos, Yaounde P.O. Box 16317, Cameroon

Abstract: *Garcinia kola* Heckel (Clusiaceae) is one of West and Central Africa's most popular agroforestry tree species. Despite its local significance, most of the current research focuses on *G. kola* therapeutic effects, omitting topics which could lead to the species' advancement in domestication. Therefore, our study aimed to provide a comprehensive understanding of *G. kola* phenotypical and genetic variation, its chemical potential as well as utilisation and management by local communities. In total, 122 farmers were interviewed, and 227 trees, along with 1,040 leaves, 1,727 fruits and 4,559 seeds, were evaluated in Cameroon's Southwest, Central, and South regions. Major regional differences in the utilisation, management and commercialisation of *G. kola* products were discovered. Even though fruit collection was harmless to the tree, bark and root harvesting was found to be invasive, threatening the species' existence in wild stands. Kolaviron, the most investigated chemical compound, appeared to be overrated regarding its therapeutic impact. Most of the elite trees originated in the South region, which exhibited higher genetic diversity than the rest of the study sites. However, no significant differences in genotype or phenotype were found between wild and cultivated trees, suggesting that the domestication of *G. kola* is still in its early stages. Promoting the species' therapeutic potential among farmers could be a successful strategy for shifting their focus from the bark to the seeds. Field trials recognising the Participatory Domestication Approach must first be established to test, monitor, and propagate possible cultivars of elite trees and ideotypes.

Agroforestry in Finland: case study of innovations in agroforestry farms in Finland

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Tanja Kähkönen[1]
Michael den Herder[1]
[1] European Forest Institute

Abstract: Agroforestry is among non-mainstream land use practices in Finland. However, those farmers, forest owners and landowners who practice it in Finland carry information that is not available in conventional agricultural and forestry advisory systems. The traditional knowledge that agroforestry farmers use and pass on in their agroforestry practices is largely silent information for conventional agriculture and forestry advisors as well as to conventional farmers. In the Agroforestry Business Model Innovation Network project (AF4EU) innovative agroforestry farm business models will be analyzed. A multi-actor regional agroforestry innovation network in Finland is used for identifying innovative agroforestry farms in Finland. In this presentation we will explore the identified innovative agroforestry farm business models in Finland by exploring three farm cases from economic, environmental and social sustainability perspectives. The data is collected through interviews and surveys of farmers involved in the identified innovative agroforestry farm cases. Besides the innovative agroforestry farm cases, we explore the associated value chains. The results of this study give new insights particularly for farmers, advisors and policy makers on agroforestry in Northern Europe, a region not typically included in global discussions on advancement of different agroforestry systems.

Commercializing of traditional non-timber forest products in the plateau region: A case study of Matsutake in Shangri-La, Yunnan Province

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Xinyang Li[1]
Ryo Kohsaka[2], Jinlong Liu[1]
[1] Renmin University of China
[2] The University of Tokyo

Abstract: Commercialization of non-timber forest products is one of the important strategies to alleviate rural poverty and forest degradation. In recent years, China has explored this strategy to get sustainable ecological products, and the commercialization of Matsutake in Yunnan Province is one of these typical cases of transition from traditional gathering to economic activity. This study conducted a qualitative approach combined with commodity chain analysis to show the interrelationship of different participants along the wild mushroom commodity process in the southwest plateau of China. Taking Matsutake as an example, our research shows that the upstream and downstream participants in the Matsutake commodity chain are constrained by different types of institutional constraints. Besides, not every actor along the chain has access to the latest market information. Compared with local people, the middleman in the Matsutake transaction process can get a high-profit margin. The protection of natural resources and the formation of a stable market order are impacted by government and non-governmental organization activity to some extent, but the impact is neither substantial nor long-lasting. Our research indicated that to enhance both socio-cultural sustainability and ecological sustainability of the commodity chain of non-timber forest products in the plateau area, it is important to balance the interests of different participants along the commodity chain and utilize local traditional knowledge.

Comparative study of nyamplung and argan oils: positioning strategies in the Korean market for nyamplung oil from Indonesia

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Mihyun Seol[1]
Seongmin Shin[1], Himlal Baral[1]
[1] 1Center for International Forestry Research and World Agroforestry (CIFOR-ICRAF), Jalan CIFOR, Situ Gede, Sindang Barang, Bogor Barat 16115, Jawa Barat, Indonesia

Abstract: This research comparatively examined the primary effects, prevalent product variants and market attributes of nyamplung and argan oils to develop an efficient market and establish branding strategies for nyamplung oil (produced from *Calophyllum inophyllum* L) in the South Korean market. Employing a systematic review methodology, we investigated the socioeconomic and environmental advantages of nyamplung-based agroforestry systems and evaluated nyamplung oil's potential as a feasible alternative to other wood-based oils, such as argan oil (produced from *Argania spinosa* L). Our conclusions indicated that nyamplung oil could have significant potential in the Korean market, particularly when positioned as a natural, eco-friendly and fairly-traded product. We propose a three-stage positioning strategy for nyamplung oil: 1) analyzing current position in the market as a cosmetic product; 2) developing a product line extension as a medical product; and 3) considering image creation as a unique tree oil with environmentally valuable features. These approaches could support nyamplung oil's reception in the market by leveraging similarities with argan oil while differentiating itself through emphasis on its special benefits and environmental values. Through these approaches, we argue that nyamplung oil could contribute to the economic, social and environmental well-being of producers in Indonesia while providing Korean consumers with a high-quality, sustainable and effective natural product. For future studies, we recommend to investigate Korean consumers' preferences, establish a chain of custody study for sustainable production, or build a certification strategy for nyamplung oil.

Contribution of Oyster nut Women growers to Household Income in Northern Tanzania

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

PHILIPINA F. SHAYO[1]
ERNEST R. MBEGA[2], ANNA C. TREYDTE[2]
[1] MBEYA UNIVERSITY OF SCIENCE AND TECHNOLOGY
[2] NELSON MANDELA AFRICAN INSTITUTION OF SCIENCE AND TECHNOLOGY

Abstract: Oyster nut [*Telfairia pedata* (Smiths ex Sim)] Hook is a native vine that is cultivated in East Africa, it produces nuts which can be consumed raw or cooked and used as cooking oil. They are highly preferred by nursing mothers due to their lactogenic properties, which increase their milk flow. The study was undertaken to examine the contribution to household income by women growers of oyster nuts by using semi-structured questionnaires and ecological survey from a sample of 346 respondents in the districts of Lushoto, Bumbuli, Arumeru, and Same in Northern Tanzania. Factors influencing productivity and market participation among oyster nut growers were examined and those affecting women's participation in oyster nut cultivation are provided. Also the number of women growers, in the traditionally male-dominated communities, who contribute to household income from oyster nuts is less known. The market participation of oyster nut growers varied, depended on factors including gender, marital status, level of education and previous market experience to mention a few. According to the findings, oyster nuts were mainly produced by women (87%) compared to men (13%) and the majority of respondents (21%) used the nuts for cooking with other local staple meals, 18% were used by breastfeeding mothers and the least nine percent claimed to use the nuts for cultural and ritual purposes. The average annual income for women engaged in oyster nut farming in the study area was TZS. 640,000 ($273.50), and delivered 5% of the total household income. Oyster nut women growers' appear to be significantly involved and productive to household income, making it essential for increasing sustainable production, meeting expanding demand, and exploring the crop's potential as an underutilized oilseed crop.

Keywords: *Telfairia pedata, utilization, production factors, market participation*

Ecofeminism to analyze gender in geographical indications for non-timber forest products: the case of Madd of Casamance

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

María Camila Robledo Rodríguez[1]
Nathalie Cialdella[1], Claire Cerdan[2]
[1] CIRAD, UMR INNOVATION, F-34398 Montpellier, France. INNOVATION, Univ Montpellier, CIRAD, INRAE, Institut Agro, Montpellier, France.
[2] CIRAD, UMR INNOVATION, F-97455 Saint-Pierre, Réunion, France. INNOVATION, Univ Montpellier, CIRAD, INRAE, Institut Agro, Montpellier, France.

Abstract: Recognizing a product as a geographical indication (GI) generates positive effects on territorial development. Yet, GIs' labels implemented in many contexts and scales lack gendered conditions, representations and abilities to face environmental and social challenges. Rare studies suggest that GIs generate negative gender effects such as invisibilizing women and their know-how. This communication explores potential effects of the GIs' process on gender, by analyzing a non-timber forest product (NTFP): Madd of Casamance (MOC) in Senegal. We mobilize an ecofeminist framework, which focuses on the relationship between the subordination of women and the degradation of nature stemming from the ethics of care. Our methodology is based on a literature review, documents analyses and interviews with key stakeholders of the MOC value chain. We collect data in all Casamance's subregions. The gender system within the GI of MOC is analyzed and compared to the traditional gender system of Casamance's rural communities. Our results describe the role of women and men within the value chain, while highlighting the work of women and their know-how in the transformation of the Madd. While looking at exploitation levels regarding an emerging market, we, furthermore, analyze, according to gender, the changes affecting the control of Madd resources. We confirm that in this case, the GI registration seems to highlight the work of women and their know-how in the transformation of the Madd. Regarding the control of a market and its resources, our adoption of an ecofeminist framework to describe gender systems in the GIs' labeling process for NTFP gives evidence on the inclusion—or exclusion—of women and their know-how. Our findings can be used to analyze gender systems in other GIs with NTFP.

Effects of socio-ecological determinants on carbon accumulation in traditional agroforestry: A Case of Vhembe Biosphere Reserve, South Africa

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Lucky Makhubele[1]
Paxie Chirwa[1], Mulugheta Araia[1]
[1] University of Pretoria

Abstract: Traditional agroforestry has been explicitly recognised worldwide for its positive contribution to biodiversity conservation, climate change mitigation, sustainable land use and improving socio-economic livelihood. Little has been reported regarding the effects of socio-ecological determinants on the carbon sequestration potential of traditional agroforestry in South Africa, especially in the Vhembe Biosphere Reserve (VBR). The main objective was to quantify the tree carbon stock in the VBR traditional agroforestry landscapes along the distance levels, immediate, intermediate, and far distance from villages to the forest. The data were collected and analysed using Diversity indices, Important value index, Allometric equation, Anova, Generalised linear model and Pearson correlation. The results showed no statistically significant differences in total carbon stocks ($F= 0.888$, $p= 0.413$) between the distance levels, with the same amount of carbon stocks stored in the vegetation at all distance levels. When all socio-ecological determinants were considered together, elevation, density and basal areas were the significant predictors of carbon stock. This study concludes that maintaining and enhancing species diversity in traditional agroforestry landscapes can be an effective strategy to achieve the climate change mitigation goals provided this is finely balanced with the livelihoods needs of the local communities.

Mangrove forest food products as alternative ways for mangrove conservation in Muara Gembong, Bekasi Regency, Indonesia

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Kevin Muhamad Lukman[1]

Abstract: Mangrove forests provide diverse ecosystem services, yet, are subjected to anthropogenic threats. In the case of Indonesia, where mangroves are declining due to deforestation, the government has accelerated in promoting mangrove restoration program through the declaration of the national agenda on mangrove rehabilitation. One prominent approach being adapted by Indonesia is through community-based mangrove management, in which locals can be benefited. Among the benefits is through production of Non-Timber Forest Products (NTFP). Our case study presents NTFPs of mangroves in Muara Gembong, Bekasi Regency, West Java Province. The focus group discussion (FGD) revealed that NTFPs of mangroves can be used to promote mangrove conservation, however, strong commitment from the community and support from external organizations such as government and non-government agencies are needed. Results of the FGD further showed the huge potential of NTFPs to encourage more women to part take in mangrove conservation activities, which is currently dominated by men. Overall, there are still remaining challenges of bringing NTFPs for mangrove conservation in Indonesia such as branding and marketing of products. Thus, further understanding of utilizing NTFPs is needed to enhance the existing practices in Muara Gembong, and at the same time identifying potential stakeholders for collaboration.

Native plants-based basketry: a natural, cultural, and bioeconomic forest heritage in Chile

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Juana Palma Martínez[1]
Marta García Ortega[1], Eduardo Molina Rademacher[1], Patricio Chung Guin-Po[1]
[1] Chilean Forest Institute

Abstract: Traditional basketry, made from different plant materials, is still produced by many people worldwide. In Chile, the temperate forest provides more than 15 plant species used in traditional weavings, mostly for the *mapuche* culture. This study aimed to systematize ecological, cultural, and economic information from three plant species and visualize the plant-based weaving practice as a heritage for conservation. A respectful and participatory method was conducted, considering the help of men and women involved in basketry in the *mapuche* culture. Aside from semi-structured interviews, several harvest stands in the forest were visited, as well as production workshops, and markets to gain first-hand knowledge of the materials and weaving processes. The study species were *Greigia sphacelata* (Bromeliaceae), *Boquila trifoliolata* (Lardizabalaceae) and *Luzuriaga polyphylla* (Alstroemeriaceae).

The main results indicate that the three species are an important natural-cultural heritage from forests and indigenous people for centuries. *G. sphacelata* is a perennial herbal plant growing in the forest understory. Its leaves are used to weave ropes, baskets, fish traps, and a bag as a storage container. The most important group of *mapuche-lafquenche* artisans is located in the Budi Lake Basin in the Araucanía region. *B. trifoliolata* is a common evergreen climber vine. Its flexible stems are used for basketry like baskets, decorative objects, and making ropes. The largest group of *lafquenche* artisans is located in Alepue, a coastal range in Los Ríos region. *L. polyphylla* is a hemiepiphytic climbing plant. Its particularly stable and elastic aerial roots are used by the *huilliche* of the Chiloé Archipelago in Los Lagos region, to make ropes, baskets, and other everyday objects. The three, are moderate light species, which are growing in treefall gaps, secondary forests, and old-growth forests. Although deforestation and private forest property attempt against obtaining weaving material, and traditional knowledge could be at risk, the demand for forest-based basketry is increasing. With the participation of the government, enterprises, and farmers, the weaving products have formed a development model of natural-cultural heritage from the forest, which is the basis for advancing toward a bioeconomy that incorporates basketry.

Social Forestry Capacity Development in Sub-Sahara Africa through Knowledge Co-Creation and Information Sharing

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Wanjiku Josephine[1]
Josephine Wanjiku[1], Musingo T. E. Mbuvi[1], Paul Tuwei[1], Honjo Yuki[1]
[1] Kenya Forestry Research Institute

Abstract: Many communities in Sub-Saharan African (SSA) countries depend on natural resources for their livelihood and provision of ecosystem services. However, over utilization of forests and woodlands, and unsustainable agricultural practices continue to cause environmental degradation. Recurrent and emerging environmental challenges create a need for knowledge co-creation through comprehensive partnerships and capacity development. Social forestry was therefore identified as an approach that would motivate communities in Africa to invest in sustainable environmental management. To build capacity of stakeholders within SSA in Social forestry, Kenya Forestry Research Institute (KEFRI) in collaboration Japan International Cooperation Agency (JICA) implemented a five-week training course annually in Kenya under the Third Country Training Programme (TCTP). The Programme, which was implemented from 1995 to 2018 evolved in scope to address emerging challenges in Natural Resource Management (NRM) which included: low awareness and adoption of social forestry technologies, and climate change effects. The Programme targeted to train partners from governmental and non-governmental organizations involved in NRM activities. The training curriculum was developed by identifying training needs through; Training Needs Assessment (TNA) and continuous review by applying After Course Evaluation (ACE) feedback by participants. Interactive training methodology comprising of: presentations by various experts drawn from relevant institutions; country reports presentation by participants; group work; discussions; themed field visits to selected farmers or organizations sites; field report writing; and development of implementation action plan. Knowledge co-created through research and development by KEFRI and technical cooperation by JICA provided information for addressing emerging NRM challenges. Paper presentations and discussions informed on concepts and practical application of social forestry technologies. Field visits exposed participants to technologies with high adoptability, while Action Plan development built capacity of participants in activity planning and resource mobilization abilities. Participant's feedback through ACE tool gave important information that was used in identifying; gaps, lessons and emerging challenges; as well as modifying and improving course content to ensure relevance and positive impact of the training. Kenya, having similar environmental conditions with many SSA countries, offered a good learning ground by showcasing practices for addressing environmental degradation and climate change effects.

The Effects of Pollarding on Tree Structure in the Northern Zagros: A Photogrammetric UAV Assessment

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Abstract: Pollarding is a traditional silvopastoral technique practiced in many parts of the world, including the northern Zagros mountain region in Iran, which is known as an ecologically and culturally significant semi-arid forest area. So far, the effect of pollarding on tree structure - specifically the relationship between Diameter at Breast Height (DBH) and Height (H) - has not been studied, although it is crucial for further analysis on the tree allometries across such fragile forest stands. We combined field inventories of DBH with H coordinates acquired from UAV flights to investigate DBH ~ H relationships. Results showed a linear relationship between UAV-extracted H and maximum DBH of pollarded trees, explaining 56% of the observed variation. More complex non-linear allometries did not significantly differ from the performance of the linear model. The model was consistent across oak species, although the pollarding stage had a significant effect on the DBH ~ H relationship. This research is important for biomass inventory across larger areas of northern Zagros, and for DBH estimations in stands of multi-stem coppice structure in other semi-arid ecosystems.

The influence of social capital on the poverty reduction of rangeland agropastoral communities in the Bamyan province, Afghanistan

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

YOHAN LEE[1]
[1] Seoul National University

Abstract: This study investigates the contribution of social capital to the poverty alleviation of rangeland agropastoral communities that are based on agriculture and the rearing of livestock in the Bamyan province of Afghanistan. We collect data through a field survey from the randomly selected 186 households in three rangeland villages in the Bamyan Province, Afghanistan. The relationship between social capital and household poverty was analyzed using binary logistic regression and correlation analysis. Results of our case study show that social capital has a significant impact on alleviating the poverty of rangeland households in Afghanistan. To address the poverty issue of forest dependents, the local level strategy of community development programs should target rangeland communities to build up their social capital for supporting forest tenures and benefit sharing among marginalized people.

Traditional knowledge as the foundational element for a sustainable pathway to a NTFP-based bioeconomy

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Mi Sun Park[1]
Suyeon Min[1], Pinky Dayandante[1], Eun Soo Kim[1]
[1] Seoul National University

Abstract: Forest communities have a long history of gathering, producing, and using non-timber forest products through agroforestry practices. They have maintained and transferred traditional knowledge related to non-timber forest products through their networks from generation to generation. Recognizing the diverse values of non-timber forest products, traditional knowledge also gained attention as an important social asset. Focusing on the non-timber forest product industry, traditional knowledge can be identified as a strategic value for revitalizing the non-timber forest product industry. This study has systematically reviewed and analyzed the cases of non-timber forest products and traditional knowledge. It classified the types of using traditional knowledge in producing and consuming non-timber forest products. This research indicates the changes in the values of traditional knowledge in the non-timber forest product industry and the potential of the sustainable pathway to a non-timber forest products-based bioeconomy.

Utilization Status and Conservation Factors of Traditional Knowledge existing in Mountain Villages of Nepal

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Ryutaro Ueda[1]
Kazuhiro Harada[1]
[1] Graduated School of Bioagricultural Sciences, Nagoya University

Abstract: Traditional knowledge continues to be utilized in daily life in Asian developing countries, including mountain villages, although it is rapidly disappearing. In Nepal’s mountain villages, the threat to the preservation of the traditional knowledge is evident. This is primarily due to the shift from subsistence farming to commercialized agriculture driven by the introduction of the new crop varieties aimed at improving livelihoods, as well as the migration of the population from the mountain villages to the cities. However, there are also instances where traditional knowledge is employed to promote regional development through tourism and product innovation. Therefore, in Nepal's mountain villages, there is both a loss of traditional local resources due to changes in social structure, an increase in the utilization of these resources for regional development.

This study aims to elucidate the current status of local knowledge, specifically traditional agriculture practices in Nepal’s mountain villages. It seeks to understand why this knowledge has been preserved and how it is used. The study was conducted in two villages, Bihunkot in Baglung district and Thaprek in Tanahun district. Both of which are considered to have different level of traditional knowledge preservation. In both village, traditional agricultural knowledge related to crops like, wheat, rice, finger millet and orange are maintained.

To ensure the sustainable development of mountain villages and preserve traditional knowledge, we propose the following measures: (1) establishing a comprehensive creation of the conservation system that involves various stakeholders many actors from inside and outside the region. (2) Promoting innovative approaches to utilize local knowledge, such as conservation initiatives with tourism.

Xate leaves (Chamaedorea spp.) and Ramón seeds (Brosimum alicastrum Sw.), a bioeconomy example in the Maya Biosphere Reserve, Guatemala

T2.32 Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

Juan Pablo Rodriguez Garavito[1]
Roger Villalobos Soto[1], Alejandro Imbach[1], Fernando Carrera[1]
[1] Centro Agronómico Tropical de Investigación y Enseñanza (CATIE)

Abstract: This work contains a systematization of experiences that show the social construction of a territory: the Community Forest Concessions (CFCs) of the Maya Biosphere Reserve (MBR). Xate leaves (*Chamaedorea spp.*) and Ramón seeds (*Brosimum alicastrum* Sw.) are two non-timber forest products (NTFPs) which have given rise to one of the most successful cases in the world in terms of forest management, halting deforestation and promoting a sustainable and inclusive development for the local communities. These two NTFPs form very important value chains. Both assets have contributed at different stages of the concession process to adding value to the forest, conserving and even restoring it. The community organization at different levels has been able to effectively market the products, find strategic allies, with whom more and more value has been added to the primary products extracted from the forest. A clear and ambitious plan on the part of the CFCs has led to national and international partners investing in the technification and certification of the processes, with which they have been able to enter in more and better markets. Through ethnographic methods and participatory techniques, we found that the CFCs are enterprises with an efficient organization of their finances, with which they have invested in a better knowledge of their management units and therefore in well-structured plans to maintain the supply of products for which there is a stable market, and in the promotion of forest goods without buyers yet. The main outcome of this work are 18 technical and socio-economic bases that made possible the success of these two value chains. The most important bases are local leaderships, cultural identity with the product and land tenure certainty. On the other hand we got the strengths, weaknesses, opportunities and threats with the participation of all the actors who play a role in the chain, trying not to obtain partial views. Finally, the future perspectives allow us to have clear ideas of the key factors to unlock an effective bioeconomy for common goods that, when regulated by a strong community base, are a clear example of effective governance.

T2.33 Transitioning to a Bioeconomy with Non-Timber Forest Products: Leadership from Latin America and the Caribbean

Bases for the sustainable management of a wild species for fruit production: a study case of non-timber forest products in Colombia

T2.33 Transitioning to a Bioeconomy with Non-Timber Forest Products: Leadership from Latin America and the Caribbean

Blanca Luz Caleño Ruiz[1]
María Claudia Torres Romero[1], Carolina Castellanos Castro[1]

Abstract: The sustainable use of non-timber forest products in natural forests is a promising activity. It generates additional income for peasant communities inhabiting forests and promotes conservation because it increases the value and importance of forests and reduces their conversion to other uses. However, to promote this activity in Colombia, technical and traditional information about biology, ecology, and management is necessary for correct decision-making related to the sustainable harvest rate.

Considering the necessary information and the parties involved in the correct management of the agraz species (*Vaccinium meridionale*) that inhabits the Colombian high Andean forests, we coordinated a work team with local peasant communities to obtain information about its biology, ecology, and harvesting process to evaluate its current state and plan its sustainable use. We established 41 10x10 m plots on different land covers of high Andean forests in Ráquira (Boyacá, Colombia) to evaluate population abundance and structure of the agraz. All shrubs were tagged, and the diameter of the thickest stem (cm), total height (m), crown diameter, and harvest characteristics were measured. Three local peasants monitored fruit harvest (g) on ten shrubs during February-April 2020, and the harvesting activity was characterized through semi-structured interviews and participant observation among the work team. 1071 individuals were found in the 41 plots and were grouped into 554 seedlings, 393 juveniles, and 124 adults. The average abundance of agraz species was 0.26 shrubs/m^2 (2600 shrubs/ha), and it was similar on different land covers. The population structure followed a negative exponential distribution indicating a relatively stable population unaffected by harvest activity. Each shrub produced, on average, 1.04 kg of fruits, and 0.66 kg (61.1%) were manually harvested by local peasants without causing damage or death to the shrub. The peasant harvesters were organized under the associative model to commercialize their product, which is highly attractive in the market, but their activity lacked promotion and cultural and traditional recognition. Our results suggest that this activity is highly sustainable due to its ecological, economic, and social potential, but it requires the support and promotion of local institutions. Finally, we recommended keeping harvest rates of fruits under 70%.

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Assessing ecosystem services of tropical forests and peatlands based on multiple restoration project scenarios

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Cholho Song[1]
Chul-Hee Lim[2], Hyun-Ah Choi[1, 3], Woo-Kyun Lee[4], Eunho Choi[5], A-Ram Yang[5]

[4] Division of Envionmental Science and Ecological Engineering, Korea University, Republic of Korea
[5] Divison of Global Forestry, National Institute of Forest Science, Republic of Korea

Abstract: Many international organizations have tried to launch proper conservation and restoration projects, as tropical forests and peatlands in Indonesia are considered to be an important carbon sink globally. Thus, understanding the potential impact of conservation and restoration is required before the decision-making process. In this study, we assessed the value of ecosystem services with the possible restoration project scenarios including remaining current status, expanding agricultural area, and ecosystem restoration. First off, we focused on the assessment at the provincial level within Sumatra Selatan and Jambi provinces. We analyzed land cover changes from 1992 to 2020 and developed various scenarios based on the historical trends of land cover changes. Ecosystem services of carbon storage, habitat quality, water yield, and crop yield were spatially analyzed with InVEST (Integrated Valuation of Ecosystem Services and Tradeoffs) model and other assessment approaches. Second, we narrowed down the assessment scope at the local level to design more suitable projects for the local communities. A systematic review, scenario building based on assessing ecosystem services of forests and peatlands status at the local level was conducted in Perigi, Sumatra Selatan and the Londerang, Jambi for in-depth ecosystem services assessment. Each scenario showed different benefits and pitfalls. However, the ecosystem restoration scenario had the strongest benefits on carbon storage and habitat quality. Some anthropogenic pressures, such as agricultural land conversion and urban expansion, negatively affected ecosystem services in numerous scenarios. Through the quantification of scenarios, we found that proper conservation and restoration approaches could be identified in the project development phases. This study may contribute to the future ecosystem services-oriented project management for a wise climate change adaptation and securing global carbon sinks.

Assessment of peat forests disturbances in the Central Congo Basin

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Karimon Nesha[1]
Martin Herold[2], Johannes Reiche[1], Robert Masolele[1], Kristell Hergoualc'h[3]
[1] Wageningen University & Research
[2] HelHelmholtz GeoResearch Center Potsdam (GFZ)
[3] Center for International Forestry Research (CIFOR)

Abstract: The Cuvette Centrale in Africa encompasses one of the largest tropical peatland complexes. However, information is yet limited on peatland disturbances in the Cuvette Centrale. We assessed the peat forest disturbances and their drivers occurring between 2019 and 2021 in the Cuvette Centrale, spanning the Republic of Congo (ROC) and the Democratic Republic of Congo (DRC). We utilized Sentinel-1 based RADD alert forest disturbances data for analyzing the spatial-temporal distribution of these disturbances. Further, we employed the monthly planet data from NICFI platforms to investigate the drivers behind these disturbances. We sampled 2000 RADD alert events randomly over the Cuvette Centrale for assessing drivers. The alert events were defined as the individual connected patches in the alert dataset. The preliminary findings revealed that the most of peat forest disturbances occurred in the DRC, with high-intensity disturbances concentrated in the northwest region of the DRC and along the Congo River across both in the DRC and ROC. Between 2019 and 2021, we identified five primary drivers: agriculture, logging, floods, road development, and small settlements. Agriculture was the most prevalent driver, accounting for over 80% of the sampled events, followed by logging at approximately 10%. More than 90% of the agricultural events were located in the DRC. Although logging was also more prevalent in DRC, ROC had a relatively large share of these events (~ 25%). The majority of the drivers corresponded to small events (< 0.5 ha in size). For two prominent drivers - agriculture and logging, around two-thirds and three-quarters of events, respectively, were small. Although large agriculture events comprised only 3% of all events, they cover around 20% area of all events. A great majority of large events (~95%) were agriculture. Notably, agricultural events exhibited a seasonal pattern, occurring more frequently during dry periods. Whereas logging events showed no such pattern indicating they occur regardless of the time of the year. These insights from our study provide valuable information regarding peat forest disturbances and their drivers that would serve as a useful reference for scientists and policymakers involved in the protection and restoration of peat forests in the Cuvette Centrale.

Composition and Structure of Secondary Peat Swamp Forest and Comparative Analysis on Individual Tree Detection using LiDAR for Carbon Measurement

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Ajeng Adventiaputri[1]
Taryono Darusman[1], Dwi Puji Lestari[1], Desra Arriyadi[1]
[1] Katingan Mentaya Project

Abstract: Although there are few existed applications of airborne laser scanning or LiDAR in terms of the composition and structure of the vegetation in peat swamp forests, the costs of LiDAR are decreasing. With the help of the packages lidR and lidaRtRee from the Rstudio package for Forest carbon monitoring measurement, we try to assess the vegetation and compare it to the lidar tree detection. In six different plots with varying sizes (two 25x25-meter plots, three with five 20x20-meter subplots, and one 100x100-meter plot), we measured the tree composition and DBH above 10 cm. We discovered that *Tetractomia tetrandra* (Rutaceae), *Campnosperma coriaceum* (Anacardiaceae), and *Diospyros areolata* (Ebenaceae) dominate the largest plot, with percentages of Important Value Index of 51.69%, 34.99%, and 22.98%, respectively. The density of each life stage reveals the structure of the vegetation. We discovered 95 individuals per 100 m2 (or 9500 individuals/ha) in seedlings, 459 individuals per 125 m2 (or 6496 individuals/ha) in saplings, and 676 individuals/ha in poles and trees. The method we used for tree detection makes use of the Canopy Height Model (CHM) raster (lidaRtRee) and point cloud base data (li2012, Local Maxima Function (lmf), and fixed window size). We acquire the number of trees in each plot after applying lidR and lidaRtRee to the cloud-based data, which results in the lowest RMSE and MAPE in the 20cm up DBH using LMF Function and lidaRtRee (RMSE=16.79, MAPE= 0.31 and RMSE= 18.75, MAPE=0.38 respectively). We analyze the lidar dataset's crown area and height for the carbon measurement, and then use allometry to determine each tree's diameter. We presumed that each tree's carbon fraction and wood density would be the same. Utilizing the lmf function and employing height information to calculate DBH yields the carbon measurement result that is most accurate to the actual data.

Fires and diversity of tropical peat swamp forests

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Luba Volkova[1]
Haruni Krisnawati[2], Muhammad A. Qirom[2], Wahyu C. Adinugroho[2], Rinaldi Imanuddin[2], Freddy J Hutapea[1, 2], Michael A. McCarthy[1], Julian Di Stefano[1], Christopher J. Weston[1]
[1] School of Ecosystem and Forest Sciences, Faculty of Science, The University of Melbourne, Australia
[2] Research Center for Ecology and Ethnobiology, Research Organization for Life Sciences and Environment, National Research and Innovation Agency (BRIN), Indonesia

Abstract: Tropical peat swamp forests contain diverse plant communities that support many endangered flora and fauna species. These forests are increasingly threatened by disturbances such as drainage, logging, and subsequent fire, yet little is known about tree species recovery from these threats.

Tree species richness and diversity were measured in peat swamp forests of Central Borneo regenerating naturally after fires from 139 chronosequence plots. Our findings indicated that two to three decades after fire, similar levels of richness and diversity to relatively undisturbed reference forest are reached within sites.

However, when averaged across landscapes our modelling shows that fires of average frequency of 50 years, or even 100 years, can substantially suppress tree species richness and diversity. Thus, even rare fires can reduce the species richness and diversity of tropical peat swamp forests.

Two groups of tree species drove the difference in richness and diversity between disturbed and reference forests: ‘decreasers’, occupying recently burnt forest and declining with fire exclusion, and ‘increasers’, that were only present in less disturbed forests and absent or rare in recently burnt forests. The decreasers were more common than the increasers.

We conclude that peat swamp forests can recover adequately from fires through natural regeneration, and it is possible that artificial planting may speed up this process. Where possible, excluding fire from tropical peat forests will help to maintain the diversity of these threatened ecosystems and promote their recovery.

How to measure Peatland restoration success: Principles, Criteria and Indicators for assessing outcomes

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Rupesh Bhomia[1]
Anna Sinaga[2], Siti Chaakimah[2], Meli Saragi-Sasmito[2], Arimatea de Carvalho Ximenes[3], Daniel Murdiyarso[2]

[2] CIFOR-ICRAF, Situ-Gede, Bogor, Indonesia
[3] CIFOR-ICRAF, Sao Paolo, Brazil

Abstract: Preserving and restoring peatlands is critical for climate change mitigation, ecosystem health and community development in many parts of the world. But existing pressures lead to peatlands drainage and conversion to other land uses. These degraded peatlands can be targeted for restoration to reduce the loss of carbon and other important ecological services natural/undrained peatlands provide. Successful restoration of degraded tropical peatlands in Indonesia could mean significant progress towards country’s commitment for reducing emissions and meeting its NDC pledges while ensuring sustainable and equitable growth.

Indonesian peatland restoration follows strategies that target future sustainable land use and management, social justice, livelihoods and governance. These strategies underpin restoration activities such as re-wetting, re-vegetation, revitalization of communities and avoidance of peat fires. But effective long-term restoration must be carefully monitored to adapt designs, strategies and management approaches that can meet specified goals.

Availability of tested standard tools to assess the outcomes of restored ecosystems can help practitioners to determine successes and failures of peatland restoration. Availability of simple, easy to recognize, measurable indicators for monitoring progress over time can be very helpful. We developed robust, reliable, and practical set of criteria and indicators (C and I) to help assess progress and outcomes of peatland restoration through collaboration of relevant govt. institutions, expert consultations, and field verification at actual restoration sites. Using four broad categories (Bio-physical, Economic, Social and Governance) to determine restoration progress, we found identified C and I provide a reliable practical tool that can be used by mangers. This C and I approach can be applied to assess restoration progress at a site over time or to compare different restoration sites. In this presentation, we will share the set of C and I for peatland restoration monitoring and discuss the nuances of our iterative process to formulate these.

Landowners' perceptions of carbon farming and livelihoods' improvement in South Sumatra, Indonesia based on adoption of agrosilvofishery models

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Mihyun Seol[1]
Seongmin Shin[1], Yustina Artati[1], Himlal Baral[1]
[1] Center for International Forestry Research and World Agroforestry (CIFOR-ICRAF), Jalan CIFOR, Situ Gede, Sindang Barang, Bogor Barat 16115, Jawa Barat, Indonesia

Abstract: Tropical peatlands in Indonesia have substantial potential to store vast amounts of carbon yet experience extensive degradation caused by conversion for agriculture, logging and mining. This has led to the pursuit of solutions for restoration of peat-ecosystem functions. One of the potential solutions, agroforestry, was recommended as a best practice for peatland restoration by the Indonesian Ministry of Environment and Forestry. This study examined the socio-economic factors influencing adoption of agrosilvofishery practices, which could support both peatland restoration and livelihoods' improvement. A structured questionnaire survey was conducted with landowners and farmers in Central Kalimantan to assess their perceptions of, and willingness to adopt, agrosilvofishery models for carbon farming and livelihoods' improvement. Findings implied that family roles, education level and experience with tree-based livelihoods significantly affected the willingness of farmers to adopt agrosilvofishery practices. On the one hand, some agricultural characteristics and lack of knowledge of technical aspects negatively influenced their adoption. On the other, the perception of potential improved well-being from the agrosilvofishery practices positively influenced farmers' willingness to adopt. This study highlighted the importance of effective communication strategies and teaching methods to address perceived barriers. We anticipate that the adoption of the agrosilvofishery practices by the farmers could be positively increased through strategies that targeted decision-makers, promoted local connections, simplified technical information, emphasized well-being benefits and addressed productivity concerns.

Net CO2-eq Emissions from Rewetted Peatlands and Other Land-Uses

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Taryono Darusman[1]
Desra Arriyadi[1], Zidna Sabiila Husna[1], Dwi Puji Lestari[1], Impron impron[2], Daniel Murdiyarso[2, 3]

[3] Center for International Forestry Research – World Agroforestry (CIFOR-ICRAF), Jl. CIFOR, Situgede, Bogor 16115, Indonesia

Abstract: There is no silver bullet to reduce greenhouse gas emissions from degraded peat swamp forests (PSF). Rewetting has been proposed to be one of the candidates, but at the same time, CH_4 emissions will be increased. While revegetating the degraded landscape with agroforestry practice, the choice and combination of species are poorly understood. Our five years long measurements (2019-2023) using Ultraportable Greenhouse Gas Analyzer (UGGA) showed that the annual average of total CO_2 emission in the rewetted peat swamp forest (PSF) site was the lowest (10.04 ± 0.4 CO_2 Mg $ha^{-1}ar^{-1}$) followed by undrained PSF (11.3 ± 0.7 CO_2 Mg $ha^{-1}yr^{-1}$) and agroforestry practices on peatland (22.1 ± 1.5 CO_2 Mg $ha^{-1}yr^{-1}$). On the contrary, the annual average of CH_4 emissions was the highest in the undrained site (168.9 ± 6.8 CH_4 Kg $ha^{-1}yr^{-1}$) compared to the rewetted site (74.2 ± 11.4 CH_4 kg $ha^{-1}year^{-1}$), and the agroforestry site (4.9 ± 1.3 CH_4 kg $ha^{-1}yr^{-1}$). Therefore, the net CO_2-eq emissions from re-wetted, undrained, and agroforestry on peatland were 11.9 ± 0.5 Mg $ha^{-1}yr^{-1}$, 15.5 ± 0.7 Mg $ha^{-1}yr^{-1}$, and 22.2 ± 1.5 Mg $ha^{-1}yr^{-1}$ respectively. While it is not entirely new, agroforestry in peatland ecosystems offers opportunities to explore appropriate practices regarding the choice of species from the perspectives of climate and local community agenda.

Keywords: *Peat restoration*; *heterotrophic respiration; GHGs emissions; nature-based solution; peatland agroforestry.*

Net greenhouse gas balance of fibre wood plantation on peat in Indonesia

Abstract: Tropical peatlands are important sinks of atmospheric carbon dioxide (CO_2), having accumulated at least 75 gigatonnes of carbon over millennia. However, they are threatened by changes in climate and land-use - particularly those that affect the groundwater level dynamics. When groundwater levels fall below the peat surface, stored carbon decomposes, resulting in CO_2 emissions. Yet, estimates of greenhouse-gas (GHG) exchanges in tropical peatlands have been highly variable owing to a dearth of high-quality contemporary measurements. Given the role of tropical peatlands as nature-based mitigators of climate change, having accurate estimates of contemporary GHG exchanges and their relationship with controlling factors, can improve our understanding of their global climate impact, and support responsible peatland management and optimization of emissions mitigation measures.

Between mid-2016 and mid-2022, we measured GHG exchange in intact forest, degraded forest and *Acacia crassicarpa* plantation (17–22 years after initial plantation establishment) in the same peat landscape of Sumatra, Indonesia. We used the eddy-covariance technique to measure the net exchanges of CO_2 and methane between the ecosystem and atmosphere, and the chamber to measure soil nitrous oxide exchanges. The plantation's CO_2 emissions is calculated as the sum of net ecosystem CO_2 exchange and harvested wood carbon export, conservatively assuming that all harvested wood carbon will be returned to the atmosphere as CO_2. To our knowledge, this study is the first investigation of GHGs in any peatland-based fibre-wood plantation to cover a full plantation-rotation period and to encompass all major GHG flux terms.

The CO_2 emissions from the *Acacia* over a full plantation rotation were half of the current Intergovernmental Panel on Climate Change Tier 1 emission factor for this land-use type. The

conversion of intact forest to *Acacia* plantation results in a long-term net increase in GHG emissions equivalent to 18 tonnes of CO_2 per hectare per year, which is smaller than the increase associated with the degradation of intact forest. Our results confirm that conserving, restoring and sustainably managing peatlands will be important for meeting nationally determined contributions (as defined by the Paris climate agreement) to limit global warming to 1.5 °C above pre-industrial levels.

Peat greenhouse gas emission factors: Concepts, applicability, and research needs

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Kristell Hergoualc'h[1, 2]
[1] Center for International Forestry Research (CIFOR), Lima, Peru
[2] Centre de coopération International en Recherche Agronomique pour le Développement (CIRAD), UMR Eco&Sols, Montpellier, France

Abstract: Over millennia, peatlands have slowly accumulated vast amounts of carbon (C) and nitrogen (N) in their soil. When disturbed through degradation, drainage, fire or land-use conversion, C and N dynamics in peat soils are profoundly altered as are their greenhouse gas (GHG) emission rates. Quantifying accurately peat GHG flux and flux changes resulting from disturbances is essential for appraising the potential of peatlands to mitigate climate change or the high burden caused to atmospheric GHG concentrations, depending on their fate. In its wetland supplement, the IPCC has developed guidelines for reporting national peat GHG emissions/removals and defined general concepts for developing peat GHG emission factors. While peat-rich countries are employing these guidelines and moving towards higher Tier reporting, some scientific barriers remain to fully and accurately report peat GHG emission/removals, especially in the tropics. Furthermore, anthropogenic activities for which default Tier 1 emission factors are available remain incomplete hampering some countries to report their peatlands emissions. This talk will navigate the wetland supplement, present existing default peat emission factors for the tropics, and explain conceptual basis for producing them. It will showcase two countries of the tropics, Indonesia and Peru, which contrast in terms of anthropogenic activity and emission rates and will highlight critical research gaps.

PEAT REWETTING IMPACT ASSESSMENT USING HYDROLOGICAL MODELING IN CENTRAL KALIMANTAN

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Dede Sulaeman[1]
Hidayah Hamzah[1]
[1] World Resources Institute Indonesia, Jakarta, Indonesia

Abstract: Indonesia is one of the world's largest tropical peatland-covered countries with 14.43 million hectares or more than 30% of the global tropical peat area. Peatlands are fragile ecosystems with essential biological and hydrological functions. However, peatland in Indonesia has been managed extensively for agriculture, especially commercial plantations and other urban needs. This land-use change is relatively well advanced where most of the peatland area has been deforested, drained, and converted. This has resulted in not only losses of biodiversity but also emissions of greenhouse gases and loss of carbon from peatland that consequently contribute to climate change. The Government of Indonesia committed to restoring degraded peatlands by implementing rewetting infrastructures with the main objective to raise the peat water table depth (WTD) and keep the peat moist to prevent fires. However, there are still gaps in identifying the impact of rewetting activities. Hydrology modeling seems to be an attractive option for solving this issue and is widely used to predict peatland hydrological processes. This study aims to assess the peat rewetting impact using a deterministic and physically-based model (MIKE SHE) coupled with a fully dynamic and one-dimensional modeling system (MIKE Hydro River). The study was conducted in Kahayan-Sebangau Peat Hydrological Unit (PHU) in Central Kalimantan Province. There were three main steps in conducting the study, including data collection and analysis, followed by hydrological model setup and calibration, and scenario analysis. The model was calibrated by matching simulated peat WTD against observed WTD obtained from the government-owned peatland water monitoring system (SIPALAGA). The calibrated hydrological model then be used to assess the restoration impact. Scenario analysis was performed to simulate the water table rise by comparing peat WTD in degraded peatlands with and without rewetting infrastructures implementation. Results showed that the peat WTD can be predicted using the hydrological model with RMSE, R^2, and NSE range values by 0.15 – 0.37, 0.62 – 0.82, and 0.64 – 0.91, respectively. This study also indicates that the impact of rewetting activities can be scientifically quantified by using hydrological modeling with the percentage of the rewetted area compared to the PHU’s total area was around 3.9 – 6.9%.

Peatland Rewetting in Oil Palm Plantations Reduces CO2 but no impact on CH4 fluxes: A Case Study from West Kalimantan

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

[4] Ministry of Environment and Forestry, Indonesia

Abstract: Decades after peatland drainage and destruction mostly into oil palm and acacia plantations, at present, there is a growing interest in peatland rewetting for restoring the hydrological system in degraded peatlands in Indonesia. A recent study reported that peatland rewetting is expected to contribute up to 13% of Indonesia's total mitigation potential from natural climate solutions analysis. However, Indonesia's 2nd Forest Reference Emission Level submitted to UNFCCC does not consider peatland rewetting for historical greenhouse gas emissions calculation, causing a loss of the opportunity to claim emission reductions from this critical effort. To our knowledge, no comprehensive assessment has been performed to understand the overall dynamic patterns of annual CO_2 and CH_4 fluxes simultaneously from rewetted Indonesia's peatlands, particularly from oil palm plantations. In this study, our primary objective was to investigate the impacts of peatland rewetting by constructing canal-blocking structures on CO_2 and CH_4 fluxes along with associated soil physicochemical properties and relevant environmental variables. We biweekly monitored carbon fluxes using LiCOR LI-7810 Trace Gas Analyzer from the two sites of secondary forests and oil palm plantations, respectively, located in Mempawah and Kubu Raya regencies, West Kalimantan, Indonesia. Soil carbon fluxes measurements were carried out for over a year, from January to December 2022 until now. ANOVA or Kruskal Wallis test, followed by Tukey's honestly significant difference test, was used to analyze differences in carbon fluxes, environmental variables, and soil physicochemical properties between the treatments. Our results show that peatland rewetting significantly lowered soil CO_2 emissions, and no clear impact of peatland rewetting on CH_4 fluxes in oil palm plantations. Rewetting drained peatlands in oil palm plantations can significantly reduce a third (34%) of heterotrophic emissions and a fifth (20%) of total respiration. Even though the water table depth in secondary forests is deeper than in rewetted oil palm plantations, total soil respiration is still higher in oil palm plantations. This results indicates that rewetting will not reach the reference emission in the secondary forest without revegetation. We translate our results into policy action by prioritizing peat conservation first and then restoration to optimizing climate change mitigation actions.

Peatlands of Amazonia: current knowledge, distribution and threats

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Charlotte Wheeler[1, 2]
Kristell Hergoualc'h[2, 3]
[1] University of Cambridge, Department of Plant Sciences, Cambridge
[2] Centre for International Forestry Research and World Agroforestry Centre (CIFOR-ICRAF), Bogor, Indonesia
[3] Centre de coopération International en Recherche Agronomique pour le Développement (CIRAD), UMR Eco&Sols, Montpellier, France

Abstract: Substantial peat deposits are known to exist across Amazonia. The peatlands of the Pastaza-Marañon Foreland Basin in Northern Peru have received increasing attention from researchers in the past decade, however, peatlands found in other Amazonian countries remain relatively unstudied. Most notably the peatlands of Brazil and Venezuela, which are predicted to cover 260,000 km^2 and 39,000 km^2, respectively. Peatlands are known to be the most carbon dense terrestrial ecosystem, once soil carbon is accounted for, and due to the remote and inaccessible location of many Amazonian peatlands most of them are believed to remain relatively intact. Thus, these ecosystems are likely to harbour large stocks of carbon and unique biodiversity, which need to be protected. We undertook a systematic review to determine the current state of knowledge of Amazonian peatlands. We then used remotely sensed and spatial datasets to assess the potential threats to peatlands from fire, deforestation, oil and gas exploration and hydroelectric dam construction, based on our current understanding of peatland distribution. Our systematic review found 169 studies published about Amazonian peatlands, with 70% of studies published in the last 10 years. Most research was done in Peru (48% of all studies), followed by Venezuela (15%) and Brazil (12%). Analysis of peatland threats found that between 2015 and 2020, 13,400 km^2 of peatlands were burnt and 4000 km^2 of forested peatlands were cleared of tree cover. The greatest threat to peatlands from dam construction and oil and gas production were in Western Amazonia where several large dams are operational and large areas of land are either being exploited or have the potential for oil & gas exploitation. Our analysis highlights that whist research into Amazonian peatlands has increased in the past decade, there are still large gaps in our knowledge and as some areas are under threats of different forms. This analysis allows us to highlight key areas where further research is needed and make recommendations for policy makers, to help improve our knowledge of this important ecosystem.

Peatlands, People and Policy: Analysing the Relationship between Amazonian Indigenous Knowledge and State-Led Conservation in the Imiria Lake, Peru

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Melissa Felipe Cadillo[1, 2]
[1] University of Oxford
[2] Instituto de Estudios Peruanos (IEP)

Abstract: Tropical peatlands play a key role in climate change mitigation due to their remarkable carbon density. While the importance of Southeast Asian peatlands as significant carbon reservoirs has been widely acknowledged, the recognition of tropical peatlands in the Amazon region has emerged more recently. Peru ranks second in South America in terms of peatland area, with an estimated area of 75,614 km2, according to the latest Global Peatlands Assessment. Thanks to landscape-scale efforts, the ecological knowledge of Peruvian peatlands has improved in the last two decades. However, there still exists a considerable knowledge gap regarding their boundaries, condition, ecological processes, as well as their social and cultural importance, utilization, management, and preservation by local communities.

This poses a latent problem, potentially excluding marginalized communities from participating in conservation and development programs and decision-making processes. To address this issue, the present research endeavours to bridge the knowledge gap by investigating the relationships with peatlands in the Regional Conservation Area of Irimia, situated in Ucayali, Peru. The study will specifically concentrate on comprehending the socio-economic uses, cultural significance and the relationship with state-led conservation strategies implemented in the area.

Firstly, it aims to identify both direct and indirect socio-economic activities derived from the natural resources of peatlands. Secondly, it strives to explore the cultural values and practices associated with peatlands among both indigenous and non-indigenous communities. Lastly, it identifies the conservation approaches implemented in the area. The findings will contribute to a comprehensive understanding of peatland ecosystems, their role in socioeconomic development, and their potential for effective conservation initiatives. Additionally, this research aims to ensure inclusive decision-making processes that actively involve marginalized communities in peatland conservation and development efforts. Ultimately, this study aims to bridge the existing knowledge gap and promote sustainable management practices that support biodiversity and the well-being of local communities.

Refinement of tropical peat greenhouse gas emission factors with process-based modeling

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Erin Swails[1]
Kristell Hergoualc'h[1], Jia Deng[2], Steve Frolking[2]
[1] Center for International Forestry Research
[2] Earth Systems Research Center, Institute for the Study of Earth, Oceans and Space, University of New Hampshire

Abstract: Oil palm plantations on peat and associated drainage generate sizeable GHG emissions. Current IPCC default emission factors (EF) for oil palm on organic soil are based on a very limited number of observations from young plantations, thereby resulting in large uncertainties in emissions estimates. To explore the potential of process-based modeling to refine oil palm peat CO_2 and N_2O EFs, we simulated peat GHG emissions and biogeophysical variables over 30 years in plantations of Central Kalimantan, Indonesia. The DNDC model simulated well the magnitude of C inputs (litterfall and root mortality) and dynamics of annual heterotrophic respiration and peat decomposition N_2O fluxes. The modeled peat onsite CO_2-C EF was lower than the IPCC default (11 Mg C ha^{-1} yr^{-1}) and decreased from 7.7 ± 0.4 Mg C ha^{-1} yr^{-1} in the first decade to 3.0 ± 0.2 and 1.8 ± 0.3 Mg C ha^{-1} yr^{-1} in the second and third decades of the rotation. The modeled N_2O-N EF from peat decomposition was higher than the IPCC default (1.2 kg N ha^{-1} yr^{-1}) and increased from 3.5 ± 0.3 kg N ha^{-1} yr^{-1} in the first decade to 4.7- 4.6 ± 0.5 kg N ha^{-1} yr^{-1} in the following ones. Modeled fertilizer-induced N_2O emissions were minimal and much less than 1.6% of N inputs recommended by the IPCC in wet climates regardless of soil type. Temporal variations in EFs were strongly linked to soil C:N ratio and soil mineral N content for CO_2 and fertilizer-induced N_2O emissions, and to precipitation, water table level and soil NH_4^+ content for peat decomposition N_2O emissions. These results suggest that current IPCC EFs for oil palm on organic soil could over-estimate peat onsite CO_2 emissions and underestimate peat decomposition N_2O emissions and that temporal variation in emissions should be considered for further improvement of EFs.

THE CORRELATION BETWEEN PEAT WATER TABLE DEPTH AND SATELLITE-BASED SOIL MOISTURE DATA IN BURNAI-SIBUMBUNG PEAT HYDROLOGICAL UNIT

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Dede Sulaeman[1]
Hidayah Hamzah[1]
[1] World Resources Institute Indonesia, Jakarta, Indonesia

Abstract: Peat fires have been recognized as an enormous problem in recent decades and caused peatland degradation in Indonesia. Excessive drainage caused the depletion of water table depth and soil moisture on the surface and makes peat soil highly flammable. In 2015, the country suffered one of its worst burning seasons in years. Large parts of the country's peatland area were burned out of control impacting the health, education, and livelihoods of millions of Indonesians living in the areas with the worst burning. The peat fire event also caused carbon released into the atmosphere. The Indonesian Government is carried out rewetting activities in the form of canal blocking and canal back-filling implementation to prevent excessive water drainage from the peatlands and keep the peatland's water table at a specific elevation to control soil moisture and avoid peat fires. The peat water table is known to correlate with surface peat soil moisture through capillary movements. Therefore, it is important to understand peat soil moisture's characteristics and its relationship with peat water table depth. This study aims to assess the relationship between peat water table depth and soil moisture data. Another objective is to formulate an empirical equation to estimate peat water table depth based on peat soil moisture data. Peat water table depth data were obtained by conducting field observation and were measured by installing piezometers equipped with peat water level loggers. Meanwhile, soil moisture data were gained from the System for Earth Observation Data Access, Processing, and Analysis for Land Monitoring (SEPAL), a big-data platform for forest and land monitoring developed by the Food and Agriculture Organization of the United Nations (FAO). The relationship between soil moisture and water table depth was analyzed using correlation analysis. Results showed that soil moisture correlates sufficiently against peat water table depth data with the coefficient determination (R^2) value ranging between 0.64-0.81. With this finding, it is expected that monitoring activities of peat wetness in preventing fires can be carried out more efficiently using satellite-based soil moisture data since it can be used to predict the peat water table depth in the field.

The SWAMP Program: Past, Present, and Looking into the Future

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Randy Kolka[1]
[1] USDA Forest Service Northern Research Station

Abstract: Carbon-rich tropical peatlands are important in climate change adaptation and mitigation strategies and provide numerous ecosystem services such as storm protection, nursery areas for fish, habitat for rare species, long-term storage of carbon, and food, fiber, and fuel for humans. Because of their importance we developed the Sustainable Wetlands Adaptation and Mitigation Program (SWAMP) to assist countries with their accounting and conservation of tropical wetlands. SWAMP is a collaborative effort between the Center for International Forestry Research and the USDA Forest Service through support from the US Agency for International Development. The goal of SWAMP is to provide policy makers and natural resource professionals with credible information and training to make sound decisions regarding the role of tropical wetlands in climate change adaptation and mitigation strategies. For the past 10+ years SWAMP has developed a global network of peatland studies in the tropics, led training and numerous other capacity building activities, and has led to both in-country and global polices on peatland conservation and their role in climate change. We anticipate that more research on mapping of peatlands and better greenhouse gas emission accounting across an array of tropical peatlands and disturbance gradients to further help in country and international reporting requirements.

Understanding the central Congo Peatlands to enhance their protection

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

[10] MARUM - Center for Marine Environmental Sciences University of Bremen

Abstract: In 2017 the extent of the central Congo peatlands was first mapped, bringing them to world attention. This mapping showed that the central Congo peatlands are the world's largest tropical peatland complex. This newly described system is formed of hardwood-dominated tropical peat swamp forest and palm-dominated tropical peat swamp forest. Spanning millions of hectares, it is wildlife rich, home to elephants, lowland gorillas and bonobos. In 2018 the Brazzaville Declaration was signed to protect the newly mapped peatlands, and protect the ~30 billion tonnes of carbon stored in the peat. Here we provide a synthetic update on our understanding of the genesis, development, contemporary functioning and potential futures of the peatlands from the large interdisciplinary project called CongoPeat, a collaboration between universities in the Democratic Republic of the Congo and the Republic of the Congo and the UK. We show that back in 2017 we underestimated the extent of the peatlands, and have substantially reduced the uncertainty on how much carbon is stored in the peat; understood that the peatlands are much older than we initially thought; their developmental history is now documented from one site for the first time; and we show that they are much closer to a tipping point than we anticipated, where they may begin to release the stored carbon. We also include some discussion of how people utilise the peatlands. This knowledge can help craft plans to better protect the peatlands while increasing the incomes and improving the lives and livelihoods of the people who live adjacent to and utilise the peatlands.

Using JULES to Model the Congo Peatlands

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Peter Cook[1]
Richard Betts[1, 2], Sarah Chadburn[3], Eleanor Burke[2]
[1] Global Systems Institute, University of Exeter, Exeter, UK
[2] Met Office Hadley Centre, Exeter, UK
[3] Department of Mathematics, University of Exeter, Exeter, UK

Abstract: The Cuvette Centrale swamp forest around the Congo river has the most extensive peatland complex in the tropics, but due to its remoteness the peat was only recently discovered. The international project CongoPeat, which includes scientists from the Republic of the Congo and the Democratic Republic of the Congo and works with the local people of the Cuvette Centrale, is studying the peatlands to determine how they formed and the possible threats since it is vital that the peat is preserved. While the peatlands are at least 20,000 years old the peat is thin compared to other tropical peatlands of similar age. The JULES land surface model has been used to simulate the development of the peatlands, by means of a reconstruction of the past annual rainfall and with other climate variables from a long paleo run of the HadCM3 global climate model. The results support the hypothesis that a long period of reduced rainfall a few thousand years ago lead to a large loss of peat and recreate the age-depth profiles of the peat in measured soil cores. This confirms that a constantly high water table is needed to keep decomposition of the peat to a minimum and hence preserve the peatlands. JULES was then run with future climate projections from five global climate models to simulate how the peatlands could change up to 2100. In most projections the increased temperatures lead to increased evapotranspiration, lower water tables and increased decomposition of peat. So that in most cases peat is lost overall, particularly when rainfall is also reduced further lowering the water tables. In-spite of an increased atmospheric CO_2 concentration affecting the vegetation by increasing the productivity and litterfall while reducing the amount of transpiration. The risk to the peatland Carbon is greater at higher levels of global warming.

What do we need to know to create effective, science based national peatland policy?

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Moira Hough[1, 2]
Rodney Chimner[1, 2], Erik Lilleskov[2, 3], Randall Kolka[2, 3]
[1] Michigan Technological University, Forest Resources & Environmental Science, USA
[2] Sustainable Wetlands Adaptation and Mitigation Program
[3] United States Department of Agriculture Forest Service

Abstract: This work creates a guide illustrating what information is needed to develop science-based national policy regarding peatlands. It is designed to be useful for government agencies, and their partners in NGOs, as well as academic scientists wishing to produce information that can contribute to peatland protection. Peatlands store enough carbon to double the current atmospheric content if released, meaning their protection, management, and restoration represent a key opportunity to mitigate, or avoid further contributions to, climate change. Maintenance and restoration of peatlands for climate mitigation frequently requires trade-offs with land uses important to human livelihoods such as grazing or drainage for agriculture, pasture, or plantation. Despite their economic incentives, such uses lead to carbon loss through degradation, increased decomposition, and increased risk of fire. Many nations have policies for wetland or forest management but limited policy regarding peatlands specifically. This may be due to a lack of available information on peatland extent and typology or lack of awareness of the importance of policy specific to peatlands. Here, we aim to identify foundational knowledge and best practices for development of tools such as emissions factors as well as policy impacting peatland management such as nationally determined contributions to climate change mitigation.

Where are the knowledge gaps in Brazilian scientific perceptions of peatlands tropical forests?

T2.34 Tropical Peatland Forest Conservation and Sustainability: Challenges and Opportunities

Arimatea C. Ximenes[1]
Rupesh K. Bhomia[1], Daniel Murdiyarso[1, 2]
[1] CIFOR-ICRAF
[2] IPB University, , Bogor 16680, Indonesia

Abstract: Peat is characterised by its high soil carbon content, and the categorization of soils is a subject of ongoing debate in Brazil, leading to uncertainty in the classification used by official soil maps. In Brazil, the number of research organisations dedicated to studying peatlands is limited, resulting in significant gaps in information that impede scientific progress in this field. Our objective is to identify existing gaps in the knowledge about peatlands and strategize pathways to fulfill those gaps through planned research. A survey will be conducted using the expert-based participatory technique, with the inclusion of peatlands, wetlands specialists, and soil researchers from Brazil as participants. Therefore, the involvement of peatlands, wetlands specialists, and soil researchers from Brazil as components in this participatory technique is crucial. By bringing together experts from various disciplines, we can bridge the existing knowledge gaps and enhance scientific progress in understanding the ecological services provided by peatlands in Brazil. This collaborative approach will not only help identify areas of little knowledge among academics but also prioritize research efforts to ensure the sustainable management and conservation. Furthermore, the involvement of Brazilian specialists and soil researchers is essential as they possess invaluable local knowledge and expertise that can contribute to a comprehensive understanding of peatland ecosystems. Their participation will also ensure that the research addresses specific challenges and opportunities unique to Brazil's peatlands. By fostering a collaborative approach, we can encourage knowledge exchange, foster innovation, and ultimately drive effective conservation strategies that benefit both the environment and local communities dependent on this ecosystem.

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Assessing the performance of new bio-based surface gel treatment in outdoor applications

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Daouia Messaoudi[1]
[1] Groupe Berkem, France

Abstract: Many species of wood that are suitable for use in construction need to be pressure impregnated before they can be used. Pressure impregnation requires expensive equipment, specialised and trained operators, very restrictive environmental and human protection measures, and regulatory authorisations to operate for sawmills, all of which are becoming increasingly difficult for wood industry these days. R&D Laboratories from Groupe Berkem has developped a new generation of bio-based gel treatments that can protect impregnable and refractory wood with a good diffusion and penetration rate in the treated material. Effective treatment with this new technology requires good understanding of how the preservatives diffuse through wood. This paper reports on the penetration kinetics and retentions obtained over six weeks with three types of wood (pine sapwood, spruce and douglas fir) treated at ambient temperature on all sides at fixed application rate with fine spray of a bio-based insecticide and fungicide gel. For each type of wood, three samples measuring 140 to 180 cm x 15 cm x 5 cm were prepared and then conditonned at 20°C and 65% RH for 7 days before application of the test products with the Unisprayer equipment . For each sample, a piece was weighed and removed by lateral cutting 25 cm from one end after 1, 2, 3, 4 and 6 weeks. These pieces were used for diffusion analysis by visual inspection (on the freshly cut cross-section) and by analysis and for biological testings (termites, basidiomycetes). The chemical diffusion of the test products was determined using wood shavings taken to a thickness of 2 mm beyond the first and second centimetres, on both sides. Satisfactory penetration of gel treatments and good resistance to termites and wood rots appeared within a few weeks.
The data suggests that this new bio-gel-based surface treatment could protect all types of wood worldwide with a simple that does not demand specialized equipment, low-cost device and in a minimum of time using local resources and labour, thus replacing the copper solutions used by vacuum pressure.

Boron preservative treatment of minor species for extended carbon storage in the built environment

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Tripti Singh[1, 2]
Dave Page[1], Ian Simpson[1]
[1] Scion, Rotorua, New Zealand
[2] National Centre for Timber Durability & Design Life, University of the Sunshine Coast, Australia

Abstract: Early research in New Zealand with boron indicated that the dip/diffusion method for green timber would give adequate preservative retention in sapwood for most species and in some cases would also penetrate heartwood. This was widely accepted by the industry as being the case for species other than radiata pine including those regarded as resistant to preservative treatment such as Douglas-fir (*Pseudotsuga menziesii*). Some further work was done on treatment of radiata pine (*Pinus radiata*) and Douglas-fir framing using boron-glycol formulations and low-pressure systems but the treatment of species other than radiata pine with boron using current commercial processes has not been widely tested.

The inclusion of alternative species to radiata pine, predominantly exotic species, in the building code (NZS 3602) raises questions as to whether they require preservative treatment and, if so, whether they can be adequately treated using current industry processes.

This work summarises research conducted at Scion on the performance of boron preservatives applied to species other than radiata and similar plantation-grown pines. The boron-treated wood is resistant to fungal decay and can extend the service life and subsequently carbon storage for a longer period in the built environment.

Challenges and Possibilities for Protection of Non-Durable Wood. A retrospective and prospective analysis.

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Daouia Messaoudi[1]
[1] Groupe Berkem

Abstract: Non-sustainable wood needs protection! The challenge today is how to ensure its sustainability in the face of the impact of climate change and with safer, sustainable alternatives to chemical pesticides that will have no impact on human health or the environment. A retrospective and prospective analysis is presented here. All wood preservatives used in timber construction are made from synthetic fossil pesticides, whereas wood is a bio-based material. Growing interest in ecology, protecting the planet and protecting human health have for many years stimulated research aimed at replacing these fossil preservatives with safer sustainable products. A review of the literature and experimental analyses have been carried out from 1950 until today to illustrate the evolution in the formulation of wood preservatives. New treatments and technologies based on Bio-based solutions and Plant polyphenolic extracts from Berkem Biosolutions are also described.

Comparative in-ground durability, termite and decay resistance of some Malaysian and exotic wood species related to biological hazard class situations

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Andrew H.H. Wong[1, 2]
Wei Khong Tan[1], Carlson Tawi[1]
[1] previously, Universiti Malaysia Sarawak (UNIMAS), 94300 Kota Samarahan, Sarawak, Malaysia
[2] International Wood Culture Society (IWCS), c/- 798 Lorong Song 3C1A, Tabuan Heights, 93350 Kuching, Sarawak, Malaysia

Abstract: Classifying overall biological resistance of a wood species for terrestrial end-use product applications depends on the intended biological hazard class of exposure involving specific types of wood biodeteriogents. A comprehensive Malaysian study compares the biological durability of 51 native renown/commercial or lesser-used native medium and light hardwoods of Sarawak and Peninsular Malaysia including 3 imported woods Burmese teak, Australian radiata pine and Oregon Douglas Fir, against subterranean termites (*Coptotermes curvignathus*), white rot (*Pycnoporus sanguineus*), soft rot (mixed microflora of unsterile soil with *Chaetomium globosum*) decay and in-ground natural durability. This work partly aims to also understand the overall durability of the lesser-used (secondary) hardwoods of mainly Sarawak. Percent mass loss data for each wood decay type, visual termite attack ratings and stake test visual ratings form the basis for assigning a 4-point relative biological resistance classification (Class 1 to 4) for each evaluation type on each wood species. Overall durability class for each wood being the worst resistance class among the 4 assessed attack types are shown among the H2 to H5 biological hazard classes of wood in service. Light hardwoods are generally of low overall durability class in all hazard classes while mixed durability classes exist among the medium hardwoods among hazard classes. Species with Class 3-4 overall durability predominate, requiring wood protection strategies for target biological hazard class situations. Hence assigning overall wood durability of each wood species to each hazard class situation as such would augment the end-use guidelines for these untreated (or else treated) native light and medium Malaysian woods.

Decay resistance, color properties, and polyphenol contents in heartwood of the third-generation Acacia mangium grown in Indonesia

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Masendra MASENDRA[1, 2]

[4] National Research and Innovation Agency, Indonesia

Abstract: The tree breeding of *Acacia mangium* in Indonesia has entered in the third-generation. In this study, the mass loss by a white-rot fungus *(Trametes versicolor*) and a brown-rot fungus *(Fomitopsis palustris*), color properties, and polyphenol contents were investigated for inner heartwood and outer heartwood of total 60 trees (20 half-sib families originated from four different provenances by three individuals, 10-year-old) of the third-generation *A. mangium* planted in Wonogiri, Central Java. The mean values of Y, x, y, the amounts of extractive contents, total phenol contents, and total flavanols contents in all 60 trees were 24.14, 0.38, 0.37, 5.7%, 28.29 µg/mg, and 6.76 µg/mg, respectively. Among measured properties, high family-mean heritability was found in outer heartwood color of Y (0.636) and y (0.509), while those of total phenol contents and total flavanol contents family-mean heritability were relatively low (0.087–0.112). The Y value was significantly negatively correlated with total flavanol contents at the family levels. These results indicate that the wood color with lower Y value in heartwood could produce progenies with higher total flavanol contents in heartwood.

Drying and heat treatment of large cross-section timbers for enhancing durability and performing long-term carbon storage role

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

[4] Department of Wood Science and Technology, College of Agriculture and Life Sciences, Jeonbuk National University, Jeonju, Republic of Korea

Abstract:
After World War II and the Korean War, the Republic of Korea, which started afforestation on bare mountains, has succeeded in reforestation by diligently cultivating and preserving, and is currently showing the world's fastest growing rate of tree accumulation.

Due to the short history of afforestation, the Korean wood industry, which uses domestic wood as raw material, had until recently been forced to use small diameter trees harvested from young forests. Most of them have been crushed and supplied to the thermal power energy industry, paper industry, or board industry in the form of chips, and used as wood products serving as short-term carbon storage.

However, since the proportion of old forests in Korea's forests is higher than that of young forests, it is time to harvest timber from these old forests and establish and implement measures to use them.

The large logs harvested by felling the large standing trees that make up this old forest provide an opportunity to create high value-added, large-scale building members with large cross-sections in an eco-friendly way without gluing or connecting processes, rather than chips or small square materials.

In order for such large-sized timber, which is expensively supplied as a building material for important large-scale buildings such as palaces, religious facilities, exhibition halls, and public centers, to serve as carbon storage for a very long time, artificially well-controlled drying processes and the development of durability enhancement processes are required.

In this study, a defect-free kiln drying process and a chemical-free heat treatment process were developed and applied so that large cross-section timbers can faithfully play their role as long-term carbon storage.

The processes were optimized by analyzing the moisture content distribution and temperature distribution inside the wood during the drying and heat treatment processes. Sectional temperature and humidity inside the wood were remotely monitored in real time by electronic sensors, and the

humidity signal was converted to moisture content by the equilibrium sorption equation.

By considering the directional moisture movement and heat transfer within the wood, internal moisture and temperature gradients are well controlled, reducing process time and energy consumption while maintaining quality.

Examining Heartwood Formation in European Oak Trees

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Andrea Ponzecchi[1]

[2] Forest Genetics and Diversity, University of Copenhagen, Denmark

Abstract: Oak trees are widely planted across Europe due to their resilience against climate change and the production of high-quality, long-lasting timber.

The heartwood, the most valuable part of the tree, is the inner and darker portion of a tree trunk that is distinguished by its durability and strength. It is the non-living core that forms as a result of the gradual accumulation of secondary metabolites called extractives.

These compounds can include resins, tannins, lignins, and provide natural protection against biotic and abiotic attacks. While extractives play a crucial role in protecting the tree's structure, the process of heartwood formation and the genes influencing its quality are still under investigation.

We collected 5 mm diameter oak (*Quercus robur*) wood cores from 300 trees representing 100 maternal sources. To investigate heartwood formation, we employed widefield fluorescence microscopy and Confocal Laser Scanning Microscopy (CLSM) to track the distribution of extractives within the heartwood from the micron to the sub-micron scale. Hydrophilic and hydrophobic extractives were extracted using Soxhlet extraction techniques. Then, steady-state fluorescence spectroscopy was utilized to profile the extractives. Additionally, tree genotyping was performed to explore genetic factors associated with heartwood formation. Variation in fluorescence properties among half-siblings and unrelated oak trees was observed. Additionally, fluorescence profiles of the inner heartwood in the pith and newly formed heartwood were analyzed.

The observed fluorescence variations provide insights into the chemical composition of the heartwood, particularly the behavior and role of tannins. These findings contribute to understanding heartwood formation and heartwood aging and the role of extractives in this process, and how much of the variation between trees can be ascribed to genetic variation.

Import commodities: tracing and monitoring the sustainability effects of the EU wood supply

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Paola Pozo Inofuentes[1]
Matthias Bösch[1], Jörg Schweinle[1]
[1] Thuenen Institut of Forestry, Germany

Abstract: In the view of reducing dependency on non-renewable materials and fossil fuels, bioeconomy has emerged as an option towards a more sustainable economy in different national and international strategies. Sustainability impacts of a bioeconomic system occur along the complete value chain, most severe impacts, however, are associated with biomass production. Therefore, an appropriate assessment of a sustainable bioeconomy has to consider all impacts along the value chain independent of where they occur. The European pulp demand has been partly met by imports of highly export-oriented pulp factories in South America. This development has been accompanied by an increasing attention on the sustainability of supply chains in the policy arena, specifically considering import commodities. A novel hybrid physical accounting model combined with a material flow approach were used to track wood origin and sustainability impacts of the most important wood suppliers for the European production and consumption in 2018. Around one third of the wood fibre input present in finish paper products and in the form of pulp consumed in Europe was imported. The main origins were Brazil, the United States and Uruguay. As a case study we used the example of Uruguay, which is a key player regarding the production of roundwood and pulp for Europe and is expected to become the second world largest producer of short-fiber pulp in the next years. The assessment of sustainability impacts in Uruguay covers environmental sustainability impacts including land use change (grassland afforestation) and GHG emissions, socio-economic impacts including employment and value-added generation. The results reveal synergies and trade-offs between socio-economic and environmental impacts as well as a disproportional share of impacts in the EU. This approach captures the impacts along the different steps of the supply chain and identify which sustainability impacts are connected to the production of wood and in which steps of the supply chain there are opportunities to improve sustainability. We highlight the need to consider not only territorial sustainability impacts in isolation but from a global perspective. We strongly support the importance to assess impacts in the three dimensions of sustainability in order to have a holistic overview.

Induction of heartwood formation in young sandalwood (Santalum album)

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Xiaojin Liu[1]
Qilei Zhang[1], Zhou Hong[1], Daping Xu[1]
[1] Research Institute of Tropical Forestry, Chinese Academy of Forestry.

Abstract: Sandal (*Santalum album* L.), commonly known as East Indian Sandalwood, is the most famous valuable tree species belonging to the Santalaceae family and is highly valued for its fragrant heartwood, which has various applications in the perfumery, religion, cosmetic, wood carving, and pharmacological industries. Sandal was first introduced into China in 1962 and has exhibited encouraging growth performance in most planting areas in the recent decades in southern China. However, very few sandal plantations formed aromatic heartwood naturally when they were young, and the quality of essential oil distilled from those young sandals was quite poor. Therefore, induction of fragrant heartwood formation in young sandal plantations has great importance in large-scale cultivation practices because the values of sandal at harvest will depend largely on the volume and the quality of heartwood. Several studies have shown that some chemical elicitors, such as $CuSO_4$, ethrel, paraquat, benzyladenine and H_2O_2 can induce heartwood formation in young sandals. However, all these chemical elicitors were used as liquid solutions, and the induced heartwood was generally formed around the injection holes; moreover, the amount was quite low. In this study, induction of heartwood formation in 6-year-old sandal by treatment with carbon dioxide, ethylene, nitrogen, and wounding was investigated. All treatments induced fragrant heartwood formation upward and downward from the drill hole. The amount of heartwood formed above and below the drill hole depended on the treatment in the order nitrogen>carbon dioxide>ethylene>wounding, whereas the radial extension proportion was, in order, nitrogen>carbon dioxide>ethylene=wounding. Based on the chemical analysis (GC–MS) and evaluation of the essential oil quality and heartwood properties, heartwood induced by carbon dioxide showed the maximum similarities to naturally formed heartwood, which included the same color, similar chemical composition, reasonable oil content, and quality essential oil, whereas ethylene, nitrogen, and wounding treatment showed fewer similarities to natural heartwood. The results suggest that carbon dioxide is a promising candidate gas elicitor for inducing heartwood formation in young sandal.

Termite resistance of weathered Malaysian hardwood kempas envelope-treated with new generation biobased/vegetal extracts in water-borne solutions

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Daouia Messaoudi[1]
Andrew H.H. Wong[2, 3]
[1] Groupe Berkem, R&D Laboratories, 20 rue Jean Duvert, 33290 Blanquefort, France
[2] previously, Universiti Malaysia Sarawak (UNIMAS), 94300 Kota Samarahan, Sarawak, Malaysia
[3] International Wood Culture Society (IWCS), c/- 798, Lorong Song 3C1A, Tabuan Heights, 93350 Kuching, Sarawak, Malaysia

Abstract: In fulfilling the need to develop fit-for-purpose, cost-effective, and environmentally-friendly wood protecting chemicals for permanent wood protection, equatorial tropical termite field tests were conducted on Malaysian hardwood kempas (*Koompassia malaccensis*) test blocks envelope-treated by brushed-on with either a proprietary formulation containing cypermethrin boostered with vegetal extracts (SYNERKEM® technology), or dip-treated for 3 minutes with either a permethrin-based micro-emulsion proprietary formulation or cypermethrin-based micro-emulsion formulation. Conditioned enveloped-treated woods were then artificially weathered to simulate aboveground indoor exposure conditions (H2 hazard class: lab evaporative ageing of treated wood) or aboveground outdoor conditions (H3: lab leaching plus evaporative ageing of treated wood) before subjected to a unique (Wong 2005) Malaysian/Australian H2-hazard class (aboveground and not exposed to wetting) field termite test against *Coptotermes curvignathus* at a humid near peatswamp forest site in Kota Samarahan, Malaysia. After 6 months test, untreated kempas was clearly termite-susceptible (both high percent and absolute (=milligram) wood mass losses, poor termite visual ratings) unlike those treated with the SYNERKEM® technology biocide and 2 pyrethroid-biobased micro-emulsion solutions, reference permethrin-based LOSP (3 minutes dipping) and reference CCA-treated radiata pine, all these displaying total hardwood protection (negligible mass losses, highest termite rating). These three novel wood preservatives are clearly suitable for "permanent" protection of up to H3-weathered envelope-treated hardwood against *Coptotermes* termites under both aboveground indoor (H2-hazard class) and aboveground outdoor (H3-hazard class) situations for contructed wood in service where only minimal quantities and adequate dosages of biobased preservatives are desired in an increasingly environmentally-conscious society in favour of green building constructions.

The durability of preservative-treated Glulam as a timber bridge component

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Tripti Singh[1, 2]
Dave Page[2]
[1] National Centre for Timber Durability & Design Life, University of the Sunshine Coast, Australia
[2] Scion, Rotorua, New Zealand

Abstract: For the last 70 years, New Zealand Forest Research Institute (now Scion) has had an in-service testing programme for wooden products, including timber bridges. Based on the conditions of those bridges, history, and evidence, the following conclusions can be drawn;

- Preservative-treated radiata pine laminated bridge beams have been in service for 60 years in and have shown few problems with durability associated with decay, particularly if glue laminated beams are not in direct contact with soil.
- Preservative treatment of laminated components after assembly with heavy oil-based or creosote preservatives is not available in New Zealand. However, treatment with water-based CCA formulations before lamination has been just as successful as treatment with oil-based formulations after lamination.
- While we have little experience with treatment of Douglas-fir laminated products in New Zealand, the refractory nature of Douglas-fir and its poor natural durability indicates that it is less suitable for laminated bridge beams than CCA-treated radiata pine.
- For exterior components, the use and type of glue are critical. Only resorcinol-formaldehyde (RF) or phenol-formaldehyde (PF) glues have shown long-term durability in Scion test bridges. More recent PU (Polyurethane) and PUR (polyurethane reactive) glues have not been included in long-term exposure trials at Scion although anecdotal overseas data indicates that they may be a suitable replacement for RF and PF glues.
- Evidence from service testing indicates that the use of film-forming surface coatings to protect glue laminated components have some benefits in extending the service life providing coatings are well maintained.
- Design and maintenance are the key elements of timber bridge durability. If glue laminated beams are not in direct contact with soil and decaying vegetation, the service life of the elements can be extended. Laminated beams that are on the exterior of the structure and fully exposed to weather, particularly where the upper edge is exposed, are likely to deteriorate more rapidly than those which are partly protected by decking.

Unlocking innovation: novel durability assessment techniques paving the way for preservative-free wood protection methods.

T2.35 Wood durability and wood protection strategies for long-term carbon storage of wood products

Liselotte De Ligne[1, 2]
Jan Van den Bulcke[1, 2], Joris Van Acker[1]
[1] UGent-Woodlab - Laboratory of Wood Technology, Department of Environment, Faculty of Bioscience Engineering, Ghent University, Ghent, Belgium
[2] Centre for X-ray Tomography (UGCT), Ghent University, Ghent, Belgium

Abstract: In order for future cities to become more sustainable and serve as carbon sinks, the wood volume used in buildings needs to substantially increase. However, wood(-engineered) products are (to some extent) biodegradable when used in applications with fungal decay risk. There is need for sustainable wood protection methods that can be applied on a large scale. Wood protection against fungal decay used to focus on durable wood species, often from tropical regions, or non-durable wood species treated with wood preservatives. However, preservatives should ideally be replaced by techniques with a reduced environmental impact. Extending service life of wooden elements through other means than preservative treatment have gained attention, most of which evolve around moisture control, such as wood modification and protection by design.

Current methods for assessing durability leave little room for assessing the impact of improved moisture dynamics or the structural design of a wood product, due the small size and large end grain to surface ratio of the tested wood samples. Here, we present a novel X-ray CT scanning set-up and analysis pipeline for assessing the influence of material structure on degradation progress under laboratory conditions. The influence of anatomical features, such as the vessel orientation and the number of growth rings, as well as the impact of modified barrier layers on wood degradation patterns is demonstrated. In addition, a floating test was performed to derive the influence of additives, manufacturing process and material structure on the liquid water absorption and desorption behavior of wood-based panels and wood-fibre insulation materials. Hydrophobic properties achieved by thermal treatment or hydrophobic additives significantly decreased water absorption rates. However, the manufacturing process (wet or dry) had a decisive influence on the absorption rates and could overrule the addition of hydrophobic substances. Water was less easily released from oriented strand board and plywood due to the material structure, which enhances the risk of water entrapment in practice.
Through combination of assessment methods we aim to unlock innovation potential, especially with regards to engineered wood products, as there are many opportunities to modify material structure, incorporate barrier layers and integrate moisture control functionalities.

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

A design-based view of species richness estimation with applications to forest surveys

[4] Department for Innovation in Biological, Agro-food and Forest Systems - University of Tuscia (Italy)

Abstract: For the first time, the estimation of species richness is approached from a design-based perspective. In this framework, the properties of estimators are derived from the schemes actually adopted for sampling ecological communities, without any unrealistic assumption about sampling and communities widely exploited in model-based approaches. Probabilistic sampling of species is considered, and the widely applied estimators automatized in the SPADE software are considered in a design-based setting. A simulation study performed on two real communities of trees highlights the massive presence of negative bias due to loss of rare species that invariably affects the SPADE estimators. Then, a data integration is attempted in which the lists of rare species usually compiled by purposive surveys are exploited and richness estimation is performed on the residual community of those species not included in the purposive lists. The Chao & Lee (1992, doi: 10.1080/01621459.1992.10475194) estimator is adopted for estimating the residual richness and a bootstrap mean squared error estimator is applied.
The strategy has been empirically checked by the same simulation study adopted for checking SPADE estimators, achieving much better and encouraging results. The proposal is applied to the estimation of the richness of plant species in chestnut forests of Sabatini Mountains (Central Italy).

A European platform of forest multi-taxon biodiversity and stand structure data

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

[11] University of Padua
[12] Centre for Ecological Research
[13] WENR Wageningen Environmental Research

Abstract: Forestry implementation significantly impacts forest biodiversity. Despite the promotion of Sustainable Forest Management (SFM) in Europe, sustainability assessments hardly account for direct biodiversity indicators accounting for multiple taxonomic groups. Indeed, multi-taxon biodiversity sampling and analysis requires significant funding, time, and a broad range of expertise and competences.

The challenges of multi-taxonomic field sampling, including exhaustive species censuses across single- or multiple sites are being increasingly addressed at the local or regional scales to assess the effects of forest structure and management on the diversity of multiple taxonomic groups.

Here we present an effort to: i) gather and map the existing information on forest multi-taxon biodiversity associated with stand structure and management in Europe; ii) identify knowledge gaps for forest biodiversity research; and iii) discuss the research potential associated with multi-taxon biodiversity data.

We established a research network focused on multi-taxon biodiversity, stand structure and management data of European forests; and fitted species records, standing trees, lying deadwood, and sampling unit metadata from 34 local datasets.

Suitable information was available for 3,591 sampling units, each surveyed for on average 4.6 taxonomic groups. Standing tree diameters, tree height deadwood and tree-related microhabitats were sampled in respectively 2,889; 2,356; 2,309 and 1,388 sampling units. Sampling unit metadata includes spatial coordinates, and compositional and management descriptors.

Available data cover all the 14 European forest compositional categories but are unevenly distributed among them, with European beech forests being over-represented as compared to thermophilous and boreal forests.

Overall, the available information has the potential to inform the development of conservation and SFM strategies for European forests by supporting: (i) methodological harmonization and coordinated monitoring; (ii) the definition and testing of SFM indicators and thresholds; (iii) data-

driven assessment of the effects of environmental and management drivers on multi-taxon forest biological and functional diversity, (iv) multi-scale forest monitoring integrating *in-situ* and remotely sensed information.

A simple measure of habitat heterogeneity is a good proxy of species of conservation concern

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Anne-Maarit Hekkala[1]
Joachim Strengbom[2], Mari Jönsson[3], Simon Kärvemo[2], **Jörgen Sjögren**[1]
[1] Swedish University of Agricultural Sciences, Department of Wildlife, Fish and Environmental studies
[2] Swedish University of Agricultural Sciences, Department of Ecology
[3] Swedish University of Agricultural Sciences, Species Information Center

Abstract: Biodiversity assessment is a fundamental part of sustainable forestry and biodiversity conservation. Nevertheless, measuring biodiversity is far from simple and remains a challenge for practitioners who must make management decisions and report the national state of biodiversity at the EU-level. We tested if habitat heterogeneity or a set of habitat amount measures could predict biodiversity in Swedish boreal forests. We used 77 mature coniferous forest stands (2ha each) varying from structurally simple production forests to woodland key habitats, to evaluate the relationship between habitat heterogeneity, habitat amount and richness and abundance of species of conservation concern (SoCC) belonging to fungi, bryophytes, lichens and vascular plants. As the most important result, we found stand-level habitat heterogeneity to be the best proxy to explain the richness of SoCC, but when only red-listed species were included, volume of dead trees (deadwood) and age of the oldest tree proved to be more precise proxies. Habitat heterogeneity score was most often the best predictor of the number of SoCC among the different organisms groups. Also deadwood proved to be an important characteristic predicting the number of species, emphasizing its essential role in the mitigation of biodiversity loss in boreal forest systems. Finally, we calculated threshold values for deadwood volume and habitat heterogeneity score depicting the level above which the number of red-listed species is significantly higher, and found this value to be higher in the southern region (22.4 m3 ha−1 deadwood and a habitat heterogeneity score value of 17) than in the north (20.0 m3 ha−1 and 16). These values can be used as guidance when identifying coniferous forests with high enough qualities to support red-listed species. The more intensively managed southern region revealed an alarming species loss; despite the similar habitat availability, the average number of SoCC was only half of the richness and one fourth of the abundance in the north.

We conclude that habitat heterogeneity can be used as a reliable proxy for the number of species of conservation concern, but it must not be used to prioritize conservation between geographical regions.

Added Value and Limits of Citizen-Science Approaches supported by Artificial Intelligence to Monitor Ecological Forest Conditions

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Markus Meyer[1]
[1] Anhalt University of Applied Sciences, National and International Nature Conservation, Germany

Abstract: AI (Artificial Intelligence) approaches are already being used for species recognition in images to identify individual plant species, especially trees. To monitor the ecological status of forests, it is necessary to extend and improve AI-based species and structure recognition on forest images of image data from different sources. Image data is partly collected via citizen science approaches to improve coverage and resource utilization. Specifically, the usability of citizen science generated images for AI image recognition provides a likely fruitful pathway. Here, it is necessary to examine whether citizen science-supported recording of parameters of the ecological condition of forest habitats can usefully complement traditional monitoring.

This contribution will explore the quality of citizen science provided images to monitor the ecological status of different forests in Saxony-Anhalt (Germany). These will cover amongst others floodplain forests in conservation areas as well as intensively managed low mountain range forests with severe calamities. In collaboration with outdoor navigation and exploration app providers, we will explore the suitability of citizen-science based imagery sources to monitor the ecological status of forests. The collaboration with the Outdoor app providers will likely increase the spatial and temporal coverage of images from citizens in the target regions. We will explore different approaches to classify and predict e.g. forest development phases, conservation status and forest health supported by AI image recognition. The application will be tested for nature conservation relevant spaces (e.g. riparian forests) and use intensities for recreation (e.g. urban forest, biosphere reserve).

Approximating the Complexity of Biodiversity in Tropical Forest Ecosystems

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Maïri Souza Oliveira[1]
[1] INRAE (Institut National de la Recherche Agronomique)

Abstract: Tropical forest ecosystems are complex and diverse, making it difficult and costly to exhaustively identify all the species present at different spatial scales. These forests may be home to rare, endemic or poorly known species, making it difficult to estimate their diversity. In addition, data collection methods are costly, time-consuming and difficult to standardise, making it difficult to obtain complete and representative data on biodiversity.

To overcome these difficulties, it is important to develop forest biodiversity indicators as proxies, such as species assemblages. In this study, we propose to identify and characterise natural tropical forest ecosystems at different scales (from in situ to national level in Costa Rica) using a network analysis of species spatial distribution patterns. This method allows to approximate the biodiversity of these ecosystems from the species networks obtained, and to understand the structure and dynamics of ecological assemblages by highlighting the relationships between different species. We used global databases, as well as national and local forest and botanical inventories containing about 80,000 occurrences. We are working on Costa Rica, divided into twenty ecoregions that follow a climatic, edaphic and topographic gradient. It is one of the leaders in biodiversity conservation, with 54% of the country's surface area protected, but it is also a fragmented country under pressure from agriculture.

The methodology of this study consists of three steps: (i) Species network analysis, based on biogeographical bipartite network, to approximate the biodiversity and characterise the structure of forest ecosystems representative at different scales, up to the Costa Rican ecoregions; (ii) Botanical verification of the results to validate the modelled species networks; (iii) Study of the interactions between species in each network and their functional traits to understand why they characterise these forest ecosystems.

The species assemblages obtained in this study can be considered as indicator species for the forest ecosystems they define. They can then be included in multi-species distribution models to approximate the distribution of biodiversity in these forest ecosystems, in order to better assess and monitor the biodiversity of tropical forests.

Arthropod species biodiversity in forest inventories: challenges and implications for regional conservation

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Gerardo Vergara-Asenjo[1]
Fermin M. Alfaro[2, 3], Jaime Pizarro-Araya[2, 3]
[1] Instituto Forestal (INFOR), Chile
[2] Laboratorio de Entomología Ecol´ogica (LEULS), Departamento de Biología, Facultad de Ciencias, Universidad de La Serena, La Serena, Chile
[3] Instituto de Ecología y Biodiversidad (IEB), Santiago, Chile

Abstract: Despite global efforts to identify and classify species to improve biodiversity baselines, there still remains large knowledge shortfalls that affect our understanding of the functioning of ecosystems and the design of effective conservation practices. Using the results of the first ongoing large-scale biodiversity inventory for Chile which has already recorded more than 2,000 species and discovered 103 new species of arthropods, in this presentation we explore the role of forest inventories, and discuss taxonomy (Linnean) and distribution (Wallacean) shortfalls that preclude large-scale knowledge of biodiversity of vegetated lands for one of the lesser studied groups in the world -the arthropods. Moreover, we explored spatial indicators of richness, abundance and new species with structural and compositional flora. Linnean shortfalls are mainly associated to the lack of funding of monitoring and inventory initiatives and the bias towards most charismatic or umbrella species, which in turn trigger effects on the experts' availability, recruitment of taxonomists in research centers, journal impact factors, and the as well as the availability of scientific collections of type specimens. Instead, Wallacean shortfalls are related to accessibility to remote areas, and the spatial and temporal resolution of sampling efforts. Based on our results and literature review, we discussed the findings and also proposed a novel conceptual framework aimed to reduce data gaps and support biodiversity conservation policies, particularly in developing countries. The framework has three main components: (1) the ecosystems, their species, and the threats; (2) the key elements for a biodiversity assessment strategy, and (3) an action plan for protecting biodiversity.

Assessing the precise dietary spectrum of the white-bellied pangolin in Benin using DNA metabarcoding

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Stanislas ZANVO[1, 2]

[3] 3- University of Exeter, United Kingdom

Abstract: Accurate data on dietary profiles is a perquisite to understanding how wild animals, especially cryptic and elusive species such as pangolins, make use of their habitats, in order to design effective conservation plans. Using 23 rejected fecal samples and 29 gut content samples, this preliminary molecular analyses of the feeding ecology of white-bellied pangolin assesses the efficacy of a DNA metabarcoding approach to performing dietary analyses. This extends to the dietary profile and the variation in dietary preference of the focal species following a latitudinal gradient and across varied habitats. Our study demonstrated the potential of DNA metabarcoding in assessing the diet of the white-bellied pangolin when combined with the capture, amplification, sequencing and detection of prey species DNA barcodes within the feacal/stomach content samples. We observed a relatively wide prey spectrum for the white-bellied pangolin compared to that previously recorded through visual observation using radio-tracking. The detected prey species included *Camponotus acvapimensis, Camponotus conradti, Camponotus (Myrmotrema) carbo, Camponotus (Tanaemyrmex) maculatus, Cataulacus guineensis, Lepisiota capensis, Oecophylla longinoda, Pheidole megacephala, Platythyrea conradti, Polyrhachis militaris, Dorylus nigricans,* with eight other photo-based ant species *(2 Ppheidole sp. and 6 Crematogaster sp.)* and eight termite species. *Pheidole sp., Camponotus sp.* and *Cremastogaster sp.* were the genera with the most abundant reads. DNA metabarcoding analyses confirmed the prey selective behaviour previously observed for pangolin species using traditional methods. The alpha diversity of detected prey items varied significantly ($p<0.05$) following sample types, habitats and regions, with our limited data suggesting that individual sex, and a variation to sample pre-processing did not. Bray-Curtis dissimilarity index showed highly significant dietary profile dissimilarities ($p<0.001$) between southern and central regions. Our study demonstrated that DNA metarbarcoding is a promising tool for disentangling the diet intake of pangolins, providing substantial knowledge on their feeding ecology which can inform management decisions for the conservation of the species in its wild habitat. It supports the need for further investigations with a balanced number of sample types to clearly elucidate the dietary profile variation following the latitudinal gradient and ecosystems.

Assessing the utility of eDNA to characterize diversity and dynamics of tropical forests

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Francesc Borràs Sayas[1]
Robert Muscarella[1], Glenn Dunshea[2]
[1] Plant Ecology and Evolution, Uppsala University, Sweden
[2] Department of Natural History, Norwegian University of Science and Technology, Norway

Abstract: Characterizing community composition is the bedrock of community ecology and monitoring biodiversity dynamics. There has been increasing excitement for the prospect of using environmental DNA (eDNA) over the past decade. The proposed advantages of this nascent approach are that it is rapid, highly scalable, and does not require the taxonomic expertise that traditional community surveys demand. Consequently, there has been an exponential rise in publications using eDNA approaches to infer biodiversity patterns and processes. However, eDNA can be physically transported after original deposition and may derive not only from host organisms (the so-called 'ecology of eDNA'), thus potentially be uninformative. The overarching objective of this study is to assess the utility of soil eDNA to infer composition of tropical forest plant communities by comparing eDNA data with traditional censuses of extant communities in Puerto Rico.

We have produced a reference library of P6-loop sequences for all tree species present in the 16 ha Luquillo Forest Dynamics Plot (LFDP). We compared several methodological approaches for sampling and generating eDNA data, such as sample storage and isolation of DNA. Then, we assessed the correspondence between biodiversity estimates based on eDNA data and those based on field observations by leveraging the long-term and spatially explicit data on forest composition and dynamics from the LFDP.

The resulting dataset will be available open-access online and uploaded to appropriate online genetic database. The plant meta barcode derived from soil eDNA in the LFDP will be published online and freely available as well.

Biodiversity reporting trends in the Finnish forest industry

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Marileena Mäkelä[1, 2]
Panu Halme[2, 3]

[2] University of Jyväskylä, School of Resource Wisdom, Finland
[3] University of Jyväskylä, Department of Biological and Environmental Science

Abstract: Globally, biodiversity in forests is declining. The main drivers are forest loss and the conversion of natural forests into managed forests. Forest industry companies use sustainability reports to inform the stakeholders on their sustainability impacts and actions. Biodiversity actions are part of companies' sustainability work. The aim of our research was to study how the Finnish forest industry companies report on biodiversity in their sustainability reports. We focused on the changes and trends of the reporting in 1998-2021. We analysed sustainability reports of the three largest Finnish forest industry companies (Stora Enso, UPM and Metsä Board) with qualitative content analysis. First, we read the reports and identified sections that focus on biodiversity. Second, we coded these sections with themes to describe the content of biodiversity reporting in each section. We identified three trends in our data. First, the amount of biodiversity reporting increased over time. The early reports have only a few mentions and a few sentences on biodiversity, whereas the late reports have entire sections devoted to it. Second, the content of the reporting varies over time with four main themes (risks, values, aims and actions). In the first reports, loss of biodiversity was seen as a major environmental risk, whereas in the last reports, it was seen as a financial risk. The first reports emphasized the "value talk": Protecting biodiversity was seen as important for the companies and the whole industry. From quite early on, companies started to set biodiversity aims, but the early reports failed to describe both indicators and actions to meet the aims. Biodiversity actions were reported steadily during the analysis period but with varying emphasis. The first reports highlighted the role of legislation and certification. The last reports focused on companies' own actions in their own forests and other actions towards biodiversity aims. As a conclusion, the Finnish forest industry companies have a long tradition in biodiversity reporting. The early reports have only a few mentions on biodiversity while the last reports are rather comprehensive descriptions with biodiversity aims, indicators and actions.

Deadwood structure as a potential indicator of boreal forest biodiversity.

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Abstract: We are experiencing a biodiversity crisis. To address biodiversity loss, we need to safeguard high quality sites. Detailed inventories of multiple taxa are preferred for differentiating site quality for biodiversity, but they are difficult, time consuming, and expensive. Finding cheaper and easier ways of recognizing high biodiversity, like assessing easily inventoried physical attributes of sites, is crucial for effective prioritisation of areas to conserve. The links between different taxa diversity and their physical environment is very complex, though, so we must ensure that surveyed structural qualities do indicate high biodiversity value.

We aim to address the question of which forest structural features are the most appropriate for indicating high biodiversity sites in boreal forest. We take a multi-taxon, whole-assemblage, approach, where we ask how epiphytic moss, lichen, polypore, and carabid beetle diversity in Finland and Sweden relate to key structural components including deadwood volume, deadwood diversity, and living tree density and species composition. The relationship between biodiversity and forest structural features is context specific, so we assess relationships across three important forest management types: set-asides (not intensively managed for forest production), retention patches (areas left unharvested within clearcuts stands) and young forests (harvested 25-30 years ago).

We have 240 plots split evenly between Sweden and Finland and the three forest management types. Species experts surveyed all species of target taxa within 10-20m radius plots during 2021 and 2022. We also collected data on potential indicators of biodiversity at these sites, including deadwood decay stage, type and volume, and living tree size, and density. We used Bayesian hierarchical models to regress different aspects of biodiversity against potential site structural indicators.

The suitability of different potential indicators may vary between taxa and forest management type. Deadwood quality should relate more closely to polypores than other taxa, likely because these species live directly on deadwood whereas deadwood may be a less direct indicator of general high quality sites for other taxonomic groups. Our results will suggest appropriate biodiversity indicators in boreal forests, and elucidate some of the complex relationships between species habitat requirements, biodiversity, and management decisions in commercial forestry landscapes.

Drivers of acoustic diversity in managed forests

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

[3] Universität für Bodenkultur Wien, Institut für Zoologie
[4] Georg-August-Universität Göttingen, Silviculture and Forest Ecology of the Temperate Zones

Abstract: Forests harbour large parts of terrestrial biodiversity; at the same time, large parts of the global forests are actively used. Management decisions require reliable information on their consequences for biodiversity. The possibility to observe large temporal and spatial scales make eco-acoustic techniques attractive to forest biodiversity monitoring. Acoustic indices, just like well-known diversity indices (e.g. Shannon diversity), are related to the species richness of vocal taxa, and their vocal activity, but are also driven by abiotic and anthropogenic sound sources. To make sense of large-scale monitoring programs, we need to understand the effects of forest management, structure and regional land use on these.

We collected acoustic data throughout several months and regions in managed forests in Germany. Through structural equation modelling, we tested if bird richness versus bird abundance explained acoustic diversity better and how forest management and forest structure as well as landscape parameters such as distance to forest edge and distance to nearest road mediated this relation.

Results: Forest management negatively affected acoustic diversity, which was directly driven by bird abundance, rather than bird species richness. Although, bird abundance and bird richness were strongly correlated on our study sites. Forest management directly affected bird richness as well as abundance of birds. Forest structural complexity had no direct effect on bird species richness and abundance but on bird composition.

Despite certain limitations, the presented results suggest that acoustic diversity indices add a powerful metric to other biodiversity measures when detecting biodiversity changes in managed forests.

Forest biodiversity monitoring: the example of bird survey in Finland and their responses to forest habitat at multiple scales

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Jérémy Cours[1, 2]
Aleksi Lehikoinen[3], Rémi Duflot[1, 2]
[1] University of Jyväskylä, Department of Biological and Environmental Sciences, Finland
[2] University of Jyväskylä, School of Resource Wisdom, Finland
[3] Finnish Museum of Natural History, University of Helsinki, Finland

Abstract: Long-term biodiversity and forest habitat surveys are scarce and, therefore, precious to study the land management-biodiversity relationship. The response of biodiversity to habitat heterogeneity measured at a fine resolution and on a landscape scale, is not yet fully understood due to the lack of such habitat mapping on a global scale. In Finland, standardized national bird transects and forest structure data have been available since 2009. We explore how these data can be used to better understand the forest habitat-biodiversity relationship at various scales and indirectly inform about the effects of management practices. We mobilize 566 bird transects, multisource national forest inventory, and disturbance map to investigate the bird assemblage responses to landscape habitat heterogeneity (i.e., composition and configuration). We characterize landscapes based on land cover and forest habitat diversity (e.g., mean patch size, area of old and broadleaf forests, age class diversity, etc.). We also implement habitat functional heterogeneity indices such as richness, evenness, and the Rao's Q index, based on vegetation structural features (i.e., tree canopy closure, mean tree diameter, age, height, vegetation type). We study bird assemblages through species compositions but also included functional traits and specialization indices. We hypothesize a positive response of taxonomic and functional biodiversity to both landscape compositional and configurational habitat heterogeneities. We expect to see a greater effect of compositional heterogeneity, particularly when studied through the functional prism of vegetation structure. We also expect that the amounts of old forests (i.e., ≥ 100 years) and broadleaf forests (i.e., ≥ 80 % of broadleaf tree volume) have a positive effect on forest bird species, since they are scarce in Finnish landscapes but associated with multiple key (micro-)habitats (e.g., deadwood, large old trees, tree-related microhabitats). In contrast, we expect mixed effects of disturbances: quadratic effect of the natural disturbance severity to the overall bird community, while amount of clear-cuts in landscape should have negative effects on forest bird species but could also represents opportunities for open-land species.

Forest reserves of Hungary: monitoring of the natural processes

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Bálint Horváth[1]
Gábor Illés[1], Tamás Bedenek[1], Tamás Molnár[1], András Szabó[1], Bence Bolla[1]
[1] University of Sopron, Forest Research Institute, Bajcsy-Zs. srt 4., Sopron, H-9400

Abstract: Designation of forest reserves have been started in the late 80's in Hungary. The majority of the first-growth forests disappeared by the end of the world wars, therefore most of the reserves were managed stands of forests. The Forest Reserve Monitoring Program (FRMP) involved 63 forests with a total cover of 3635.7 hectares that represented a wide scale of natural woodlands of Hungary. FRMP set sights on the investigation of undisturbed natural processes, focused mainly on the understory, stand structure and soil composition. Sampling points were assigned in the intersections of 50x50 m grid in each forest. Survey of herb layer was performed in 6 m radius circles, using 30 pieces of subunits (randomly marked) with 0.4 m radius. We registered the presence of herb species and woody plants under 0.5 m height in each subunit. Sampling plots of shrub layer (1.13 m radius) assigned along the 6 m radius circle, using cardinal- and intercardinal directions. Regeneration layer defined between 0.5 m to 1.3 m height. Shrub layer was specified over 1.3 m height, but under 5 cm diameter at breast height (DBH). Survey of stand structure was carried out in 8.92 m radius circles, supplemented with relascope sampling method (using k=2 factor). Trees were defined as woody plants over 5 cm DBH. The examination of soil composition and structure were performed in laboratory, using bore hole samples from different topographical conditions within the examined forest. The standard FRMP often complemented with further investigations, e. g saprophagous beetles and Lepidoptera assemblages.

GoProForMed – Monitoring the conservation status of Mediterranean forest habitats through sound biodiversity indicators

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

[5] Centre National Propriété Forestièr - CRPF

Abstract: Due to unique biogeographical features, the Mediterranean-European region includes an extraordinarily high number of tree taxa, almost 200 tree taxa more than in the central European region[1]. Forests of the Mediterranean underwent thousands of years of human influence through forest logging, fires, grazing, agriculture, soil disturbances, water uptake, changes in the distribution of native species, and introductions of alien taxa[2]. As a result, Mediterranean forest habitats are unique and worthy of conservation efforts for both their biodiversity and cultural values.

On the one hand, their conservation poses strong challenges as the incidence of extreme drought and fires increases with the ongoing changes in climate [3]. On the other hand, novel indicators of forest conservation state and sustainable management were designed and tested mostly in central Europe[4]. These premises undermine the conservation and sustainable use of Mediterranean forest habitats.

The LIFE project GoProForMed, focuses on four key habitats within the region, covering evergreen broadleaf (dominated by either Quercus ilex or Q. suber), pine-dominated and chestnut forests across France, Greece, Italy and Spain.

We selected twelve sites in which reference and intervention area could be identified for the four target habitats and sampled these sites for multi-taxon biodiversity (vascular plants, lichens, insects), stand structure, tree-related microhabitats and the Index of Biodiversity Potential (IBP).

To define sound indicators for the assessment of the Mediterranean forest conservation status, we studied the relationships between species diversity for multiple taxonomic groups and structure-based indicators that until now have been used mainly in the forests of central European forests.

How to optimize passive acoustic monitoring of forest birds to support rapid biodiversity assessments?

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Frederik Sachser[1]
Robin Sandfort[2], Janine Oettel[1], Martin Steinkellner[1], Owen Bradley[1], Katharina Lapin[1]
[1] Austrian Research Centre for Forests (BFW), Department of Forest Biodiversity and Nature Conservation, Seckendorff-Gudent-Weg 8, 1131 Vienna, Austria
[2] capreolus e.U., Fadenbachstrasse 19, 2304 Orth an der Donau, Austria

Abstract: Biodiversity in forests include an overwhelming number of species and their composition is driven by a multitude of factors. To support effective management decisions, conservation efforts and restoration strategies, many research projects are dedicated to developing rapid biodiversity assessment methods that yield reliable data. These projects aim to identify key indicator species, including various bird species as they provide ecosystem services or exhibit a pronounced habitat association with specific forest characteristics.
Acoustic monitoring techniques are generally more important in forest bird surveys than visual identification, but the courtship of some migratory species is comparably short and their detection is limited to only a few weeks before incubation. Due to time and budget constraints for field work, such behavior can result in data deficiencies. These methodological challenges are especially pronounced in remote areas with low infrastructure such as close-to-nature forests in mountainous regions. Recent advancements in conservation technology facilitate research at those sites as they enable simultaneous data collection and open up the possibility to increase sample size.
Our study encompasses a network of 40 forest sites located as stepping stones and sites in two national parks aimed to be connected. Throughout the entire breeding season, we deployed autonomous recording units at these sites. Target species were cavity-breeders with particular emphasis on three long-distant migratory species belonging to the genus *Ficedula*, all of which breed in forests and co-occur within our study area. Naturally, these species compete with other non-migratory species from the family Paridae for cavities and their occurrence indicate a sufficient number of such breeding sites in forests. In fact, the inclusion of *Ficedula parva* in the Austrian woodland bird index highlights its significance as a reliable indicator for species richness. Occurrence data is however insufficient in some regions, underscoring the need for further research to enhance monitoring effectiveness. We used hierarchical modeling to analyze parameters that potentially influence the detection probability of selected species, including environmental and methodological factors. Our study aimed to propose an optimized workflow for passive acoustic monitoring of forest birds and to provide insights towards the integration of this method within rapid biodiversity assessments.

Improving Forest Habitat Monitoring and Biodiversity Assessment: National Inventory and Innovative Sampling Design

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Henrik Hedenås[1]
Åsa Ranlund[1]
[1] Swedish University of Agricultural Sciences

Abstract: There is an increasing recognition of the need to enhance information on biodiversity, habitat conservation status and trends. This data is crucial for reporting to national and international forums and supporting policy development. To address this, the new revised National Inventories of Landscapes in Sweden (NILS) program was initiated in 2020. NILS consists of several inventories, including the NILS Deciduous forests inventory, NILS Grassland inventory, NILS Alpine mountainous inventory, and THUF Sea shore inventory, all operating within a general framework. The objective is to collect and analyse data on habitats that are underrepresented in other monitoring programs, typically because they are rare or neglected.

The new sample design of NILS allows for additional inventories to be included based on new needs at both national and regional levels, using the same design. This enables monitoring of both uncommon and common habitats by choosing different sample densities depending on the prevalence of the focal habitat type. The consistent sample design allows for the use of the same estimation procedures and algorithms at national, regional, and different sample density levels. The new design incorporates several innovations aimed at establishing a long-term, flexible, and sustainable inventory methodology. While some of these innovations have been used individually in previous inventories, to our knowledge, they have never been integrated within a single design before. Overall, the new design employs a two-step sampling approach that combines remote sensing and field inventories. During the first step, a coordinated sample of tracts is randomly selected using a spatially balanced sampling technique. In the second step, specific plots for field inventory are chosen.

Specifically, the NILS Deciduous forests inventory complements data from the Swedish National Forest Inventory by focusing on relatively rare forest habitats that cover small areas and their quality and biodiversity. These include Broad leaf forests, Alluvial forests, Deciduous swamp woods, and old deciduous forests in the western taiga, which are included in Appendix 1 of the EU Species and Habitat Directive. The field inventory includes diverse number of variables that may act as biodiversity indicators, providing valuable information on forest habitat status and potential changes over time.

Mapping forest habitat types from satellite hyperspectral imagery: challenges and opportunities

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

Anna Barbati
Chiara Zabeo[1], Diego Giuliarelli[1], Gaia Vaglio Laurin[2]
[1] University of Tuscia, DIBAF, Viterbo, Italy
[2] CNR IRET, Roma, Italy

Abstract: Tree canopy species play an important role in creating and maintaining biodiversity in the forest habitat. Mapping the extent of different forest habitats, based on forest canopy composition, can help to optimize the sampling design for monitoring other biodiversity indicators at scales relevant to research and decision-making in biodiversity conservation.

However, this task can be challenging even with the support of remote sensing technology, because the possibility to discriminate differences in forest canopy composition from optical imagery is primarily determined by the similarity or uniqueness of the biochemical and structural properties of the foliage among tree species.

Hyperspectral satellite missions offer a tremendous opportunity to explore new approaches for the delineation of forest and other natural habitat types, thanks to the ability of hyperspectral data to measure the spectral reflectance of plant canopies in a huge number of bands of the electromagnetic spectrum.

In this contribution we discuss whether satellite imaging spectroscopy can offer a solution for the automated delineation of forest habitat types. Lessons learned from a study conducted in a pilot site of nearly 6000 ha in central Italy will be presented, where methods to process and analyse PRISMA hyperspectral satellite imagery (30 m spatial resolution, 234 spectral bands throughout VIS-NIR-SWIR regions) have been tested to map the extent of forest habitats and heathland habitat types (matorral, maquis, garrigues). In particular, one (or two) tree canopy species are expected to dominate the signal at pixel level of the following groups: broadleaved deciduous (*Quercus cerris, Quercus frainetto, Fraxinus sp., Populus sp.*), broadleaved evergreen (*Quercus ilex, Quercus suber*), needleleaf evergreen (*Pinus pinea*).

Monitoring forest biodiversity at a national scale: how to build upon existing monitoring networks

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

[5] INRAE, University of Bordeaux, BIOGECO, Cestas, 33610, France

Abstract: Due to the scarcity of rigorous species monitoring across several taxonomic groups, sustainable forest management indicators related to the biodiversity criterion in Europe are mainly indirect indicators based on tree-related data. Direct monitoring of species, however, often permit more thorough monitoring of the status of biodiversity and its dynamics, with a more rapid assessment of the impact of forest management and forest policies. Using French metropolitan forests as a case study, the PASSIFOR2 project combined the use of direct forest biodiversity indicators as well as associated dendrometric and management-related variables in designing monitoring templates. The project was developed based on (i) the specification of refined monitoring objectives, (ii) a broad consultation of existing networks for collecting biodiversity data in forests and (iii) some methodological research to improve the quality of sampling and data analysis. We present our lessons learned as well as the four main advances that have been made: (i) a method and a protocol for building multi-network biodiversity monitoring templates; (ii) an objective choice of taxa to be favored in monitoring in French forests, based on a multi-criteria analysis, and associated protocols to monitor them (direct biodiversity indicators); (iii) proposals for dendrometric and management variables to be documented and be related to the direct biodiversity indicators; and (iv) statistical results to guide the choices in terms of sampling schemes and data analysis.

National Biodiversity Monitoring in Forests (NaBioWald) - a federal-state initiative

T3.1 Advances towards more accurate forest biodiversity indicators and monitoring

[11] German Centre for Integrative Biodiversity Research

Abstract: The conservation of biodiversity is of great societal interest. The status and future development of biodiversity in German forests cannot be sufficiently determined by the national monitoring programs already existing. NaBioWald aims to close this gap by providing comprehensive and representative information on the development of biodiversity and on the effects of influencing variables. NaBioWald is intended to provide an important basis for biodiversity-oriented forest management, to support the forest and nature conservation policies of the federal and state governments, and to contribute to the fulfilment of national and international reporting obligations.

A working group consisting of representatives of federal and state institutions in forestry and nature conservation including further experts from scientific institutions is currently working on a monitoring concept. One focus is on the possible influences of forest management, climate change, air pollution and air borne pesticides on biodiversity.

To implement the necessary monitoring work, existing German-wide (forest) surveys are to be supplemented with additional surveys and interfaces to ongoing and developing biodiversity monitoring programs are to be created. This approach will be integrated into the activities of the National Biodiversity Monitoring Center. Due to the manifold anthropogenic influences, as well as the complexity of the topic and the effort of monitoring, a shared workload among the many different actors from science, administration, forestry and nature conservation on federal and state level is required. A draft concept is to be discussed in an extended circle of experts and presented as a final draft to politicians for a decision on implementation.

The poster presents the current state of work and the further process of NaBioWald.

The Index of Biodiversity Potential (IBP): A success story of 15 years of Research and Development

Abstract: The Index of Biodiversity Potential (IBP) is a biodiversity evaluation tool created in 2008 to help forest managers to easily take taxonomic biodiversity into account in their daily working routine. This rapid habitat assessment method combines ten historical, structural and compositional key factors for forest-dwelling species. These factors are easily and directly measurable in the field by forest managers with no specialized taxonomic skills. By comparing threshold values with field observations recorded along a standardized route inside the stand, a scoring system awards a score of 0, 1, 2 or 5 per factor. Seven factors directly concern the stand and its current management; three supplementary factors concern site history and context. Both factors and scores were calibrated by large-scale taxonomic data. The observer effect was estimated and helped us to refine factor definitions and shape optimal training sessions. A huge development effort has been rolled out, which includes developing methods for a wide range of forest contexts, numerous training sessions and communication actions through a large array of media. A sociological study showed that the IBP is not only used by forest managers but also by a wide range of actors not initially targeted, due to both its intrinsic features and the strategies used to relay it to these actors. As a boundary object, the IBP facilitates discussion and negotiation among actors with different beliefs and interests within territories. Started in 2009, the research and development programme is continuing. Widely used in France, the IBP is currently spreading in Europe under the guidance of an international expert committee.

Abstract: Monitoring the state and dynamics of forest biodiversity to assess sustainability of forest management remains a challenge since most biodiversity indicators are based on structural proxies issued from national forest inventories. In addition, the metrics used to qualify and quantify these

indicators generally are abundance indices, while ecological theory predicts that the diversity of habitat may have a greater role than abundance.

Within the framework of the COST Action Bottoms-up (CA18207), we gathered data on multi-taxonomic biodiversity and forest structure across more than 3,000 plots in Europe. Building on biodiversity indicators from Forest Europe, we calculated novel metrics of forest structure describing diversity in addition to abundance. We then tested and consolidated new biodiversity indicators based on sustainable forest management reportings, and tested them on six model taxa: tracheophytes, bryophytes, birds, saproxylic beetles, lichenized fungi, and non-lichenized fungi.

While current indicators have been chosen for their availability and the fact that they are understandable to most stakeholders within the forest sector, our analyses show that, depending on the taxa studied, some indicators based on diversity indices perform better than those currently used to assess biodiversity. Our work can contribute to a better assessment and reporting on forest biodiversity at a large scale.

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Accelerating innovation in forest operations for Ecosystem Restoration: How improve genetic material to achieve restoration at scale

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

René Zamora Cristales[1, 2]
[1] Initiative 20x20 Coordinator and senior Policy Manager, World Resources Institute
[2] Courtesy Faculty, College of Forestry, Oregon State University

Abstract: Global targets including the recently launched Post-2020 Biodiversity framework from the Convention on Biological Diversity call for restoration in millions of hectares. In addition to this challenge, Climate Change is affecting precipitation and temperature patters impacting natural forest and slowing down efforts to restore degraded lands. To achieve the scale needed a set of sustainable forest operation are required to improve the genetic material demanded and ensuring the quality of the restoration process. Most of genetic material available for planting in Latin America is distributed in a few commercial species, however the multiple objectives of landscape restoration demand the use of a diverse set of species. The production of the genetic material as well as the distribution to the planting sites constitutes challenges and potential bottlenecks to reach the desired outcomes in times of urgency. In this presentation we will present a diagnostic focused in seven countries in Latin America, Mexico, Guatemala, Costa Rica, Colombia, Peru, Chile, and Argentina that analyses the gaps along the supply chain and provides recommendations for improvement. We will also share a framework to assess the structure of seed and plant supply systems based on adaptive management. The results from the diagnostic showed that gaps around finding local material are present in many countries. Also, the definition of what constitutes a "native" specie bring problems when selecting genetic material for restoration. Additionally, the lack of long-term objectives provides challenges when defining the "quality" of the genetic material. As many areas under restoration are severely degraded part of the quality of the genetic material needed relates to the adaptability to hard conditions in the field. We finally provide policy recommendations for governments to take into account when designing National Restoration Strategies and key operational aspects to consider.

Adaptive Silviculture for Climate Change: where are we?

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Courtney Peterson[1]

[4] USDA Forest Service, Office of Sustainability and Climate, Michigan, United States

Abstract: The Adaptive Silviculture for Climate Change (ASCC) project is a collaborative effort that has established a series of experimental silvicultural trials across a network of different forest ecosystem types throughout the United States and Canada. Scientists, land managers, and a variety of partners have co-developed fourteen experimental sites as part of this international study to research long-term ecosystem response to a range of climate change adaptation approaches, enabling forest ecosystems to continue to provide valuable ecosystem services into the future. The big question ASCC is poised to answer is: What actions can be taken to enhance the ability of a system to cope with change while continuing to meet management goals and objectives? Silvicultural treatments at each ASCC study site were developed following the adaptation framework in *Forest Adaptation Resources: Climate Change Tools and Approaches for Land Managers* (Swanston et al. 2016). Treatments approximate a gradient of climate-adaptive management approaches: (1) resistance – maintaining relatively unchanged conditions over time; (2) resilience – allowing some change in current conditions, but encouraging an eventual return to reference conditions; (3) transition – actively facilitating change to encourage adaptive responses; and (4) no action control – allowing forests to respond to climate change without direct management intervention. This presentation will cover an overview of the ASCC Network experimental design, some key climate change challenges and opportunities across the sites, how these are being addressed through innovative silvicultural practices and management, examples of forest assisted migration being applied across ASCC sites, and preliminary results and lessons learned from this collaborative manager-scientist Network.

Challenge of ozone FACE experiments in Mediterranean Europe

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Yasutomo Hoshika[1, 2]
Elena Paoletti[1, 2]
[1] IRET-CNR, Sesto Fiorentino (FI), Italy
[2] National Future Biodiversity Center (NBFC), Palermo, Italy

Abstract: Tropospheric ozone (O_3) is an oxidative air pollutant with causing a significant negative effect on forest tree species. Free-air controlled exposure (FACE) facilities are considered as an ideal tool which can provide realistic estimates of tree response to O_3 under real world conditions. Since 2015, a last generation of O_3 FACE facility has been available at the CNR experimental garden in central Italy (FO_3X), which is a unique facility in Europe within an AnaEE (Analysis and Experimentation on Ecosystems) European research platform. This facility permits the exposure of plants to three levels of O_3 concentrations (ambient, 1.5- and 2.0-times ambient concentration, denoted as AA, 1.5×AA and 2.0×AA, respectively), with main environmental variables continuously monitored. The phytotoxic nature of O_3 can impair forest productivity. In addition, O_3 affects stomatal functions, by both favoring stomatal closure and impairing stomatal control. Ozone-induced stomatal sluggishness, i.e., a delay in stomatal responses to fluctuating stimuli, has the potential to change the carbon and water balance of forests. In particular, the O_3-induced stomatal sluggishness becomes more important in water-limited environments such as Mediterranean Europe where stomatal regulation of water losses under low soil water availability are critical. In this presentation, we will introduce our FACE facility with a future perspective, and recent experimental results about stomatal sluggishness will be summarized.

Fluctuating asymmetry of pedunculate oak leaves as an indicator of abiotic stress

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Lazar Kesić[1]
Saša Orlović[1], Erna Vaštag[2], Martina Zorić[1], Danijela Miljković[3], Srđan Stojnić[1]
[1] University of Novi Sad, Institute of Lowland Forestry and Environment, Antona Čehova 13, 21000 Novi Sad, Serbia
[2] University of Novi Sad, Faculty of Agriculture, Trg Dositeja Obradovića 8, 21000 Novi Sad, Serbia
[3] University of Belgrade, Institute for Biological Research „Siniša Stanković“, National Institute of the Republic of Serbia, Bulevar despota Stefana 142, 11060 Beograd, Serbia

Abstract: Fluctuating asymmetry (FA) is characterised by deviations from "ideal" symmetry in bilateral structures and, therefore, it is used as a reliable indicator of the impact of different types of stress on plants. FA indices have been widely used in monitoring the habitat of individuals, assessing habitat quality as a measure of environmentally induced developmental instability. In this study, the FA, and its relationship with the climatic variables (i.e. air temperature, precipitations and relative air humidity), are analysed in pedunculate oak (*Quercus robur* L.) leaves originating from nine *in situ* populations located at the species rear edge, in Serbia. The results showed that FA was primarily influenced by mean annual air temperature, while relative air humidity and annual precipitation sums had smaller effect on this phenomena. These methods can be used to better understand how environmental changes (on a spatial scale, at a distance of approximately 350 km) affect leaf growth and development within populations. Ultimately, these insights may benefit conservation efforts for this economically and ecologically important deciduous forest tree species in Europe and its unique adaptations. By continuing to explore the variability in developmental instability of pedunculate oak leaves among populations, we can deepen our understanding of this remarkable tree species and its place in our natural world.

Keywords: pedunculate oak, populations, fluctuating asymmetry, development instability.

Genome-Wide Diversity across Natural Populations and Varieties of Ponderosa Pine (Pinus Ponderosa)

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Sean Collins[1]
Anna Lincoln[2], Amanda De La Torre[1]
[1] Northern Arizona University School of Forestry, Forest Genomics Lab, Flagstaff, AZ 86001 USA
[2] Bureau of Land Management Grand Junction Field Office, CO 81506 USA

Abstract: Ponderosa pine is one of the most widely distributed conifers in North America, and also has one of the most unclear histories, in terms of migration and intra-specific varieties, in any North American conifer. Previous microsatellite studies have produced results that could support two, four, eight or nine varieties within the species and morphological studies have postulated up to five varieties within the species. Better understanding varieties within ponderosa pine can help better inform future conservation efforts as conservation efforts can become variety specific. A genome-level approach to examine ponderosa pine varieties across the range has never been done. The goal of our project is to examine relatedness and genomic variation of ponderosa pine populations throughout the range using pool-seq exome capture to see if an exome-level approach may provide clearer inferences on the number of varieties within the species compared to previous studies. DNA was extracted from 12-20 individuals across 26 locations across the range of ponderosa pine. Within each location 4 individual samples were pooled to create 3-5 composite exomes for each location. 55,000 capture probes, from 40,000 coding regions and 15,000 intergenic regions, were designed using publicly available transcriptome data and the *Pinus taeda* genome to supplement intergenic regions. A genome and environmental association will also be conducted to examine what environmental factors may drive differences among varieties. The results of our study will help aid restoration efforts on public lands, as land managers can select varieties that are best adapted for their specific area and to future climate change, which can help ensure the persistence and health of the species across its wide range.

Impact of wildlife browsing on genetic diversity in the young forest tree population

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Natalija Dovč[1]
Rok Damjanić[1, 2], Andrej Breznikar[2], **Kristina Sever**[2], Marjana Westergren[1], Marko Bajc[1], Andreja Gregorič[2], Hojka Kraigher[1]
[1] Slovenian Forestry Institute, Večna pot 2, 1000 Ljubljana, Slovenia
[2] Slovenia Forest Service, Večna pot 2, 1000 Ljubljana, Slovenia

Abstract: Wildlife browsing is known to have significant impacts on forest ecosystems. Ungulate game selectively target certain tree species or individuals, giving an advantage to other species that are less preferred by browsing animals. Therefore it strongly influences the structure, composition, growth and succession of forest. That may in the long run lead to species diversity reduction and threaten the resilience of the forest to future disturbances. In the last century, the density and spatial distribution of large herbivores, especially roe deer (*Capreolus capreolus*) and red deer (*Cervus elaphus*) has increased significantly in most of European countries. The monitoring of a wildlife browsing is crucial for assessing its effects. The Life Systemic project experiment findings and the results from the monitoring of wildlife browsing in Slovenia over the previous 14 years will be presented. Results also include an assessment of how wildlife browsing affects the genetic diversity of silver fir natural regeneration. The experiment is being conducted on 8 experimental plots (4 fenced and 4 unfenced) in a forest stand, dominated by silver fir in Slovenia. All saplings were counted, measured and assessed for browsing damage. 50 saplings from each plot were sampled for genetic analysis, totalling 400 samples. Another part of the experiment was carried out nearby, in a region that had been fenced more than two decades prior. Additional 400 saplings were sampled, including 200 samples from a fenced area and 200 samples from outside the fenced area with comparable conditions. For the purpose of managing forests and implementing conservation efforts, it is crucial to comprehend how wildlife browsing affects forest genetic diversity. It can guide strategies to lessen the effects of browsing, such as installing fencing or taking other steps to keep ungulates out of sensitive areas.

Is beech forest management driving soil microbiota?

Abstract: Vital soil resulting from interaction of physical, chemical and biological soil properties is critical for sustaining forest growth and ecosystem services. High soil biodiversity supports functional flexibility for adaptation to unknown changes that may occur in the future. Forest management practices result in numerous direct and indirect changes that can affect soil quality, including the soil microbial biodiversity. Nevertheless, the effects of forest management on soil microbiota remain largely unexplored.

In our study, soil and root samples were collected from nine beech (*Fagus sylvatica* L.) forests with different forest management regimes (unmanaged forest nature reserve, low close-to-nature forestry, medium combined system) in Italy, Croatia, and Slovenia. Soil samples were analysed for pedological characteristics, while bacterial, fungal, and archaeal communities were analysed using Illumina MiSeq. Root samples were used to characterize the active community of ectomycorrhizal (ECM) fungi by a combination of morpho-anatomical and molecular approach (Sanger sequencing). In addition, environmental parameters that may affect the microbial community were collected.

Species richness of bacteria, fungi, and a subgroup of ECM fungi were significantly affected by the forest management regime. However, no significant relationship was found with the species richness of the active community of ECM fungi on beech roots, which varied among the sites. Weather parameters, specifically temperature and precipitation in certain months of the year, were positively correlated with species richness of active ECM fungi. Soil pH was found to be a significant driver of bacterial and fungal community in the beech forests studied.

These results suggest that the forest management practices should be considered in the context of preservation of the soil microbial pool.

The study was carried out within the LIFE SySTEMiC project - LIFE18ENV/IT/000124.

Landscape genomics to support Sustainable Forest Management

Abstract: Forest ecosystems represent complex adaptive systems that cover a wide range of climatic zones and form different forest types. Forest areas are important for ecosystem services, ranging from economic and social serving to the biodiversity they host and represent. Climate change, unsustainable forest management, invasive species, urbanization, and fragmentation reduce forest biodiversity, may adversely affect genetic diversity, and put at threat the future adaptive potential and sustainability of forests ecosystems. The genetic diversity in locally adapted forest is essential for adapting to changing environmental conditions. Nowadays, many forest species were found to be threatened or subject to genetic erosion, making forests less resilient and compromising future adaptability to changing environmental conditions. Therefore, it is extremely important to provide a sustainable forest management (SFM) for a correct sustainable use of forest products but preserving biodiversity. In particular, forest genetic resources (FGR) are the basis of the long-term evolutionary processes maintaining the adaptive potential of forests. LIFE SySTEMiC (LIFE18 ENV/IT/000124) examines best close-to-nature forest managements regarding FGR in different European Forest Types, for diverse forest management systems comparing to non-managed forests to preserve adaptability of forest ecosystems. The principal aim is to use a combination of advanced landscape genomics, applied genetics, modelling and silvicultural methods resulting an innovative Genetic Biodiversity and Silvicultural model (GenBioSilvi) to be used as tool for a SFM. The Project involved a multidisciplinary study approach: (i) the study concerning the adaptive component of the genetic variability of the stands; (ii) the study of biodiversity at species and ecosystem level obtained through the study of the fungal and microbial communities of the forest soil; (iii) the study of past and current silvicultural management. The information processed on biodiversity and genetic

characterization enabled the definition of biogenetic indicators useful in providing the best adaptive management of the forest, with respect to climate change, also considering the species and different silvicultural treatment conditions (for details see our presentation in Session T3.7). Here, we have reported the results obtained at the end of the LIFE SySTEMiC project.

Phylogeny and evolution of molecular response to abiotic stresses: a comparison between angiosperms and gymnosperms

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Cesare Garosi[1]
Cristina Vettori[1, 2], Roberta Ferrante[1, 3], Donatella Paffetti[1]
[1] University of Florence, Department of Agriculture, Food, Environment and Forestry, Piazzale delle Cascine 18, 50144 Florence, Italy
[2] National Research Council, Institute of Bioscience and Bioresources, Division of Florence, Via Madonna del Piano 10, 50019 Sesto Fiorentino, Italy
[3] NBFC, National Biodiversity Future Center, Palermo 90133, Italy

Abstract: The study of forest species adaptation to abiotic and biotic stresses has always been of great interest. Adaptation to environmental stresses has been studied using a variety of approaches. Comprehending the evolutionary history of this molecular response can help to understand how different abiotic and biotic stressors have driven the adaptation of major forest species, leading to their current distribution across geographic ranges. However, the size and complexity of higher plant genomes has always been a major obstacle to genetic and genomic analyses of these species. Studies on the evolution and phylogeny of forest species are characterized by the analysis of only a few species (often model species) and/or a limited number of gene sequences. In this work, we used a newly identified database of 616 gene sequences representative of responses to abiotic stresses to perform evolutionary analyses and compare two major taxonomic groups: Conifers and Deciduous trees. The analyses performed led to interesting results regarding the phylogeny and evolutionary history of the molecular response of these species. The results show that the response to abiotic stresses is remarkably conserved in the two taxonomic groups studied. Despite the different evolutionary histories over the past 300 million years, genetic diversity is not abysmal. As expected, the evolutionary history appears to reflect an already widely held assumption: a slowdown in the overall mutation rate of conifer orthologs relative to those of angiosperms. This finding is consistent with an increase in the fixation of nonsynonymous mutations that could be beneficial for adaptation

Stronger together: genetics and ecophysiology of drought stress in Fagus sylvatica

T3.2 Can adaptive genomic drive sustainable forest management under climate change?

Tobias Bruegmann[1]
Alexander Fendel[1], Maike Woith[2], Friderieke Schwarzer[3], Alina Fomin[1], Sebastian Hass[2], Boas Pucker[3], Matthias Fladung[1], Manfred Forstreuter[2]
[1] Thünen Institute of Forest Genetics, Genetic Technologies, Grosshansdorf, Germany
[2] Freie Universität Berlin, Plant Ecology, Berlin, Germany
[3] Technische Universität Braunschweig, Plant Biotechnology and Bioinformatics, Braunschweig, Germany

Abstract: European beech (*Fagus sylvatica* L.) has a large distribution area across the European continent. At its southern edge, this species is confronted with different climatic conditions than in Central or Northern Europe: average annual temperature is higher; precipitation is lower. To investigate possible different drought stress tolerances of beech provenances, a provenance trial ("climate forest") was established in the Grunewald Forest in Berlin/Germany, where individual trial members (a group of trees) can be irrigated, while other trial members are affected by the (naturally occurring) drought conditions in summer. A drought stress experiment was initiated in the summer of 2022 with one provenance each from Germany, France, Italy, and Spain. In a unique interdisciplinary approach, ecophysiological, biochemical and genetic analyses were performed following different stress intensities. The data will be used to unravel possible different drought stress tolerances of individual European beech provenances.

Genetic regulation of drought stress will be investigated by transcriptome analysis. For this purpose, mRNA was isolated from leaf samples of selected trial members and a sequencing approach was conducted. Based on the deciphered mRNA sequences, the activity of the different genes will be determined. Biochemical measurements will be performed for the levels of the drought stress markers proline, malondialdehyde and peroxide, among others. Together with physiological data such as photosynthetic activity, stomatal conductance, and water potential, the analytical triad should provide a comprehensive picture of the drought stress response of the trees in this trial.

We expect answers to the questions: what is the overall response of European beech under drought stress? Do the selected provenances differ in their drought stress response? Which genes are switched on or off, and how fast or how strongly is gene activity regulated? Is the provenance-dependent differential stress tolerance related to differential gene regulation? The findings from this collaborative research may be helpful to develop genetic, biochemical and/or ecophysiological markers which can be used to select suitable drought-tolerant provenances.

T3.3 Disappearing oak woods: conservation and management of global oak forests

An integrative perspective of species limits, gene-flow and local adaptation in Southeast European white oaks

T3.3 Disappearing oak woods: conservation and management of global oak forests

[2] Transilvania University of Brasov, Brasov, Romania
[3] University of Forestry, Sofia, Bulgaria

Abstract: Oaks (genus *Quercus* L.) are considered potential winners under future drier and warmer climates. The white oaks species-complex includes some of the most widespread oak species in Europe – namely *Q. robur*, *Q. petraea*, and *Q. pubescens* – and is strikingly diverse in Southeast Europe, where a number of minor lineages have been reported. To date, it is unclear what evolutionary processes underlie this taxonomic richness. We hypothesize that local adaptation and (adaptive) introgression likely driven by post-glacial secondary contact play a major role. Our project features whole-genome resequencing (WGR) and leaf morphological data of 46 populations (ca. 15 individuals per population) scattered across Eastern Austria, Hungary, Croatia, Romania, and Bulgaria, including some white-oaks diversity hotspots. We test if leaf morphology can be used to discriminate among main and minor lineages and identify putative hybrids, extending knowledge from previous studies to a larger geographic scale. Further, we explore which demographic scenarios of secondary contact and gene-flow better explain the present white oak genetic composition. Lastly, we exploit populations growing under dry and warm conditions at the limit of the ecological range to better understand the adaptive potential of white oaks to the future climate. We show that leaf morphology can be used to characterize hybrids, which are intermediate between the parental species. While at least 5 leaf traits are significantly different between the main species, the same traits fail to discriminate between major species and minor taxa, mainly due to the large within-species variation. Ongoing analyses of WGR show very little to no reference-species bias when mapping genomic reads of different sample species to the *Q. robur* chromosome-level reference genome v. 3, likely as a consequence of frequent hybridization. These initial results support our approach towards a better understanding of the evolutionary processes underlying species and adaptive richness in white oaks.

Assessment of forest structures, soil carbon stocks, TREMs and deadwood in four secondary old-growth English Oak Forests in the Basque Country, Spain

T3.3 Disappearing oak woods: conservation and management of global oak forests

Nahia Gartzia Bengoetxea[1]
Elaia Iriarte[1], Antonio Gazol Burgos[2], Jaime Uria Diez[1], Ander Arias Gonzalez[1]
[1] Department of Forest Sciences, NEIKER-Basque Institute for Agricultural Research and Development, Basque Research and Technology Alliance (BRTA), Parque Científico y Tecnológico de Bizkaia, P812, 48160 Derio, Spain
[2] Instituto Pirenaico de Ecología (CSIC), Avda. Montañana 10005, Zaragoza 50009, Spain

Abstract: Old-growth forests contribute to biological diversity at many levels of the biological hierarchy. Old-growth primary forests disappeared from the Basque Country in the Middle Ages due to the iron industry. As a result of the presence of the iron industry, forests were cut down and its timber was used for chacroal production. Today the region's forests are shaped by humans through extensive planting. In the last 120 years, coniferous forests have mainly been planted with the aim of production of raw materials, being *Pinus radiata* the main species. Planted forests occupy 68% of the forest surface in the Atlantic watershed of the Basque Country while forests dominated by English oak (*Q. robur*), that is the main potential forest system in the region, only covers 5,1% of this area.

Some small secondary old-growth forests are still present in the region and this study aims to assess forest structures, forest soil carbon stocks, quantity of deadwood, and tree related micro-habitats (TREMs) in four secondary old-growth oak forests in the Basque Country, Spain.
We aim to enhance our knowledge of the ecological characteristics, conservation significance, and potential relationships among these factors.

Preliminary results indicate variations in forest structural diversity among the four study sites, reflecting differences in stand age, disturbance history, and management practices. These variations are expected to have implications for tree-related micro habitats. The analysis of age and TREMs data reveals distinct assemblages associated with different forest structures, including species that are dependent on specific microhabitats provided by mature oak forests. Regarding to soil organic carbon stocks show that past forest management led to overuse of the forest and soil carbon stocks are still far from their potential carbon sequestration.

The findings contribute to the understanding of forest dynamics in these vulnerable ecosystems. The results can inform forest management practices and conservation strategies aimed at maintaining and enhancing the ecological integrity of English oak forests, ensuring the long-term persistence these ecosystems and their associated biodiversity.

Divergent climate responses in radial growth among three spatially displaced oak species along an altitudinal gradient

T3.3 Disappearing oak woods: conservation and management of global oak forests

[3] School of Ecology and Nature Conservation, Beijing Forestry University, Beijing 100083, China
[4] Chinese Academy of Forestry, Beijing 100091, China

Abstract: Elucidating the underlying mechanisms driving the geographic and niche differentiation of forest tree species is amongst the key issues in studies of phytogeography as well as for determination of the climate-forest structure relationships. However, an explicit knowledge on the controls of the spatial displacement of congenic tree species by climatic factors is still lacking. Here we investigated changes in the radial growth of three deciduous oak species (*Quercus variabilis, Quercus aliena* var. *acuteserrata*, and *Quercus wutaishanica*) occurring sequentially along an altitudinal gradient on Mt. Taibai of the Qinling Mountains. We found that changes in moisture conditions with altitude, inferred by the standardized precipitation-evapotranspiration index (SPEI), dominated the influences on the radial growth of the three oak species. While an increase in temperature appeared to favor the radial growth in both *Q. aliena* var. *acuteserrata* and *Q. variabilis* across their altitudinal range, the association between rising temperature and drought (decreasing SPEI value) suppressed the radial growth of the high-altitude oak species *Q. wutaishanica*. Moreover, the growth in *Q. aliena* var. *acuteserrata* and *Q. variabilis* recovered better from extreme drought than that in *Q. wutaishanica*. Our findings suggest that with projected future warming and more frequent and severe drought events, a range contraction would likely occur in *Q.wutaishanica* at its upper limit, whereas the distributional range of *Q. aliena* var. *acuteserrata* and *Q. variabilis* would possibly shift upwards or remain unchanged due to their higher plasticity to environmental changes.

Dual RNAseq Analyses of the Oak Wilt Disease Complex: Unraveling the Silent Battles of Oak Hosts Against the Fungal Pathogen Bretziella fagacearum

T3.3 Disappearing oak woods: conservation and management of global oak forests

Abstract: Oak (*Quercus* spp.) trees have significant economic and ecological value as urban landscape and forest resources. In addition to commercial demand, contributing factors that challenge tree health include vascular diseases such as oak wilt which is caused by the fungal pathogen *Bretziella fagacearum.* North American oaks differ in their susceptibility to oak wilt disease. Infected red oak species may die 4-6 weeks following infection due to vascular blockages by overproduction of tyloses. Whereas white oak species have shown moderate to high resistance by slowing and containing the infection. European white oak species are less resistant to oak wilt disease than their North American counterparts. Our understanding of the underlying host-resistance mechanisms involved in the differential defense responses to oak wilt disease among different oak species is severely limited. Our objective was to use a dual-RNAseq experiment to identify and characterize gene clusters that contribute to white oak resistance to oak wilt and genes involved in the pathogenicity and virulence of *B. fagacearum*. To accomplish these goals, first, we conducted a greenhouse experiment to test *B. fagacearum* virulence level with eight isolates collected from four regions and selected a highly virulent and a low virulent isolate. Then, we inoculated 52 container-grown red oak (*Q. rubra*) and 52 white oak (*Q. alba*) trees with one of three treatments: high virulent isolate, low virulent isolate, or water-glycerol treatment. To categorize changes in host responses to *B. fagacearum* inoculation, xylem tissues were sampled above the inoculation on days 0, 1, 3, 7, and 21 post-inoculation. Data are forthcoming. We expect that white and red oak transcriptomes will respond differently to infection. Particularly, we expect that in red oaks, gene clusters that are related to host defense responses will be up-regulated at later disease stages compared to white oak. In red oaks, we anticipate delayed and potentially uncontrolled expression of genes related to tylosis formation leading to tyloses overproduction resulting in system-wide vasculature blockage. The outcome of this study will inform future disease management strategies and develop biomarker(s) valuable for selecting oak wilt-resistant genotypes for selective breeding programs.

Genomic basis of Quercus robur resistance to acute oak decline in Britain

T3.3 Disappearing oak woods: conservation and management of global oak forests

Abstract: Acute oak decline (AOD) is a complex syndrome characterised primarily by fluid exudation from necrotic inner bark lesions and is affecting thousands of oaks in the UK, many of which die each year. Prevalence of AOD at UK sites has been associated with multiple biotic and abiotic risk factors, but the genomic basis for AOD susceptibility has yet to be investigated. We phenotype and sequence the whole genome of 1478 oak trees and use a combination of genome-wide association study (GWAS) and genomic prediction models to understand for the first time whether there is a heritable basis to AOD susceptibility. Firstly, we identify single-nucleotide polymorphisms (SNPs) associated with AOD, some of which were in, or close to, genes with functions that could credibly be involved in insect, bacterial or stress response. Secondly, while we find that SNP heritability to AOD is relatively low (0.391), there was a high correlation between genomic estimated breeding values (GEBVs) and AOD phenotype. A Bolt-LMM prediction model trained with the 5000 most significant SNPs predicted the health status of individual trees with 87% accuracy. These results suggest resistance to AOD is a polygenic trait, and that genomic prediction tools can be used to select individuals with high breeding values. This should enable future selection of planting stocks, and if necessary, could inform a breeding programme aimed at rescuing threatened oak populations in the UK.

How the interaction of competition, annual climate variation and site conditions modulate tree growth – experiences from Nelder trials

T3.3 Disappearing oak woods: conservation and management of global oak forests

Dominik Ambs[1]
Enno Uhl[1], Peter Biber[1], Hans Pretzsch[1]
[1] Chair of Forest Growth and Yield Science, Department of Life Science Systems, TUM School of Life Sciences, Technical University of Munich, GER

Abstract: Pedunculate oak (*Quercus robur* L.) is considered as a tree species with high potential regarding climate stability of forests in Central Europe. However, some studies report a decline in oak in certain regions, particularly at the edge of its geographical distribution range. In addition, despite different approaches, natural and artificial regeneration of oak is still difficult to manage. Thus, the regeneration of oak is a field of intensive research worldwide.

To improve the understanding of intra-specific interactions in oak stands, Nelder trials were set up along a climatic gradient on five sites across Europe, from Belgium and Germany to Italy and Hungary 10 to 15 years ago. Nelder wheels allow to analyse development and growth at a single tree and stand level as a function of local stand density and site conditions. This emulation of complex ecosystems contributes to the understanding of basic tree interactions, while the results can also be relevant for forest management and stand regeneration.

In our study, we use the annual increment of biomass as an indicator for the reaction of trees on the different growing conditions and analyse it with linear mixed models. We further investigate if larger trees react differently from the smaller ones.

Our preliminarily results show (i) a significant influence of size, competition, site index and climate on tree growth dynamics. The negative effect of competition is (ii) increased on sites providing more beneficial growing conditions while (iii) more arid periods are likely to intensify the observed growth reduction by competition. This supports the importance of early thinning in stands with high growth potential to reduce competition induced growth losses.

Impact of black cherry on pedunculate oak vitality in mixed forests: balancing benefits and concerns

T3.3 Disappearing oak woods: conservation and management of global oak forests

Abstract: The vitality of European forests continues to decline due to increasing pressures such as new pests and diseases, climate-change related disturbances and high loads of atmospheric deposition of nitrogen. Deteriorating soil health and low overall biodiversity are major factors underpinning the low vitality of West-European oak forests. Boosting tree species diversity and, particularly selecting tree species with soil ameliorative traits, could be an avenue to counteract soil acidification and improve overall vitality. Here we evaluate the impact of black cherry (*Prunus serotina* Ehrh.) on the vitality of neighboring pedunculate oak (*Quercus robur* L.) in ten mixed forests on sand in Germany, Belgium and the Netherlands. Black cherry is a known rich litter species yet also considered an alien invasive species negatively impacting forest ecosystem functioning. As proxies for oak vitality, we measured foliar nutrient concentrations, total chlorophyl concentrations and leaf damage by herbivory. In this study, we tested the hypothesized positive effect of black cherry on litter decomposition and consequently soil nutrient availability, i.e. the 'improved soil health' pathway via structural equation modelling (SEM). Our analyses showed that black cherry admixture in the forest overstory causes reductions in foliar Mg concentrations of neighbouring oaks but increases in foliar N and P concentrations. Moreover, black cherry also leads to lower accumulation of organic material in the humus layer resulting in higher soil base saturation. This improved soil health has a positive effect on oak foliar Ca yet a negative effect on oak total chlorophyll via increased nitrification. Moreover, herbivory of oak leaves decreases when black cherry is admixed, both directly via dilution and indirectly via improved soil health. Our study showed that the combined positive and negative impacts of black cherry on oak vitality are limited, which tempers the potential benefits of using the rich litter species to counteract oak decline via improved soil health – yet, the concern of black cherry as an invasive alien species negatively affecting the vitality of mature pedunculate oak trees may also be overestimated.

Impact of thinning intensity on growth and regeneration of natural oak forests based on meta-analysis: implications for Chinese oak forest managenment

T3.3 Disappearing oak woods: conservation and management of global oak forests

Jianfeng Liu[1]

[1] Key Laboratory of Tree Breeding and Cultivation of National Forestry and Grassland Administration, Research Institute of Forestry, Chinese Academy of Forestry, Beijing 100091, China
[2] Key Laboratory of Forest Ecology of National Forestry and Grassland Administration, Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Beijing 100091, China
[3] Research Institute of Topical Forestry, Chinese Academy of Forestry, Guangzhou 510520, P.R. China

Abstract: According to the "9th National Forest Resources Inventory Report" (2014-2018), oaks are the largest tree species group in China, which accounting for 11.95% and 9.98% in the total forest area and standing volume, respectively. However, despite the abundance of oak resources, the lack of scientific and effective management measures has led to the low quality of oak forests, which severely restricts its ecological, economic and social functions. As one of the most important forest management measures, thinning is of great significance to improve stand quality and achieve sustainable forest development. In this study, by carefully screening published relevant literature data (37 valid literatures; 149 pairs of data), a meta-analysis method was used to explore the effect of thinning intensity (mild, moderate, strong and heavy) on the average annual growth of diameter at breast height (DBH, mm / yr), average annual increment of stand volume (m^3 / ha·yr) and seedling density (individuals / 100 m^2). The results showed that moderate (20-39%) and strong thinning (40-59%) significantly faciliated the increment of stand DBH and volume, especially for middle-aged forests (21-40yr). All thinning intensities, except the mild intensity, significantly promoted the seedling density. Meanwhile, the three studied variables in the stands under sunny slope aspect or bottom slope position responsed more positively to thinning. The promoting effects of thinning generally lasted less than ten years, suggesting thinning interval with about ten years could contribute to persistently improve stand productivity and recruitment of oak forests in China. This study provides a certain scientific reference for the formulation and implementation of sustainable management strategies for oak forests in China. In the future, it is necessary to combine the long time series observation to obtain the optimal thinning mode, thinning intensity and thinning interval of oak stand with different density (age) under different site conditions, so as to lay a more solid foundation for further improving the production and service function of oak forests in China.

Investigating silvicultural methods using soil-scarification to overcome failed regeneration of Quercus crispula.

T3.3 Disappearing oak woods: conservation and management of global oak forests

Hina Haratani[1]
Toshiya Yoshida[2]
[1] Graduate School of Environmental Science, Hokkaido University, Hokkaido, Japan
[2] Nayoro Station, Field Science Center for Northern Biosphere, Hokkaido University, Hokkaido, Japan

Abstract: Quercus crispula provides excellent wood, which is currently in high demand in the market.
However, in Hokkaido, northern Japan, where Quercus crispula is widely distributed, the resource of high-quality, large-diameter trees are declining by selective harvesting. In forests in the region, dwarf bamboos dominate the understory of forests, causing failed regeneration for this species. Therefore, regeneration techniques, in relation to the competition with dwarf bamboos and other tree species, need to be developed to consider the silvicultural method for its sustainable utilization.
The study was conducted in the Uryu Experimental Forest of Hokkaido University. In 2006, scarification treatment using heavy-machinery was carried out in non-wooded site to reduce competition from dwarf bamboos, followed by sowing of Quercus crispula acorns (c.a. 7 acorn /m^2). Then we measured establishment and growth at years 5, 6, 11 and 17.
Our results demonstrate that the scarification treatment effectively removed competition from dwarf bamboos, resulted in early establishment of Quercus crispula seedlings (5.51±sd 4.43 stems/m^2 at 5th year). However, in the 11th year, Quercus crispula (mean height 2.11±sd 0.56 m) was being suppressed by naturally regenerated Betula ermanii Cham. (2.86±sd 0.94 m), which gradually dominated the site. This suggests that thinning within this period (5-11th year) is essential for the growth of Quercus crispula, although the presence of dense Betula ermanii might have a positive effect to suppress excessive branching from the bole of Quercus crispula. Therefore, we carried out tree-stem analysis to identify the appropriate timing for thinning, and discussed silvicultural scenarios for the growth of Quercus crispula.

Long-term survival and growth response of large oaks following conservation cutting in mixed, structurally complex forests in southern Sweden

T3.3 Disappearing oak woods: conservation and management of global oak forests

Abstract: Anthropogenic activities and a changing climate have put forest ecosystems worldwide under increasing pressure. Forest owner's preference of fast growing tree species in production forest and plantations further influence ecosystems with high biodiversity that support not only important ecosystem services but also have a high resilience to disturbances and environmental stress. Oak (*Quercus spp.*) can be regarded as a foundational species in many of these ecosystems that provide critical habitats for red-listed invertebrates, lichens, fungi, birds and microbes. Further, oak trees are highly interesting for production purposes such as high-quality timber, forage and firewood. The Swedish Oak Project was established in 2000 at 25 experimental study sites in temperate mixed forests across southern Sweden. All sites are part of forest reserves and woodland key habitats with a substantial component of large oak with ages ranging from 80-250 years. The study sites were divided and randomly assigned into one (almost untouched) reference plot and one experimental plot (selective cutting) with a size of one hectare, each. The selective cutting for removing ca. 25 % of the initial basal area was carried out in winter 2002/2003. In all reference and experimental plots, old oaks were further selected and treated with release cutting or not. Results of this long-term research will show how large oaks respond to selective cutting and release cutting in terms of growth, development and survival. Early results suggest that released oaks show a higher vitality and increased diameter growth which promotes their associated biodiversity. In addition, it will enable us to address conservation management options for sustaining survival and development of large oaks necessary for essential ecosystem functions and biodiversity conservation.

Post-glacial migration haplotypes of Quercus robur possess specific morphology features

T3.3 Disappearing oak woods: conservation and management of global oak forests

Mindaugas Ilciukas[1]
Darius Danusevicius[1], Virgilijus Baliuckas[1]
[1] Faculty of Forest Science and Ecology, Agricultural Academy, Vytautas Magnus university, Lithuania

Abstract: In the PhD project, we studied crown, stem and bark morphotypes of cpDNA haplotypes of old growth Quercus robur trees nature-monuments located allover Lithuania. Based on three commonly used cpSSR loci, the haplotypes were assigned into Balkan, eastern Italian, western Italian and German postglacial migration lines. In total, 305 single standing ca. 300 to 700 years old Quercus robur trees were morphotyped and genotyped, assuming that the advanced age and unrestricted growth of standing alone trees would well reveal the morphologic features of Quercus robur. The results showed that the geographical distribution of the haplotypes was not random: the eastern Italian haplotypes were more common in the east, while the western Italian in the west of the country. Such distribution well corresponds to the postglacial migration patterns observed in earlier studies, where eastern Italian haplotypes approached Lithuania from the east and western Italian – from the west. The Balkan and German haplotypes were among most common all over the country. The eastern Italian haplotype was distinguishing by multi-stemmed umbrella-like crowns and bark type with small plates with horizontal cracks. The western Italian haplotype often possessed dichotomic stems. The German haplotype possessed commercially better stem morphotypes. We conclude that the postglacial migration continues at present bringing new genetic variants with discrete adaptive properties, such as the Italian haplotypes. Such organization of genetic diversity must be considered while designing gene conservation units.

Provenance trials of oaks in Austria: advancing forestry and forest management

T3.3 Disappearing oak woods: conservation and management of global oak forests

Roman Ufimov[1]
Florian Irauschek[1], Lambert Weißenbacher[1], Jonathan M. Kormann[2], Mirko Liesebach[2], Silvio Schüler[1], Marcela van Loo[1]

[2] Thuenen Institute of Forest Genetics, Grosshansdorf, Germany

Abstract: Oaks (*Quercus* spp.) are widely distributed across various countries and provide valuable ecosystem services such as high-quality timber but also high biodiversity levels. Projected changes in the climate system will lead to a significant shift from coniferous spruce forests to more drought-tolerant broadleaved forest ecosystems in central Europe. Oak species are specifically interesting due to their high resistance against summer drought and high phenotypic plasticity. Provenance trials offer a valuable opportunity to deepen our understanding of oak adaptability, growth characteristics, and performance under local environmental conditions, provide insights into selecting suitable seed sources, optimising silvicultural practices, and guiding evidence-based decision-making in sustainable forest management. The present study aims to present the results of a provenance trial with pedunculate oak (*Q. robur*) and sessile oak (*Q. petraea*), of which progenies were already used for establishing seed orchards. The trial includes five ecologically different experimental sites established in 2006–2007, where 22 provenances, originating from Austria and neighbouring countries, are being tested. We focus on assessing the genetic variation, growth performance, form characteristics, resistance to abiotic stresses, responses to changing environmental conditions in different climate regions, and the suitability of provenances for potential oak cultivation in Austria. Various tree traits were recorded at the age of 2, 5, 10 and 15 years. We assess the provenance plasticity across the tested sites by differences in tree volume and stem quality with the joint regression analysis (JRA). The application of the Weighted Average of the Absolute Scores (WAAS) as a stability parameter enables the classification of provenances into generalists and specialists. Provenances were also genotyped using nuSSR and cpSSR markers. The establishment of the oak provenance trial in Austria contributes to the development of guidelines for species and provenance selection, site preparation, and sustainable forest management. By considering the genetic variation and adaptive capacity of oak populations, the trial supports the cultivation of resilient forests that can withstand future challenges, including climate change impacts.

Regenerating Oak Trees in the Eastern Himalaya

T3.3 Disappearing oak woods: conservation and management of global oak forests

Til Bahadur Subba[1]
[1] Til Bahadur subba

Abstract: Regenerating Oak Trees in the Eastern Himalaya

Til Bahadur Subba

The eastern Himalaya is renowned for its verdant temperate oak forests whichprovide varied ecosystem services. The main genera in the Fagaceae family include Lithocarpus, Quercus and Castanopsis. However, natural regeneration of the Quercus and Lithocarpus genus is largely absent on the forest floor thereby raising serious concerns on the future of these forests. Conventional nursery techniques to artificially regenerate these trees is not successful as the acorns are attacked by weevils at the flower stage itself. Also, traditional forestry techniques focussed on replacing these forests with fast growing conifers, and hence there is limited knowledge in practice as well. In this paper, we present the process and findings of a field experiment taken up in the Sikkim State of India during 2022-23 to raise oak seedlings in the nursery. The techniques and methods for collection of acorns, seed separation, screening, pretreatment, substrate, germination chamber, planting, transplantation and weeding is explained in detail. A germination percentage of eighty percentage was achieved and it is hoped that the seedlings will attain a height of 60 cm by the end of the second year and will be ready for out planting. We hope that the learnings from this experiment will help to standardize the regeneration techniques of oak trees and contribute towards the restoration of these forests.

Abstract: Sustainably managing forests as targeted in SDG 15 requires understanding the current state of forests, the factors that constrain or threaten this sustainability, and the factors or actions that facilitate it. Monitoring the dynamics of trees and forest development, as a whole, needs to be ensured to understand the most limiting factors and promote adaptive management actions to ensure the sustainability of the forests. In the case of oaks in temperate regions and those with Mediterranean influence, situations of fragility in guaranteeing sustainability have been reported for some species (e.g. *Quercus suber*, *Q. ilex*), with forests developing with a very low density or undergoing decline mainly due to biotic threats. Climate change may make this scenario even more complex, with an expected increase in summer temperatures and/or a potential reduction in rainfall, conditioning seed production, seedling development and tree survival. These forest systems' fragility often worsens when operated as intensive agro-pastoral or silvoagropastoral systems.

Assessing the existing oak forests' and monitoring the development of representative oak forest is therefore fundamental to diagnosing the current state and deciding on the appropriate practices to guarantee forests' conservation, restoration or improvement. With this presentation the authors summarize activities developed under the Mobilizing Agenda "TransForm- Digital transformation of the forest sector towards a resilient and low-carbon economy", supported by the PRR-Recovery and Resilience Plan and the European NextGeneration EU Funds, involving data collection and the establishment of a network of experimental forest plots to analyze and forecast forest dynamics. The network will facilitate the assessment of the development of the forests under different situations and practices, providing valuable information regarding current pressures and in the context of climate change. By implementing this plot-based analysis, it is aimed to ensure the long-term sustainability and productivity of oak forests, benefiting the entire forestry sector value chain. Additionally, the authors will explore measurement protocols for assessing natural regeneration, providing valuable insights into the restoration process. By leveraging the analytical power of plot-based analysis and combining it with expertise in oak forest management, we can develop effective strategies to enhance the resilience and productivity of Mediterranean oak forests.

Status and drivers of oak decline in Western European forests

T3.3 Disappearing oak woods: conservation and management of global oak forests

Gauthier Ligot[1]
Hugues Claessens[1]
[1] Gembloux Agro-Bio Tech, University of Liège, Belgium

Abstract: In Western European temperate forests, oak (*Quercus petraea* and *Quercus robur*) covers vast areas, provide habitats for a wide range of organisms, deliver essential ecosystem services, and are often considered more resilient than other native species. Yet, oak populations are declining due to changes in forest management, ungulate herbivory, and interspecific competition. In this presentation, we will synthesize different research studies - that we published between 2010 and 2023 – on the status and drivers of oak decline in Belgium. According to the regional forest inventory, oak-dominated stands cover 23 % of the forest area (32% of the standing stock), often mixed with beech (*Fagus sylvatica*) and hornbeam (*Carpinus betulus*). Although oak is abundant, the lack of young oak trees with a diameter of less than 30 cm is obvious and concerning. In oak-beech forests managed with continuous cover forestry (CCF), we studied the interspecific competition between naturally regenerated oak, beech and hornbeam seedlings in 23 sites and 242 fenced plots between 2009 and 2011. We modelled and evidenced that oak seedlings grew significantly slower than beech and hornbeam across the whole range of light conditions studied. We also monitored regeneration in 734 pairs of fenced and unfenced plots between 2016 and 2021. Ungulates strongly reduced the growth of oak, hornbeam, birch and rowan seedlings whereas the growth of beech and spruce was little or unaffected. Nevertheless, oak seedlings grew more slowly than the mixed species regardless of herbivory pressure. We also found that oak regeneration may not benefit from being surrounded by palatable neighbors as the positive effect of browsing diversion would likely be offset by increased interspecific competition. To successfully regenerate oak with CCF, we then recommend maintaining a closed canopy (PACL < 5%) until oak seedlings emerge, then protecting seedlings from browsing, reducing overstory density (PACL > 20%) and manually releasing oak seedlings from competition. In the study area, oak can regenerate spontaneously outside the forests but is unlikely to regenerate in forest understory without manual intervention.

The impact of mammals on seed fate of Castanopsis indica in a subtropical forest

T3.3 Disappearing oak woods: conservation and management of global oak forests

Chen-Rui Hsu[1]
Jian-Nan Liu[1]
[1] Department of Forestry and Natural Resources, National Chiayi University, Taiwan

Abstract: Mammals, particularly rodents, play important roles as both seed predators and dispersers for Fagaceae plants. Previous studies in temperate regions have revealed that mammals' impact on the regeneration of Fagaceae plants can vary between the mast and non-mast seeding years. However, there is limited research on the effects of mammals on Fagaceae plants in tropical and subtropical areas. To address this gap, we utilized magnetic tags to track the fate of *Castanopsis indica* seeds in an evergreen broad-leaved forest in Taiwan during the non-mast years of 2022 and 2023. We distinguished the effects of rodents and medium to large mammals on seed dispersal and regeneration based on the presence or absence of exclosures. We used camera traps to identify the species of seed predators. To test the "seed effectiveness hypothesis," we compared our findings with a previous study conducted in the same area during a mast year. Our results showed that without exclosures, all 160 seeds were consumed by Formosan macaques (*Macaca cyclopis*) within three days, which was not reported in the previous study. With the implementation of exclosures, *Niviventer coninga* emerged as the primary seed predator and disperser. Out of the total seeds, 70% (n=112) were consumed *in situ*, 19.4% (n=31) were dispersed, and 10.6% (n=17) could not be located. The dispersed seeds were found across various microhabitats, including 17 in the litter layer, five in the soil layer, five under fallen logs, and four among fern roots. Approximately 80.6% (n=25) of the seeds were dispersed within a distance of less than 5 m, while the remaining 19.4% (n=6) were dispersed between 5-10 m. Of the dispersed seeds, 19 were consumed after dispersal, seven were consumed after being cached, and five were successfully cached. Fifty days later, all cached seeds either fell victim to mammalian consumption, became infested by insects, or perished due to mold. Regrettably, none of the seeds were successfully established as seedlings. These findings contrast with mast years, showcasing a higher rate of seed consumption, shorter dispersal distances, and a lower rate of seed caching, which further support the hypothesis.

Using Strip Clearcutting to Facilitate Northern Red Oak Establishment in a Mixed Appalachian Hardwood Forest

T3.3 Disappearing oak woods: conservation and management of global oak forests

Jamie Schuler[1]
[1] Division of Forestry and Natural Resources, West Virginia University, Morgantown, WV, USA

Abstract: The challenge of regenerating oak species (*Quercus* spp.) is well documented throughout eastern hardwood forests. Successful oak regeneration is often linked to the availability of competitive seedlings. In undisturbed Appalachian hardwood forests, the light levels (<5%) are often too low to allow oak seedlings to persist long enough to attain competitive sizes. While these stands are harvested, shade tolerant advance reproduction outcompetes newer oak seedlings, while fast-growing intolerant species overtop the slow growing oak seedlings on the higher quality sites. Manipulating light conditions ahead of regeneration treatments can make oak seedlings more competitive, but these treatments require 10 or more years to create competitive advance reproduction. Despite its demonstrated effectiveness, widespread adoption of such treatments (*e.g.*, midstory removal) is hindered by high costs, limited markets for small diameter stems, and the need for immediate landowner income. Therefore, alternatives that are low cost and provide meaningful harvest volumes are needed. A strip clearcut regeneration harvest, where 50% of the area is cut and the remaining 50% is harvested once regeneration is well-established (e.g., 5-10 yr), was conducted in a mature Appalachian hardwood forest as an alternative to tradition harvest techniques. Red oak seedlings were planted along a light gradient between cut and residual strips. After nine growing seasons, the northern red oak seedlings showed significant and contrasting responses to the light gradients created by the harvest treatment relative to survival and height growth—higher survival within the shaded residual strips and greater height growth in the cut portions of the stand.

Who is the winner? Effect of experimental fire and herbivory on early successional tree cover in grassland after five years

T3.3 Disappearing oak woods: conservation and management of global oak forests

[5] Inst för husdjurens miljö och hälsa, SLU, Skara

Abstract: The early history of silviculture was by and large a struggle to achieve unconstrained wood production, by active protection from both natural and anthropogenic disturbances, mainly fire or herbivory, usually in the form of grass-feeding livestock that in the past grazed on forest land. Today, fire has negligible influence on tree succession in Europe and cattle is either indoors or grazing on productive agricultural fields, with no influence on tree successions. Only browsers remain in the landscape, not capable of producing grazing lawns, but sometimes capable of slowing down successional rates into dense forest. Here, we imitated the disturbance regimes of pre-historical European landscapes by subjecting young tree successions in grasslands to fire and herbivory (both cattle and wild fauna). In many parts of NW Europe, these conditions were also characterising the reality of early foresters 200 years ago, when cattle-based economy was dominating large parts of Europe. In a full factorial experiment 2400 young trees were subject to Fire (annual spring grass fire), Herbivory, Fire+Herbivory and compared with ungrazed and unburned fenced control in a landscape scale experiment at Nordens Ark at the Swedish west coast. In 2015 we planted 480 seedlings each of oak, pine, spruce, birch and lime in 24 plots on previous forest plantation land, under a grazing restoration since 2012. After six vegetation seasons we evaluated tree cover from drone pictures. There was a strong effect of fencing on tree survival compared to both herbivory and fire. Herbivory had stronger effect than Fire on the growth of trees. We discuss our results in the, for silviculture, contrasting vegetation consumer approach, partly based on a previously published article (Amsten et al 2021) and looking at tree succession from a grassland perspective. We argue our results are of high relevance to the restoration of seminatural grasslands of NW Europe, harboring a large part of Europes biological heritage with high- value trees, especially oaks (Quercus spp) being an integrated component.

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Biodiversity conservation of ash forest in the face of an alien species invasions

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Kateryna Davydenko[1, 2]
[1] Swedish University of Agricultural Sciences
[2] Ukrainian Research Institute of Forestry & Forest Melioration

Abstract: Due to global change and human activity, forests are exposed to unprecedented threats from non-native pests and pathogens. The European ash (*Fraxinus excelsior*) is a commercially, ecologically and culturally important tree species in woodland and urban greeneries. Currently, irreversible economic and ecological losses of ash (*Fraxinus*) species related to ash dieback fungus (*Hymenoscyphus fraxineus*) in Europe and the emerald ash borer (*Agrilus planipennis*) in North America, both of which are indigenous to Asia. Recently, both of these invasive species were found in Ukraine, where they were overlapping in a forest area on the same trees of *Fraxinus exselsior* and *F. pennsylvanica*. Therefore, *Fraxinus* species, particularly *F. excelsior* and its associated species in Europe will be at a high risk for decline or extinction. Moreover, emerald ash borer-associated mycobiome could play a crucial role in ash mortality and structural failure of wood, at the same time beetles act as vector aggressive pathogens and pioneer wood degraders which contribute significantly to the tree mortality and loss of wood integrity in ash trees. Therefore, both invasive species may induce shifts in biodiversity in ash forests, but the direction of these shifts largely depends on tree resistance and fungal communities vectored by emerald ash borer. There are only a few fungal species, belonging to the phylum Basidiomycota have the capacity to degrade lignified polysaccharides, therefore, the study of the effect of new wood decomposers on local fungi is crucial. Most of the research on emerald ash borer has focused on its biology and management, and only a few studies have been published with a focus on the fungal community associated with the beetles in North America. However, tree-killing pathogens associated with xylophagous beetles represent one of the most significant contributors to forest health deterioration and may cause large-scale forest disturbances followed by loss of biomass and carbon storage, and degradation of ecosystem services Identifying the fungal community associated with emerald ash borer helps in understanding the importance these fungal species on European ash and whether new-coming species impact on local biodiversity before invasion spread through Europe.

Biological control of Ailanthus altissima based on Verticillium nonalfalfae isolate Vert56

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Benjamin Dauth[1]
Oliver Maschek[1], Thomas Kirisits[1], Erhard Halmschlager[1]
[1] University of Natural Resources and Life Sciences, Vienna, Department of Forest- and Soil Sciences, Institute of Forest Entomology, Forest Pathology and Forest Protection

Abstract: Invasive species pose significant ecological and economic challenges worldwide. *Ailanthus altissima*, commonly known as tree-of-heaven, is such an invasive tree species that has rapidly spread across various regions, outcompeting native vegetation and causing detrimental effects on ecosystem stability. *Ailanthus* usually spreads from urban heat islands into rural areas and it is expected to expand its range due to climate change. The search for effective control agents to mitigate the spread of *A. altissima* has led to investigations on the potential use of *Verticillium nonalfalfae*, a soil-borne fungal pathogen. The isolate Vert56, originating from Styria, Austria, has shown promise as a biocontrol agent due to its distinct adaption to *Ailanthus*. Successfully inoculated trees exhibit severe wilting symptoms within a short period of time leading to mortality lacking the undesired development of root sprouts or sucker shoots. Furthermore, the pathogen has the ability to spread within clonal root systems, that often develop after unsuccessful control attempts. However, the use of *V. nonalfalfae* as a control agent must also consider potentially occurring non-target effects. The genus *Verticillium* includes well-known plant pathogens, particularly in agriculture, that pose significant threats to infected plants as no directly effective plant protection measures are available to date. Therefore, risk assessment studies are essential to determine the feasibility and safety of using *V. nonalfalfae* isolate Vert56 for the biological control of *Ailanthus*. Until now, about 70 species, including the most important agricultural crops known to be susceptible, have been tested for susceptibility to isolate Vert56. So far, all tested ligneous plants proved to be tolerant or resistant to the pathogen, whereas three herbaceous plants, i.e. *Petunia x hybrida*, *Cucumis sativus* and *Spinacia oleracea,* displayed symptoms of wilting after artificial inoculation, but only *S. oleracea* was equally affected as *Ailanthus*. Based on the current results, an emergency authorization with limited indications regarding application period and area has been granted in Austria since 2017. Further investigations of non-target effects, the pathogen's persistence in the soil and potential pathways of transmission are currently ongoing with the goal to achieve an "active substance authorization" for *V. nonalfalfae* isolate Vert56 within the European Union.

Detecting the distribution of invasive plant Mikania micrantha in artificial forests using deep learning and UAV imagery

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

[5] *Corresponding Author

Abstract: This study investigates the application of deep learning and Unmanned Aerial Vehicle (UAV) imagery in detecting the presence of the invasive plant *Mikania micrantha* in artificial forests. *Mikania micrantha* is a fast-growing invasive plant that can climb and cover other plants, damaging or killing them by intercepting sunlight and causing suffocation. In addition to affecting the growth of crops in orchards and farmland, it also poses significant threats to artificial forests and secondary forests. In this research, UAVs were used to capture images of artificial forest sites affected by *Mikania micrantha*. During the flowering period of *Mikania micrantha*, it exhibits clustered white flowers, making it easier to distinguish. Therefore, we conducted UAV imaging specifically during the flowering period of *Mikania micrantha* (from November to January of the following year). The spatial ultra-high resolution of UAV imagery was utilized to capture detailed images of *Mikania micrantha*. The deep learning module in ArcGIS Pro was utilized to analyze UAV imagery, and a deep convolutional neural network (CNN) was employed for the detection of *Mikania micrantha*. The UAV images were classified and segmented to identify the distribution of *Mikania micrantha*. The classification tests of Mikania micrantha, utilizing deep learning techniques, all achieved an overall accuracy above 90%. The study demonstrates that deep learning models yield high accuracy in detecting *Mikania micrantha*. This approach holds promising applications for effectively managing invasive plants in forestry operations. Accurate detection of *Mikania micrantha*'s distribution enables the development of appropriate prevention and control strategies, minimizing its ecological impact on artificial forests.

Management of invasive tree Broussonetia papyrifera using biochar technology

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Ipsa Gupta[1]
Rishikesh Singh[1], Daizy R. Batish[1]
[1] Department of Botany, Panjab University, Chandigarh, India - 160014

Abstract: Ecosystems are seriously threatened by the rapid and uncontrolled spread of invasive plants and innovative solutions are urgently required to control the invading plant population. Massive biomass production by the invasive plants and their impacts on adjacent ecosystems necessitates the development of innovative solutions to control and sustainably manage the plant invasion. Pyrolyzing invasive plants into biochar could be one of the suitable approaches in this regard, as biochar prepared from invasive plants can serve dual benefits, by improving crop growth and assisting in management of our invasive allies. *Broussonetia papyrifera* (L.) L'Hér. ex Vent. is a commonly found invasive tree native to Asia and the Pacific islands and has emerged as one of the leading plant invaders in the subtropical urban ecosystems of an urban city of India, Chandigarh (30°45′N; 76°45′E; 348 m above sea level). To prepare the biochar, litter fall leaves of *B. papyrifera* were collected, ground, and charred in an electric muffle furnace at 400 ºC for 30 mins hold time. The obtained biochar was characterized by Fourier-transformed infra-red (FT-IR) spectroscopy and Scanning electron microscopy equipped with Electron dispersive spectroscopy (SEM-EDS). The physiochemical attributes of biochar including pH, EC, moisture, and ash content were determined. The biochar was applied in soil at the rates of 0, 0.5, 1.0, 2.0 and 4%, and growth responses of *Cajanus cajan* L. was assessed after 30 days under greenhouse conditions. The results showed a significant ($P < 0.05$) improvement in crop root and shoot growth parameters, chlorophyll content, photosynthetic efficiency, and biochemical attributes after biochar amendment, compared to the control. Most of the crop growth and biochemical attributes were found maximum at 2% biochar amendment rate, thereafter a decline was observed. However, soil properties, viz., pH, EC, moisture, enzyme activities were found to increase with the increasing biochar amendment rates. Therefore, biochar prepared from *B. papyrifera* can be utilized in agricultural fields for uplifting the growth of food crops that will further assist in sustainable management of this invasive tree in urban systems.

Keywords: Biochar, urban ecosystem, leguminous plants, plant growth, biomass

Managing an invasive species affecting multiple key sectors of economy: The example of Prosopis juliflora in Kenya

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

James Ndufa[1]
Simon Choge[1], Dub Dokata[1]
[1] Kenya Forestry Research Institute (KEFRI), P.O. Box 20412 – 00200, Nairobi, Kenya

Abstract: Biological invasions have become an important component of human-induced global change, along with other factors such as habitat transformation and climate change. Invasive species have negative impacts on biodiversity, ecosystem services and human well- being. Some of the invasive species have met the objectives for their introduction such as production of wood and non-wood products and control of soil erosion on one hand and devastation of ecosystems and habitats. Prosopis (mesquite) species epitomizes this conflict of interest dilemma in Eastern Africa. In Kenya, *Prosopis juliflora* covers over 1.5 million hectares and expands at the rate of 15- 20% every year, with a potential to cover 85% of land. From 2015 to 2021, the research project Woody Weeds (WW) was conducted in Kenya, Ethiopia, and Tanzania to assess the impacts of Prosopis on people and the environment, and to identify management practices that help mitigating negative impacts. Results from the project were shared with the Kenyan Ministry of Environment and Forestry and subsequently used as a rationale for developing a National Strategy and Action Plan for effective management of Prosopis (NPS) in Kenya. The Kenyan and Swiss partners of WW managed to secure additional funds to support Kenyan institutions in implementing the NPS in three pilot counties: Baringo, Isiolo and Tana River. This new project, Woody Weeds + (WW+) is working with stakeholders at national, county, and local levels to fast track the implementation of the NPS. The paper describes the process taken in the development of a national strategy and action plan to address an environmental problem affecting multiple key sectors of economy such as environment, agriculture and tourism among others. It further describes the establishment and roll out of a governance system and institutional arrangements to help institutions at the national, county, and local decision-making levels to concretize and operationalize the NPS by developing spatially explicit Prosopis management strategies and integrate them in land use, land restoration or integrated development plans. The model is envisaged to be useful in an African context and therefore an important guide for possible adoption by other affected countries in Eastern Africa and beyond.

On Robinia pseudoacacia L. impacts on biodiversity in Europe

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Thomas Campagnaro[1, 2]
Tommaso Sitzia[1, 2]
[1] Department of Land, Environment, Agriculture and Forestry (TESAF), Università degli Studi di Padova, Viale dell'Università 16, 35020 Legnaro (PD), Italy
[2] National Biodiversity Future Center (NBFC), Piazza Marina 61, 90133 Palermo, Italy

Abstract: Black locust (*Robinia pseudoacacia* L.) is among the most frequent and widespread non-native tree in Europe. It is commonly found in many cities and town as well as in rural and forest landscapes; it was planted in the past as an ornamental and for forestry but it is also invading abandoned and semi-natural environments. A number of studies have focused on its impacts to biodiversity by comparing different forest types and conditions. These studies have mainly focused on plant diversity; however, comparisons exist also for other taxonomic groups (e.g. birds, insects). A variety of different effects, positive, neutral and negative, have been observed, raging from reduction in species richness to hosting species of conservation interest. This tree species is also important for the array of ecosystem services and goods that it can provide. Through the use of different case studies, implications for forest and semi-natural habitat management will be discussed by considering different silvicultural approaches as well as different landscape settings (e.g. urban vs. rural).

Patch size matters to oribatid mite communities impacted by garlic mustard (Alliaria petiolata, Brassicaceae) invasion in urban forests

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Leah Flaherty[1]
Lisa Lumley[2, 3], Melissa Hills[1]
[1] Department of Biological Sciences, MacEwan University, Edmonton AB, Canada
[2] University of Alberta, Alberta Biodiversity Monitoring Institute, Edmonton AB, Canada
[3] University of Alberta, Department of Biological Sciences, Edmonton AB, Canada

Abstract: Investment in management of non-native species in forested ecosystems should be informed by knowledge of impact, including the consequences for native biodiversity and ecosystem functioning. Soil mites in the suborder Oribatida may be particularly useful to evaluate the impacts of plant invasions, since they are bioindicators of disturbance and soil ecosystem health, but more research is needed to understand how oribatid mites respond to plant invasion. The objective of this study was to determine the effect of invasion of urban forest understories by an allelopathic weed (garlic mustard, *Alliaria petiolata* (Brassicaceae)) on belowground oribatid mite (Oribatida) species and communities. We examined adult oribatid (> 300 µm) community assemblage data along with species richness, evenness, Shannon diversity, and abundance in central Alberta, Canada, in plots invaded with garlic mustard as well as uninvaded plots with native vegetation at two sites over two years. We also evaluated the impact of several environmental covariates. Results suggest that the impact of garlic mustard invasion on oribatid mite communities is mediated by the size of the invaded patch. No community-level impacts were detected when considering invasion as a binary variable, but garlic mustard patch area influenced oribatid mite community composition and was positively related to species richness and several abundance metrics. Site was also dominant factor influencing oribatid mite communities, influencing every community-level metric evaluated as a main and/or interactive factor. Significant impacts of year, litter depth, and canopy cover were also detected. Our results indicate that the impact of forest understory invasion by garlic mustard on oribatid mite communities depends on the size of the invaded area, and we discuss implications for management of invasive weeds in forested ecosystems.

Population predictive growth models: Invasive plant species in Natural and Established Forest Ecosystem

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Samson Ojunga[1]
Jared Mullah Amwatta[1], Cyril Otulo[2]
[1] Kenya Forestry Research Institute
[2] Technical University of Mombasa

Abstract: Models can be used to predict population dynamics and assess various management options. Population dynamics description by matrix models provides powerful means of understanding the factors that affects population structures. This study aimed at developing population projection model for estimation of invasive structures distributions within forest ecosystems and agricultural lands. Mt. Elgon forest ecosystem blocks consisting of *Kimothon, Kiptogot, Saboti, Suam and Kitale* were considered for the study. Experimental design was adopted with transects (1km long) and plots 300m apart depending on the environmental variability within different forest blocks. The plots were 10 by 10m for assessing mature trees, 5 by 5m for sapling and 1 by 1m for seedling.Data on the invasive tree species were collected on height, diameter at breast height and also on the soil characteristics, mean temperature, mean rainfall, altitude collated and forest disturbances patterns due to grazing, logging, footpaths and roads of all the sampled plots. This study mapped invasive species distribution using occurrence data and distribution model to identify occurrence and project population using the growth rates. The variables used to predicts population distribution included: elevation, ecological factors like rainfall, soil, temperature and factors such as grazing, disturbances to forest through harvesting and deforestation.The model predictions shows that the distributions of *Cestrum aurantiacum* is on the increases under different climatic scenarios; with current extents estimation expected to increase at differential rate with growth values λ (Lambda) for different forest blocks of Kiptogot at λ=4.48, Kimothon λ=3.31, Saboti λ=3.37, Suam λ=2.89 and Kitale township area at λ=3.91. The forest is continued to be invaded by *Cestrum aurantiacum* with the five year assessment of Mt Elgon ecosystem forest blocks showing invasion of blocks at Kimothon currently covering 356.45 ha constituting 3.23% of the total area within the block, Kiptogot 307.74ha (3.0%), Saboti 295.38ha (2.94%) and Saum 16.75ha (0.70%). This study provides critical information that is useful to decision makers in rehabilitation and management of the current state of invasive species within the forest ecosystems, agricultural lands and in achieving the Sustainable Development Goals aimed at the protection, restoration, and promotion of sustainable use of terrestrial ecosystems.

Raccoon impacts in German forests – status quo and future prospects

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Dr. Berit Michler[1]
Dr. Tanja Sanders[1], Dr. Frank-Uwe Michler[2]
[1] Thünen Institute of Forest Ecosystems
[2] Eberswalde University of Sustainable Development

Abstract: Predatory mammals are an integral part of ecosystems worldwide. Sustainable management of these species relies on sound knowledge of biological-ecological relationships. The North American raccoon is an introduced carnivore species in Germany and one of the most omnivorous mammals worldwide. These and other alien species can play a significant role in the eco-lo-gi-cal balance of their newly encountered biotopes, particularly if their habits overlap and com-pete with those of the native animals. Due to a vast in-crease of raccoon numbers over the last years and its continuous expansion, a controversial dis-cus-sion arose regarding the influence of the new inha-bi--tants on indigenous and especially protected species, as well as the poten----tial trans-mission of diseases and parasites.

Despite a high demand for management strategies and recommendations, the development of sustainable and efficient measures often fails due to insufficient knowledge about the species and extensive evidence-based know-ledge about the actual consequences of raccoon settle-ment, primarily in natural land-scapes, is still lacking. Aiming to elucidate the wildlife biology and potential impact of this intro-duced spe-cies, a long-term and integrated research project was conducted from 2006 to 2017 in the north-eastern area of distribution (Müritz National Park; Mecklenburg-Western Pomerania; www. projekt-waschbaer.de). In 16 different sub studies and by telemetric control of 69 raccoons, profound data on the population biology in the allochthonous distribution area was collected for the first time. Based on the hypothesis that raccoons may affect local stock of ecological relevant species through predation, raccoon faecal samples from this semi-natural lowland beech forest were analysed in terms of food ecology and endoparasite infestation, and linked to available resources in the study area, which is a prerequisite for assessing local impact.

The poster highlights the ecological background of raccoon settlement Germany and shows the potential influence as well as future management options.

Tree insect pests and pathogens: socio-economic and environmental impacts in urban areas

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

Susanne Raum[1]
Stephan Pauleit[1], Monika Egerer[2]
[1] Technical University of Munich, Chair of Strategic Landscape Planning and Management
[2] Technical University of Munich, Chair of Urban Productive Ecosystems

Abstract: Trees contribute greatly to urban environments and human well-being, yet relatively little is known about the extent to which a rising incidence of tree insect pests and pathogens may be affecting these contributions. To address this issue, we undertook a systematic review and synthesis of the diverse global empirical evidence on the impacts of urban tree insect pests and pathogens, using bibliographic databases. Following screening and appraisal of over 3000 articles from a wide range of fields, 100 studies from 28 countries, spanning 1979–2021, were conceptually sorted into a three-part framework: (1) environmental impacts, representing 95 of the studies, including those reporting on tree damage, mortality, reduced growth, and changes in tree function; (2) social impacts were reported by 35 of studies, including on aesthetics, human health, and safety hazards; and (3) economic impacts, reported in 24 of studies, including on costs of pest management, and economic losses. There has been a considerable increase in urban impact studies since 2011. Evidence gaps exist on impacts on climate-regulating capacity, including temperature regulation, water retention, soil erosion, and wind protection, but also on specific hazards, nuisances, human well-being, property damages, and hazard liabilities. As a knowledge synthesis, this article presents the best available evidence of urban tree insect / pathogen impacts to guide policy, management and further research. It will enable us to better forecast how growing threats will affect the urban forest and plan for these eventualities.

Using Unmanned Aerial Systems)Drones) to Monitor Invasive Species and Hazard Rate Urban Forest Trees

T3.4 Ecological and socioeconomic analysis of invasive species in forest ecosystems under changing environmental scenario

David Kulhavy[1]
Daniel Unger[1], David Creech[1], I-Kuai Hung[1], Yanli Zhang[1]
[1] Arthur Temple College of Forestry and Agriculture, Stephen F. Austin State University, Nacogdoches, Texas, USA

Abstract: Unmanned Aerial Systems (UASs) or drones are increasing in technology and camera design. UASs were used to hazard rate urban forest trees for pests, including invasive species. By taking images directly above the desired species, an accuate position can be acquired. Both the image and the location can then be located in a Geographic Information System (GIS) for information on the host and the impact of species species. Data can then be saved in the GIS sysstem and shared via ArcGIS Online or saved into the Citizen Science base of iNaturalist or another archival data base. By using the UAS, multiple maps and images of change over time can be captured to monitor pest progression. UAS data can be collected in the visable spectral or uisng multispectral sensors to domcument impact. Using UASs for mapping produces both two dimensional and three dimensional images of the pest occurrence and change in the host plant. For increased accuracy of location, a base station or Ground Control Points can be used for mapping. Examples of monitoring include the occurrence and distribution of the crapemyrle bark scale and the associated sooty mold as an invasive species. In one case, severe investations were countered by removal of the crapemyrtle and replacing with spire oak. Following a cold snap, UASs were used to map out damage over time and the impact on the crapemyrtle. The invasive emerald ash borer can be mapped by UASs and utilized for removal and replanting of non-susceptible species. Using UASs to hazard rate urban forest pests indicated no differences compared to the stand visual method from the ground. For leafy mistletoe, twice as many plants were counted compared to traditional ground methods. During a severe ice storm, UASs were used to evalute each tree for damage and the information was used to remove damage limbs and improve the tree vigor from bark beetle pests. The use of UASs are increasing and the improved cameras and sensors expand the capabilty of of the urban forest pest managers to make informed decisions on both native and invasive speices in a changing climate world.

T3.5 Emerging socio-economic dynamics in Wildland-Urban Interface forest landscapes

A novel framework for wildfire risk management in touristic infrastructures

T3.5 Emerging socio-economic dynamics in Wildland-Urban Interface forest landscapes

Pascale Vacca[1]
Maria Pipió[2], Enrico Ronchi[3], Bruno Guillaume[4], Philippe Meresse[5], **Elsa Pastor**[1]
[1] Universitat Politècnica de Catalunya
[2] Diputació de Girona
[3] Lund University
[4] EFECTIS France
[5] Entente Pour la Fôret Méditerranéenne

Abstract: Forest fires in Europe pose an increasing challenge to populated areas at the wildland-urban interface (WUI), where people and assets are exposed to fire and smoke hazards. This vulnerability is particularly evident in tourist destinations within WUI areas, especially in Mediterranean Europe, which heavily relies on nature and culture for its touristic appeal.

The impact of forest fires on tourism is multidimensional. It can affect the touristic population which includes groups of people having different background in terms of their culture, spoken language(s), risk perception, and past experience with fire. In addition, fire can directly damage tourism facilities, accommodations, infrastructure, and services, which can take a significant amount of time to replace. Furthermore, wildfires can lead both to a direct decrease in revenue within the tourism industry, as well as long-term consequences in terms of reduced tourism demand and loss of tourist expenditure.

Unfortunately, local authorities often lack an appropriate approach to managing the wildfire threat in tourist destinations and installations. Tourists themselves are generally unaware of the fire risks, while tourism-oriented buildings and facilities do not consistently incorporate fire preparation measures. There is hence a need of adopting common and coherent messages and recommendations for prevention and protection practices in this sector.

This communication introduces a novel framework for wildfire risk prevention and protection planning in touristic infrastructures. It encompasses new methods, tools, and guidelines for analysing fire exposure and vulnerability of assets and people, as well as proposing risk mitigation actions for specific touristic infrastructures (e.g., hotels, resorts, camping areas, etc.). The practical application of this framework is demonstrated in the cross-border touristic region of Cap de Creus, situated on the Spanish-French border within the province of Girona. Developed with the objective of establishing harmonized criteria throughout Mediterranean Europe, this approach offers a comprehensive solution that enables touristic areas across the European Union to increase their resilience against wildfires. By adopting this approach, these areas can effectively safeguard the well-being of both their visitors and the local communities that rely on tourism for their sustenance.

Assessing residents' tradeoffs between wildfire risk and environmental benefits in California's Wildland-Urban Interface

T3.5 Emerging socio-economic dynamics in Wildland-Urban Interface forest landscapes

Jose Sanchez[1]
Lorie Srivastava[2], Emily Schlickman[2]
[1] US Forest Service
[2] University of California, Davis

Abstract: Wildfires across the state of California are becoming larger, more frequent, and more severe. This shift has been primarily attributed to a global change in climate along with local changes in wildland fuel quantity. An expansion of the wildland-urban interface (WUI) has heightened the risks for communities and people living in the WUI. In California, 3 out of every 10 homes are in the WUI – a number that is expected to increase in the coming years. Further research is needed to better understand how to minimize the effect of wildfires on communities in California's WUI, especially for vulnerable residents.

This project investigates how the impact of wildfire might be reduced in diverse WUI communities across California by better understanding residents' perceptions of fuel treatments and their associated environmental benefits. A multimodal survey approach was conducted in 16 WUI communities, that represent a mix of wildfire risk, wildfire history, population size, geographic location, and social vulnerability. The survey included questions about the geography and vegetation around participants' residences and neighborhoods, preferred fuel treatment activities to reduce wildfire risk, and socio-demographic information.

The economic value of the trade-offs between wildfire and ecosystem benefits from fuel treatments was quantified using a choice experiment survey of residents. Through the choice experiment, survey respondents selected their preferred type of fuel treatment(s) (e.g., prescribed fire, mechanical thinning, etc.) and the level of benefits they and their communities could receive from ecosystem services (e.g., improved air quality, water quality, and greater recreation opportunities).

The survey results may help resource managers develop more research-based planning processes for the WUI. For example, the results may help stakeholders better understand residents' preferred fuel treatment activities and their potential ecosystem service benefits in WUI watersheds. Second, the results may help land and fire managers better target spatially-specific fuel management strategies by better accounting for vulnerable communities' preferences for their surrounding landscapes. Lastly, insights gathered from this project may provide critical information to improve policy uptake and decision-making such as the recent Climate 21 Memo's opportunities for the USDA to address development in the WUI and the increased use of prescribed fire.

Changes in forest structure and community composition in the wildland-urban interface of the northern United States

T3.5 Emerging socio-economic dynamics in Wildland-Urban Interface forest landscapes

Nancy Sonti[1]
Jonathan Knott[1], Rachel Riemann[1], Miranda Mockrin[1], Grant Domke[1]
[1] USDA Forest Service Northern Research Station

Abstract: Given the myriad ecological and social benefits of forest ecosystems, there is a need to better understand how development in the wildland-urban interface (WUI) alters the structure and composition of forested ecosystems. It has been asserted that the WUI concept is relevant for a broad suite of natural resource management challenges beyond fire risk, and yet little is known about how WUI expansion affects forest stand structure and composition, particularly in regions where fire is less prominent. In a space-for-time analysis we utilized US Forest Service Forest Inventory and Analysis (FIA) plots and housing density data to examine differences in forest characteristics of the northern US across three WUI change classes based on whether the WUI housing density threshold was reached before 1990 (old-WUI), between 1990-2020 (new-WUI), or not yet reached (non-WUI). Forest in the WUI had greater carbon storage, with greater aboveground biomass, relative stand density, and more live trees per hectare than non-WUI forest. WUI forest also had less structural diversity compared to non-WUI forest, with significantly fewer saplings, seedlings, and dead trees per hectare, suggesting a reduced capacity for forest regeneration. We found that WUI forest was more likely to be privately owned than non-WUI forest, but less likely to be under corporate ownership than non-WUI forest. However, we did not find evidence of differences in harvesting intensity between WUI classes. Using a longitudinal approach, we then examined two decades of remeasurement data from FIA plots in the northeastern US to identify changes in forest composition using four major forest communities identified via a Bayesian hierarchical model. We found that fir-spruce and maple-beech-birch occurred at higher mean proportion and were more often the dominant community type in non-WUI forest than ash-cherry or pine-hemlock communities. While individual communities consistently increased or decreased over time, rates of change did not vary substantially among WUI change classes. Longitudinal forest inventory data and space-for-time substitutions can shed light on processes of tree mortality, forest regeneration, and community composition change inside and outside the WUI, with implications for ecosystem services for surrounding communities and management-relevant advice for forest landowners and landscape planners.

Funding Forest Resilience in the Wildland Urban Interface with Environmental Markets

T3.5 Emerging socio-economic dynamics in Wildland-Urban Interface forest landscapes

[5] University of California, Berkeley
[6] Northern Arizona University

Abstract: Globally, there is a substantial need to improve the pace and scale of landscape management in order to conserve natural resources and limit the negative impacts of climate change. Many of the management activities occur in WUI areas in order to protect and preserve resources for human communities. However, the cost of performing such management is often restrictively large, resulting in needed work going unfunded. At the same time, active management of these landscapes is crucial for the provision of ecosystem services, including water, carbon sequestration, wood products, and protection from wildfire. There is a growing market for ecosystem services, whereby management is funded by benefiters of one or several of these services. As a result, the careful monetization of ecosystem services can help cover the funding shortfall of management and improve forest resilience within the WUI. In this study, we develop an economic model of environmental markets based on the ways in which the benefits of ecosystem services are internalized by potential investors. Several ecosystem services, including water provision, water quality, and wood products, are private goods whose benefits might be directly internalized or realized by investors. Others, such as carbon sequestration, biodiversity, or cultural amenities, are public goods which can be internalized by private investors only through their reputational or marketing benefits. Despite the fact that the private benefits can be directly internalized by investors, our model shows that the private reputational benefits obtained from funding non-excludable ecosystem services can be used to increase the financial attractiveness of the investment by lowering the cost of the project relative to the excludable private benefits obtained by investors. After demonstrating this, we apply it to a WUI landscape in Northern California. We utilize an ensemble of landscape models, including models of landscape processes, forest disturbances, hydrological resources, and management activities. We use the model ensemble to estimate the management requirements to achieve a pre-defined management target whereby disturbance return intervals match historic averages. Next, we calculate the costs of achieving this. We use our economic model to both value ecosystem services, and construct the optimal funding mechanism for the landscape.

Grazing amidst forests as Nature-Based Solution for wildfire risk mitigation

T3.5 Emerging socio-economic dynamics in Wildland-Urban Interface forest landscapes
Elena Górriz-Mifsud[1]
Marc Rovellada[1], Marc Taüll[1], Guillem Castellano-Durán[1], Mar Gallego-Soriano[1]
[1] Forest Sciences and Technology Center of Catalonia (CTFC)

Abstract: Wildfire risk poses severe challenges to human lives and assets (particularly in the Wildland-Urban Interface), including forest investments, cultural landscapes and identities, and to the conservation of natural features. In response to those, substantial public (and in some areas also private) funding is devoted to fire suppression, yet their limited efficiency lately increases the interest towards interventions to reduce fire hazard, exposure and vulnerability. These fire risk reduction measures typically manage the vegetation mechanically to control the fuel load, and consequently hinder the chances for high intensity fires. However, these interventions are costly and not free from environmental impacts.

Nature-Based Solutions (NBS) rely on natural processes and inputs as alternative to grey, non-renewable-based alternatives. Two main NBS emerge in wildfire risk management suiting the WUI: use of crop belts, and controlled grazing around a security fringe.

This study analyses the controlled grazing agreements within the metropolitan area of Barcelona (Spain), based on existing experiences and prospective agreements in additional municipalities. We analyse socio-economic and governance aspects, to draw lessons learned for highly urbanised areas. Focus groups with main stakeholders, in-depth interviews and surveys constitute our data sources.

Our preliminary results show that shepherds working in the WUI are in a very delicate situation due to the highly anthropized territory, the numerous (often inconsistent) administrative requirements, and social conflicts with locals. These challenges add to their economic vulnerability -also present in extensive grazing elsewhere. The marketing of their produce jointly with the current incentives seem not to suffice in some areas, as shepherds tend to abandon the activity. Ensuring (e.g. with municipal funds) supporting infrastructure (e.g. water points, night shelter following all animal welfare and urban requirements) can overcome some of their productive function barriers. These findings call for a coherence review of the administrative framework to facilitate non-productive-focused activities (e.g. wildfire oriented) related to grazing, as well as to define a fair payment scheme to incentivise and socially recognise the shepherd's work. We also detected the larger acceptance among the local population of the grazing interventions when accompanied with educational and awareness campaigns.

Why can't they just burn it? Organizational barriers to implementing hazardous fuel treatments in the WUI

T3.5 Emerging socio-economic dynamics in Wildland-Urban Interface forest landscapes

David Flores[1]
[1] USDA Forest Service, Rocky Mountain Research Station, 240 W Prospect Rd. Fort Collins, CO 80525, (970) 498-1193, (David.flores2@usda.gov)

Abstract: In 2022, the Secretary of Agriculture and the Chief of the Forest Service in the United States charged the Forest Service with implementing a 10-year Wildfire Crisis Strategy (WCS) (Vilsack, 2022). In response, the US Forest Service has implemented a robust prescribed fire plan that aims to build a workforce capacity in the agency to treat and assist in treating millions of acres of forest land in the Wildland Urban Interface (WUI) across the western United States (USDA, 2022). One way to address the challenge of performing hazardous fuel treatments in the WUI is to investigate organizational barriers, knowledge gaps, and resource needs for successful implementation of hazardous fuel programs. While scholars in a variety of disciplines have investigated barriers to addressing wildfire risk and prescribed fire burning (Jakes 2002; McCaffrey 2006; Christianson 2015; Lake 2021), they have not investigated the everyday workplace and workforce organizational barriers to implementing large scale prescribed burning along the WUI. We employ a mixed methods approach through use of surveys, focus groups, and in-depth interviews to gather data for both developing quantitative statistical models and qualitative information that can provide greater coherence, depth, and density to questions related to organizational barriers, knowledge gaps, and resource needs for successful implementation of the WCS. Using a mixed methods approach, this study investigates and uncovers 1) innovative operational capacities being leveraged by US Forest Service to meet the heavy demands placed on the agency's fire service; 2) How the US Forest Service fire program is implementing prescribed fire treatments at the scale specified in the WCS; 3) real and perceived organizational barriers, and 4) innovations to implement the WCS over the next 10 years.

T3.6 Extent and ecological consequences of hunting in the forest ecosystems

Assessment and prioritization of threats to biodiversity in Benin

T3.6 Extent and ecological consequences of hunting in the forest ecosystems

CHABI DJAGOUN[1]

[1] Laboratory of Applied Ecology, University of Abomey-Calavi, Benin

Abstract: Biodiversity loss is a pressing global issue, and understanding the specific threats faced by different regions is crucial for effective conservation efforts. Using literature review and survey of 32 conducted study to identify and prioritize threats to biodiversity in Benin, a country in West Africa. Data from the survey of 32 experts were analyzed to determine the frequency of citation for each threat, categorized by threat level and taxon or ecosystem. Benin is home to a diverse array of species, including approximately 2,807 plant species, 552 higher fungal species, 603 bird species, 157 mammal species (with two-thirds comprising small mammals), 103 reptile species, 221 freshwater fish species, 136 marine and brackish fish species, and 51 amphibian species. Despite the existence of protected areas and forest reserves, which cover approximately 25% of the national territory, the data indicated a decrease in species populations over time. The main threats identified in the assessment were associated with agriculture and aquaculture, resource exploitation (particularly in the forestry sector), and residential and commercial development. These threats consistently emerged across different sources, highlighting their significant impact on biodiversity in Benin. This assessment provides valuable insights into the threats faced by biodiversity in Benin and serves as a basis for developing targeted conservation strategies. It underscores the need for proactive measures to mitigate these threats and ensure the long-term sustainability of Benin's rich and unique ecosystems.

Impact of game browsing and hunting strategies on climate resilience and development of our forests.

T3.6 Extent and ecological consequences of hunting in the forest ecosystems

Claudia Jordan-Fragstein[1, 2]
[1] Claudia Jordan-Fragstein
[2] Prof. Dr. Michael G. Müller

Abstract: The predicted far-reaching climate changes make it necessary to adapt the management of forests. Investigations into the effects of different management strategies is the aim of the joint project WiWaldI. Maintaining functional diversity in forest ecosystems means being able to secure a minimum of adaptation options for forest development in the future.

The Chair of Forest Protection at the Technical University of Dresden is responsible for assessing the effects and potential of regulation measures with regard to the influence of game. For this purpose, the occurring game species, game condition, game management and habitat structures are considered. Strongly distributed herbivores such as roe deer and their influence on forest development are in conflict with human objectives. In this context, the results obtained from the investigations and the comparison of interdisciplinary data collections by the project partners are used to derive statements on ecological and economic assessment, forest development influenced by game, an adapted hunting and the implementation of a future-oriented development of forests. A multifactorial approach is the new approach in order to approximate dynamic processes. Biodiversity conservation is a decisive objective in politics and practice to prepare ways into the future under today's impacts on forest ecosystems.

The presentation will discuss the embedding of stability factors that can be influenced by humans, the experimental design and methodology for recording influencing factors and preliminary results for sustainable development.

SPECIES PREFERRED AND HUNTING TOOLS NORMALLY USED IN PROTECTED RAINFOREST AREAS IN GHANA

T3.6 Extent and ecological consequences of hunting in the forest ecosystems

Edward Debrah Wiafe[1]

[1] University of Environment and Sustainable Development

Abstract: Hunting in the rainforests protected areas has been a secrete business because the laws frowns on that yet, local people sneak into these areas to hunt for wildlife species. The goal of this study was to learn more about this illegal hunting, focusing in particular on the species that are hunted and the typical hunting techniques. Data was collected from 17 poachers who were arrested in the Kakum Conservation Area in Ghana over a period of 12 months. The data revealed that 69 animals were poached belonging to 12 species being recorded. Most of the animals were mammals, with primates being the most prominent species among the animals poached. Shotguns and wire snares were the main hunting methods used. The findings of this study can be used to inform conservation efforts in protected rainforest areas, as well as to develop strategies to reduce poaching and protect vulnerable species.

Wildlife trade at the interface between deep-rooted animal-based traditional medicine and unregulated harvesting of wild animals in West Africa

T3.6 Extent and ecological consequences of hunting in the forest ecosystems

Stanislas ZANVO[1]
Chabi A.M.S Djagoun[1], Fortuné Azihou[1], Brice Sinsin[1]
[1] 1- Laboratory of Applied Ecology, University of Abomey-Calavi, Faculty of Agronomic Sciences, 01 BP 526, Cotonou, Benin

Abstract: Local/or domestic trade remains one of data poor components of wildlife crime that is essential to fill the gap for an enlightened combat against the illegal wildlife trade at national, regional and international scales. The study constitutes the first larger field-based sampling efforts that deciphered wildlife trade in West Africa through the distribution of wildlife markets, diversity of species traded and the extent of trafficking chain using the georeferencing of wildlife sale sites, and semi-structured interviews with 75 vendors in the 10 largest traditional medicine markets in Benin. GPS coordinates of wildlife markets were used to map their geographic distribution and assess their spatial patterns. We used a generalized linear model to determine the drivers underlying the spatial patterns of wildlife markets. A circular layout was designed to delineate the geographic extent of wildlife trade in terms of supplying sources. The wildlife trade took place through 121 sale sites including 15 and 106 bushmeat and traditional medicine markets respectively. The spatial analysis of wildlife markets exhibited an aggregative distribution pattern with a spatial temporality (permanent vs. periodic) that was significantly explained by the type of market, the number of stalls in the markets ($P < 0.001$) and the status of occurrence municipalities of markets ($P < 0.001$). Wildlife trade for traditional medicine affected 61, 96 and 268 reptile, mammal and bird species respectively, and included high concern conservation profile species on both the IUCN Red List, the Red List for Benin and CITES Appendices but also the fully protected species under the National legislation. Our study delineated a national wildlife trade that violated Beninese laws, contrary to international commitments, and that was substantially fed by all countries of the West African Economic and Monetary Union (WAEMU) except (Guinea-Bissau) and 12 out of the 15 countries of the Economic Community of West African States (ECOWAS) as source countries. It provided substantial data on wildlife trade structure and driving forces that could help informed decision-making for strict regulation to protect threatened species in Benin, an effective law enforcement in order to eradicate national and regional illegal wildlife trade.

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Changes in tree diversity in response to elevation and climatic gradient

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Shyanika Lakmali[1]
Hashani Shanika[1], Senani Karunaratne[2], Sumithra Gunathilake[3]
[1] Department of Plantation Management, Faculty of Agriculture and Plantation Management, Wayamba University of Sri Lanka
[2] CSIRO Agriculture and Food, Canberra, Australia
[3] Forest Department Sri Lanka, Rajamalwatta Road, Battaramulla, Sri Lanka

Abstract: Conservation of tree species and their diversity becomes the key concern in light of climate change. Nowadays, climate change implications are beginning to emerge even in tropical belts. As a result of that, species diversity and richness in tropical forests are shrinking. Species diversity patterns over the landscape scale are difficult to understand due to the complex integration of various factors. The link between the spatial distribution of the tree species and variability in climate and other abiotic factors is yet to be investigated at the country level of tropical Sri Lanka. Studying the variation of tree diversity along the elevation and climatic gradient will enhance our understanding of how species diversity and richness vary in response to various climatic and edaphic factors. The current study hypothesises that a critical biodiversity zone can be created and expanded along the gradient of climate and elevation. Therefore, our study aims to assess and analyze the diversity variation and distribution pattern of the plant species in forest cover along an altitudinal gradient of Sri Lanka and study the effect of elevation and climatic factors on species diversity and species richness.

Our study was extended from the Southern to the Eastern provinces along the transect. The area lies between 6° 4'38.40" N and 8° 6'8.68"N latitude, covering the cross section of the Sri Lankan landscape across three agroclimatic zones and three elevation zones. Tree-level data were adopted from the National Forest Inventory (NFI) database of the Forest Department of Sri Lanka, and Bioclimatic (BIOCLIM) data were extracted from Worldclim.org. Generalized Additive Models (GAMs) were used to explore the relationship between diversity and abiotic factors.

Results revealed that the lowest number of species was recorded at higher elevation areas. This implies that higher elevation areas should be conserved with necessary conservation measures. The highest species richness and Shannon diversity were recorded in the mid-elevation. The lower altitudinal areas preferred moderate species richness, Shannon diversity and related parameters. This study concluded that the high elevation was the critical point of species richness and Shannon diversity.

Key Words: Tree diversity, Richness, Elevation gradient, Climate change

Development and implementation of genetic and forest indicators for monitoring biodiversity in forest stands

Abstract: Over the past few years, anthropogenic activities and climate change are causing a substantial loss of biodiversity at ecological, specific, and genetic diversity level. Indeed, it has long been established that forests should be managed in an ecologically sustainable way. Given the fundamental role of forest ecosystems for life on earth, the genetic resources and biodiversity that characterize forest systems must be conserved because they are important resources from social, economic, and environmental perspectives. Biodiversity conservation is one of the main goals of ecologically sustainable forestry. In this regard, it is necessary to develop a predictive model for sustainable forest management (SFM). The objective of this work is to develop genetic and forest indicators in different European Forest Types (EFTs) to implement the predictive model for sustainable forest management. The indicators were developed considering two conditions, unmanaged forest and managed forest to identify the best silvicultural practice that presents higher biodiversity which is a powerful tool in response to climate change. To achieve this goal, genetic and forest indicators were calculated using collected data regarding trees species and the complex symbiont relationship between ectomycorrhizal and trees from the 20 demonstration sites of the project LIFE SySTEMiC located in Italy, Croatia, and Slovenia. Forest indicators such as stand structure, deadwood, species diversity, and species evenness were calculated. Whereas for genetic indicators, we decided to use the *Essential Biodiversity Variables* (EBVs) specifically genetic diversity, genetic differentiation, *inbreeding*, and effective population size (*Ne*) to synthesize complex biodiversity data obtained by mediating observations of genetic diversity within species, populations, and ecosystems. Both types of indicators represent an input to the predictive model by providing information on the best adaptive management of forest stands in response to climate change, considering both species and different silvicultural treatment conditions.

Diversity and Distribution of Caddisfly (Trichoptera) in Molawin-Dampalit Subwatershed in Mt. Makiling Forest Reserve, Philippines

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Dianne Joy Aguilon[1]
Christine Apple Sigua[1]
[1] Department of Forest Biological Sciences, College of Forestry and Natural Resources, University of the Philippines Los Baños, 4031, Laguna, Philippines

Abstract: Caddisflies are one of the most diverse groups of aquatic insects and are members of the EPT (Ephemeroptera, Plecoptera, and Trichoptera) which are considered as important indicator species in freshwater ecosystems. The survey of immature stages of caddisflies was done in six sampling sites comprising the upstream, midstream, and downstream gradients of the Molawin-Dampalit Subwatershed in Mt. Makiling Forest Reserve, Philippines. A total of 336 caddisflies belonging to 12 morphospecies and three families (Hydropsychidae, Philopotamidae, and Rhyacophilidae) were assessed in the Molawin-Dampalit Subwatershed. The family Hydropsychidae or the net-spinning caddisflies were the most abundant comprising 86% of all individuals recorded. The highest occurrence of caddisflies was observed in the upstream sites. While the highest species diversity was recorded in sites situated in the downstream areas. High similarity values were measured in caddisfly assemblages in upper and midstream areas. The caddisfly assemblages can be useful in identifying differences in the level of disturbances in streams. The study serves as a baseline on caddisfly diversity in Mt. Makiling Forest Reserve. A more in-depth study should be done on their ecology which can be later crucial in environmental monitoring leading to proper management of their habitats and protection of other possible endemic caddisfly species in Mt. Makiling Forest Reserve.

Drought diminishes successional trajectories and aboveground biomass accumulation rate during secondary succession in a tropical forest of China

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Yi Ding[1]
Lixing Tian[1]
[1] Ecology and Nature Conservation Institute, Chinese Academy of Forestry; Key Laboratory of Forest Ecology and Environment of the National Forestry and Grassland Administration, Beijing, 100091, China

Abstract: Tropical secondary forests play an increasing role in biodiversity conservation and climate change mitigation, but the relative importance of biotic and abiotic factors and demographic progresses driving successional trajectory and biomass dynamics in these ecosystems remain largely unclear, especially under increasing drought intensity. We compared the variations in demographic rates, community composition, and aboveground biomass (AGB) dynamics among three successional stages, with four 1-ha plots each in young secondary forest (YS), old secondary forest (OS), and old-growth forest (OG) on Hainan Island, China, using ten years of census data (2010 – 2020). The result showed that the diameter growth, mortality, and recruitment rates were the highest in the YS and the lowest at the OG. Growth decreased and recruitment increased during the second census period (2015-2020) during which there were two extended droughts, but there was no significant change in mortality rate. The successional trajectories of YS and OS showed a slow but directional trend towards the OG, with a weak stochastic component. The five species groups made different contributions to the successional trajectory. Generalists contributed to the convergence of secondary forests to old-growth forests, while old-growth specialists contributed to divergence. Secondary species usually contributed to divergence with old-growth forest, and young-secondary specialists had a stronger effect than old-secondary specialists. The divergence effect of rare species on similarity occurred only when presence data were used. When based on abundance data, rare species had little effect on community similarity. The different drought frequency between the two intervals was the dominant factor predicting the net change of AGB. With high-frequency droughts, the loss of AGB intensified and the increment rate of AGB decreased, especially in old-growth forests. Successional stage was another major factor affecting AGB and its dynamics, showing a positive relationship with AGB stock and a negative relationship with net AGB change. Species richness and fungal richness had a significant positive association with AGB, while soil available nutrient had a significant negative relationship. Thus, with the intensification of global climate change, the effects of high-frequency drought events should be taken into account when studying the factors affecting recovery in tropical secondary forests.

Effect of microclimate on wood decay fungi

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Anika Gossmann[1]
Erik Öckinger[1], Martin Schroeder[1], Thomas Ranius[1], Kadri Runnel[2]
[1] Swedish University of Agricultural Sciences
[2] University of Tartu

Abstract: Wood decay fungi play a central role in decomposition and carbon cycling. It has been hypothesized that fungal decay rates are affected by microclimate. So far, the effect of microclimate on fungal communities affecting decay processes have been shown in the lab environment, but not in natural conditions. Thus, by measuring inner-wood temperatures, calculating wood decay rates and sampling fungi communities, we test in this research project for the first time hypotheses related to this. We expect i) the highest decomposition rate in dense forests in southern Sweden and the lowest decomposition rate on clear-cuts in northern Sweden, and ii) that fungi communities vary on a latitudinal and on a shade gradient and thus, certain decayer profiles dominate in various microclimatic conditions. In 2020, 450 Norway spruce logs were distributed along a 1200 km long latitudinal gradient in Sweden and wood samples were taken from each log. The logs were set up under varying microclimatic conditions and their inner-log temperature was measured hourly. In 2023, we will take new wood samples to measure the decompositions rate and identify the fungi communities of the logs. Preliminary results will be presented at the conference.

Enhancing forest monitoring by biodiversity indicators - a case study in Britz, Germany

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Tanja Sanders[1]
Berit Michler[1], Franz Kroiher[1], Marco Natkhin[1], **Inken B. Krüger**[1]
[1] Thünen Institute of Forest Ecosystems, Eberswalde, Germany

Abstract: The loss of biodiversity - especially due to climate change and intensive land use - calls for effective solutions and targeted recommendations. For this purpose, comprehensive data-sets from existing monitoring networks like ICP Forests or the NFIs deliver information to describe state and change of biodiversity. Unfortunately, important character-species requiring specialist knowledge cost intensive equipment are not considered there. To gain a deeper insight it is therefore important to complement the existing monitoring systems with in-depth studies to understand links and feedback-systems and determine thresholds which later allow up-scaling.

To develop methods bridging the gap between widely available data and in-depth studies we use our intensive forest monitoring site “Britz” in Germany, a highly equipped site stocked with five different tree species. We encourage and facilitate research from colleagues collecting high-resolution biodiversity data like e.g. insect abundance, bird diversity, or pollen occurrence. This data can be combined with detailed ecological data following the internationally harmonised manuals of ICP Forests. Furthermore, we assess forest structure and vitality by UAV and remote sensing, measure light regimes, and provide meteorological and increment data.

Through this we create a data base for understanding the drivers on species and biodiversity and to define the linkages to parameters available at larger-scale. Here we present our approach of linking the long-standing ground-based monitoring to provide structural information as a basis for up-scaling high-resolution data to specialists working on our site. This poster is an invitation for using existing infrastructures and increase their value by adding further studies.

FOREST GENETIC MONITORING: PRELIMINARY RESULTS OF A MICROSATELLITE-BASED GENETIC STUDY OF SCOTS PINE AND PEDUNCULATE OAK IN LITHUANIA

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Darius Kavaliauskas[1, 2]
Virgilijus Baliuckas[1, 2], Darius Danusevičius[1]
[1] Vytautas Magnus University, Agriculture Academy, Studentų str. 11, LT-53361 Akademija, Kauno r., Lithuania
[2] Lithuanian Research Centre for Agriculture and Forestry, Institute of Forestry, Liepų St. 1, Girionys, LT-53101 Kaunas distr., Lithuania

Abstract: Scots pine and Pedunculate oak are among economically and ecologically most important forest trees species covering 36.8% of total forest area in Lithuania (34.5% and 2.3% respectively). Ongoing climate and environmental change, human activities have been recognised as one of the main threats to forest trees and its ecosystems. Thus, high genetic diversity of forest tree populations ensures that forests can grow, adapt and evolve under rapid environmental change. The objective of Forest Genetic Monitoring (FGM) is to assess the current state of forest genetic resources (FGR) (e.g. gene conservation units) and quantify relevant changes at a temporal scale, in order to preserve long-term adaptive evolutionary potential. At EU level several projects (FORGER, LIFEGENMON, GENTREE, etc.) and European forest genetic recourses programme (EUFORGEN) has emphasized the importance of FGM and presented various FGM methods. Moreover, EUFORGEN recognise FGM of the forest genetic conservation units as important tool for conservation and sustainable use of FGR. Therefore, our study is presenting DNA marker-based case study of FGM of Scots pine and Pedunculate oak in four forest genetic reserves (Marcinkonys and Braziūkai for Scots pine; Ignalina and Dzirmiskis for Pedunculate oak) in Lithuania. In total we genotyped 350 trees of Scots pine and 400 trees of Pedunculate oak (two generations adults and natural regeneration in each). Our results based on microsatellite (nSSR) markers (11 for Scots pine and 14 for Pedunculate oak) provides us a baseline DNA markers-based data and shows how nSSR's can be used for FGM system in Lithuania.

First results indicate that genetic diversity was distributed evenly from adults to natural regeneration in both species. Data regarding genetic variation and genetic differentiation among Scots pine and Pedunculate oak FGM plots and among adult trees and natural regeneration within the plots will be presented. Furthermore, continuation of FGM in future will allow us to draw conclusions about the population's evolutionary capacities through comparison to the recently assessed baseline data.

Impact of climate change on biodiversity and food security: an implications for challenges of feeding the future

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Melese Genete Muluneh[1]
[1] Wollo University

Abstract: Abstract
Climate change is happening due to natural factors and human activities. It expressively alters biodiversity, agricultural production, and food security. Mainly, narrowly adapted and endemic species are under extinction. Accordingly, concerns over species extinction are warranted as it provides food for all life forms and primary health care for more than 60–80% of humans globally. Nevertheless, the impact of climate change on biodiversity and food security has been recognized, little is explored compared to the magnitude of the problem globally. Therefore, the objectives of this systematic review are to identify, appraise, and synthesize the link between climate change, biodiversity, and food security. Data, climatic models, emission, migration, and extinction scenarios, and outputs from previous publications were used. Due to climate change, distributions of species have shifted to higher elevations at a median rate of 11.0 m and 16.9 km per decade to higher latitudes. Accordingly, extinction rates of 1103 species under migration scenarios, provide 21–23% with unlimited migration and 38–52% with no migration. When an environmental variation occurs on a timescale shorter than the life of the plant any response could be in terms of a plastic phenotype. However, phenotypic plasticity could buffer species against the long-term effects of climate change. Furthermore, climate change affects food security particularly in communities and locations that depend on rain-fed agriculture. Crops and plants have thresholds beyond which growth and yield are compromised. Accordingly, agricultural yields in Africa alone could be decline by more than 30% in 2050. Therefore, solving food shortages through bringing extra land into agriculture and exploiting new fish stocks is a costly solution, when protecting biodiversity is given priority. Therefore, mitigating food waste, compensating food-insecure people conserving biodiversity, effective use of genetic resources, and traditional ecological knowledge could decrease further biodiversity loss, and meet food security under climate change scenarios. However, achieving food security under such scenario requires strong policies, releasing high-yielding stress resistant varieties, developing climate resilient irrigation structures, and agriculture. Therefore, degraded land restoration, land use changes, use of bio-energy, sustainable forest management, and community based biodiversity conservation are recommended to mitigate climate change impacts.

Indicators of habitat quality in a national inventory of deciduous forest

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Åsa Ranlund[1]
Henrik Hedenås[1]
[1] Swedish University of Agricultural Sciences

Abstract: Traditionally when monitoring forests field effort in different forest types is proportional to how common the forest is. It is a robust method to give an unbiased general view of forests. In a largely forested country such as Sweden however, with a high proportion of managed and coniferous forest, that gives inadequate information on the less common older deciduous forests. Therefore, the Swedish Environmental Protection Agency initiated a national inventory of deciduous forest in 2020 with the aim to collect data on older deciduous forests as a complement to the Swedish National Forest Inventory. The responsibility fell on the National Inventories of Landscapes in Sweden (NILS).

In a hierarchy of samples NILS now inventories older deciduous forests in dense samples focusing on forest habitats included in the Habitat Directive in EU:s Article 17 (Annex I-habitats), and forests that could be restored to such habitats. To further acquire information on aspects of quality in these forests a number of field variables are collected in a slightly larger area than the plot level with the more general aim to assess the quality of the forest for conservation, in addition to plot level variables on tree, shrub and field layers. A species inventory supplements the biotope aspects of quality.

Two indicators, biotope and species value, are combined from variables measured in the field. Together they provide categories that we use to estimate the proportion of area with good conservation status for different types of deciduous forest. A similar method could also be used to estimate proportion of areas in need of restoration. In both cases, using a monitoring program with field inventory gives an unbiased method to follow the development of forests with respect to these indicators over time.

Metapocyrtus Weevils: Potential Forest Biodiversity Indicator in the Philippines

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Sheryl A. Yap[1, 2, 3]
Romeo R. Patano, Jr.[3, 4]
[1] Institute of Weed Science, Entomology and Plant Pathology, College of Agriculture and Food Science, University of the Philippines Los Banos, Los Banos, Laguna, Philippines
[2] Museum of Natural History, University of the Philippines Los Banos, Los Banos, Laguna, Philippines
[3] Biological Sciences Division, National Research Council of the Philippines, Department of Science and Technology, General Santos Avenue, Bicutan, Taguig City, Philippines
[4] Graduate School, Department of Biology, College of Arts and Sciences, Central Mindanao University, Musuan, Maramag, Bukidnon, Philippines

Abstract: *Metapocyrtus* is a genus of weevils belonging to the Tribe Pachyrhynchini and is endemic to the Philippines. These weevils have gained attention in recent years as potential indicators of forest biodiversity for effective forest management strategies. This abstract provides an overview of *Metapocyrtus* and highlights its significance as a forest biodiversity indicator. These weevils are small in size, measuring approximately 5 to 15 millimeters in length, and are characterized by their distinctive body shape and coloration. They exhibit a wide range of morphological variations within the genus, making them an interesting subject for taxonomic and ecological studies. *Metapocyrtus* species are mainly found in forested areas, particularly in lowland and montane tropical forests across different islands of the Philippines. These weevils are documented in association with 46 species of host plants belonging to 31 families, primarily flowering plants and ferns, which are dominant in Philippine forests. The presence and abundance of different *Metapocyrtus* species can indicate the overall health and diversity of these host plant communities. As weevils are sensitive to environmental changes, their population dynamics and species composition can reflect alterations in forest structure, disturbance levels, and habitat quality. Forest management practices often require efficient monitoring tools to assess the impact of management interventions on biodiversity conservation. *Metapocyrtus* weevils have the potential to serve as reliable indicators due to their specificity to certain host plants and their sensitivity to forest disturbances. By conducting surveys and monitoring the presence and abundance of *Metapocyrtus* species, forest managers can gain insights into the success or failure of conservation efforts and make informed decisions regarding sustainable forest management practices. Further research and collaborative efforts are needed to fully understand the ecological role of *Metapocyrtus* weevils and their potential for practical application in forest management. Such studies will provide a solid scientific basis for incorporating these weevils into comprehensive forest monitoring programs and conservation strategies, ultimately enhancing the sustainable management and preservation of the rich forest biodiversity in the Philippines.

Monitoring biodiversity impact of reforestation: insights from a pilot project to assess the potential of soil environmental DNA metabarcoding

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Josephine Haas
Koen Kramer[1, 2]
[1] Land Life Company, the Netherlands
[2] Wageningen University and Research, the Netherlands

Abstract: Monitoring the impact of reforestation projects on biodiversity is essential to assessing the effectiveness and ecological benefits. Traditional methods for measuring biodiversity often rely on time-consuming and resource-intensive approaches, which makes them difficult to scale up for large-scale reforestation projects. Advancements in environmental DNA (eDNA) metabarcoding hold great potential to circumvent that limitation.

To explore the potential of eDNA metabarcoding to assess the biodiversity impact of reforestation projects, we conducted a pilot project focused on soil biodiversity. Soil communities are ubiquitous, respond rapidly to changes in the environment, and are a vital component of ecosystems, making them potentially suitable indicators for reforestation monitoring. The pilot, conducted in Spain, compared fungal, bacterial, and invertebrate biodiversity of a degraded area set aside for reforestation with a mature coniferous and a mature broadleaf forest. Biodiversity indicators related to species composition, species richness, and functional and evolutionary diversity were compared between the different sites. Most soil biodiversity indicators were found higher in the mature forests, marking a potential reference for soil biodiversity for the reforested site.

We found that the advantages of soil eDNA metabarcoding as a biodiversity metric are numerous. Firstly, it provides a non-invasive, relatively easy, and cost-effective alternative to traditional sampling methods, reducing the need for labor-intensive field surveys by experts. Secondly, it provides a robust and standardizable method to monitor biodiversity across large spatial scales and over extended periods, providing valuable insights into long-term biodiversity dynamics. Despite its potential, we found the application of soil eDNA metabarcoding as a biodiversity metric has some challenges. These include protocols for selecting reference forests, identification of the most informative soil biodiversity indicators to assess reforestation success, and analyses and reporting methodologies.

We think the application and acceptance of eDNA as a biodiversity metric would benefit from standardized and internationally agreed methodologies. By sharing experiences from this pilot, we aim to discuss potential solutions to the above-named challenges to accommodate the applicability of soil eDNA metabarcoding as a method to measure the biodiversity impact of reforestation projects.

Options and scenarios for voluntary commitments to biodiversity in the ASALs of Kenya: A case of Kajiado County

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Anthony Macharia[1]
Joram Kagombe[1], Magrate Kaigongi[1], Catherine Mungai[2], Halima Nenkari[3], Obadiah Mungai[4]
[1] Kenya Forestry Research Institute

[3] Ministry of Agriculture and Livestock Development, State Department for Livestock
[4] National Environment Management Authority

Abstract: Approximately 80% of Kenya is arid and semi-arid with land degradation being a major threat to biodiversity. There is a need to reverse biodiversity loss in ASALs by mainstreaming biodiversity in the key economic sectors. The BIODEV2030 project, funded by the French Development Agency (AFD) and implemented by the International Union for Conservation of Nature (IUCN) and the Ministry of Environment, Climate Change and Forestry (MECCF) assessed options for mainstreaming biodiversity in the livestock, forestry, and crop production sectors for sustainable and resilient economies. We assessed possible scenarios for voluntary commitments to biodiversity by private sector actors in Kajiado County, Kenya. The Species Threat Abatement and Restoration (STAR) metric was used to identify key economic sectors with a potential to drive degradation in Kenyan ASALs while the Drivers, Pressures, State, Impact, and Responses (DPSIR) framework was applied in conceptualizing the study. A desktop review of literature, key informant interviews (KII), and focus group discussions (FGDs) were used for data collection. Value Chain Analysis (VCA), weights and scores, and participatory ranking techniques were used for data analysis. Target respondents for the assignment included value chain actors, government agencies, and Civil Society Organizations (CSOs). The main drivers of degradation were overgrazing and overstocking (44%), deforestation (24%), conversion of land to crop production (17%), and intensive horticulture production (15%). Possible voluntary commitments to biodiversity in the livestock sector were building the capacity of actors, adherence to grazing management plans, adoption of sustainable stocking rates, and use of certification schemes for livestock inputs and products. In the crops sub-sector, capacity building, adopting efficient farming technologies, and use of sustainability standards were ranked highest. Promotion of alternative energy sources, efficient charcoal production and utilization, adoption of nature-based enterprises, payment for ecosystem services, and forest certification were recommended by actors in the forestry sector. These commitments could be promoted to mainstream biodiversity in the three sectors thus improve on biodiversity conservation and the livelihoods of ASAL communities.

[4] Área de Biodiversidad y Conservación, Universidad Rey Juan Carlos, C/Tulipán s/n, 28933 Móstoles, Madrid, Spain

Abstract: Resilience is addressed from multiple perspectives dealing with the planning and management of forest social-ecological systems. However, we lack a unified framework for the operational application of related indicators for resilience quantitative assessment. We show a framework aiming to provide (i) a common terminology and procedure to be used across different perspectives, and (ii) an operational approach to assess forest resilience in front of disturbances or stressors challenging biodiversity and climatic emergences.

The proposed resilience operational framework (ORF) is built upon several elements: *system variables* (e.g., ecosystem services and elements of the ecosystem-related value chain), *disturbances and stressors* acting at given spatio-temporal scales, *reference state* whose characteristics are intended to be maintained or achieved, and *metrics* that compare the observed values of the system variables with the reference state. These elements fit into a rationale devoted to identify co-drivers and manageable predictors that reflect the mechanisms involved in the resilience of the selected system variables. So, system variables represent indicators describing forest social-ecological systems, while resilience predictors correspond to indicators predicting resilience performance. In both cases biodiversity-related indicators play a major role to resilience assessments.

To validate and ensure the consistency of ORF, we conducted a review of studies assessing resilience in forest social-ecological systems. We screened 524 papers for identifying the use of the abovementioned ORF elements. This review demonstrated that ORF elements were commonly acknowledged in most studies. Additionally, most studies identified resilience predictors, a key element for planning and developing actions to promote resilience. Nevertheless, the complete rationale behind the framework was not always evident, particularly in socioeconomic-focused studies, in which quantification was infrequent. Therefore, this exercise identified major gaps in the current assessment of forest resilience.

The proposed ORF allows to standardize terminology and facilitates the measure and the promotion of resilience in forest systems, by providing a common procedure for its assessment. This procedure permits comparability and identification of key factors that determine resilience, and therefore the establishment of targets for decision-making and management.

This research has been conducted in the RESONATE H2020-RUR-2018-2020/H2020-RUR-2020-2 (Grant 101000574) project.

Phenology, seed conservation improvement and moisture sorption isotherms of the endangered African rosewood (Pterocarpus erinaceus).

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

James Amponsah[1]
Joseph Asomaning[1], Eli Gaveh[2]
[1] CSIR-Forestry Research Institute of Ghana.
[2] Department of Horticulture, Kwame Nkrumah University of Science and Technology, Kumasi, Ghana.

Abstract: Phenological observation enables us to understand and predict the response of species to climatic changes. Generating information on phenology, seed propagation and storage improvement techniques of threatened species, remain critical for their long-term conservation. African rosewood (*Pterocarpus erinaceus*), is, highly exploited and endangered tree species in arid and semi-arid forest zones of West Africa. This study assessed the timing of the reproductive life cycle of the species relative to local climatic variables for 3 year period within the forest and savannah zones of Ghana. The effects of four pretreatments on seed germination, and seedling vigour was also evaluated. We further examined varying temperature, duration and packaging material on seed storage deterioration. Period and intensity of leaf flushing, flowering, fruiting and seed dispersal among individual trees were monitored, scored and analysed with drone-captured images. Seed moisture sorption isotherms at 20, 25 and 30°C were characterized by equilibrating seed samples on series of lithium chloride (LiCl) solutions. Data were fitted to four mathematical models to determine the most suitable for describing phenology seed moisture sorption isotherms. Results indicate that fruiting and seed dispersal phenophases occurred between November -February, with a strong positive correlation ($r = 0.93412$) with mean monthly maximum temperatures. Moisture sorption isotherms showed a sigmoid (*S*-shape) profile, characteristic of orthodox seeds, and best described by the Henderson equation. Our findings show ideal ideal seasons for seed collection and we recommend the adoption of orthodox seed storage protocols for effective *P. erinaceus ex-situ* conservation.

Remote Sensing Based Forest Indicators in Support of Restoration Monitoring

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

[4] Environment Agency Austria, Austria

Abstract: The UN decade on Ecosystem Restoration has put the need for ecosystem monitoring high on the political agenda. The European Commission has reacted by putting forward a proposal for a European Nature Restoration Law (NRL), which is currently in consultation stage. This and other biodiversity targets heavily rely on indicators to measure the policies' impacts and to allow for enforcement measures. Suitable indicators need to be accurate and meaningful, they should be cost-effective and quickly accessible, transparent in their generation, and provide spatially explicit information – ideally all at once. One of the problems with most indicators is, that they are typically either not specific enough or not easy to generate because they require very specific data. Remote sensing (RS) is a way to provide indicators in a spatially explicit manner and over larger areas than field assessments.

Here, we analyzed different forest related indicators (forest area, forest fragmentation, species distribution, canopy height and vertical structure) over time for the assessment of restoration progress in both forest areas and wetlands. We evaluated multi-temporal assessments of forest restoration after severe disturbance (e.g. from bark beetle) and for bog restoration monitoring. We found that LiDAR is especially important for monitoring restoration success, i.e. for identifying areas of shrub and tree encroachment in a bog, where apparently the water table was not increased sufficiently or still had an unwanted drain. LiDAR can also be used to detect drainage infrastructure such as channels and dams. For the forest restoration, we found foliage height diversity to be a useful indicator to monitor progress, as it includes the vertical forest structure. Satellite-based disturbance detection further helps to keep up with changes. With regards to the NRL, the technology for monitoring using a combination of remote sensing and in-situ tools is available, but there is still a significant lack of clarity in terms of targets. Assessing the naturalness of forest ecosystems is based on the comparison of structure and tree species composition of the current forest with a natural forest of the same type.

Resilience Indicators for Assessing Resilience of Forest Biodiversity: A Multi-Criteria Analysis Approach

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Blasius Schmid[1]
Alice Ludvig[1], Luciana Jaime[2], Stefanie Linser[1]

Abstract: Forest ecosystems play a crucial role in maintaining biodiversity and providing essential ecological services. However, the increasing pressures from human activities, environmental changes and climate change emergencies necessitate effective forest management strategies to ensure their long-term resilience. In our study we aim to develop a comprehensive set of indicators suitable for assessing forest resilience, with a particular focus on biodiversity. The indicators chosen should be sensitive to maintenance or enhancement of forest biodiversity through active forest management.

To accomplish this objective, first, an extensive preselection of potential indicators and parameters relevant to forest resilience was conducted. These indicators encompass a wide range of ecological, social, and economic aspects, reflecting the multifaceted nature of forests and forestry. In a next step we applied a multi-criteria analysis together with relevant stakeholders. By integrating multiple quantitative and qualitative criteria, we have identified the most pertinent indicators to assess forest resilience through forest management planning and decision-making.

Our study aims to generate a concise set of key indicators that can effectively capture and monitor changes in forest resilience. These indicators will serve as easily applicable tools for assessing the fitness, functionality, and adaptive capacity of forest ecosystems, particularly in terms of biodiversity maintenance and enhancement. The concise set of indicators will provide a practical framework for monitoring and evaluating forest resilience, enabling informed decision-making and the formulation of targeted management strategies. By aligning active forest management practices with the identified indicators, it becomes feasible to optimize management interventions towards fostering resilient forest ecosystems.

Status and dynamics of deadwood in Austrian forests

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Janine Oettel[1]
Thomas Gschwantner[2]
[1] Austrian Research Centre for Forests, Department Forest Biodiversity and Nature Conservation, Austria
[2] Austrian Research Centre for Forests, Department Forest Inventory, Austria

Abstract: The positive correlation between deadwood occurrence and dependent species richness of a forest is widely recognized, which is likely a reason that deadwood volume is often used as an indicator for forest biodiversity or naturalness. However, it's important to note that an evaluation of forest biodiversity by using the amount of deadwood has to take into consideration forest type. A comparison between different forest types may not be reliable, as values do not account for varying growing conditions at different sites. Moreover, while the deadwood amount is an important metric, it's not sufficient for assessing the conservation value and naturalness of forests. The compositional diversity of deadwood is equally important as it determines the potential habitats for dependent species. Accordingly, shaping the compositional diversity of deadwood, e.g. in terms of species, diameter, decomposition, and position, can enhance the conservation status of certain saproxylic species that require high structural diversity. In many managed and but even also in currently unmanaged temperate forests of Europe, especially standing deadwood is occurring in small quantities. To date, few studies have examined how environmental factors, forest management, and changing climate affect the availability and dynamics of standing deadwood. This presentation provides critical insights into how tree-, forest stand- and landscape-level parameters, forest management, and climate affect the characteristics and dynamics of deadwood in different forest types of unmanaged and managed forests of Austria. Understanding the impact of various factors on deadwood availability and dynamics is crucial to ensure the continuity of deadwood supply and the conservation of deadwood-dependent species.

SUSTAINABILITY INDEX OF BIODIVERSITY AND CARBON RESOURCES FROM SELECTED REHABILITATION AREAS IN QUEZON PROVINCE, PHILIPPINES

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Erwin Tabaco[1]
Nelson Pampolina[1]
[1] Department of Forest Biological Sciences, College of Forestry and Natural Resources, University of the Philippines Los Baños

Abstract: The forest landscape of the Philippines is subject to intensive rehabilitation through the national greening program and carbon sink Initiatives due to years of deforestation that contributed to biodiversity loss, climate change, and sustainable development goals. This study focused on the evaluation of the sustainability index (SI) regarding biodiversity and carbon resources in monitored and assessed rehabilitation from Pagbilao and Padre Burgos, Quezon Province. Rehabilitation from mangroves (Ilayang Polo, Marao, Ibabang Kinagunan) and upland (Binahaan, Ilayang Palsabangon, Ilayang Bagumbungan) was selected. Bioindicators (species composition, diversity, conservation, biodiversity, growth, regeneration, biomass, and carbon) were described and indexed using a Likert scale to correlate values with the natural ecosystem. All bioindicators of biodiversity and carbon resources defined the progress of rehabilitation. SI of regeneration was very high in mangroves (525-5,850 seedlings ha^{-1}) than in upland (1,150-11,425 seedlings ha^{-1}) and positively correlated ($r<1$) with natural forest, indicating succession. Carbon aboveground was higher in upland than in mangroves with high scale and positively correlated similarly with diversity, conservation, and biometrics with the natural forest which indicates a more functional upland ecosystem that mimics natural forest. Overall, success in mangrove and upland rehabilitation can contribute to biodiversity conservation to mitigate climate change. Monitoring biodiversity and carbon hence can ensure the sustainability of ecosystems for generations but should further study other factors to improve the index.

The Foamy World of Spittlebugs: Indicator of a healthy environment in the Philippines

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Abstract: The Cercopidae is the largest family of Cercopoidea and form the largest group of xylem-sap sucking insects. They are commonly known as froghoppers or spittlebugs. Mostly land-dwelling worldwide, their juveniles can live in spumous frothy excreta sometimes called ‘bubble nest’ or ‘crachat de coucou’ (cockoo spit) in French. The presence of the protective frothy excreta has been traditionally identified as a protection against predation, parasitism and it creates a microclimate that reduces the risks of overheating and desiccation. This group of insects including its counterpart familyfrom the new word region, the family Ischnorhinidae, has been reported to be a serious pests of some economically important crops in some parts of the world. However, in the Philippines, all the 70 species recorded in the country werenot reported to be attacking the crops. Philippine Cercopids are sensitive to any changes in the environment or any disturbances, as indicated by very few to almost no species observed in the human intervened area. Most of the species are found in the forest ecosystem. The higher the number of Cercopidae in a particular ecosystem, the less disturbance in the ecosystem. This makes Cercopidae a good candidate as tool in monitoring the status of the environment. For the last 7 to 9 years of studying the taxonomy and systematics of the Philippine Cercopidae through collection trips and expeditions, a series of taxa new to science were described. Along with their taxonomy, their ecology, associated hosplants from different families were also observed, mostly are only found the in the found in the undisturbed forest ecosystem. Despite these available data about their taxonomy, host plants and ecology, knowledge remains very limited and further research is relevant to fully understand the value of Cercopidae in the Philippine biodiversity. These informations could then be used in formulating effective management strategies in protecting our forest ecosystem and also conserving the species, which are forest dependent and are used as bioindicator.

The FOrest Biodiversity Index (FOBI): monitoring the biodiversity potential of Britain's public forests over space and time

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Stephen Bathgate[1]
Chloe Bellamy[1], **Alice Broome**[1], Colin Edwards[2], Robin Jarvie[1], Nora Kerecsenyi[1], Kenny Kortland[2], Darren Moseley[1], Andrew Rattey[1], Andrew Stringer[3], Eleanor Tew[3], Kevin Watts[1]

[2] Forestry and Land Scotland, UK
[3] Forestry England, UK

Abstract: A third of British forests are owned or managed by public forest agencies. In adherence with the UK 25-year environment plan and international, legally binding treaties and targets, such as the post-2020 Global Biodiversity Framework, these government bodies have a statutory duty of care to safeguard and enhance the biodiversity value of these areas. However, they often lack the information and tools with which to evidence progress towards meeting these obligations and to justify their decision making. To help fill this information need, we have co-developed the FOrest Biodiversity Index (FOBI), a quantitative, transparent and repeatable approach for assessing the biodiversity potential of Britain's publicly owned forests. This index is a composite of several extent, condition, connectivity and diversity 'metrics', or proxies of forest biodiversity, which are measured using forest survey data and other spatially explicit landcover information. Scores are assigned to individual forests and are aggregated using a stepped approach to provide FOBI indices at Local and Landscape levels, and four sub-indices levels. These can be interrogated and reported at annual intervals, at all levels of the index and at a range of scales (for individual forest, regionally and nationally). The results can therefore inform locally targeted action, as well as national long-term monitoring and reporting. We will provide insights from the co-development of this approach and application to several annual time stamps in England and Scotland. We discuss the steps taken to ensure the statistical robustness of the index, the use of benchmarks to assess changes over time, and the provision of online, interactive tools for visualising and exploring results over space and time. Opportunities and challenges for future enhancements and applications will be also considered, such as the potential to extend the approach beyond the public forests to relatively data-poor private forests.

The role of leaf phenology in the carbon and biodiversity cobenefits in a tropical forest

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Alice Rodrigues[1, 2]
Andreza Neri[1], Lhoraynne Gomes[1, 2], Pedro Villa[2, 3]
[1] Laboratory of Ecology and Evolution of Plants - LEEP, Department of Plant Biology, Postgraduate Program in Botany - Universidade Federal de Viçosa, Viçosa, Minas Gerais, Brazil

[3] Department of Biological Sciences, Postgraduate Program in Botany - Universidade Federal de Feira de Santana, Feira de Santana, Bahia, Brazil

Abstract: Second-growth tropical forests offer important carbon and biodiversity cobenefits (i.e., positive aboveground carbon stock (AGC) and species richness relationship), and different leaf functional types of tree species. Leaf deciduousness is an important functional trait that can contribute to seasonal and spatial changes in carbon balance. In this context, we investigated the distribution pattern of AGC, species richness, and functional dominance among trees with differing leaf phenology as well as the carbon and biodiversity cobenefits of tree communities in contrasting topographical conditions in a second-growth tropical Atlantic forest. We sampled fourteen 20 m x 40 m plots established in the forest and classified tree species into three categories groups with respect to the leaf phenology (deciduous, semideciduous, and evergreen species) according to field observations and literature. The AGC were estimated from the allometric equations for forest biomass. We calculated community-weighted mean metrics based on mean functional traits related to AGC capacity in tropical forest: wood density and maximum tree height. We found that evergreen species showed higher richness, while the deciduous species had a greater contribution to AGC. Our tested models showed a significant positive relationship between AGC and species richness. Thus, the variation in AGC had the strongest positive effect on species richness of evergreen, and semideciduous trees. Furthermore, when analyzing the interaction between predictors, it is observed that evergreen and semideciduous trees are responsible for a strong and positive relationship between AGC and species richness. However, no effects of deciduous trees were observed. Thus, the leaf phenology groups can affect the relationships between species richness and AGC. For example, deciduous species are key to maintaining higher carbon stock with smaller numbers of species; meanwhile evergreen species are important to maintain a higher species richness. Thus, leaf phenology groups could be responsible for important cobenefits in tropical forests. Therefore, this study showed a relevant result on the relative contribution of leaf phenology groups in the carbon and biodiversity cobenefits along topographic gradients. This study can allow the selection of key tree species to improve the management, conservation, and restoration practices in tropical forests.

The role of riparian buffers for biodiversity in boreal forests: does one size fit all?

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Élise Berthiaume[1, 2]
Guillaume Grosbois[1, 2], Miguel Montoro Girona[1, 3]
[1] Groupe de recherche en écologie de la MRC Abitibi (GREMA), Forest Research Institute (IRF), Université du Québec en Abitibi-Témiscamingue (UQAT), Amos, Québec, Canada

[3] Grupo de Análisis y Planificación del Medio Natural, Universidad de Huelva, Huelva, Spain

Abstract: Forest harvesting can have abiotic and biotic impacts on adjacent aquatic ecosystems, ranging from nutrient leaching to an extra input in sediments, which may permanently alter aquatic communities and food webs. Riparian buffers are strips of forest left uncut along water bodies and wetlands following harvests. These buffers have been used across the world as the only silvicultural tool aiming to mitigate the impacts of forest harvesting on aquatic ecosystems. Furthermore, it has been suggested that riparian buffers may play an important role in landscape connectivity, hence in preserving biodiversity. As they make up a large proportion of residual forests following a clear-cut, riparian buffers could offer key habitats to forest dwelling species. However, the long-term role of riparian buffer strips in the maintenance of boreal forests' biodiversity and connectivity is poorly understood, as it has never been investigated before.

Therefore, this study aims to assess the role of riparian buffer strips in preserving biodiversity and habitat in boreal forests. This study will be carried out in Eastern Canada (Québec), in the MRC of Abitibi, in the balsam fir white birch bioclimatic region, in stands dominated by jack pines (*Pinus banksiana*) or black spruces (*Picea mariana*), on either clay or sand substrate. In Québec, buffers 20 meters wide have been applied for over three decades. In these 20 meters wide riparian buffers, larger buffers, as well as natural riparian zones, we will evaluate diversity and species composition, 15 to 20 years after logging. Following a multi-taxa approach, plants, birds and mammals will be surveyed using, respectively, transect and microplot surveys, acoustic recorders and camera traps. A total of 60 sites will be surveyed over the summer of 2023. Riparian connectivity will later be assessed using spatial analyses.

Ultimately, this study will provide silvicultural prescriptions for the implementation of riparian buffers in boreal forests, acting as a guideline for forest management. In addition, it will determine the long-term effects of forest harvesting on riparian biodiversity and address knowledge gaps regarding aquatic-forest interactions.

Thresholds for biodiversity in boreal forests: how structural indicators affect the diversity and richness of epixylic and saproxylic species

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

[3] Swedish University of Agricultural Sciences, Swedish Species Information Centre, Sweden
[4] Natural Resources Finland (LUKE), Finland

Abstract: In forests, diversity and amounts of structures such as deadwood, broadleaved trees, and large trees are often used as biodiversity indicators. Such indicators are commonly used to determine which forests should be preempted from forestry. Hence, it is of great interest to understand if there are certain amounts of these indicators that are required to significantly promote biodiversity, i.e., if it is possible to identify thresholds, and if such thresholds vary across different environments, taxonomic species groups, and spatial scales.

To explore this, we set up a multi-taxon study covering Finland and Sweden along a gradient of forest management intensity. In total, we established 240 plots situated in set-asides (unmanaged in recent decades), retention plots (tree groups left unharvested), and old clearcuts (harvested 25-30 years ago). These plots were surveyed for epixylic and saproxylic bryophytes, lichens, and fungi. Simultaneously, detailed data on every tree in these plots were collected pertaining to tree condition, size, species, and decay stage. With threshold analyses, we studied tree- and plot-level thresholds for individual species and various biodiversity measures.

We uncovered tree-level thresholds for many species. For these species, we obtained knowledge on the requirements these species have from trees in terms of sizes, species, and decay stages and were able to compare the threshold values between threatened and non-threatened species, and between species with different functional traits and taxonomic classifications. On a plot-level basis, we showed the threshold values relating to the amount and variety of deadwood, tree species composition, and amount of large living trees for various biodiversity measures including (threatened) species richness, the Shannon-Wiener index, and functional diversity measures. Differences between forest management types were also elucidated in terms of the tree-level thresholds for species and the plot-level thresholds for the various diversity measures across sites.

In conclusion, understanding threshold values above which species become increasingly present and biodiversity rises significantly is important in our consideration of forest biodiversity indicators. Our findings improve our knowledge of individual species' needs and set clear goals on how to increase taxonomic and functional biodiversity across differently managed forests for stakeholders involved in forestry and conservation.

Tree-related microhabitats on retention trees as biodiversity indicators in Fennoscandian planted forests

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Maria Trinidad Torres-Garcia[1]
Per-Ola Hedwall[1], Laurent Larrieu[2, 3], Adam Felton[1]
[1] Southern Swedish Forest Research Centre. Swedish University of Agricultural Sciences (SLU), Alnarp, Sweden
[2] Université de Toulouse, INRAE, UMR DYNAFOR, Castanet-Tolosan, France
[3] CNPF-CRPF Occitanie, Auzeville Tolosane, France

Abstract: In Sweden, forests cover 70% of the land area, and the majority are intensively managed using even-aged silviculture. Over recent decades, retention forestry has emerged as a conservation tool to counteract the effects of clear-felling on biodiversity, particularly in the short term. However, there is an increasing necessity to assess how and to what extent retention trees contribute to biodiversity in planted forests throughout the rotation period. In this sense, tree-related microhabitats (TreMs) have been proposed as a meaningful indicator of the state of biodiversity at the stand scale. TreMs are structures such as cavities or injuries occurring on trees that constitute an essential habitat resource for numerous species during at least part of their life cycle. TreMs have been widely studied in the temperate forests of central Europe, but are only just beginning to be considered in Fennoscandia. In this study we: 1) identify archetypes of TreMs on retention trees in coniferous planted forests; 2) evaluate the role of different retention tree species (*Quercus robur, Populus tremula, Betula sp,* and *Fagus sylvatica*) to provide TreMs; and 3) evaluate the effect of forest management (i.e. stem density or distance to the retained trees) on the abundance and richness of TreMs. To do so, we measured TreMs on 114 broadleaf retention trees located within 20 Norway spruce (*Picea abies*) production stands in southern Sweden. We observed that older trees, particularly oaks (*Q. robur*), within this production context do host a higher abundance and richness of TreMs, and that a higher density of production stems surrounding the retention trees is associated with the development of some TreM groups (e.g. exposed sapwood, crown deadwood). Outcomes may be explained by shade-induced dieback and the closer proximity of management interventions creating TreMs via artificial disturbance. However, this management can also prevent the development of other types of TreMs. TreMs could play a more central role in deciding which trees should be retained in planted forests, and we discuss using this approach as a biodiversity indicator for setting conservation targets in Fennoscandian forests.

Untapped Treasures of Forest Biodiversity Indicators in the UNECE Region: Unlocking their Potential for Monitoring Biodiversity in Climate Emergencies

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Stefanie Linser[1]
Katharina Lapin[2], Janine Oettel[2], Martin Braun[2]
[1] University of Natural Resources and Life Sciences Vienna, Department of Economics and Social Sciences, Austria
[2] Austrian Research Centre for Forests, Department Forest Biodiversity and Nature Conservation, Austria

Abstract: The urgent need to address biodiversity loss in relation to climate emergencies necessitates the development of effective monitoring tools to assess the pressures on and state of forest biodiversity. This research explores the untapped potential of forest biodiversity indicators within the UNECE region, focusing on their applicability for monitoring forest biodiversity facing these pressing environmental challenges. A comprehensive review was conducted, analyzing 56 national reports on forests and forestry from all UNECE countries to identify existing national biodiversity indicators utilized or applied within these reports. A wealth of indicators was found not depicted in international reporting efforts. We aim to assess their potential for international reporting on forest biodiversity in Europe and beyond. Additionally, our objective is to evaluate indicators identified, considering their availability, replicability, and reproducibility. This evaluation will enable us to gain inside into the existing data gaps within forest biodiversity monitoring. By assessing these aspects, we seek to strengthen the robustness and reliability of future biodiversity assessments. The findings from this study have profound implications for forest management, conservation strategies, and international reporting frameworks. By uncovering and evaluating previously underutilized indicators, we can enhance our understanding of forest biodiversity dynamics and adopt a more comprehensive approach to assessing its status. Additionally, this research will shed light on crucial considerations for selecting indicators in the face of future biodiversity scenarios under increasing climate emergencies, ensuring that monitoring efforts remain relevant and effective in addressing the challenges ahead.

Variation among ghaf (Prosopis cineraria) trees within one square kilometer in the United Arab Emirates

T3.7 Forest biodiversity indicators: supporting our response to the biodiversity and climate emergencies

Muhammad Shahid[1]
[1] International Center for Biosaline Agriculture, Dubai, United Arab Emirates

Abstract: Ghaf (*Prosopis cineraria*) is an evergreen tree that inhabits the dry and hot regions of the Middle East and South Asia. It is a useful tree that generously supplies food to humans, livestock, and wild animals. The green canopy of the *Prosopis* also provides cool shade from the blistering desert heat to a wide range of wildlife. Given its importance to the people, domestic animals, and wildlife of the country, it is the national tree of the UAE. In some of its natural range areas, it is an important agroforestry species. The exploitation of its genetic variation in other regions may bear fruit. With this in mind, a study was undertaken by the Plant Genetic Resources Program of the International Center for Biosaline Agriculture (ICBA) to find the diversity of all ghaf trees (82 total) within an area of one square kilometer in the UAE. For this purpose, different morphological characteristics of the tree, including angle/shape of the tree crown, leaf color, number of leaves per 30 cm of branch, leaf area, leaf dry weight, date of flowering, maturity date of the pod, inflorescence color, inflorescence length, inflorescence weight, pod length, pod weight, number of seeds per pod, number of seeds infected with insect, seed width, seed length, seed thickness, seed color, and seed weight have been studied in detail. Initial results indicate the presence of considerable genetic variability within the local ghaf trees. The sizeable genetic diversity of *P. cineraria* can be exploited for different breeding purposes, including introducing it to other non-natural range areas.

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

A candidate gene association analysis identifies SNPs potentially involved in several abiotic stress tolerance in European beech (Fagus sylvatica L.)

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Local adaptation is one of the essential evolutionary mechanisms that allow species to thrive in heterogeneous environments. Understanding the dynamics and mechanisms of local adaptation in natural populations provides the basis for predicting responses to environmental changes, including those associated with global climate change. Local adaptation is expected to alter the allele frequencies of genes that influence fitness in particular environments. Local adaptation is best studied in long-lived sessile organisms with large effective populations covering large and variable environments such as forest trees. European beech (*Fagus sylvatica* L.) is one of the most economically and ecologically important deciduous trees in Europe, yet little is known about its genomic adaptive diversity and its adaptive potential. The adaptation potential of beech to climate change has been widely discussed. Although beech is considered a sensitive tree species in the context of projected environmental changes, some authors conclude that beech will not lose its importance and adaptive capacity in the future. However, changes in beech marginal populations have already been observed, and several modelling studies predict range shifts of this species in the context of global warming. Therefore, a deeper understanding of its potential to adapt to changing environmental conditions is needed. In this study, using a candidate gene approach, we investigated the association between SNPs and environmental factor variation in 12 beech (*Fagus sylvatica* L.) populations located in 5 different biogeoclimatic regions and subjected to different silvicultural regimes. This work presents for the first time the results of the study of genetic differentiation among European beech populations in different management conditions, presumably associated with adaptation to different climatic conditions, based on a pooled analysis of many bioclimatic variables, together with a large number of genetic markers, single nucleotide polymorphisms (SNPs). In total, 5,143 SNPs were genotyped in 194 individuals. Among them, both climate region-specific and population-specific polymorphisms were observed. Association analyses are currently in progress. Four different methods (PCAdapt, LFMM, BayeScEnv, and RDA) were used for the analyses to observe a correlation between SNPs and variation in some environmental factors and presumably associated with local adaptation.

A journey through the inside: exploring the endophytic microbial biodiversity of ancient beech forests in central Italy

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Irene Giubilei[1]
Silvia Turco[1], Federico Brugneti[1], Mounira Inas Drais[1], Angelo Mazzaglia[1]
[1] Dipartimento di Scienze Agrarie e Forestali, Università degli Studi della Tuscia, 01100, Viterbo, Italia

Abstract: The World Heritage Forests composed mainly by beech forests (*Fagus sylvatica*) located in the Mediterranean Basin are considered an hot spot of both climate change and biodiversity. This ecological biodiversity is currently threatening by global warming, deforestation and tree decay, which would lead to habitat loss and even extinction. Immediate actions are needed to better identify forests natural mechanisms of adaptation to environmental changes and thus, a careful monitoring of the biodiversity shifts at local level could give insights on the forests health status. The biodiversity and abundance of the endophyte community is strictly linked to the plant health, environmental conditions and plant organs. We investigated the endophyte communities of two unmanaged ancient beech forests recognized by UNESCO World Heritage and located in central Italy "Faggeta Vetusta del Monte Cimino" (UNESCO site) in Soriano Nel Cimino (VT), "Faggeta Vetusta di Monte Raschio" (UNESCO site) in Oriolo Romano (VT), together with a third beech forest located in Monte Terminillo (RI). In each site, seeds and leaves were collected from five different trees and at two different sampling area. Microbial biodiversity was then investigated throught classical culture-based isolation methods to be compared with metabarcoding analysis of both fungal ITS and bacterial 16S amplicons sequenced in Illumina platform. Given that not all the endophytes are cultivable, the metagenomic analysis will provide a more detailed picture of the microbial community. We aim to identify the "**core microbiome**" composed by endophytes constantly associated with beech, independently from any external condition or geographic location, the "**resiliome**" composed by the endophytes present in healthy and vigorous plants that contribute to the resilience of plants living in difficult condition, and the "**weakness pathobiome**" composed by those endophytes that could shift from a neutral behaviour to a pathogic habitus, especially when plants are weakened by different stress conditions. Since the influence of these organisms in shaping the adaptability of the species is more than a hypothesis, these outcomes will represent a basis for a pioneering natural approach to understanding of the endophytic community under specific conditions for a more precise preservation and conservation of European beech forests.

Application of genomic methods in moso bamboo biodiversity

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Zhimin GAO[1, 2]
Yan LIU[1, 2], Chenglei ZHU[1, 2], Kebin YANG[1, 2], Huayu SUN[1, 2]
[1] Institute of Gene Science and Industrialization for Bamboo and Rattan Resources, International Centre for Bamboo and Rattan, Beijing, China
[2] Key Laboratory of National Forestry and Grassland Administration/Beijing for Bamboo & Rattan Science and Technology, Beijing, China

Abstract: Moso bamboo (*Phyllostachys edulis*) is the most representative bamboo in China, which forest area exceeds 5.2 million hectares. Due to long-term adaptation to different habitats, natural selection and artificial selection, many forms of moso bamboo with various morphological characteristics have been generated. However, the association of phenotype with heredity in those bamboo forms is too limited. Here, the main difference of phenotype among those forms were subdivided into 15 indicators. The correlation matrix and R-type cluster analysis of morphological character markers showed that several marker pairs were significantly related, among which color variation and node or internode shape variation were the main markers differentiating one variant from another. To explore the genetic differences among the forms, 20 forms were collected for genome sequencing on the Illumina platform, and a total of 1.26 Tb sequences were generated, with an average sequencing depth of 30.04× per variant. Totally, 3,230,107 high-quality single nucleotide polymorphisms (SNPs) and 742,564 InDels were identified. Interestingly, the density of SNP and InDel distributed on the different chromosomes were highly consistent. Most SNPs (84.04%) were distributed in intergenic regions. There had 4496 SNPs located in 3676 genes were annotated with high level effecting variation, which were uneven distributed on the chromosomes. Moso bamboo forms were characterized with high genotype heterozygosity, 30 low and 40 high long continuous heterozygous regions (LCHRs) were identified, respectively. Based on gene functional enrichment analysis, the genes located in high-LCHRs were related to the zeatin biosynthesis and brassinosteroid biosynthesis. According to the established phylogenetic tree and morphological characters, moso bamboo forms were divided into node/internode variation group (VG) and node/internode normal group (NG). Moreover, 1512 genes were identified as candidate genes responsible for the differentiation between VG and NG groups during evolution. Most of the candidate genes were related to plant hormone signal transduction and MAPK signaling pathway. These results provided a comprehensive insight of SNP markers into moso bamboo genome, which would facilitate further research related to moso bamboo evolution, marker-assisted selection, diversity conservation and functional identification of genes related to agriculturally important traits.

Assessing genome-wide patterns of hybridization among members of Fraxinus section Melioides in the Great Smoky Mountains National Park

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Zane Smith[1]
Cody Roberts[1, 2], Eli Thurston[1, 2], Esmeralda Mattarazzo[1, 2], David Holdridge[1, 2], Aubrey Horner[1, 3], Jennifer Koch[4], Denita Hadziabdic[1], Margaret Staton[1]

[2] University of Tennessee, School of Natural Resources, United States
[3] University of Tennessee, Department of Ecology and Evolutionary Biology, United States
[4] Northern Research Station Delaware, Ohio, United States Department of Agriculture Forest Service, United States

Abstract: Since its introduction in the 1990s, emerald ash borer (EAB) has extirpated over 100 million ash trees (*Fraxinus* spp.) across the eastern United States (US). The sudden endangerment of US-native ash, primarily within *Fraxinus* section *Melioides*, has prompted extensive efforts to characterize and breed resistance to EAB, however, substantial knowledge gaps still remain in the fundamental ecology and diversity of this lineage. Specifically, recent genomic evidence suggests that species delimitation due to polyploidy and cryptic hybridization may be obstacles to the efficient application of conservation effort within *Fraxinus* section *Melioides*. Due to the rapid decline of this lineage in the US, a more precise understanding of gene flow among congeners within ecologically intact populations may be critical to future restoration efforts, while little time remains to characterize these dynamics due to EAB-induced mortality. In this study, we assess whether green and white ash (*F. pennsylvanica* and *F. americana*, respectively; two sister taxa within *Fraxinus* section *Melioides*) show patterns of admixture and introgression in the Great Smoky Mountains National Park, a UNESCO world heritage site and temperate biodiversity hotspot. Furthermore, we explore how local environmental conditions may impact gene flow among green and white ash across fine spatial scales. Extensive surveys reveal that the mountainous terrain within the Great Smoky Mountain National Park harbors not only stark environmental clines over short distances, but rare, mountain alluvial forests, presenting an uncommon opportunity for green and white ash to thrive proximally along stark elevational gradients. We propose that hybrid genomic mosaics arising from recent admixture and/or historical introgression events may have had lasting effects on the genomic architecture of these taxa due to differential fitness across microclimates. Using traditional botany, whole-genome sequencing, computational hybrid detection, ecological modeling, and landscape genomics approaches, we assess the genomic and ecological diversity of green and white ash to inform the conservation management and future restoration of two critically endangered forest tree species.

Assessing the effects of adaptive responses of black spruce (BS) on future carbon sequestration through genomic approaches and dendroecology

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Forest ecosystems around the world can help mitigate climate change (CC) through reforestation, afforestation, and restoration, but these ecosystems, particularly the boreal forest, will also be significantly impacted by CC. To achieve their aims, these nature-based solutions will have to rely on the selection of species and seed sources adapted to future climates. Yet, predicting the long-term response of trees to climate change is a major challenge, and such predictions rarely consider the adaptive genetic variation of species. Taking advantage of four black spruce (*Picea mariana*; BS) common gardens established in the early 1970s, we leveraged genomics and dendroecological data collected from over 2,100 trees (61 provenances) to determine how intraspecific genetic variation may influence BS growth response to current and future climates. We determined: i) the number of distinct genetic clusters present within BS from 50,000 SNPs; ii) the most important climatic variables and genetic variants underlying local adaptation and iii) the association between climate and genetic variation. Genomic analyses revealed three major genetic clusters dividing populations in western, central, and eastern Canada. In parallel, we modeled BS growth as cumulated biomass using a random forest algorithm trained with dendroecological data and genetic cluster information. This model was then used to project growth until 2100 within a climate change context. The genetic clusters were then shown to have an influence on local adaptation and on responses of BS populations to climate change, with the western cluster being more impacted than the others. Among climate variables, mean annual climate moisture index, total annual precipitation, and total annual temperature range were best associated with genome-wide variation, and overlapped a major allelic transition between Central and Eastern genetic clusters, as shown by a gradient forest analysis. However, the random forest model also revealed that mean summer and autumn temperatures were the most relevant climate factors to consider for future adaptation to climate change, as high temperatures were detrimental to growth. Therefore, BS appears headed toward a general climate maladaptation, which may negatively impact the carbon sequestration potential of the species.

Characterization of organellar genomes in Santalum album L. (Indian sandalwood) to understand parasitism

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Progya Dasgupta[1]
Senthilkumar Shanmugavel[1], Muthulakshmi Eswaran[1], Modhumita Ghosh Dasgupta[1]
[1] Department of Plant Biotechnology and Cytogenetics, ICFRE-Institute of Forest Genetics and Tree Breeding, Coimbatore, Tamil Nadu, India.

Abstract: *Santalum album* L. (Indian sandalwood) is an economically and culturally important species belonging to the Santalaceae family, and is valued for its essential oil and fragrant heartwood. It is a facultative root hemiparasite parasitizing on vast spectrum of angiosperms. While several studies have dealt with the functional attributes of *S. album*, presently, the genomic footprints of parasitism in the genus *Santalum* is absent. In this study, organellar genomes of *S. album* were characterized to understand the effect of parasitism on these extra nuclear genomes. Chloroplast (cp) genome of *S. album* (NC_048953) was annotated with *Osyris alba* (NC_027960) cp genome as reference and was compared with previously published Cp genomes of 27 plants including autotrophs, hemiparasites and holoparasites. A total of 109 genes were predicted including 4 rRNAs, 31 tRNAs and 74 protein coding genes, with total GC content of 38.0%. Comparative analysis revealed considerable shrinkage of Cp genome caused by loss of five genes (*ndhA*, *ndhF*, *ndhH*, *ndhI, trnR-UCG*) and pseudogenization of 7 genes (*infA*, *ndhB*, *ndhC*, *ndhD*, *ndhE*, *ndhG*, *ndhK*), all of which are known to be involved in photosynthetic activity Phylogenetic analysis revealed three distinct clades with *S. album* being placed in hemiparasitic clade with phylogenetic relatedness to *Osyris alba* and *O. wightiana,* both belonging to the family Santalaceae. Mitochondrial (mt) scaffolds were assembled from leaf transcriptome of *S. album*, annotated and compared with complete mt genomes of three autotrophs and two hemiparasites under order Santalales. The annotation results revealed pseudogenization of three tRNAs and loss of protein coding genes *atp*9, *ccm*B, *ccm*Fc, *mat*R, *mtt*B, *rpl*2, *rpl*10, *rps*1, *rps*2, *rps*10, *rps*11 and *rps*12. Traces of Cp genes (*rpo*C2 and *ndh*H) were found in the mt genome, suggestive of possible horizontal gene transfer between the organellar genomes. The present study revealed that the lifestyle transition from autotrophy to parasitism led to gene loss, pseudogenization and horizontal gene transfer of photosynthetic genes in the organellar genomes of *S. album*. It also provided an insight into the probable effect of parasitism on reconfiguration of organellar genomes, specifically the chloroplast genome in parasitic plants.

Characterizing the Genome-Wide Impact of Tree Improvement in Scots Pine

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Tree breeders aim for improved trees that grow better, are well adapted to local conditions (e.g. Berlin et al. 2016 Silva Fenn 50), have sufficient variability, as it increases resilience to environmental changes and pathogen resistance, and will not suffer from inbreeding depression. To meet these goals, all stages of breeding and seed production (breeding populations and seed orchards) are to be carefully designed. Further, possible effects on diversity at different stages of the process should be monitored. To understand the effects of early stage breeding and selection on Scots pine in Finland, we compare the genetic composition of natural populations, plus trees, and an early breeding generation across the genome, using the newly developed SNP genotyping array for Scots pine, the Axiom PiSy50k. Further, we explore potential effects of different management and selection strategies on the genetic diversity of Scots pine with simulations. We find in general weak differences in genetic diversity between natural and plus trees. Likewise, we found little to no loss of overall genetic diversity in our simulated selections based on several traits. However, our findings highlight the importance of carefully accounting for ascertainment bias when assessing overall patterns of genetic diversity with a genotyping array. In our results, the small effects we found may be largely due to this bias, but, importantly, ascertainment bias has a smaller relative effect when apparent differences are larger as we illustrate with simulations. Overall, our study emphasizes the usefulness of the PiSy50k to monitor genetic diversity in Scots pine.

Forecasting through the lens of landscape genomics: local adaptation in the foundation species Nothofagus pumilio

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Climate change will alter relationships among genetic factors and environmental conditions, and thus it has the potential to change the selection pressures acting upon adaptive gene variants. The southern Andes mountain range presents an ideal study site because it contains two distinct orthogonal environmental gradients: temperature and day length (South-North) and precipitation (West-East), which allows us to disentangle environmental effects on genetic adaptation. We used the foundation tree species *Nothofagus pumilio* as a model because it inhabits a 2,000-kilometer-long range within these gradients. We assessed local adaptation patterns using a landscape genomic approach that encompassed a paired site sampling design, population structure analysis, and association analyses among genetics, environment, and phenotype for 493 adult trees within 20 sampling sites. Data sources include current and future projected environmental conditions, phenotype variables derived from annual increment tree rings, and over 47,000 SNPs from candidate genes related to growth, circadian rhythm, and stress response. Among our main results, we found that genetic groups were oriented along the north-south latitudinal transect, likely due to past glacial-interglacial cycles. Outlier tests and genotype-environment association analyses showed that *Nothofagus pumilio* has notable signatures of adaptation to current climate. Namely, 457 SNPs were strongly differentiated among subpopulations and/or associated with environmental covariates related to temperature, day length, and, to a lesser extent, precipitation. We extrapolated these findings across space and time to assess genomic offset and thereby predict the impacts of coming change. Since *N. pumilio* populations are adapted to current geographic configurations of environmental conditions including the static variable of day length, any new combinations created by climate change could have dire consequences for both natural adaptation and the practices of conservation and forest management.

Generation of genomic resources in Pterocarpus santalinus, an endemic high value tropical timber species for conservation of its genetic resources

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Modhumita Ghosh Dasgupta[1]
Shanmugavel Senthilkumar[1], Eswaran Muthulakshmi[1], Aiyar Balasubramanian[1], Muthusamy Muthupandi[1], Sivanantham Bhuvanam[1]
[1] ICFRE-Institute of Forest Genetics and Tree Breeding, Coimbatore, Tamil Nadu, India

Abstract: *Pterocarpus santalinus* Linn. f., popularly known as Red Sanders is a medium sized deciduous tree endemic to Southern parts of Eastern Ghats of India and is known for its deep red color, fragrant heartwood and wavy grained texture. Due to unsustainable harvesting, slow regeneration and habitat loss, the genetic resources have drastically reduced and the species has been classified as 'endangered' by IUCN and listed in Appendix II of CITES. Conserving the available genetic resource in this endemic species is essential to minimize the risk of extinction under future environmental change. With the aim to generate genomic resources in *P. santalinus*, near-complete chloroplast genome was assembled from leaf transcriptome dataset and phylogenomic analysis revealed closest relation with *P. dalbergioides*, a species endemic to Andaman Islands in India. The analysis could also demarcate the African and Asian species of *Pterocarpus.* The chloroplast genome was mined and five novel barcodes including *ndhF-rpl32, atpA-trnR, trnH-psbA, psbA, psa1-ycf4* were identified and validated for species discrimination. Concurrently, a high quality draft genome was assembled using short and long reads generated from Illumina and Oxford Nanopore Sequencing platforms and the hybrid assembly showed 99.60% genome completeness. The haploid genome size was 541 Mb with high proportion of repetitive sequences (29%). The. A total of 51,713 consensus gene set was predicted and 31,437 were functionally annotated. The age of whole genome duplication event was dated at 30-39 mya, indicating genome duplication event during the Eocene period. Subsequently, whole genome re-sequencing of 36 diverse genotypes spanning the complete distribution range of the species was conducted and more than 20 million variants were predicted, with maximum SNPs in the intergenic regions. Understanding the spatial genetic structure and adaptive diversity of *P. santalinus* populations using genome-wide SNP markers is in progress. The unprecedented genomic information generated in the study is expected to provide deeper insight into the population divergence in relation to its endemic nature. The genome-scale markers will accelerate trait based breeding program, facilitate development of conservation strategies and aid in development of diagnostic tool for timber forensics.

Genetic diversity, population structure and demographic history in Fagus crenata

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

[5] Department of Forest Molecular Genetics and Biotechnology, Forestry and Forest Products Research Institute

Abstract: Nowadays, by applying the population genomic data generated by next generation sequencing, evolutionary history and the genetic background associated with local adaptation in non-model species can be studied more easily than in the past. Japanese beech (*Fagus crenata* Blume, Fagaceae) is dominant in tracts of the cool temperate deciduous broad-leaved forest in Japan. Although its current genetic diversity and population structure have been evaluated using allozymes, organelle DNA and microsatellites (SSR), the evolutionary history of populations, i.e., population demographic history, remains unclear. In this study, by applying the SNP data generated using RAD-seq and a new reference genome of *F. crenata*, we first re-evaluated genetic diversity and population structure in *F. crenata* populations distributed across the species' range. As revealed by the previous study with SSRs, two genetically divergent lineages, Japan Sea and Pacific were detected, and the latter was further divided into northeastern and southwestern lineages. The clinal decrease from southwest to northeast in within-population genetic diversity, revealed by the SSR study, was not detected with the SNP data. Next, to infer the population demography of *F. crenata*, we constructed four population divergence models with parameters based on the population structure we found. The best fit model was decided by the maximum likelihood estimation of parameters using coalescent simulation and the calculation of Akaike information criteria. According to the best fit model determined by coalescent simulation, it was inferred that the ancestral population diverged into two lineages, Japan Sea and Pacific, before the Quaternary, and the Pacific lineage then diverged into northeastern and southwestern lineages during the Pleistocene. The probable vicariance due to the global cooling occurred during the Pliocene to the Pleistocene may have resulted in the present three lineages. The estimated parameters suggest that population sizes were generally increasing and that secondary contacts that occurred among the three lineages resulted in significant increases in gene flow rates after the late Pleistocene. These findings are the baseline for understanding vulnerability, resilience and adaptation to climate change and addressing conservation and sustainable management, for *F. crenata* and beech forest ecosystem.

Genetic effects of continuous cover forestry

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Promotion of uneven-aged forestry with selective cuttings in Scandinavia have raised questions on the genetic consequences of CCF (Continuous Cover Forestry) practices. The long history of high grading, exploitative timber harvesting practice, resulted in regionally poorly growing, sparse forests and a worry of negative effect of the methods to genetic composition of forests, and to future forest health, productivity, and stem form of trees. While modern methods of CCF practices deviate strongly from high grading, it is still important to study genetics of this management method, e.g., for recommendations on selection harvesting practices.

We study the degree of inbreeding, spatial genetic structure and kinship structure of experimental uneven-aged forest plots (ERIKA sites) that have undergone three cuttings of selective harvesting between 1980-2020 and where e.g., growth, demography, and flowering of the trees have been followed. Three cohorts: all reproducing trees, and samples from understory and saplings were genotyped with a 50K snp chip.

The degree of inbreeding was low in all cohorts. However, substantial spatial genetic structures were found with rather high degree of kinship between individuals within and between cohorts and study plots. With the genetic information, and other existing data from ERIKA plots, we assess the possible effect of selection harvesting to growth characteristics of trees and genetic composition of CCF forests. Detailed genetic analyses will help to assess sustainable methods in selection harvesting for contemporary continuous cover forestry.

Genetic Isolation in a high-elevation marginal population of Sakhalin fir: implications of pollen immigration revealed by nuc- and cp-SSRs

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Keiko Kitamura[1]
Atsushi Nakanishi[1], Wataru Ishizuka[2]
[1] Hokkaido Research Centre, Forestry and Forest Products Research Institute, Japan
[2] Corporate Department, Hokkaido Research Organization, Japan

Abstract: Global temperatures are rising, despite some fluctuations, and the rate of increase is particularly large in the high-latitude regions of the Northern Hemisphere. The effects of potential climate change that may occur in the near future have already been observed in alpine ecosystems. According to climate change prediction models, habitats suitable for alpine vegetation will disappear or decrease substantially along with changes in subalpine forest vegetation. However, these predictions, based on wide-ranging climatic conditions, do not take into consideration certain practical factors that limit vegetation change. As for the establishment of forest vegetation, there are various constraints such as seed dispersal distance, time required for seedlings to grow and mature, biotic and abiotic competition, and emergence of new diseases and pests. In particular, the low genetic diversity of marginal populations can be critical. In order for a population to adapt and evolve to a new distribution area, it is necessary to maintain genetic diversity in the source population. However, a decrease in genetic diversity is often detected in populations at the edge of a distribution limit; i.e., the forefront of distribution expansion, and this is considered to be one of the factors that limit distribution. Sakhalin fir (*Abies sachalinensis*) is a major component of mixed coniferous and broad-leaved forests in northern Japan. This species has a wide vertical distribution range and the species traits such as growth, morphology, physiology, and phenology, vary with altitude. The distribution limit of the species reaches the subalpine zone, where it forms a small low-density patch population adjacent to the alpine zone. In this study, population differentiation was analyzed among populations of Sakhalin fir at different elevations by nuclear and paternally inherited chloroplast microsatellite loci. The results showed that the high-elevation marginal population was genetically distinct from populations at lower elevations. This could be due to certain restrictions in gene flow in the subalpine zone. Our findings also include paternal identification of seeds at the high-elevation margin. Along with flowering phenology, we discuss the maintenance and acquisition of genetic diversity in Sakhalin fir populations at the high-altitude distribution limit.

Genetic variation within and among populations underlies adaptation to climate in a Mediterranean pine species

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Genetic variation is the raw material for population adaptation to climate change. Although forest trees often exhibit extensive genetic variation within and among populations, they may be particularly at risk under climate change due to their long generation times and slow migration rates. We studied the genetic variation within and among 34 rangewide populations of maritime pine (*Pinus pinaster* Ait.) using about 10 000 single nucleotide polymorphisms (SNPs) and phenotypic traits from five clonal common gardens located within the species natural range. Within-population quantitative genetic variation for early height growth, a fitness-related trait, was lower in maritime pine populations from climates with cold winters. This reduced genetic variation may result from adaptation to harsh climates but may also hinder future adaptation to novel climates. Genetic variation among populations was also associated with large-scale climatic gradients, and we predicted the extent to which the current gene-environment relationships will be disrupted under climate change for each population, using a proxy of potential maladaptation, often referred to as the *genetic offset*. As the genetic offset predictions were highly dependent on the modelling approach used to generate them, we evaluated which approach best explained phenotypic data from common gardens and mortality rates from natural populations, using National Forest Inventory Data from France and Spain. Approaches to predict potential maladaptation in natural populations are still under development, in particular for species with strong population structure such as maritime pine, and our results confirm that their predictions should not be used in conservation or management strategies without validation steps based on independent data.

Genetics of adaptive seedling traits in Scots pine - views from natural and breeding populations

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Seedling traits in many tree species show systematic clinal variation, which implies important adaptive roles for these traits. Seedlings with northern origins set their bud earlier, grow less, and have higher frost tolerance than seedlings from southern origins. We study timing of bud set, cold tolerance and seedling height in Scots pine, a widespread conifer species with important economical role in nordic countries. Data is derived from both natural and breeding populations mainly in Southern Finland.

GWAS (Genome Wide Association Study) analyses are utilized to find the genetic loci controlling the trait variation. Multilocus analyses are best fitted for this data, as strong single locus effects are not found in a sample of unrelated trees in Southern Finland. Earlier multipopulation analysis shows genetic heterogeneity between northern and central European areas in timing of bud set.

Genetic prediction (GP) models are built and evaluated to assess the feasibility of inclusion of adaptive seedling traits into genomic selection models in Scots pine breeding. We do not find strong trade-offs with traditional breeding targets such as growth and external stem/branch quality. Phenotypic comparisons between natural and breeding populations show that artificial selection for better growth and exernal qualities in breeding population has not affected the distributions of seedling traits so far.

Analyses of natural selection in the seedling traits show that within population selection pressure is moderate by the age of 9 years, and that earlier bud set and taller status (compared to population average) are favored. Within population distribution, and therefore selection pressure, is likely affected by gene flow from south. Seedling traits seem genetically mostly independent, as correlations within population are rather weak despite strong between population correlations.

Genome-wide association of water use efficiency traits in Puerto Rican populations of Pterocarpus officinalis to better inform riparian restoration

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Tropical wetlands are some of the most threatened ecosystems in the world due to climate change, projected sea level rise, agriculture and other land development practices. Tropical wetlands are also some of the most productive ecosystems in the world and offer many essential ecosystem services. *Pterocarpus officinalis* creates swampy wetlands in riparian and coastal areas across the neotropics. While *P.officinalis* forests create habitat for a variety of species and offer many essential ecosystem services; it is an understudied species and the IUCN lists the species as near threatened. Restoration efforts are key to preserving this species along with the habitat and ecosystem services it provides. In order to better inform restoration efforts, the species' physiology and genome-wide diversity needs to be better understood, because the limited studies in *P.officinalis* have mostly examined salinity tolerance and genetic diversity using a small number of microsatellites. The goals of our study were to examine, and identify candidate loci for, water use efficiency and leaf traits across 12 locations of *P.officinalis* located in Puerto Rico, so that future restoration efforts can be better informed and more successful. Seed stock from 9 mother trees was collected from each of our 12 locations across Puerto Rico and planted in a nursery in San Juan, Puerto Rico. DNA was extracted from 7-10 individuals from each of the 12 locations and sequenced using a whole-genome sequencing platform with an observed coverage of 15-20X per sample. 13 Water use efficiency traits were collected from individuals in 11 of the 12 locations. A de-novo genome assembly was created and used to call single-nucleotide polymorphisms (SNPs) for each sample. Trait differences and associations were examined at a multivariate and univariate level. A high amount of trait variation was observed within and among locations for each trait. A significant effect of longitude, elevation and isothermality was observed for physiological traits, indicating that restoration effects may need to use seed sources specific to their longitude, elevation and that have similar temperature ranges.

Genome-Wide Identification and Expression Analysis of GDP-D-mannose pyrophosphorylase (CYT) and KATANIN (KTN) in Corymbia citriodora

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Chubiao Wang[1, 2]
Wenliang He[2], Yuduan Ou[1]
[1] Guangdong Ocean University, Zhanjiang 524088, China
[2] Research Institute of Fast-Growing Trees, Chinese Academy of Forestry , Zhanjiang 524022, China

Abstract: The vascular cambium serves as the primary source of wood production, with GDP-D-mannose pyrophosphorylase (GMP, or named CYT) and microtubule severing enzyme KATANIN being present in its cells. GMP provides GDP-D-mannose for cell wall carbohydrate biosynthesis, protein glycosylation, and ascorbic acid (vitamin C) biosynthesis, while KATANIN is responsible for maintaining ordered microtubule structures within cells. In this study, we performed genome-wide identification and comprehensive analysis of CcCYT&CcKTN genes in *Corymbia citriodora*, a eucalypt species, by bioinformatics methods, and the expression of the CcCYT&CcKTN genes was specifically analyzed by qPCR. As a result, 8 CcCYT and 4 CcKTN genes were identified. Among them, CcCYT4 and CcKTN4 genes exhibited highly homology with AtCYT1 and AtKTN1, respectively. Our findings indicate that, with the exception of CcCYT1, 8 and CcKTN2 genes, the expression levels of all other genes exhibited a positive correlation with diameters at breast heigh (DBH). This suggests that these genes play a crucial role in secondary xylem synthesis, particularly the CcCYT4 and CcKTN4 genes. The findings will enhance our comprehension of the intricacy of CcCYT&CcKTN across diverse DBHs and furnish valuable insights for future functional characterization of specific genes in *C. citriodora.*

Genomic Imprinting in Scots pine (Pinus sylvestris)

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Robert Kesälahti[1]
Sandra Cervantes[1, 2], Tanja Pyhäjärvi[3]
[1] Department of Ecology and Genetics, University of Oulu, Oulu, Finland
[2] Biocenter Oulu, University of Oulu, Oulu, Finland
[3] Department of Forest Sciences, Faculty of Agriculture and Forestry, University of Helsinki, Helsinki, Finland

Abstract: Scots pine has an excellent ability to adapt to local environments, proven by its wide distribution across Eurasia. Genomic imprinting could be one of the factors behind its local adaptation. Genomic imprinting is an epigenetic phenomenon where the expression level of a gene depends on the parental origin. It is caused by epigenetic modifications ("imprints") made to genes, regulatory regions, and histones. These imprints can completely silence the expression of a gene or repress it. Imprinted genes have been found in angiosperm, mammal, and insect species. Numerous theories have been developed for the origin of this phenomenon, but none is widely accepted. According to the popular kinship theory, genomic imprinting is caused by competition between the parents for the allocation of resources to the development of offspring. This competition mainly takes place in the tissues in charge of resource allocation for the developing offspring: endosperm in angiosperms and placenta in mammals.

We investigate whether genomic imprinting also exists in gymnosperm species, using Scots pine as our model species. Gymnosperms have a haploid maternally inherited endosperm. The parental conflict, described in the kinship theory, cannot take place in the haploid megagametophyte. Alternative theories for the origin of genomic imprinting do not require parental conflict. As conflict could exist in systems where coadapted maternal-offspring traits have large fitness effects. Imprinted genes have also been found in embryos in both angiosperms and mammals, thus hinting at the possibility of another reason behind it.

Reciprocal crosses, required for the identification of imprinted genes, were performed for selected Scots pine pairs and seeds collected. RNA-seq was performed for the embryonic tissues and exome capture for the megametophytic tissues of the same seeds. Haploid megagametophyte allows the identification of maternal and paternal alleles. We can then compare the expression levels of a gene when it has been inherited both paternally and maternally. Previous results of allele-specific expression in Scots pine indicate abundant allele-specific expression in embryos. This ongoing study aims to provide information on whether genomic imprinting has evolved convergently in angiosperms and animals or has a shared history.

Genomic variation of European beech across its distribution range reveals patterns of local adaptation and future maladaptation

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Niels A. Müller[1]
Cornelia Geßner[1], Malte Mader[1], Céline Blanc-Jolivet[1], Matthias Fladung[1], Bernd Degen[1]
[1] Thünen Institute of Forest Genetics, Grosshansdorf, Germany

Abstract: Local adaptation is key for ecotypic differentiation and species evolution. Understanding the underlying genomic patterns allows the prediction of future maladaptation and ecosystem stability. We used whole-genome resequencing to analyze more than 1000 individuals from 100 range-wide populations of European beech (*Fagus sylvatica*), one of the most important forest tree species in Europe. We show that genetic variation closely mirrors geography. Putatively adaptive variation identified by genotype-environment and genotype-phenotype associations exhibits highly polygenic architectures, involving thousands of associated sequence variants across the genome. By modelling the 'genomic offset' of these sequence variants under projected future climate conditions, we identify broad- and fine-scale variation highlighting geographic regions as well as populations at potential elevated risk of mortality or local extinction. Our results emphasize the importance of considering natural genetic variation within species for forest conservation under climate change.

New insights into the population structure and evolutionary history of two closely related Picea species from a large hybrid zone

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Geographic patterns in genetic diversity are the result of the complex interplay of demographic and evolutionary history of populations with local adaptation. Gaining insight into the forces that shaped genetic diversity is of paramount importance if one wants to be able to predict species' responses to climate change. Norway Spruce (Picea abies) and Siberian spruce (P. obovata) are closely related species which dominate the boreal forests in Eurasia. Following main glacial cycles, the two species probably did not evolve independently but entered into contact several times. Studies based on mitochondrial DNA or on nuclear DNA suggest a recent introgression from P. obovata into the eastern range of P. abies. However, this pattern can be due to a lack of sampling in the westernmost range of P. obovata, precisely on the hypothetic hybrid zone between the two species. In the present study, we collected Picea individuals from 55 populations, ranging from the European mainland and Fennoscandia to the Yenisei River far east, including a dense sampling in the North-Baltic and western Russia to cover the main hybrid zone between P. abies and P. obovata. A total of 546 individuals from P. abies, P. obovata, and putative introgressed individuals were genotyped at 480K SNPs using exome capture for the past demographic and admixture history inference. Nine well-separated clusters were identified despite extensive current gene flow between the two species. Estimated effective migration surfaces (EEMS) identified multiple migration barriers as well as corridors, suggesting a biased gene flow from P. obovata toward the northern range of P. abies and a significant contribution of P. abies genetic background into P. obovata southern domain. Demographic history inference suggested multiple historical contacts between the two species and two cryptic refugia in the current hybrid zone during LGM. The expanded diversity through introgression possibly increases the capacity of the two species to cope with changing environments. This study sheds light on the complex dynamics between the two species and paves the road for further analyses on the potential role of adaptive introgression contributing to long-term adaptation to climate change.

Probing the Role of Adaptive Introgression in Timberline Ecosystems' Response to Climate Changes Using Exome Capture Sequencing

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Living species have adapted to climate changes through migration, mutations, genetic diversity, and genetic introgression. Adaptive introgression, which involves acquiring advantageous traits from closely related species, enables faster environmental adaptation. Understanding this process is crucial to assess adaptation to future global warming.

Timberline ecosystems, as highlighted by the Intergovernmental Panel on Climate Change (IPCC), are known to be vulnerable to global warming. Japanese stone pine (*Pinus pumila*), which grows in timberline zones in Japan and the cold regions of northeastern Eurasia, is expected to have faced the challenge of adapting to climate changes, particularly warming.

In Japan, organellar DNA introgression is observed between *P. pumila* and the closely related *P. parviflora*, which grows in warmer environments. Introgression from *P. parviflora* may have contributed to *P. pumila*'s adaptation to past climate changes, however, previous studies lack nuclear genome-level analysis due to the large genome size of pinus species.

To compensate for this issue, we extended the HyRAD-seq method and implemented a new cost-effective probe design for exome capture. First, we collected leaves of *P. pumila* and *P.parviflora* from mountain areas in Japan and extracted DNA and RNA. RNAs were used to construct probes for exome capture sequencing, while DNAs were used to prepare next generation sequencing libraries, then target regions were captured with the probes.

The population structure and the admixture status of the two species exhibited signs of introgression, aligning with expectations based on species divergence and population distances. These results indicated the effectiveness of exome capture using cost-effectively designed probes for population genetic analysis of species with large genomes.

Further analysis will focus on identifying admixed genomic regions and their correlation with environmental variables. The findings from this research will provide valuable information to assess the adaptability of timberline ecosystems to global warming.

Rapid differentiation, ecological stasis, and edaphic adaptation during the temperate to tropical transition in Mexican firs

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Understanding and disentangling the main drivers of local adaptation within and between species is a pre-requisite of any forest breeding, management, and conservation plan. Insights from past adaptive events may indeed help predicting future evolutionary trends and fine-tunning specific management actions. However, differentiating between adaptive and non-adaptive processes may be complex, particularly for long-lived and slowly-evolving species, like conifers. We explored which evolutionary processes occurred during the migration and diversification of firs (*Abies*, Pinaceae) between the Southwestern United States and Central America at various geographic and evolutionary scales. Using genomic data, we inferred a well-resolved phylogeny that showed four main fir lineages that fitted a North-South isolation by distance framework. Such lineages further had diminishing values of *Ka/Ks* towards the Equator, indicating reduced purifying selection efficiency. Groups showed a strong phylogenetic signal for morphological and climate variation, suggesting a random walk model of differentiation. However, early adaptation to tropical conditions was inferred in the ancestor of the southernmost firs, as all modern southern taxa were climatically differentiated from the northernmost species (*A. concolor*). Interestingly, autapomorphic traits were observed for soil properties, suggesting possible species-specific adaptations. We explored such adaptations in *A. religiosa* at the range-wide and local (within-population) scales. Genome-soil association analyses revealed a series of candidates correlated to various soil traits. Multilocus clines indicated a significant contribution of geographic proximity to both soil and candidate gene variation, which is consistent with the geological history of the mountains where this species is distributed. Altogether, our results show that a combination of non-adaptive and adaptive processes operated along different environmental and phenotypic axes during the southward migration of this plant lineage from North America, and its subsequent radiation in the Neotropics. Looking beyond climate change is thus advised when planning future forest management plans. For instance, integrating soil variation and the accumulation of partially deleterious variants should be a priority for such plans.

Reassessing the role of local seed sources in climate change - Exploring the genetic structure and adaptive potential of white oak species in Europe

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Simon Jansen[1]
Nicolaos Tourvas[2], Devrim Semizer-Cuming[3, 4], Colette Blyth[1], Deborah Leigh[5], Christian Rellstab[5], Aravanopoulos Filippos[2], Zeki Kaya[6], Pelin Acar[7], Cigdem Kansu[6], Funda Özdemir Değirmenci[6], Asia Çiftçi[6], Charalambos Neophytou[3]

[7] National Botanical Garden of Turkey, Ankara (TAGEM), Turkey

Abstract: As climate change progresses, it is likely that the pace of forest tree adaptation will lag behind changing environmental conditions. Therefore, the transfer of forest reproductive material (FRM) from seed sources that are well-adapted to the anticipated conditions (known as assisted migration) has been proposed as a promising strategy to ensure future forest resilience. However, each large-scale transfer of FRM alters the natural genetic structures within populations, potentially even augmenting the lag in adaptation through selective consideration of specific adaptive traits while neglecting others. Consequently, the consideration of regional-scale environmental variation in studies concerning the local adaptation of tree species is crucial, as it holds the potential to unveil pre-adapted seed sources at a localized scale. Hence, it is particularly meaningful to explore the genetic variation of species with wide ecological amplitude and distribution ranges, such as the three closely related white oak species *Quercus robur*, Q. petraea, and Q. pubescens. Within the framework of the BiodivERsA project 'ACORN', an extensive sampling was conducted, encompassing over 120 populations of the aforementioned oak species. The sampling strategy was designed to encompass a wide geographic range from Central Europe to the Eastern Mediterranean Basin as well as contrasting site conditions on a regional level of the sampled populations. Using a comprehensive set of genetic and genomic tools, our objective was to identify populations that exhibit a high adaptive potential in a changing climate. We performed genome-wide environmental association analyses, aiming to uncover signatures of local adaptation. Specifically, we investigated the association of certain genes and genomic regions with drought-related environmental parameters, as well as the presence of a shared signature of drought adaptation among the populations. Our study provides valuable insights into the genetic diversity and adaptive potential of the three white oak species, which can serve as a guide in identifying potential candidates for future seed selection and breeding programs. Furthermore, our research underscores the significance of considering genetic variation and local adaptation in the development of effective conservation and management plans for white oak species, but also for other tree species facing similar challenges in the face of climate change.

Resilience of genetic diversity in forest trees over the Quaternary

Abstract: Past environmental changes have shaped the demographic history and genetic diversity of natural populations, yet the timescale and strength of these effects have not been investigated systematically and simultaneously for multiple, phylogenetically distant species. We performed comparative population genomic analyses and demographic inference for seven widely distributed and ecologically contrasted European tree species across their natural ranges, namely *Picea abies*, *Pinus sylvetsris*, *Pinus pinaster*, *Quercus patraea*, *Fagus sylvatica*, *Populus nigra* and *Betula*

pendula. While patterns of genetic diversity and differentiation were species-specific and best explained jointly by geographic range and dispersal ability, ancient population expansion events were shared and largely synchronous across species. Effective population sizes increased or remained stable over time, indicating that despite major changes in their geographic ranges and extents, dominant forest tree species have been remarkably genetically resilient to the drastic environmental challenges of repeated glacial cycles. Our results suggest that forest trees with large geographic distributions might be able to cope better than initially thought to current climatic change and therefore have important implications for the management of genetic resources. This study is major contribution from GenTree consortium through a European Union's Horizon 2020 project "Optimizing the management and sustainable use of forest genetic resources in Europe".

Role of hybridization in plastic and heritable changes leading to adaptation to warming climates in Douglas-fir

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Amanda De La Torre[1]
Kailey Baesen[1], Pablo Pelaez[1]
[1] Northern Arizona University, Flagstaff, Arizona, USA

Abstract: Hybridization and environmental stress may produce widespread genomic and epigenomic changes that can be transmitted to subsequent generations and may contribute to the ability of plants to persist in variable environments. This research project investigates the contribution of hybridization to genomic and epigenomic changes that could lead to increased growth and drought tolerance in hybrids between the two varieties of the economically important timber species Douglas-fir (*Pseudotsuga menziesii var. glauca and var.menziesii*). Warming temperatures and more frequent heat events will reduce the growth capacity of the commercial, less drought tolerant, Douglas-fir coastal variety. In contrast, the DF interior variety is more drought-tolerant, but grows slowly therefore is not ideal for commercial purposes. Our studies suggest extensive asymmetric introgression in two main contact zones in the US and Canada. Intervarietal hybrids between varieties show increased drought and heat tolerance than pure varieties, which could be due to transgressive segregation or adaptive introgression. The effects of hybridization across the species' geographic distribution range are also discussed.

The role of open chromatin in local adaptation of Scots pine (Pinus sylvestris) and silver birch (Betula pendula)

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Jenni Sirén[1]
Jaana Vuosku[2], Sonja T. Kujala[3], Katri Kärkkäinen[3], Tanja Pyhäjärvi[1]
[1] Department of Forest Sciences, University of Helsinki, Finland
[2] Ecology and Genetics Research Unit, University of Oulu, Finland
[3] Natural Resources Institute Finland (Luke), Oulu, Finland

Abstract: As sessile organisms, plants depend on their ability to respond to environmental cues. Adjusting the timing of growth and reproduction will be essential in the changing climate as the combinations of light, temperature, and biotic conditions change. Forest trees are excellent model species for understanding the genomic determinants of local environmental adaptation because they are often widely spread, occupy diverse conditions, and have hereditary, adaptive phenological differences among populations. On the molecular level, regulatory regions have been shown to be important for adaptation to different environments because they regulate gene expression according to internal and environmental cues. Regulatory regions are often found in non-coding open chromatin parts in the genome. The location of open chromatin is a heritable trait and therefore a potential subject to natural selection which indicates its importance in local adaptation.

Interestingly, despite being separated by 300 million years of divergence, Scots pine (*Pinus sylvestris*) and silver birch (*Betula pendula*) display similar clinal patterns of growth cessation timing across a latitudinal gradient in common garden studies. The genomes of the species, however, are vastly different with Scots pine having a 22 Gbp genome, of which only 0.2% is coding sequence, and silver birch having a 440 Mbp genome with roughly 10% of coding sequence. The disparity indicates possible differences in the size of non-coding open chromatin locations between the species and thus differences in evolutionary responses to environmental selection pressure.

ATAC-seq is a method that allows genome-wide identification of open chromatin location, and nucleotide-level regulatory variation coinciding with the open chromatin. In this study, we will use it to sequence the open chromatin and to identify population level differences in the open chromatin amount and location as a response to day-length changes. When coupled with RNA-seq data on differential gene expression, the information on regulatory variation obtained with ATAC-seq allows the linking of the regulatory variation to genes that confer the phenotypic response as a result of local adaptation. The results are important for understanding the molecular basis of forest tree adaptation as well as key differences in adaptive dynamics between conifers and broadleaved forest tree species.

Understanding the genetic basis of silver birch adaptation to local environments and disease in Britain

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

Abstract: Bold annual targets have been set for planting new woodland in Britain by 2050, within the context of a more extreme climate and increasing pathogen prevalence. The genetic diversity of existing native tree populations represents an invaluable resource to mitigate these threats, although a limited understanding exists of the scale and pattern of this adaptive differentiation.

Here, we present data from two different - but complementary - approaches to investigate genetic adaptation in UK silver birch (*Betula pendula*) to environmental stress. The first method utilised common-garden experiments for silver birch (ie. forestry provenance trails) first established in 2003. Whole genome sequence data was generated for approximately 2000 trees, and performance and adaptive traits such as tree growth, tree health (prevalence of dieback), and water use efficiency (C^{13} discrimination) were recorded. The second experiment examined the genomes of natural populations of *B. pendula* sampled by the UK National Tree Seed Project (UKNTSP), identifying genetic loci that exhibited patterns of polymorphism that correlate with environmental variables (ie. a genome-environment association study, or GEA).

Combining genomic analyses of provenance trials with GEAs on natural populations provides a two-pronged approach to determine the genetic basis of adaptation. This project, conducted by Royal Botanic Gardens Kew and Forest Research as part of the Centre for Forest Protection, sought to harness both methods to discover the extent and pattern of genetic diversity in silver birch in Britain. Cross-validating provenance trial and GEA approaches will allow adaptive trajectories to be predicted at a wider scale and inform seed sourcing for new plantings, and test the efficacy of both methods to help understand the utility of applying them to other British tree species.

Variable maladaptive outcomes characterize responses of southwestern white pine populations to changing climates across southwestern North America

T3.8 Forest genomics as a vantage point to biodiversity and adaptation under global change

[5] Department of Biological Sciences, Northern Arizona University, Flagstaff, AZ, USA

Abstract: Populations of forest trees are often adapted to local climates. As local climates change, mismatches occur as rates of climate change usually outpace evolutionary changes to adaptive genetic architectures. The magnitudes of these mismatches quantify accumulated degrees of maladaptation, which can inform future modelling and management activities. Here, we use a genotype-phenotype-environment correlation framework to quantify standing and predicted levels of maladaptation for southwestern white pine (*Pinus strobiformis* Engelm.). More specifically, we quantify levels of maladaptation across 51 pairs of high-low elevation plots of southwestern white using 70,000 SNPs, predicted dendrophenotypes based on a previous genome-wide association study, and past, current, and future climate models. We document southwestern white populations as locally adapted to climate, although current patterns are confounded with accumulated degrees of maladaptation relative to past climates. Predicted degrees of maladaptation to future climates vary drastically across the sampled range, with mismatches based on allele frequencies differing from those based on predicted dendrophenotypes. In general, however, there appears to be sufficient genetic diversity to sustain evolutionary responses to changing climates across populations of southwestern white pine, especially with active and informed management of connectivity across adaptive gene pools. We leverage these results to examine best practices for use of genomic offsets in forest management across the southwestern United States.

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

A policy mix for achieving ambitious goals on forest landscape restoration: Analyzing coherence and consistency in forest related policy.

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

Musse Tesfaye Gebre[1]
Jude Ndzifon Kimengsi[1], Lukas Giessen[1]
[1] Chair of Tropical and International Forestry, Faculty of Environmental Sciences, Technische Universität Dresden, Dresden, Germany

Abstract: Due to the increasing global trends of land degradation and deforestation, the concept of forest landscape restoration (FLR) has gained recognition worldwide as an approach that complements cross-sectoral integration and aims to restore multiple forest ecosystem services across a broader landscape. Within this context, numerous studies have emphasized the significance of aligning policies across different sectors and integrating them effectively. However, existing studies often fail to adequately capture the intricate and dynamic nature of integrated policy goals and instruments across various policy domains. This study argues that addressing this gap requires a deeper understanding of the elements and characteristics of policy (mix). This involves scrutinizing policy instruments in various domains to gain insight into complex policy design problems. In this regard, we present a new methodological approach, the Cross-Impact Matrix (CIM), to analyze the interaction between goals and instruments as a specific characterization of policy mix in FLR related policies. We demonstrate the proposed concept and methodology by utilizing the example of Ethiopia's policy aimed at achieving comprehensive restoration targets. The results reveal varying levels of coherence based on 121 interactions among eleven goals in the CIM. Additionally, the consistency of instruments was analyzed through 2116 interactions among 46 instruments. Based on these interactions, certain regulatory instruments, such as the acquisition and use of agricultural land, exhibited a negative ripple effect throughout the system. On the other hand, the 'Reducing Emissions from Deforestation and Forest Degradation' (REDD+) creates a positive and conducive environment for implementing other instruments. In conclusion, this paper emphasizes the importance of examining the connections between policy integration and policy mix within the context of FLR, to envision congruent outcomes.

Forest and Landscape Restoration Opportunities Assessments for Mt. Kulal Biosphere Reserve and Mukogodo forest in Kenya

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

Jonah Kiprop[1]

[3] Ministry of Environment Climate Change and Forestry

Abstract: Forest and landscape restoration has been a national priority of many countries in the context of climate change and the rapid reduction of forest areas in the last few decades. By enhancing carbon sequestration and boosting carbon sinks, forest restoration is a key strategy to reduce climate change. In Kenya, initiatives are being made to restore the country's natural forests and landscapes, which are essential for delivering environmental services like carbon sequestration, biodiversity preservation, and watershed protection. In addition, forest restoration will play a key role in achieving Kenya's commitment of restoring 5.1-million-hectares by 2030 under the Bonn Challenge and AFR100. Successful restoration is achieved by strategically addressing the drivers of land degradation and analysing feasible restoration opportunities suited for each landscape. It is against this backdrop that Sub-National Forest Landscape Restoration Assessment (SNFLRA) was undertaken for Mt. Kulal biosphere reserve and the Mukogodo forest landscapes in Kenya using the Restoration Opportunities Assessment Methodology (ROAM). The SNFLRA process took into cognizance of the importance of stakeholder engagement throughout the process. The results of the SNFLRA identified the following as feasible restoration options and area within the two landscapes: Rehabilitation of degraded natural forests (46,687 ha); Agroforestry on Cropland (7,072.2 ha); Tree-based Buffer Zones along roads (6,710.44 ha); Tree-based Buffer Zones along Water Bodies and Wetlands (1,965.4 ha); and Rangeland's restoration (360,118 ha). In terms of economic analysis of the restoration options, the findings revealed that the transition for each option is economically viable since they have the ability to pay for themselves within a 30 -year time period. This analysis provides information necessary to design Forest and Landscape Restoration Interventions that can be implemented with specific attention paid to the severity and type of degradation in these areas, and the contributions landscape restoration can make to food security, resilience against climate change, and biodiversity conservation.

Forest landscape restoration (FLR) policy program in a developing country: Ecosystem vs community development discussion

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

Md Nazmus Sadath[1]
Md Saifur Rahman[2], Abdullah Al Mamun[1]
[1] Forestry and Wood Technology Discipline, Khulna University, Bangladesh
[2] Ministry of Environment, Forest and Climate Change

Abstract: The United Nations has declared 2021- 2030 as the decade of forest landscape restoration (FLR). Globally, there are over two billion hectares of degraded forests that need to be restored. Like other tropical countries deforestation and forest degradation is an issue in Bangladesh too, hence the forest ecosystem restoration with native species in degraded forest areas in Bangladesh has emerged as an essential policy program of Bangladesh forest sector. This study is focusing on the restoration policy programs implementation success, which is measured by how well the ecosystem functions and its synergy with livelihood context of the forest people. The study was carried out in the Cox's Bazar Forest division of Bangladesh. Content analysis was applied to analyze policy program documents. The research involved site assessment using the site survey method to collect the information regarding degraded sites. Additionally, the study applied individual interview and focus group discussion to identify forest people's perception on the FLR policy program. The study finds that the restoration effort has initial success in terms of replanting and enrichment planting. However, the forest people's perception on the restoration species choice is not in synergy with the interest of the forest administration. There is an interest conflict among the community and the forest administration regarding the policy program outcome. 70% of the forest people are in favor of fast-growing timber species against the slow growing native species which are chosen for habitat restoration. From the policy program dimension, the study finds that there is lack of policy coordination among the different sectors, especially the forest land scape restoration policy program is facing challenges from the country's foreign policy agenda of that region along with economic development agendas.

FOREST LANDSCAPE RESTORATION IN HIMALAYA COMMUNITY FOREST: BRIDGING FOREST MANAGEMENT AND SUSTAINABLE DEVELOPMENT GOALS

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

HONEY BHATT[1, 2]
[1] Honey Bhatt, Govind Ballabh Pant National Institute of Himalayan Environment, (GBPNIHE), Kosi- Katarmal, Almora, Uttarakhand, India.
[2] Harshit Pant Jugran, Govind Ballabh Pant National Institute of Himalayan Environment, (GBPNIHE), Kosi- Katarmal, Almora, Uttarakhand, India.

Abstract: The Himalayas, a region of enormous ecological significance, reflects a dynamic and complex landscape that requires immediate attention for constructive Forest Landscape Restoration (FLR) efforts. This mountainous terrain harbors diverse forest ecosystem crucial for climate regulation, biodiversity conservation, and wellbeing of local communities. However, the Community managed Forests (CFs) pertinent to Himalayan region plays a significant role in the landscape formation, its management and sustainable conservation.

In our study, we examined the status of Forest Landscape Restoration (FLR) and its interrelation with Sustainable Development Goals (SDGs) role in six CFs (commonly known as Van Panchayats - VPs) in Himalayan state.We employed participatory approach, involving local people through village level governance (head of the village- Pradhan) and forest level governance (president of community forest-Sarpanch), while also considering the involvement of forest department.

The study is focused on identifying and developing various indicators for selected SDGs for wellbeing of the dependent community on the basis of management status of CFs, health, social, economical and, environmental wellbeing through selected frameworks, focused group discussion and semi-structured questionnaire-based interview using Participatory Rural Appraisal techniques like listing and ranking.

The major governance challenges restricting FLR in CFs were property right conflict, decision-making, sharing of cost and benefits, community ownership and land-use fragmentation. Acknowledging and addressing these challenges and managing it through natural resources based solutions adopted by the local community and their coupled relationship with ecosystem services and human well-being for the future by strengthening community land tenure and forest rights, with involving them in CFs restoration via indigenous species plantation, provisioning of socio-cultural conservation based incentives, accrued benefits and implications to develop some amalgamated solutions to assist the policy and governance interface for the CFs is also essential towards eco-centric approach for the local and global acceptance.

In general, outcomes of the study have potential to ameliorate the effect of FLR through restoring degraded forestland, aligning with the Bonn challenge commitment, attaining nation’s INDCs (Intended Nationally Determined Contributions) and subsequent SDGs targets.

Key words: Community based restoration, nature-based solutions, ecosystem services, Forest and land tenure, socio-cultural values

Forest Landscape Restoration interventions for conservation and sustainable development in Sri Lanka: a case study

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

Deepani Alawathugoda[1]
Nishantha Edirisinghe[1], Isuru Alawatta[1]
[1] Department of Forest Conservation, Sri Lanka

Abstract: Severe shortage of land resources to fulfil the demand for various needs particularly for development work is a main threat on available natural forests in Sri Lanka at national level. Further, present economic crisis of the country demands to assure food security through increased food production. Poverty alleviation and increased national income are crucial to address the economic crisis.

Forest Landscape Restoration (FLR) provides an opportunity to integrate conservation, production, poverty alleviation and increased national income to achieve SDG.

A case study was conducted to analyze the issues and possible solutions in a forest landscape, which consists of different forest types, water streams and water tanks associated with adjacent agricultural communities. A part of forest landscape is degraded due to anthropogenic disturbances, and it is being developed for ecotourism which is a main target of government policy. This landscape lies within a popular tourist area featured by attractive wildlife, cultural heritage and natural beauty.

Primary data and secondary data were collected using formal and informal discussions with various stakeholders. The issues were identified in relation to different land-uses, and stakeholders suggested potential solutions to restore the landscape. The main issues in conservation were timber felling, excessive firewood and forest products collection, encroachment, fire, waste disposal in forest, and scarcity of food and water for wildlife. In terms of livelihood maintenance, water scarcity for agriculture and homegardens, low diversity in homegardens, food and water shortage for livestock and unsustainable harvesting of fish were identified as main concerns. Low diversity of tourism activities, poor interpretation service, insufficient facilities, and unequal benefit sharing were identified as issues for developing sustainable tourism.

Rehabilitating small tanks, Wildlife habitat improvement, Degraded forest restoration, Improving irrigation facilities, Diversification of homegardens, Intensifying livestock management, Agroforestry, Diversifying tourism activities, Training interpreters were among the potential activities identified for landscape restoration to regain ecological functionality and enhance human wellbeing.

The selected activities will contribute to at least 4 SDG goals: 1-No poverty, 2-Zero hunger, 8-Decent work and economic growth, and 15-life on earth.

Protecting an artificial savanna as a nature-based solution to restore carbon and biodiversity in the Democratic Republic of the Congo

Abstract: A large share of the global forest restoration potential is situated in 'unstable' mesic African savannas, contributing about 23% to the global mismatch between potential and actual terrestrial carbon stocks. However, uncertainty on Central African forest recovery rates impedes science-informed implementation of forest restoration efforts. Here, we quantify the forest restoration success of 17 years of fire exclusion within a mesic artificial savanna patch in the Kongo Central province of the Democratic Republic of the Congo. Since 2005, the local community of the Manzonzi village has conserved an 88-ha artificial savanna with support from World Wildlife Fund. In 2010, we established 101 permanent plots (total area of 40.4 ha) and remeasured them (at the threshold of 10 cm DBH) in 2014 and 2022, by considering two species categories: savanna and forest specialists. Between 2010 and 2022, mean stem density switched from 122.3 ± 9.0 to 27.0 ± 3.8 tree/ha and from 45.8 ± 7.5 to 178.6 ± 10.1 tree/ha for savanna specialists (*e.g. Hymenocardia acida* and *Maprounea africana*), and forest specialists (*e.g. Xylopia aethiopica* and *Albizia adianthifolia*) respectively. We found that aboveground carbon (AGC) recovery of forest specialist after 17 years was on average 11.9 ± 0.2 Mg C ha^{-1}. Using a model fitted to the data, we predicted that AGC stocks take 110 ± 3 years to recover to 90% of AGC stocks in old-growth forests. Applying this recovery trajectory, we show that 'unstable', artificial savannas across DRC, Congo, and Angola have a total carbon uptake potential of 13.5 ± 1.6 Gt C by 2100. Species richness recovered to 33.1% after 17 years and we predicted a 90% recovery at 57 ± 1 years. In contrast, the recovery of species composition was much slower, with an estimated 90% recovery after 125 ± 3 years. We conclude that carbon and biodiversity recovery trajectories are indispensable to developing policies promoting forest restoration in artificial African savannas. However, more long-term, *in situ* monitoring efforts are needed to quantify variation in carbon and diversity recovery

owing to resource availability (rainfall and soil fertility), prior vegetation and land-use history, and surrounding forest cover.

Small-scale farmers' preferences for the adoption of tree-based restoration systems: Empirical evidence from a discrete choice experiment

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

Karin Begazo Curie
Iris Vanermen[1], Liesbet Vranken[1]
[1] KU Leuven, Department of Earth and Environmental Sciences, Division of Bio-economics, Celestijnenlaan 200E, 3001 Heverlee, Belgium.

Abstract: Despite the recognition of tree-planting and agroforestry systems as effective forest restoration practices, their adoption remains low among small-scale farmers. To increase their participation, it is crucial to understand farmers´ preferences and the factors influencing their decision-making. Therefore, this study assesses small-scale farmers´ willingness to adopt tree-based restoration systems on degraded forestlands, investigates their preferences for characteristics of these systems, and identifies the possible sources of preference heterogeneity. For this, we conducted a Discrete Choice Experiment (DCE) embedded in a survey among 400 small-scale farmers equally distributed over two districts in the northern Peruvian Amazon, a region that is experiencing high pressures of land use change. In the past, several bottom-up projects, with limited farmer participation during the planning and design, were implemented in this area. This caused a mismatch between project objectives and the needs of farmers, resulting in low adoption rates of restoration systems. Based on the DCE, we evidence that generally small-scale farmers were willing to enroll in the proposed scheme and showed positive preferences for the attributes proposed. They generally preferred higher monetary incentives, agroforestry systems (providing food and cash income) over tree plantations, technical assistance and implementing the system on a fraction of their degraded forestland (instead of their total degraded area). Furthermore, two groups of small-scale farmers with contrasting preferences related to two attributes were found. Specifically, one group (73%) was highly interested to engage in the proposed scheme and significantly preferred agroforestry systems over tree plantations, while the other group (27%) had a negative preference for adopting the proposed scheme and was indifferent to the type of tree-based system. Respondents not willing to enroll in the proposed schemes have participated significantly more in organizations in the past, had a significantly higher area of permanent crops but lower area of annual crops and primary forest, were engaged more in agriculture and were less forest dependent. These findings provide useful insights to design community supported policies promoting agroforestry systems that ensure small-scale farmers´ land rights to increase participation and for achieving land restoration while improving rural livelihoods (through food security and cash income).

Sustainable forest landscape restoration and management within Rohingya refugee camps in Bangladesh

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

Dr. Md. Mahbubur Rahman[1]
Yohei Mitani[1]
[1] Division of Natural Resource Economics, Graduate School of Agriculture, Kyoto University, Kyoto 606-8502, Japan

Abstract: Bangladesh hosts the world's largest refugee population— over one million Rohingya people residing in heavily congested conditions across 34 camps in the Cox's Bazar District of southeastern Bangladesh. Consequently, approximately 3,244 hectares of forest were lost, including 2,500 hectares for camp construction and 744 hectares for woodfuel and bamboo harvesting. Since 2018, FAO, Bangladesh Forest Department and humanitarian agencies have restored about 720 hectares within the camp and another 2,000 hectares outside the camp areas aimed to restore and regenerate the forest coverage in the region. This study in Kutupalong-Balukhali Mega Camp interviewed 430 Rohingya refugees from 11 out of 23 camps. The study revealed that forest landscape restoration (FLR) activities consisted of four components: forest restoration, land stabilization, reforestation, and capacity building. For producing quality planting materials, seeds and vegetative propagation were distributed for seedling raising in nurseries outside the camps. The FLR approach prioritizes the revival of multiple vegetation layers, including bamboo and fast-growing exotic and native tree species, for extensive plantation and soil stabilization. Both skilled and unskilled male and female Rohingyas participated in the restoration activities under a 'Cash for Work' program for site preparation, plantation, management, and site maintenance. Agencies promote a collaborative restoration management approach through community engagement, awareness campaigns, and capacity building for sustainable FLR management. About 91% of Rohingyas reported that restoration efforts empowered women and youth, and 85% reported that restoration improved the sense of community and solidarity among Rohingyas. Although Rohingyas are not given ownership and benefits of planted trees, 81% continued to participate in or support the restoration work in the future, while 88% perceived the long-term sustainability of the restoration program. The findings of this study will help develop a sustainable FLR management plan that takes into account the cultural, ecological and social aspects of the Rohingya refugees.

Towards Good and sustainable forest governance in Kenya- A Water-Energy-Food nexus security approach

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

Devinia Akinyi[1]
David Langat[1], Collins Obonyo[1], Roxventa Ongugo[1]
[1] Kenya Forestry Research Institute

Abstract: In Kenya, forests are estimated to contribute 3.6 per cent of the Gross Domestic Product (GDP). Apart from climate regulation, forests support various other production and consumption services. Policies within the forest sector have greatly impacted the country's development goals and agenda. The current target is to increase tree cover to 15 billion by the year 2050. This, without a doubt, will have a great impact, especially on the 15 Sustainable Development Goals enshrined within the United Nations Agenda on sustainable development. These policies and targets have helped the country and households to improve consumption and production patterns, especially for non-timber forest products (NTFP). Other impacts include empowering rural women, increased food production through the shamba system, climate regulation, and biodiversity protection among others. However, unsustainable consumption and production may conflict with the achievement of such other development goals as clean energy, climate action, peace and justice brought about by illegal logging activities. The linkages that exist between the forest industry and the SDGs are complex. Past studies have typically considered individual economic sectors in isolation, lack temporal depth, and focus on a single SDG dimension. This study fills this knowledge gap by integrating a long-run economic analysis within the Policy Coherence for Sustainable Development (PCSD) framework to capture the impact of forest policies in Kenya on the SDGs over time and before they were formally adopted. A key focus will be on the Water, Energy, and Food (WEF) nexus security indicators. PCSD ensures the implementation of one goal does not impede the achievement of other goals. A historical perspective that considers the broader policy environment and evolution in Kenya over the past 50 years, will enable a more embedded understanding of current developments in the sector. More so, forest policies can have positive (synergies) or negative effects (trade-offs) on the realization of different SDGs, as well as interact with policies in other sectors of the economy across time. A long-run economic analysis using a range of indicators liked to the SDGs will help identify these interactions as well as pathways to minimize the trade-offs and maximize the synergies.

Village relocation: an approach to Forest Landscape Restoration

T3.9 Forest landscape restoration (FLR) and SDG Goals from the lens of forest policy and governance

CHANDRASEKARAN BALA[1]

[1] Deputy Conservator of Forests, Amravati Forest Division, Forest Department, Maharashtra, India
[2] Deputy Conservator of Forests, Wildlife Wing, Forest Department, Maharashtra, India
[3] Forest Development Corporation of Maharashtra (FDCM) Limited

Abstract: Forest landscape restoration is considered as a process in which the soil is allowed to regain its ecological potential which was on continues pressure by different anthropogenic factors. In the current scenario, landscape approach is vital in case of conserving the Protected Area. Relocation of villages which are located in the Protected Area is carried out in order to restore the natural forest ecosystem. Eastern Vidarbha Landscape comprises of 3 National Parks and 8 Wildlife Sanctuaries which harbors a wide range of wildlife. The existence of villages inside the Protected Area is naturally prone to Human Wildlife Conflicts. Keeping the immense value of human and as well as the wildlife, rehabilitation of villages is carried out with the consensus of the community. Sixteen villages at different locations were relocated to nearby townships. The relocated forest landscape was treated with Assisted Natural Regeneration which includes native fruit bearing tree species, climbers and grasses. For a period of 3 years, the area was monitored consistently. The relocated villages in the landscape are now regenerated into a natural forest and grassland with distribution of native species. This landscape acts as a corridor for movement of wildlife. The intervention made by the government with specific guidelines made a win-win situation for both the community by means of compensation package as well as for the wildlife and ecosystem by means of restoration.

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Age estimation algorithms of living trees in natural mixed forest based on the micro-damage measurement of drilling resistance

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Jun Lu[1]
[1] Research Institute of Forest Resources Information Techniques, Chinese Academy of Forestry

Abstract: Age estimation of standing trees is the most important and basic problem in forest production and research. We studied the algorithm of tree age estimation with the series of drilling resistance as the object, so as to provide the method and basis for the tree age determination.Three kinds of algorithms for measuring the living trees age were proposed in this paper, which could be used to estimate tree age by the series of drilling resistance values.(1)When the appropriate parameter rat was selected according to their DBH, the stationary Kalman filter applied in 323 groups of drilling resistance of Larix principis-rupprechtii had better denoising effect, so that the algorithm estimating tree age closed to the actual age. (2) The algorithm frequency spectrum analysis was applied to Larix, the window parameters were selected according to the DBH of living trees, and the algorithm estimating tree age was closed to the actual age. The results showed that the accuracy of spectrum analysis algorithm for estimating the age of Larix rupprechtii was better, and the accuracy of tree age estimation by resistance was improved. (3) Peak valley analysis algorithm was applied to 113 groups of drilling resistance sequences obtained from three tree species in natural forest including Larix olgensis, Pinus Koraiensis and Abies nephrolepis. When the appropriate threshold value (Det)was selected according to the tree real age, The tree age was estimated by the peak-valley analysis, and the results showed that it was close to the real tree age. The results showed that According to the tree diameter distribution, the algorithm parameters Rat and window parameters Wid were determined, and the estimation of the age of Larix rupprechtii by using the algorithm of stationary Kalman filter and the algorithm of spectral analysis were better, in which the error of the algorithm of spectral analysis was slightly lower than the algorithm of stationary Kalman filter; Using peak valley analysis algorithm to estimate the age of Korean larch, Pinus Koraiensis and Abies nephrolepis was better. The next step was to apply the algorithm to age estimation of more kinds of natural forest living trees.

Clonal multiplication from seedlings of Cordia trichotoma, Calophyllum brasiliense and Cariniana legalis

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

[4] UNESP-FEIS - Faculdade de Engenharia - Câmpus de Ilha Solteira
[5] Embrapa Florestas

Abstract: Many alternative native and exotic forest species have potential for commercial exploitation, but to establish production systems with these species, research in silviculture is necessary, mainly in genetic improvement and biotechnology. Therefore, tests were proposed for the optimization of vegetative propagation via cuttings of three native species of great economic, social, and productive importance: Cordia trichotoma (Vell.) Arráb. ex Steud., Calophyllum brasiliense Cambess e Cariniana legalis (Mart.) O. Kuntze. For the development of vegetative propagation protocols, rooting tests were performed with six different doses of indolbutyric acid (IBA) and a control. The IBA concentrations tested were: 0, 500, 1.000, 3.000, 5.000, 7.000 and 10.000 ppm. Therefore, the experimental design used for three species was complete randomized blocks with 7 treatments, 16 blocks and one plant per plot. The trait was evaluated: root length. The mini-cuttings were from seminal seedlings. Statistical analyzes were performed using the program R. In rooting tests with mini-cuttings, statistical differences were observed between IBA concentrations for C. brasiliense, C. legalis and C. trichotoma for root length at the 1% probability level. The best IBA concentrations for root length were 3.000 ppm for C. trichotoma, and 5.000 ppm for C. legalis and C. brasiliense. The mean root length was 2.59 cm for C. legalis, 1.71 cm for C. brasiliense and 1.45 cm for for C. trichotoma. The coefficient of variation was high for C. trichotoma, C. brasiliense and C. brasiliense (45.67%, 43.18% and 69.28%, respectively), which can be understood and expected since the mini-cuttings were used from several ministumps, which still bring great genetic variability. The established concentrations of AIB determined for the two studied species will be used to produce clonal seedlings for commercial plantings and genetic improvement.

Keywords: AIB, planted forests, wood products, genetic variability.

Effects of fertilization on growth increments, reproduction and photosynthetic physiology of Pinus koraiensis plantations

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Haibo Wu[1]
Peng Zhang[1], Hailong Shen[1], Dongsheng Yin[2]
[1] Northeast Forestry University
[2] Forestry Research Institute of Heilongjiang Province

Abstract: Global climate change place increasing great pressure on world forest, which leading to reduced stand productivity, delayed harvests and forest decline. Reasonable intensive management can improve forest productivity, promote growth increments, reproduction and shorten production rotations. Fertilization is one of the important measures of forest intensive management. In the past, intensive management of fast-growing tree species (e.g timber) was commonly practiced, but there were few reports on intensive management of long-lived tree species, especially those with dual commercial value (such as seeds and wood of *Pinus koraiensis*). To determine the impact of intensive management on its growth and reproduction needs further research. In this study, 25-year-old Korean pine plantation in Hancongling Forest Farm of Jilin Province was selected as the research object to explore the effects of different fertilization treatments on the growth increments, reproduction and physiological parameters of Korean pine. This investigation aims to understand and quantify the promotion patterns of intensive management on growth increments and reproduction. The results showed that the photosynthetic physiological characteristics and nutrient concentration of *Pinus koraiensis* showed a positive response to fertilization, and its growth and seed setting were significantly increased. No matter the single application of N, P, K fertilizer or the combined application of NP and NPK significantly promoted the DBH, crown width growth of Korean pine, significantly increased the seed setting rate and cone yield per tree. The effects on the growth and fruiting of Korean pine were NPK > NP ≥ N > P > K > CK. Compared with the control, the DBH, seed setting rate and cone yield of Korean pine treated with NPK increased by 27.7%, 121.2% and 158.3%, respectively. Fertilization significantly increased the contents of Pn, Gs, Tr, Wue and chlorophyll, as well as the concentrations of soluble sugar, starch, nonstructural carbohydrates and nutrients in Korean pine. Fertilization significantly increased the concentrations of corresponding nutrient elements in needles, branches and trunks, indicating that *Pinus koraiensis* was sensitive to fertilization.

Genotype-by-environment interaction in Khaya senegalensis provenance and progeny tests

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Bruno Marchetti de Souza[1]
Eduardo Ciriello[2], Valéria Ciriello[2], Rodrigo Ciriello[2], Felipe Garbelini Marques[3], Joselito Lovatto[4], Mario Luiz Teixeira de Moraes[1], José Cambuim[1], Bruna Anair Souto Dias[5], Ananda Virgínia de Aguiar[6], Miguel Luiz Menezes Freitas[7]

[6] Empresa Brasileira de Pesquisa Agropecuária
[7] Instituto de Pesquisas Ambientais

Abstract: The genus *Khaya* (African mahogany) have aroused interest in hardwood production in tropical countries. This study aims to generate information and tools for the development of a breeding program for one African mahogany species (*K. senegalensis*) in Brazil, focusing on solid wood production. The goal is to estimate the genetic parameters and genotype-by-environment interaction (GEI). Thus, provenance and progeny tests were established between 2017 and 2019 in six edaphoclimatic conditions in the municipalities of Garça (GAR), Porto Seguro (PSB), Selvíria (SEL), Teresina (TER), Currais (CUR), and Alvorada do Guguéia (ADG). All tests were established in randomized blocks, with 22 progenies and five provenances and one plant per plot. The total height, diameter at breast height (dbh), commercial height, and stem shape were evaluated until 2023. Then, the average annual increment was calculated for diameter and total height (AAIdbh and AAIht). Statistical analyzes and genetic parameters, including the GEI, were estimated using the REML/BLUP method. The deviance analysis was used to verify the significance of genetic and GEI effects. The MHPRVG procedure was used to estimate the productivity, stability and adaptability of the progenies and classify them according to these criteria. Regarding the growth, we observe a higher AAIdbh in PSB (2.71) and for AAIdbh in TER (1.90), showing the adaptation of the species to warm climate regions. Significant differences were found between the performances of progenies in each test for diameter or height, with heritabilities for AAIdbh ranging from 0.01 in CUR to 0.22 AAIdbh in PSB. The GEI effect also was significant on the AAIdbh trait with a correlation between sites of 0.26. This result confirms the complex nature of the GEI effect on the species. Therefore, to establish a broad breeding program for the species in Brazil or another tropical country it is necessary to balance the selection of progenies based on stability and adaptability criteria. Following the MHPRVG method, the most stable and productive progenies in diameter are 10, 14, and 13. These progenies can be indicated in a wide range of environments to increase the productivity of commercial stands of the species. Acknowledgments: FAPESP process 2020/09216-0.

Optimizing In Vitro and Cutting Culture Techniques for Asexual Propagation of High Economic Value Trees

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Phruet Racharak[1]
Wirongrong Duangjai[2]
[1] Department of Forest Biology, Faculty of Forestry, Kasetsart University, Thailand
[2] Department of Silviculture, Faculty of Forestry, Kasetsart University, Thailand

Abstract: Forest plantations and tree improvement breeding programs in Thailand traditionally depend on efficient asexual propagation methods such as cutting culture. Recently, *in vitro* culture methods have been introduced, offering advantages including controlled environment and rapid proliferation, although success with commercially valuable timber tree species remains limited. This study investigated the effectiveness of these propagation methods in eight tree species with commercial value: *Dalbergia cochinchinensis*, *Pterocarpus macrocarpus*, *Xylia xylocarpa* var. *kerrii*, *Afzelia xylocarpa*, *Hopea odorata*, *Dipterocarpus alatus*, *Millettia xylocarpa*, and *Toona ciliata*. The focus was on the use of plant growth regulators such as 6-benzylaminopurine (BAP), kinetin, zeatin, naphthaleneacetic acid (NAA), and indole-3-butyric acid (IBA), to boost adventitious shoot or root formation. The findings highlight differential responses among species, with *D. cochinchinensis*, *P. macrocarpus*, and *M. xylocarpa* exhibiting successful shoot induction in *in vitro* cultures and effective root induction through cutting. *In vitro* cultures remained unsuccessful for *X. xylocarpa* var. *kerrii*, *A. xylocarpa*, and *H. odorata*, while root induction through cutting was successful. *D. alatus* and *T. ciliata* showed limited responsiveness to both methods. These findings shed light on the comparative effectiveness of *in vitro* and cutting methods in propagating different tree species. Further research is imperative to identify efficacious propagation methodologies for *D. alatus* and *T. ciliata*, and to refine *in vitro* treatments for species such as *X. xylocarpa* var. *kerrii*, *A. xylocarpa*, and *H. odorata*. Understanding the exact plant growth regulator combinations could lead to effective asexual propagation techniques. Such knowledge would be instrumental in enhancing the effectiveness of forest plantation establishments and tree improvement breeding programs.

PREDICTION OF SECONDARY CORK INDUSTRIAL QUALITY AND POROSITY BASED ON VIRGIN CORK CHARACTERISTICS

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Joana Amaral Paulo[1]
Diana Isa Santos[1]
[1] Centro de Estudos Florestais / Instituto Superior de Agronomia

Abstract: The primary aim of this work is to research the possibility of using physical characteristics accessed in virgin cork samples, as predictors of secondary cork industrial quality and porosity. If this hypothesis is confirmed, thinning of young high tree density plantations may be based on specific selection criteria, a relevant improvement to the current forest management practices.

Virgin cork samples (n=66) were obtained from 3 different stands. Nine years after the first debarking, the same trees were resampled for secondary cork. Secondary cork samples were classified regarding industrial cork quality classes by an experienced operator. Cork color was determined in virgin and secondary raw cork samples, based on CieLab color space, in the radial and transversal directions of the samples, and also in the cork sample back and belly. Virgin and secondary cork porosity was determined also in the raw samples.

The data analysis was carried out in order to considering: i) t-test carried out to the average values of L*, a* and b* color parameters from virgin cork samples, for comparing groups of distinct cork quality classes, classified by secondary cork samples ii) the Spearman correlation coefficient (ρ) between virgin and secondary cork porosity.

Results showed that color parameters, in particular *L** (lightness) and b* (blue versus yellow) measured in transversal or radial sections of the raw virgin cork, allowed to distinguish cork quality groups from secondary cork. The L* parameter measured in the back surface was able to differentiate good cork from average and low quality cork, but was nor able to distinguish the two latest groups.
A ρ=0.40 was obtained between the porosity values of virgin cork and secondary cork, showing a moderate positive monotonic relationship. The final model for the forecast of secondary cork porosity as a function of virgin cork porosity was formulated as an hyperbole. The model parameters were expressed as a function of color L* and b* values measured in the transversal direction of the cork. No additional color parameters were added since this would imply high multicollinearity. The final model presents a R^2 = 0.445 and a MSE = 0.00086.

Prospects of Organic and Inorganic fertilizer use in Commercial forest Plantations in Kenya

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Joram Mbinga[1]
Alice Adongo[1], Martin Welimo[1], Richard Siko[1]
[1] Kenya Forestry Research Institute

Abstract: The use of fertilizer in commercial forestry is one of the key technologies for achieving fast growth and high yields of forest products. This practice has been adopted by many forestry enterprises around the world. However, there are mixed reports as to the actual levels of output achieved by the use of fertilizers. Some reports show a significant improvement, and others show marginal or no improvement in tree growth. In Kenya, the use of fertilizers in forestry has not been widely adopted and there is little information about their usefulness. To understand the impacts of fertilization in forestry in Kenya, a study was conducted at the Forest Research Institute of Kenya to determine the effects of application of organic and inorganic fertilizers during tree establishment, on survival, growth, and yield of one of the main commercial plantation species, *Eucalyptus grandis*. A randomized complete block design with four replications was used to evaluate the effects of four treatments namely, organic fertilizer – cow dung manure, inorganic fertilizer – Triple Super Phosphate, a combination of the two, and a control treatment of no fertilizer. Growth traits assessed were percentage survival, height, and stem diameter at breast height DBH, of trees in different treatments. The results of tree survival after one year of establishment showed no significant difference among the treatments. However, there was a significant difference in height and DBH growth among the treatments in the early growth upto age of six years, where the highest growth was by trees under organic fertilizer which achieved mean height of 14.25 m and mean DBH of 14.4 cm. However, by age 16, there was no significance difference in growth of the trees under different treatments. Results of this study, suggest that faster growth and higher yield can be achieved with the use of organic fertilizer only when the tree are raised for a short growing period of upto six years. Beyond this age, tree growth do not seem to benefit from fertilizer application.

Pruning Intensity and Spacing Impacts on the Growth of Terminalia brownii in the Lake Victoria Basin Eco Region, Kenya

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Osia Odula[1]
Willis Atie[1], Beryn Otieno[1]
[1] Kenya Forestry Research Institute (KEFRI)

Abstract: Pruning Intensity and Spacing Impacts on the Growth of *Terminalia brownii* in the Lake Victoria Basin Eco Region, Kenya

Osia Odula, Willis Atie and Beryn Otieno

Kenya Forestry Research Institute, Lake Victoria Eco-region Research Programme P.O Box 5199-40108 Kisumu, Kenya

Indigenous tree resources play a major socio-economic role in the lives of rural communities that depend on them for the supply of fuel, medicine, and shelter among others. *Terminalia brownii* Fresen (Combretaceae) is one such species that is native to the greater eastern Africa region. *Terminalia brownii* has been used successfully in agroforestry, afforestation and reforestation programmes in the drylands of Kenya. Despite the economic benefits associated with *Terminalia brownii* in Lake Victoria Basin Eco-Region, its exploitation continues unabated. However, there is no or little information known on the management practices.

A study was conducted to investigate the effects of pruning regimes and spacing on the growth of *Terminalia brownii* in the Lake Victoria Basin Eco-Region in Kenya. The treatments consisted of three pruning regimes (severely pruned, pruned and unpruned) and four spacing types (1 x 1, 2 x 2, 3 x 3 and 4 x 4) in a randomised complete block design. Severely pruned and pruned trees recorded significant variation in basal area ($p=0.0377^*$), stems per hectare ($p= 0.036598^*$) and diameter at breast height ($p= 0.010^*$) while there were no significant differences in tree heights ($p=0.2266$) among different pruning regimes within different sites when compared to unpruned trees. Significant differences existed in diameter at breast height ($p<0.001^*$), tree height ($p=0.003^*$), mean stems per hectares ($p<0.001^*$), basal area ($p=0.0147$) and volume ($p=0.0168^*$) among the different spacing types. However, no differences were reported between 4 x 4 and 3 x 3 spacing. Tree diameter at breast height and crown expansion increased with wider spacing (4 x 4) and reduced with closer spacing (1 x 1). We concluded that tree spacing of 3 x 3 and pruning intensity (pruning) are significant management options in *Terminalia brownii* to maximize the increase in volume productivity.

Recent Advances in Nondestructive Evaluation of Wood: In-Forest Wood Quality Assessments

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Xiping Wang[1]
[1] USDA Forest Service Forest Products Laboratory

Abstract: Recent research and development on nondestructive testing technologies has brought the in-forest assessment of wood and fiber properties of standing trees into tree breeding, forest management, resource evaluation, and harvesting operations. Significant values are associated with the wood and fiber quality of our forests for the production of structural lumber, engineered wood products, and pulping and paper. Rapid and nondestructive measurements on trees allow this value to be captured through genetic improvement and better silvicultural practices, as well as the allocation of resources to highest value users and application of best processing methods. This presentation provides an overview of recent research and development on in-forest wood quality assessments using emerging nondestructive and precision-based technologies such as SilviScan™, near infrared, DiscBot, acoustic waves, and resistance drilling. A brief discussion is followed on how these technologies and the knowledge obtained from them can support the development of the next generation of forests, e.g. through tree breeding and silviculture.

Relationship of standing tree strength with tree height and diameter based on site productivity: toward estimating standing tree strength

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Kiichi Harada[1]
keiko nagashima[1]
[1] Graduate School of Life and Environmental Sciences,Kyoto Prefectural University

Abstract: Stronger Japanese cedar logs yield stronger sawn wood, while stronger standing trees yield stronger logs. Stronger logs also have a smaller average annual ring width, indicating slow tree growth. Tree growth, particularly height growth, is an important indicator of site productivity in forestry. As a result of the aforementioned tendency, it is possible that site productivity affects standing tree strength. In this study, we aimed to better understand the relationship between standing tree strength and tree height or diameter based on site productivity. A site productivity estimation model based on a 5 m mesh site condition map was used to assess the productivity (divided into three classes: A for high to C for low) of a 43-year-old Japanese cedar experimental site (Mukai et al., 2023). Trees of varying diameters were selected from sites with different productivities, and tree strength, height, and diameter at breast height (DBH) were measured. Positive site classes such as A^+ and B^+ were assigned to trees taller than the average height of site productivity, while negative site classes such as A^- and B^- were assigned to trees that were shorter than the average. A weak negative correlation ($R=-0.69$, $p<0.01$) was observed between tree strength and tree height. Trees were grouped into site productivity classes of A^+, A^-, B^+, and B^-, from the weakest to the strongest, indicating a specific relationship between tree strength and site productivity. However, there was a strong negative correlation ($R=-0.81$, $p<0.01$) between tree strength and DBH. Trees from different site productivities were mixed, and no correlation was found between tree strength and DBH with respect to site productivity. This implies that the indicators influencing diameter growth are more relevant to tree strength than those influencing height growth. Therefore, indicators influencing diameter growth, such as tree density and crown volume, may be critical for predicting standing tree strength.

Response of growth and wood properties of Populus to different climate zones

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Ning Liu[1, 2]
Jan Van den Bulcke[1], Xiaohua Su[2], Qinjun Huang[2], Joris Van Acker[1]
[1] UGent-Woodlab, Laboratory of Wood Technology, Ghent University
[2] Research Institute of Forestry, Chinese Academy of Forestry

Abstract: Poplar (*Populus spp*.) is a genus providing important plantation tree species allowing the production of a fast growing wood resource mainly in temperate climatic regions, among which the *Sect. Aigeiros, Sect. Populus* and *Sect. Tacamahaca* are the main poplar species. These trees are present in many countries, they are easy to regenerate vegetatively, and the increasing demand for wood makes this an excellent tool to meet many sustainable development goals. The industrial production of wood products relates to the climate zone, meaning that the performance of poplars needs to be verified in relation to their multi-environment. Hence, determining the variation of wood properties and growth due to environment is a key task. Yet, the traditional wood property research methodology is complicated and takes a long time. The application of the X-ray CT scanning of wood cores has effectively saved workload, and hence research based on collecting a large number of samples has become possible.

This research has been carried out in 14 Köppen-climates zones from China and Europe. At each location poplars are selected from the above three sections for drilling wood cores. Historical meteorological data and parameters of the plantation are acquired for 'environment-poplar' modeling. The focus will be on the observational properties dealing with tree growth in combination with mechanical and physical properties as well as chemical composition to reveal the wood quality. In terms of responses to the environment, all the indexes acquired will be correlated with site and climate factors. Ecological zones suitable for the production of various clones will be divided according to the performance of poplar wood characteristics to provide strategies and experience for the forest industry chain based on plantation production systems.

[3] Forestry Research Institute of Sweden (Skogforsk), Sweden

Abstract: Scots pine (*Pinus sylvestris* L.) is a commercially important forest tree species in many Eurasian countries. Its wood has been commonly utilized for production of construction timber. In Sweden, a breeding program was launched in 1950s to improve Scots pine trees to better suit industrial requirements. The emphasis was mainly put on improving stem volume, vitality, stem straightness and branching characteristics whilst wood quality was neglected. However, since some of the important wood quality traits are negatively correlated with the prioritized volume production, the continuation of such an approach could in a long run lead to irreversible deterioration of wood quality.

In our study, we focused on wood quality traits that are relevant for construction timber – wood density, stiffness, strength, grain angle and sawn-board shape stability (crook, bow and twist). We linked wood quality traits that were nondestructively assessed on standing trees with those measured on sawn boards. We estimated narrow-sense heritabilities, genetic correlations and correlated responses to selection with the aim of identifying reliable techniques for wood quality assessment on standing trees and proposing suitable strategies for incorporating wood quality traits into the breeding program.

We have concluded that standing-tree drilling resistance, acoustic velocity and grain angle are good predictors of wood density, wood stiffness & strength, and sawn-board twisting, respectively. Taking into account the long-term development on wood market, we are proposing an inclusion of wood density in the breeding program, in the way that it will be retained at the current levels rather than increased, which would also positively affect wood stiffness and strength. Furthermore, we are suggesting to consider grain angle as a breeding trait although more research is needed to unravel its underlying biological mechanism.

Selected coastal Douglas-fir under global change: the effects of silvicultural interventions on forest resilience

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Fleur Damen[1]
Sirajul Mustafa[1], David Montwe[1]
[1] Department of Forest Resources Management, University of British Columbia, Vancouver, BC, Canada

Abstract: As an important commercial tree species in British Columbia, coastal Douglas-fir (*Pseudotsuga menziesii* var. *menziesii*) has been subject to recurrent selection to enhance productivity. However, it is currently not known if this selection process has affected Douglas-fir's susceptibility to extreme weather events and how such effects are modulated by competition. As climate projections for coastal Douglas-fir forests in the Pacific Northwest predict more frequent and extreme weather events such as heat and drought, maintaining resilience is critical. In 1996, the British Columbia Ministry of Forests established five replicated realized gain trials comprising four initial planting densities and three levels of genetic gain for timber volume. By comparing tree-ring widths across all factorial combinations of site, genetic gain and planting density, we evaluate the effects of selection and competition on growth resilience following years with extreme weather events. Moreover, we compare tree-ring widths with remotely sensed spectral values and structural attributes at the individual tree level. This will allow us to determine if remotely sensed indices are a good indicator of drought stress, and can therefore be used as a faster and more extensive method of assessing forest health under climate stress. Lastly, we use microsections to characterize wood quality properties such as cell wall thickness and lumen diameter, to see how these properties vary across genetic levels and spacing densities under global change pressures. We predict that genetically selected individuals are less resilient to extremes, and that increased competition has a negative effect on resilience. We therefore expect that in these less resilient trees, impacts of extreme droughts will be higher and can be tracked on short temporal timescales using the photochemical reflectance index obtained via remote sensing. We expect higher resilience to be correlated to better wood qualities such as thicker cell walls and smaller lumens. With climate and planting density as the primary drivers of Douglas-fir growth variability, selection of the best adapted trees for reforestation and flexibility in operational planting densities can ensure that future Douglas-fir forests are resilient to climatic extremes and can continue to provide their ecological, economic, and cultural functions.

Species-optimal management of group-mixed Norway spruce and silver birch for sustainable bioenergy biomass supply

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Swastika Chakravorty[1]
Urban Nilsson[2], Narayanan Subramanian[2], Dan Bergström[3], Elisabeth Wetterlund[1]
[1] Energy Engineering, Division of Energy Science, Luleå University of Technology, Sweden
[2] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Sweden
[3] Department of Forest Biomaterials and Technology, Swedish University of Agricultural Sciences, Sweden

Abstract: The Swedish Forest sector has the potential to provide biomass to produce renewable energy if forest management can ensure sustainable production of biomass for bioenergy and other materials. The presence of native broadleaves with conifer (silver birch and Norway spruce, respectively, in this study) has been advocated to increase sustainability. This study aimed to compare production and economy in monocultures of the two species with group-mixtures, either managed according to the mean values of the two species, or optimized management of the individual species.

The development of planted Norway spruce and silver birch forests in eight different sites in Sweden was simulated for three management alternatives, either monocultures of the two species, or group-mixtures managed with two management intensities. The decision support system Heureka was used to generate optimal treatment schedules. For monocultures, Norway spruce or birch was simulated for the whole stands. For group-mixtures, both species were either simulated together with the same timing of interventions or individual treatments of the tree species according to the timing of interventions found optimal in the simulations of monocultures. The rotation age of monocultures and group mixtures with average timing of interventions was decided by the highest land expectation value. The rotation age of the alternatives with group mixtures with individual tree-species treatment was selected based on the combined maximised land expectation value of the two monocultures.

Three scenarios were generated for all the management alternatives. In the base scenario, the felled trees in all operations were considered pulpwood and sawlog. In the second scenario, the first thinning was considered biofuel thinning. In the third scenario, logging residue was extracted in the final felling in addition to the base scenario. We analysed the impact of bioenergy biomass procurement from young stands on the overall profitability of a mixed forest, the economic return of the species-optimal management regime and the broadleaf growth compared to the conventional management. Initial results suggest that the species-optimal approach increases broadleaf growth compared to conventional group-mixed stand management and can be a sustainable source of biofuel. However, increased management interventions will increase the total management cost.

Whole-tree wood properties mapping of Eucalyptus pellita: toward a predictive model for wood quality

T3.10 Forest management solutions under global change: connections between tree breeding, intensive silviculture and wood quality

Listya Mustika Dewi[1]
Beata Skiba[1], Robert Evans[1], Gerd Bossinger[1], Antanas Spokevicius[1]
[1] School of Ecosystem and Forest Sciences, The University of Melbourne, 4 Water Street, Creswick Victoria 3363 Australia.

Abstract: *Eucalyptus pellita* holds significant commercial value in the tropical region, mainly due to its application in the pulp and paper industry. This species has also been considered as an ideal source for producing high quality solid wood and veneer products. Wood quality assessment is crucial aspect to determine the end-product's performance, and consequently the value of the wood products. For the best utilisation of wood as a raw material and to develop an understanding of the effects of tree growth on wood formation, it is essential to have a knowledge of how wood quality changes within trees. Hence, this study aims to determine within-tree wood properties and develop whole-tree wood quality maps of even-aged plantation-grown *E. pellita* in the dry tropics of Australia. We selected 30 trees which represent five distinct genotypic backgrounds of *E. pellita* across two different sites on the Tiwi Islands. An IML Resistograph PD-400 was used to measure bark to bark wood properties at seven longitudinal points along the stem. Disc samples with 2 cm thickness were extracted from the base, middle and top part of each tree for assessing pith to bark wood properties using SilviScan and Near-Infrared Spectroscopy (NIRS). The results provide a comprehensive set of radial and longitudinal information on wood properties such as wood density, MFA, modulus of elasticity (MoE), fibre coarseness, cell wall thickness, fibre diameters, cells specific surface area, acoustic wave velocity (AWV), kraft pulp yield, lignin, cellulose, and extractive content of *E. pellita*. Whole-tree wood properties mapping was undertaken using Akima's interpolation method in R statistical programming environment with the RStudio interface to compare cambial age-related pattern of wood properties variation. The interrelationship between the various wood properties at different positions across the stem will also be explored. Wood properties mapping in this study will be used to develop wood quality predictive models based on non-destructive testing (NDT) that can inform plantation management practices and wood processing operations.

Abstract: In natural ecosystems, the root system of successful plants has microbial partnerships to survive and grow even in harsh conditions. Arbuscular mycorrhizal fungi (AMF) are among the mutual beneficial partners to plants in the drylands. Seedlings prepared for the restoration of degraded drylands need to be inoculated and colonized in the nursery for successful survival and growth at the planting site. The objective of the paper was to analyze the status of AMF spore density and root colonization in raised nursery tree seedlings and nursery soils in lowland, midland and highland agroecology in Tigray Ethiopia. Both soil and root samples were collected from seven private, four community and nine state nurseries using stratified random sampling method. AMF Spore enumeration and root colonization analysis were done using 204 seedling containers having nine species from lowland, fourteen species from midland and six species from highland. All the 22 species found in the 20 nurseries were colonized by AMF. The highest average spore density and root colonization were enumerated in lowland ($p<0.001$) followed by mid land and highland. State nurseries had recorded higher average spore density (43.60 spores 100 g^{-1} dry soil) and percentage of root colonization (39.51%) followed by community nursery and private nursery. The spore density of the nursery soils and root colonization of seedlings was low. Seedling raised in nurseries better requires inoculation from a non-disturbed soil sources.

Biodiversity mitigates drought and disturbance stresses in the decomposer system

Abstract: Multiple facets of global change affect the Earth System interactively with complex consequences for ecosystem functioning and stability. Simultaneous climate and biodiversity change are of particular concern, because biodiversity may contribute to ecosystem resistance and resilience and may mitigate climate change impacts. Yet, the extent and generality of how climate and biodiversity change interact, remain insufficiently understood, especially for the decomposition of organic matter, a major determinant of the biosphere – atmosphere carbon feedbacks. Decomposition depends on the characteristics and diversity of plant-produced organic matter as the primary energy source, and is further regulated by an astounding diversity of soil organisms ranging from prokaryotes to macro-invertebrates that are organized in highly complex food webs. With an inter-biome experiment, we tested here how biodiversity in the multi-trophic decomposer system drives decomposition in forest ecosystems under drier conditions. Our results show at a relevant spatial scale covering distinct climate zones that forest floor biodiversity across trophic levels has a strong potential to mitigate drought effects on C and N dynamics during decomposition. Furthermore, by choosing seven locations along a climatic gradient that is invaded or non-invaded by a clonal species (*Phyllostachys heterocycle*, moso bamboo), we conducted both in situ and reciprocal decomposition experiment and manipulated soil biota community. We reported a tradeoff mechanism of soil microorganisms with litter traits and showed that macrofauna play important role in modulating decomposition under plant invasion disturbance. Preserving biodiversity at multiple trophic levels contributes to ecosystem resistance and appears critical to maintain ecosystem processes under ongoing climate change.

[4] Curtin University, Australia

Abstract: Mediterranean forest ecosystems will be increasingly affected by hotter drought and more frequent and severe wildfire events in the future. However, little is known about the longer-term responses of these forests to multiple disturbances and their capacity to maintain ecosystem function. This is particularly so for below-ground organisms, which have received less attention than those above-ground, despite their essential contributions to forest function. We investigated rhizosphere microbial communities in a resprouting *Eucalyptus marginata* forest, southwestern Australia, that had experienced a severe wildfire four years previously, and a hotter drought eight years previously. Our aim was to understand how microbial communities are affected over longer-term trajectories by hotter drought and wildfire, singularly, and in combination. Fungal and bacterial DNA was extracted from soil samples, amplified, and subjected to high throughput sequencing. Richness, composition, and putative functional groups were then examined. We found a monotonic decrease in richness and diversity with increasing disturbance with the greatest changes resulting from the combination of drought and wildfire. These changes were more apparent for fungi than in the bacterial community. There were distinct responses in community composition and putative functional groups to the disturbance types, with key mycorrhizal fungi and cyanobacteria being found at lower proportions in sites affected by drought plus wildfire. Our results suggest that microbial communities, in particular key functional groups, are highly responsive to wildfire following drought. Thus, a legacy of past climate conditions such as hotter drought can be important for mediating the responses of soil microbial communities to subsequent disturbance like wildfire.

Complementary belowground strategies underlie species coexistence in an early successional forest

Abstract: Pure coniferous plantations are widely distributed globally and generally associated with low ecosystem services, low stability, and vulnerability to disturbances. Replanting broadleaf seedlings under pure coniferous plantations is an important measure to optimize the structure of monospecific forests. Unravelling belowground strategies is critical for understanding species coexistence and successional dynamics and would have important implications in the selections of broadleaf species; yet, our knowledge of nutrient acquisition strategies of forest species at different successional stages remains limited. We measured morphological (diameter, specific root length, and root tissue density), architectural (branching ratio), physiological (ammonium, nitrate, and glycine uptake rates) root traits, and mycorrhizal colonisation rates of eight coexisting woody species in an early successional plantation forest in subtropical China. By incorporating physiological uptake efficiency, we revealed a bi-dimensional root economics space comprising of an 'amount-efficiency' dimension represented by morphological and physiological traits, and a 'self-symbiosis' dimension dominated by architectural and mycorrhizal traits. The early pioneer species relied on root–fungal symbiosis, developing densely branched roots with high mycorrhizal colonisation rates for foraging mobile soil nitrate. The late pioneer species invested in roots themselves and allocated effort towards improving uptake efficiency of less-mobile ammonium. Within the root economics space, the covariation of axes with soil phosphorus availability also distinguished the strategy preference of the two successional groups. These results demonstrate the importance of incorporating physiological uptake efficiency into root economics space, and reveal a trade-off between expanding soil physical space exploration and improving physiological uptake efficiency for successional species coexistence in forests.

Controlled germination and inoculation of holm oak (Quercus ilex L.) with two species of the genus Tuber

Abstract: Truffles (genus *Tuber*) are hypogeous **ectomycorrhizal (ECM) fungi** that enter into a mutualistic symbiosis with the roots of higher plants. Truffles are intensively cultivated due to their gastronomic value and the decline of natural production. Modern truffle cultivation is based on planting inoculated seedlings on suitable soils of appropriate ecological conditions to complete the life cycle of the fungus.

The purpose of the research is to find the optimal inoculation method that will ensure a satisfactory degree of mycorrhization. Holm oak was chosen as the host plant because it is a natural symbiont of black and summer truffles, our indigenous specie and ecologically suitable for the habitat of planned plantations. Black (*Tuber melanosporum* (Vittad.)) and summer truffles (*Tuber aestivum* (Wulfen) Spreng.)) were used as fungal symbionts, which are the most prized black truffles. In addition, the technology of plantation cultivation is known for them. The research tested three methods of storage and germination of acorns, two methods of inoculation (inoculation with substrate and inoculation by injection into substrate) with different doses of mineral fertilizer and different treatments with fulvic acid. 19 different experiments were set up with a total of 1 320 holm oak seedlings. So far, we have confirmed mycorrhiza with both truffles species. The results obtained by the end of 2023 will be presented on a poster.

The use of inoculated seedlings with truffle mycelium is very wide, such as raising plantations, reforestation and recuperation of degraded habitats or their free sale. It has been proven that mycorrhized plants grow faster and better than individuals of the same species that are not mycorrhized and have a significantly increased leaf surface. This is especially pronounced in soils with a low nutritional composition. Cultivation of inoculated seedlings would also help preserve natural truffle populations, which are increasingly under pressure due to anthropogenic influence and climate change.

Does forest age affect root-associated fungal carbon flow, soil organic matter turnover and nitrogen cycling?

T3.11 Forest resilience: the vision from belowground

Abstract: Microorganisms mediate biogeochemical processes in soil, including nutrient and carbon cycling, and stewardship of ecosystem services provided by soils in boreal forests requires understanding of these processes. In these ecosystems symbiotic ectomycorrhizal fungi influence build-up and decomposition of soil organic matter, providing trees with nitrogen, but during succession, primary production is increasingly limited by nitrogen availability. However, the role of free-living microorganisms in organic matter turnover and inorganic nitrogen cycling, and the role of moss-associated N-fixation during forest succession, which may impact both carbon sequestration and forest productivity, are poorly studied. Forest clearcutting and site preparation in conjunction with replanting disrupt the soil profile and shift the competitive balance between free-living and root-symbiotic microorganisms. Here we study the development of microbial-mediated soil processes after clearcutting and replanting.

We hypothesized that priming of soil organic matter decomposition via ectomycorrhizal fungal exudation and inorganic nitrogen cycling is more important in younger forests, and that priming via ectomycorrhizal enzymes and diazotrophic nitrogen fixation is more important in older forests where nutrients become immobilized in organic matter. We also hypothesized that dead mycelium in older forests is more recalcitrant, contributing to build-up of soil organic matter stocks. We analysed the composition of the fungal, bacterial and archaeal communities in mosses and soil layers. Genes coding for specific nitrogen transformations and abundance of bacteria and fungi were quantified using quantitative PCR to examine inorganic nitrogen cycling and fungal:bacterial ratios, and N fixation rates were quantified. Soil solution was sampled sequentially and analysed for aliphatic and aromatic acids to quantify labile carbon fluxes. Decomposition was studied by incubating mycorrhizal mycelia in soil, measuring weight loss, and characterizing chemical composition. Preliminary results indicate presence of the gene *amoA*, encoding ammonia oxidation, in all stand ages and soil layers, implying a higher risk for N loss, and bacterial and fungal community data differed significantly depending on soil layer and stand age. Mycelial decomposition was significantly affected by fungal species, stand age and incubation time, with an average mass loss of 54%. Decomposition likely varied depending on chemical composition and mass loss was highest in the 80-year-old forest stand.

Ectomycorrhizal fungal succession in naturally regenerated silver birch (Betula pendula Roth) stands on post-agricultural land

T3.11 Forest resilience: the vision from belowground

Abstract: Silver birch (*Betula pendula* Roth) is a pioneer species that often naturally regenerates on post-agricultural land. The quantitative and qualitative composition of mycorrhizal fungal communities changes with stand age. The succession of ectomycorrhizal fungi depends on many factors, including local environmental conditions, particularly soil conditions. Therefore, the objective of this study was to analyze the mycorrhizal fungal communities in four young silver birch stands regenerated by self-sowing on post-agricultural land. The stands' ages were: 1-2 years old (class I), 2-7 years old (class II), 6-11 years old (class III), and 11-16 years old (class IV). Soil samples were collected from each stand for soil and mycorrhizal analysis. Soil properties in all age classes significantly differed from forest soils. The high proportion of non-mycorrhizal root tips in age classes I and II (10.8% and 20.4%, respectively) may result from limited inoculum availability. The high proportion of non-vital root tips, up to 55.7% in age class IV, indicates that soil conditions were not conducive to mycorrhizal functioning. A total of 23 taxa of mycorrhizal fungi were detected, with *Inocybe moravica* being the most abundant and frequently occurring species (relative abundance – 34.6%). Another species present in all age classes was *Paxillus involutus*. Most taxa (14) were found exclusively in one age class. The youngest stand had only three ectomycorrhizal fungal species, while a higher number of fungal taxa was observed in the three older stands (12, 11, and 13, respectively). Dominance, Shannon-Wiener, Simpson, and Evenness indices showed similarity among fungal communities in the three older stands, differing from the first age class. The ectomycorrhizal fungal communities of the three older age classes of stands were characterized by similar biological diversity, while they differed in terms of species composition, as confirmed by the low Jaccard similarity index. These findings suggest that soil properties and mycorrhizal inoculum availability influenced the results more than stand age.

Effect of birch afforestation of post-agricultural soils on key soil macrofauna

T3.11 Forest resilience: the vision from belowground

Abstract: Birch occurs throughout most of Europe, with the highest frequency in northern countries. In Western Europe it reaches 0.5% to 15% of all hardwood standing volume. In Poland, birch trees occupy 7.0% of the forest area and contribute 4,5% to the growing timber stock on forest land. Although currently not very important to the wood industry, they perform many ecological functions. Furthermore, in the face of climate change and the associated devastating phenomena birch might be relevant pioneer tree species in forest restoration, as it adapts easily to a wide spectrum of climatic and site conditions. Therefore, an increasing interest to use silver birch (*Betula pendula* Roth.) as an alternative to other tree species for afforestation, in particular on post-arable soils, can be observed in recent years.

Even though certain data about the impact of birch on the soil environment in Central Europe are available, the understanding of belowground biodiversity and interactions between above- and belowground systems is still largely unexplored. Considering the ecological and utilitarian importance of this issue, we undertook a study on key soil biota – earthworms, which constitute most of macrofauna biomass and contribute to a number of ecosystem services.

The study covered five sites on sandy soils and five on loamy soils. The stands were of different ages (21-80). Each site included both afforested and arable plots located on the same soil type. Earthworms were sampled from three soil blocks (25 × 25 cm and 30 cm depth) on each plot. Four sampling campaigns were carried out, in spring and autumn 2020 and 2021. Upon assignment of earthworms to species and ecological groups (epigeic, endogeic and anecic), their biomass was also determined.

We identified 10 earthworm species across all plots: four endogeic, five epigeic, and one anecic. More biomass was recorded in afforested plots than on arable fields, both on loamy and sandy soils. We demonstrated that afforestation had a significant positive effect on biomass of epigeic species only, and that forest age was an important predictor of total earthworm biomass on sandy soils.

The studies were supported by the NCN, Poland, project no. 2018/31/B/NZ9/01994.

Effects of tree diversity on topsoil carbon and fungal diversity in European planted mixed forests are modulated by biotic and abiotic factors

Abstract: Mixed-species forestry has emerged as a promising approach for sustainable forest management to mitigate climate change impacts through enhanced carbon (C) sequestration while maintaining productivity, biodiversity and other ecosystem services. However, we still have a poor understanding of the mechanisms driving soil C sequestration in tree mixtures, especially in the way it is driven by plant-soil-microbe interactions and biotic and abiotic factors.Using physiochemical soil analyses across nine European sites within the global network of tree diversity experiments, TreeDivNet, along with amplicon sequencing of soil fungal communities, we quantified the influence of mixed forest plantations on topsoil C stocks, fungal community composition and diversity, and their interactions. We further investigated the influence of biotic (tree growth, fungal diversity), edaphic (soil fertility and texture, nutrient status), and climatic (temperature and precipitation) factors on the relationship between tree diversity and C stocks in the topsoil. We hypothesised that increased tree diversity leads to increased topsoil C stocks and soil fungal diversity, and that this effect is modulated by the site-specific interaction of biotic and abiotic

factors.We found topsoil C stocks in high diversity stands to be greater than in monocultures across study sites. Increased soil fertility, mean annual temperature, as well as inter-annual temperature variability, were found to negatively affect tree diversity soil C relations. While tree diversity was not found to directly influence fungal diversity, topsoil C stocks were positively correlated to fungal species richness. In addition, the net diversity effect of tree mixtures on topsoil C stocks was positively correlated with fungal species richness, suggesting indirect linkages between tree and fungal diversity.Our study shows direct and indirect linkages between tree diversity, fungal diversity and topsoil C stocks, and highlights that these interactions are mediated by local abiotic context. Our findings underscore the need for site-specific optimization of C sequestration under consideration of tree diversity.

Elucidating soil biodiversity, crucial for climate change mitigation in forest soils?

Abstract: The role of forests in climate change mitigation is widely recognized as forests can store vast amounts of carbon both above- and belowground. However, many forest ecosystems are affected by environmental pressures, and are at risk of becoming sources of CO2. This emphasizes the need to focus on boosting carbon persistence in addition to increasing carbon stocks. There is a growing body of literature that pinpoints soil biota as the missing link between forest management and carbon stabilization. Microbial communities are expected to increase in abundance and catabolic activity, which could lead to more CO_2 emissions from soils. Additionally, soil fauna are involved in almost any aspect of organic matter turnover: from regulating the activity and functional composition of microbiota to increasing the physical accessibility for the soil biome to soil organic matter and by transferring SOC throughout the soil via bioturbation. Yet at the moment, we lack the understanding of how belowground community composition relates to net carbon persistence through time. This study uses an observatory set of paired forest stands located on degraded sandy soils with a large carbon-saturation deficit to detect changes in carbon dynamics. A full array of chemical, carbon and biological analyses have been executed, allowing to investigate the mechanisms affecting C stability and how soil biota are involved. I hypothesize that the changes in carbon stability found in our study area can be linked to the composition of the soil community. Specifically, I hypothesize that belowground community composition and abundance, resulting in a certain combination of traits (a so-called trait space), represents a certain belowground functioning (emerging mechanisms), which translates into carbon stability via stabilization mechanisms. A better understanding of the mechanisms that involve soil communities and the link to carbon stabilization, is needed to optimize forest management to boost carbon persistence in soils.

Exploration of base cation transporter genes in Suillus genus in relation to mineral weathering capability

T3.11 Forest resilience: the vision from belowground

Katharine King[1]
Petra Fransson[1], Roger Finlay[1], Marisol Sanchez-Garcia[1]
[1] Swedish University of Agricultural Sciences, Department of Forest Mycology and Plant Pathology, Sweden

Abstract: The role of ectomycorrhizal (ECM) fungi in biological weathering is increasingly recognised, although the quantitative significance of microbially mediated mineral dissolution for plant growth is debated. ECM fungi can weather minerals and mobilise essential nutrients such as base cations by physical force, extrusion of low molecular weight organic acids, free radicals and chelators. *Suillus* species in particular, are found to preferentially inhabit mineral soils and are frequently reported to possess weathering capabilities. Though studies growing ECM fungi with minerals have shown heightened nutrient content in mycelia compared to growth without minerals, the mechanistic understanding of nutrient mobilisation associated with weathering remains largely unknown.

Here we focus on characterising the diversity and phylogenomic distribution of base cation transporters in ECM genomes. We hypothesise that species with extensive mineral weathering capabilities will have higher copy-numbers of transporter genes associated with the transport of base cations to enable rapid uptake and transfer of recently mobilised nutrients. We examined transporter family gene copy-numbers of 110 Agaricomycetes species, and analysed evolutionary expansions and contractions of transporter gene families across the phylogeny.

Preliminary results show large variations in copy-numbers in all transporter gene families across all species and there are rapid expansions of cation transporters at the *Suillus* node. Genome analyses will be complemented by pure culture studies comparing base cation mobilisation and uptake by *Suillus spp.* to that by other species with varying copy-numbers and ecology. Fungal cultures will be grown with and without mineral additions (granite and gabbro) and mycelial base cation uptake and biomass will be quantified. Additionally, a transcriptomic study of *Suillus* spp. when in synthesis with *Pinus sylvestris* seedlings will be conducted taking guidance from the genomic study results.

Exploring the diversity and resilience of the mycobiome in Norway spruce in response to abiotic stress and pathogenic fungi

T3.11 Forest resilience: the vision from belowground

Abstract: The mycobiome, or the community of fungi living in and on plants, may play a vital role in the health and survival of trees in the face of environmental stressors such as climate change and pathogenic fungi. As we move towards more sustainable forest management practices, understanding the complex relationships between trees and their microbial communities will be crucial in developing effective strategies to promote the resilience and well-being of forest ecosystems. The host plant genotype has been noted to be also one factor defining fungal composition. In that sense, the mycobiome is an integral part of a tree's general biology and can be seen as an extension of its genotype. As part of a continued effort to understand the effects of host genetics and environmental factors on fungal composition, we monitored the mycobiome associated with phloem and roots of rooted cuttings of Norway spruce under different watering conditions. To test the "mycobiome-associated-fitness" hypothesis, we compared the artificially inoculated *Heterobasidion parviporum* and mycobiome interaction on necrosis development. We aimed to 1) identify the specific mycobiome and certain species within Norway spruce genotype/family level and their interactions with *H. parviporum* and 2) identify mycobiome stability under abiotic disturbance (lower water availability). The mycobiome was identified by sequencing the ITS2 region. Our findings indicate notable variations in the diversity and abundance of the phloem mycobiome among the Norway spruce genotypes. These highlight the substantial influence of genetic variation within spruce genotypes on the composition and diversity of the phloem mycobiome. Variations in particular mycobiome genera in Norway spruce genotypes in response to water availability in the phloem suggest that the abundance of certain fungal genera in the phloem of Norway spruce trees is also influenced by environmental conditions. In the root mycobiome, key fungi such as *Phialocephala fortinii* and *Paraphaeosphaeria neglecta* were identified to confer inhibitory benefits in Norway spruce against *Heterobasidion parviporum* growth. Particular endophytes were also more stable under low water conditions in roots than ectomycorrhizal fungi. Ultimately, this knowledge could contribute to developing sustainable forest management practices that promote the well-being of trees and their ecosystems, enhancing forest resilience.

Greedy trees: Increased N-status Norway spruce trees enhanced Carbon allocation for the roots but not to its fungal symbionts nor surrounding trees.

Abstract: Nitrogen (N) is one of the main factors limiting tree growth in the boreal forest, and trees growing in these soils rely on ectomycorrhizal fungi symbionts that provide nutrients in exchange for carbon (C). We provided supplemental N, equivalent to 25% of the estimated N present in the needles, to Norway spruce trees either through the transpiration stream or directly to the soil. We included 1% ^{15}N to track the distribution of the added N. After eight weeks, the trees were labeled with ^{13}C via photosynthesis to evaluate the effect of the increased N-status on the allocation of assimilated ^{13}C belowground. To evaluate the effects on root and the root-associated fungal transcriptomic activity, RNA was sampled after one and four growing seasons, and the community composition of the root-associated fungi was assessed using DNA amplicon sequencing.

Needle %N increased by 29% in trees treated via the transpiration stream, and by 58% in the soil treated trees. This increase in %N was mirrored by the distribution of ^{15}N throughout the canopy. Root %N increased 13% in both treatments. We found no evidence of ^{15}N transfer from the roots of trees treated via the transpiration stream to the root-associated fungi nor to surrounding trees. Both treatments significantly increased ^{13}C allocation belowground, assessed by ^{13}C efflux soil, with transpiration stream treated trees having higher soil ^{13}C efflux than the soil treated. Amplicon data showed significant changes in fungal community composition after four growing seasons, which were associated with changes in prevalence of seven dominant genera: *Cenococcum*, *Cortinarius*, *Hyaloscypha*, *Lactarius, Piloderma*, *Russula*, and *Suillus*. Fungal metatranscriptomic analyses showed that N-enrichment induced treatment specific C-starvation responses. With the transpiration stream treatment, processes including autophagy, glycolysis/gluconeogenesis and amino acid metabolism were induced, whereas ground N-enrichment induced biosynthesis of secondary metabolites, glycolysis/gluconeogenesis and glycerolipids metabolism. Altogether, our results show that increasing the tree's N-status initially enhances C-allocation belowground but the prevalent C-starvation responses shown by the linked fungal community suggests that the increase in allocated C is metabolized in the roots rather than transferred to the fungi.

Impacts of elevated CO2 on interactions with root microbes for enhanced oak growth and defence against pathogens

T3.11 Forest resilience: the vision from belowground

Rosa Sanchez-Lucas[1]
Emma Platt[1], Victoria Pastor[2]
[1] Birmingham Institute of Forest Research, School of Biosciences, University of Birmingham, Birmingham B15 2TT, United Kingdom
[2] Metabolic Integration and Cell Signalling Group, University Jaume I, 12071 Castellon, Spain

Abstract: Trees are adapted to survive and face multiple (a)biotic stresses through millions of years of evolution. However, Climate change (CC) is increasing the number and rapidity of these stressors, endangering treescapes and the surrounding ecosystem. A crucial factor is the increasing atmospheric CO_2, the basis of the plant life, together with water. Even when it could be considered as a plant growth stimulant (e.g. increased growth), elevated CO_2 (eCO_2) has been demonstrated to trigger a plant stress response. In addition, many studies have highlighted the impacts of CC factors (warming temperatures, rising CO_2 and/or drought) on plant physiology, communities, and interactions with mycorrhizal fungi. Symbiosis between plants and beneficial soil microorganisms like mycorrhizae are known to promote plant growth and defence against (a)biotic stresses in plants. Therefore, understanding the role of mycorrhizal in plant responses facing environmental changes is critical. However, mycorrhizae role is largely underappreciated, and field experiment research is scarce. This project will test the mycorrhizae effects on oak, the eCO_2 impact on mycorrhizal colonization and their role in mediating growth-defence trade-offs. For this, microscopy and untargeted metabolomic analyses were performed in oak seedlings grown under ambient CO_2 (aCO_2) and eCO_2 and then infected with powdery mildew at the Free Air CO_2 Enrichment (FACE) facilities of the Birmingham Institute of Forest Research (BIFoR). Powdery mildew infection was monitored from May to July. At the end of the experiment, plants were removed and root traits were measured. Mycorrhizae staining was performed by ink-acid method in 20 seedlings/CO_2 levels to visualise endophytes. Root-extracted metabolites were subjected to LC-MS/MS analysis. Spectra were filtered by using XCMS R scripts. Statistical analysis, using METABOANALYST, showed statistical differences among treatments. Identification and functional pathway analysis was performed using MARVIS to select putative biomarkers. Additionally, elemental analysis was performed to quantify C/N ratios. Correlation analyses were performed to reveal the mycorrhizae relevance in powdery mildew resistance and its interaction with eCO_2. Data showed a protective role of mycorrhizae that can be limited by future CO_2 atmospheric levels, endangering forest health under climate change conditions.

Isolation, characterization and application of microorganisms to improve drought-stress tolerance in trees for restoration projects

[4] Technical University of Munich, TUM School of Life Sciences, Professorship for Land Surface-Atmosphere Interactions, Freising, Germany

Abstract: Forests play a key role in mitigating the effects of climate change. However, due to increasingly frequent periods of severe drought, more and more forests are damaged. Especially tree seedlings show a high mortality under drought. Thus, improving drought tolerance of tree seedlings is of central importance for forest restoration. Many microorganisms are known to positively influence plant growth, for example by reducing several abiotic plant stresses. In the present study, soil microorganisms isolated at different forest sites were analyzed regarding their ability to reduce drought stress or to promote plant growth. The goal is to apply the newly isolated plant growth-promoting bacteria and fungi (PGPB/PGPF) during reforestation projects.

In 2021, we isolated 1,500 bacteria and fungi from two different temperate mixed Norway spruce (*Picea abies*) and European beech (*Fagus sylvatica*) forests in southern Germany after longer periods of drought. So far, around 400 isolates were identified on genus level. The most abundant bacteria were *Paraburkholderia* (121) and *Bacillus* (43) while *Penicillium* (8) and *Umbelopsis* (7) were the most frequently isolated fungi. Biochemical characterization revealed one *Streptomyces* strain and one *Paraburkholderia* strain showing a high salt, pH and osmotic stress tolerance as well as the ability to produce siderophores, solubilize phosphate and utilize 1-aminocyclopropane-1-carboxylic acid, the precursor of ethylene, as a nitrogen source. For application to the tree seedlings in monoxenic *P. abies* cultivations, three different systems were used: two petri-dish systems based on either agar or white/black peat and perlite and a newly developed 24-deep-well system. In these, two bacterial stains and one fungal strain leading to higher seedling weight and length were identified. In subsequent pot experiments, the effects of the identified PGP strains are now verified under more realistic conditions. Moreover, the genomes of the most promising isolates will be further analyzed for a deeper understanding of the mechanisms underlying these positive interactions. Additionally, metagenomes of the soil samples taken in 2021 are analyzed to identify microorganisms that are generally associated to drought. Taken together, these data could contribute to finding nature-based solutions to alleviate the negative effects of climate change on tree seedlings during restoration projects.

Mycorrhizal Inoculation: Promoting Tree Health and Survival in a Changing Climate

T3.11 Forest resilience: the vision from belowground

Faisal Qaseem[1]
Susanna Keriö[1]
[1] Department of Environmental Science and Forestry, The Connecticut Agricultural Experiment Station

Abstract: Planting and maintaining a healthy tree canopy is one of the most effective ways to combat the negative impacts of climate change. Due to the more frequent and intense droughts caused by climate change, improving drought resilience of newly established trees is of high priority. The combined impacts of abiotic and biotic stress agents make drought resilience a critical concern for tree planting efforts. Mycorrhizal fungi form intricate networks of fine hyphae that explore a greater soil volume, thus increasing tree resilience to drought stress. Using chestnuts (*Castanea*) as a study system, we explored the combined impact of drought and chestnut blight caused by the fungal pathogen *Cryphonectria parasitica* on tree growth, biomass, leaf fluorescence, stomatal conductance, and cell death response in greenhouse conditions. We exposed one-year-old chestnut seedlings inoculated with mycorrhizal fungi to drought and chestnut blight infection. Drought had a significant impact on all growth and physiological parameters when compared to normally watered plants. Mycorrhizal infection supported tree growth under drought stress. We will discuss the interaction of pathogen and mycorrhizal infection, and the applications of mycorrhizal inoculation in improving tree health. The results serve as a base line for studying the mechanisms involved in the interaction of mutualistic and pathogenic fungal infections in chestnuts, and for investigating the mechanisms by which mycorrhizal associations enhance tree resilience.

NatureCarbonQuality - Effects of agroecosystem naturalization on carbon in different pools with varying stability and their modelling

T3.11 Forest resilience: the vision from belowground

Abstract: NatureCarbonQuality - Effects of agroecosystem naturalization on carbon in different pools with varying stability and their modelling

Agroecosystems naturalization gained increasing interest for mitigating climate change: a 0.4% increase in soil carbon stock would reduce CO2 in the atmosphere and enhance resilience. However, long-term carbon sequestration depends on microbial resistance of carbon in different pools associated with physical fractions of soil: low resistance carbon (labile) called "particulate organic matter" (POM) and high resistance (stable) called "mineral-associated organic matter" (MAOM). The effect of agroecological system naturalization on carbon quality is understudied.

Four ex-agricultural plots with varying naturalization degrees in northern Italy were identified, each with a different practice and different implementation times: mulching (1 year), cover crops (6 years), reforestation for truffle cultivation (>20 years), riparian natural reforestation (>20 years). Three replicated plots were compared with adjacent conventional agricultural systems at 0-5cm and 5-20cm depths. Samples were analysed for carbon in POM and MAOM pools. The ARMOSA process-based model, developed to simulate cropping systems, was modified to quantify the effect of reforestation on carbon pools evolution on a long-term prospective.

Results shows significant effect of naturalization on carbon storage with cover crops, riparian natural reforestation, and truffle reforestation; but not with mulching, indicating the need for sufficient time after practice implementation. POM augmented at 0-5cm but not at 5-20cm depth, while MAOM significantly increased in both depths. This effect could be explained by i) importance of exudation and carbon leaching from upper soil layers for MAOM increase, and ii) effect of surface litter on POM. The study shows a prominent role of stable deep carbon that needs to be protected and further studied to comprehend mechanisms regulating its increase and stability. Long-term modelling shows the suitability of ARMOSA to include reforestation as a modelling scenario. Results confirms that reforestation is the most suitable practice not only to increase the total soil organic carbon but also the stable MAOM pool. The results in the three sites >1yo are well above the +0.4% threshold, with an average of +145% carbon in reforested areas and +28% with sustainable agricultural practices (mulching and cover crops).

Nitrogen Addition Exacerbates the Negative Effect of Throughfall Reduction on Soil Respiration in a Bamboo Forest

T3.11 Forest resilience: the vision from belowground

YI WANG[1]
JUNWEI LUAN[1], SHIRONG LIU[2]

[2] Chinese Academy of Forestry

Abstract: Impacts of drought events and nitrogen (N) deposition on forests are increasingly concerning in the context of global climate change, but their effects, in particular, their interactive effects on soil respiration and its components remain unclear. A two-factor random block field experiment was conducted at a subtropical Moso bamboo forest in Southwest China to explore the response of soil respiration (R_s), autotrophic respiration (R_a), and heterotrophic respiration (R_h) to throughfall re-duction and N addition. Our results showed that throughfall reduction significantly decreased R_s, which is mainly attributed to the decrease in R_a as a result of the decline in fine roots biomass. The N addition led to microbial carbon limitation hence significantly decreased R_h, and thus R_s. We also observed the negative effect of throughfall reduction on R_s was exacerbated by N addition, which is attributed to the significant reduction in R_a under the interaction between throughfall reduction N addition. Our findings suggest that R_a tended to respond more sensitively to potential drought, while R_h responds more sensitively to N deposition, and consequently, increased soil N availability caused by N deposition might aggravate the negative effect of expected drought on soil carbon cycling.

Olive trees (Olea europaea L.) shape and influence the soil bacterial community of a wheat-barley Agroforestry system under different soil managements

T3.11 Forest resilience: the vision from belowground

Abstract: Agroforestry is an agriculture system that integrates woody perennials with arable crops, livestock, or fodder in the same place of land. Agroforestry systems are characterized by high species diversity providing more ecosystem services (i.e., soil fertility maintenance, carbon sequestration, climate change mitigation, and biodiversity conservation) than agricultural monocultures. Agroforestry is the most promising system in terms of adaptation to ongoing climate change. Tree rows in agroforestry systems enhance soil quality and microbial soil-related biodiversity by shaping and altering its composition and structure. The advancement of biotechnology and next-generation sequencing (NGS) have facilitated the comprehension of the mechanisms at the base of the interaction between trees and their related microbiome. Despite these progresses, there is still a knowledge gap about this topic. The aim of this work was to investigate the influence of *Olea europaea* L. in shaping and influencing the bacterial soil community of a wheat-barley agroforestry system by comparing different soil managements, namely conventional tillage versus minimum tillage, and with or without cover-cropping. The microbial community characterization was performed by sequencing the V5-V6 region of the bacterial 16S rRNA gene with the Ion Torrent Platform. NGS preliminary analyses indicate the presence of 4,760 amplicon sequence variants (ASV) belonging for the 99.8% to bacteria and the rest to archaea domain. Among the genera present, the *Bacillus* spp. is the most abundant respect to bacteria involved in nitrogen cycles (for example: *Bradyrhizobium*, *Rhizobiaceae*, *Nitrosomonadaceae*), but additional analyses are in course to better evaluate the effect of olive trees and the presence or absence of cover crops.The obtained results could raise awareness and understanding of the complex interaction between olive trees and soil microorganisms, and how the different soil management could influence this interaction in the field.

On the role of earthworms for the recovery of soil structure in skid trails

T3.11 Forest resilience: the vision from belowground

Abstract: With Central European winters getting warmer, timber harvesting operations often happen under suboptimal conditions on wet, non-frozen soils. This increases the susceptibility of soils for compaction. Fine textured soils in skid trails often stay compacted for decades. In a controlled experiment in the Vienna woods, we assessed the effects of different harvesting technologies on the degree of soil compaction and the impairment of soil functions. To measure the recovery potential of soils in skid trails after ground-based logging, we compared trails compacted 1 and 18 years ago. The soil structures under and next to the skid trails were evaluated with CT-scans of undisturbed soil cores collected at two depth levels (2.5-7.5 and 12.5-17.5 cm). We measured soil hydraulic properties at the same cores. This information was linked to earthworm data collected in a similar plot design. Earthworms were sampled with a combination of mustard extraction and hand-sorting and identified to species level. We detected five different species at the site (*Aporrectodea rosea, Dendrobaena platyura, Lumbricus rubellus, Octolasion lacteum*). Preliminary results suggest a recovery of the earthworm population in skid trails within 18 years, following a stark decline or near eradication post harvesting. It is expected that earthworms help improving the macropore structure of compacted soil. However, we assume that the upper biologically more active soil layer recovers quicker than the deeper soil, where compaction is more persistent.

Partitioning Soil Respiration in Differing Irish Forests Types for Better Climate Models

T3.11 Forest resilience: the vision from belowground

Blair Ruffing[1]
Ken Byrne[1], Brian Tobin[2], Mathew Saunders[3]
[1] Department of Biological Sciences, School of Natural Sciences, University of Limerick, Limerick, Ireland
[2] School of Agriculture and Food Science, Agriculture and Food Science, University College Dublin, Belfield Dublin 4
[3] School of Natural Sciences, Botany, Trinity College Dublin, Dublin, Dublin 2

Abstract: Forest ecosystems play a significant role in global carbon cycling, harboring a substantial portion of aboveground and belowground terrestrial carbon. Accurately understanding the balance between photosynthetic activity and ecosystem respiration is crucial for determining whether forests act as carbon sources or sinks. In this context, measuring soil respiration and partitioning autotrophic and heterotrophic components are essential to comprehend carbon and nutrient cycling in forest ecosystems. This study investigates resilience factors in Irish forests by evaluating soil carbon (C) flux dynamics in three distinct forest types: typical commercial coniferous forest on mineral soil, broadleaf-dominated native woodland on mineral soil, and a mixed species forest on peat soil. The study sites, characterized by variations in age, soil type, management practices, and species composition, provide valuable insights into respiration rates and their implications for climate change mitigation.

Since November 2022, data collection has revealed that the native woodland on mineral soil exhibited the lowest average soil respiration rates (0.23 g (CO2) m^{-2} $hour^{-1}$). The lowest value (0.15 g (CO2) m^{-2} $hour^{-1}$) was recorded in February 2023, while the highest value (0.65 g (CO2) m^{-2} $hour^{-1}$) was observed in November 2022. Conversely, the mixed forest on peat soil showed the highest average total ecosystem respiration rate (0.30 g (CO2) m^{-2} $hour^{-1}$), with the lowest value (0.16 g (CO2) m^{-2} $hour^{-1}$) in March 2023 and the highest value (0.58 g (CO2) m^{-2} $hour^{-1}$) in May 2023. Consistent with previous studies, heterotrophic flux contributed more to total ecosystem respiration than autotrophic flux across all study sites and seasons.

To enhance the understanding of soil respiration and carbon dynamics in different forest types, this project collects additional data on litterfall, coarse woody debris, fine root turnover and distribution, carbon stock estimation, moss-derived carbon, and organic matter physical fractionation. These supplementary datasets support the development of accurate models for carbon and nutrient cycling in forests, enabling better predictions of the impacts of environmental change on these vital ecosystem processes. Ultimately, the findings from this study will contribute to improved climate models, helping policymakers and land managers make informed decisions for sustainable forest management and climate change mitigation.

Persistency of Ectomycorrhizal Dipterocarp, Tomentella sp. in tin tailings reforestation

T3.11 Forest resilience: the vision from belowground

Abstract: Planting of forestry species as one means of rehabilitating the ex-mining land areas in Malaysia and has started since 1980's. Indeed, the necessity to repurpose mined land has been recognized since the early twentieth century. The majority of these initiatives have been on finding ways to improve the physical and chemical conditions of the sites. Forest Research Institute Malaysia (FRIM) is one of the organizations that devoted to such operations and achieved success. In Bidor, Perak, Malaysia, a trial plot was established on ex-tin tailings soil, with aim of utilising ectomycorrhizal fungi (EMF) in rehabilitation of heavily degraded sites. The study begins with planting of *Acacia mangium* and is followed two years later by two dipterocarp species (*Hopea odorata* and *Shorea leprosula*). Before out-planting, these tree species were pre-inoculated with an indigenous ectomycorrhiza, *Tomentella* sp. During the early establishment, the inoculated plants outperformed non-inoculated plants. From the morphotyping, supported with PCR and ITS study confirmed the persistency of the inoculated EMF strain even after 18 years. It was discovered that treatments with inoculation had higher mycorrhizal abundance than treatments without inoculation. The performance of *A. mangium* and dipterocarp plants after years of out-planting, as well as their response to ectomycorrhizal inoculation and diverse EMF that remain during succession, will all be covered in this study.

Regeneration failure after forest disturbance alters soil microbial communities with consequences for carbon storage

T3.11 Forest resilience: the vision from belowground

Abstract: Increasing forest disturbance is among the most profound impacts of climate change on terrestrial ecosystems. Insect outbreaks, storms, or wildfires can destroy the whole tree layer, with serious consequences for biogeochemical cycles until succession returns the ecosystem back to a forested state. However, tree regeneration is often inhibited by ungulate herbivory and herbaceous competition, and disturbed ecosystems remain in non-forested states for decades. The impact of such tree regeneration failures on soil carbon (C) and nitrogen (N) cycles is highly unknown, because a multitude of plant-soil feedbacks are involved, and underlying processes have hardly been investigated. Here, we studied soil microbial community structure, gene abundance of bacteria, fungi, and N cycling microorganisms, soil enzymes, and C-N dynamics across a disturbed forest landscape in Central Europe, covering a range of successional stages after storm damage and bark-beetle attacks. We used a chronosequence-approach including disturbed sites regrown with *Picea abies* stands, and disturbed sites dominated by herbaceous pioneer plants, particularly *Calamagrostis* grasses. Soil C and N stocks increased under a prolonged herbaceous cover. Three decades after disturbance the stocks were ca. 45% higher than those of regrown forest stands. We link this increase to changes in the structure and functioning of the microbial community, which reduces the decomposition of organic matter. With a prolonged herbaceous cover, decreasing fungal abundances coincided with declining activities of phenol oxidase and of hydrolytic enzymes used to acquire nutrients. Since ectomycorrhizal fungi were almost absent compared to regrowing forest stands, this may be linked to reduced ectomycorrhizal mining for organic N. Moreover, ammonia-oxidising (*amoA*) gene abundances increased along with ammonium and nitrate concentrations, pointing towards an accelerated inorganic N cycle under a prolonged herbaceous cover. A surplus of inorganic N and grass-rhizodeposits renders it also likely that saprotrophs are less dependent on organic matter-bound C and N. Taken together, we found strong evidence for a linkage between above- and belowground communities following forest disturbance. We suggest a prolonged cover of herbaceous pioneer plants opens the nitrogen cycle through microbial communities which reduces mining for organic N and thus, increases soil C storage.

SERVICE CROP AS A SOIL QUALITY IMPROVER IN PLOTS DESTINED FOR FOREST LANDSCAPE RESTORATION

T3.11 Forest resilience: the vision from belowground

[2] Itaipú Binacional, Paraguay

Abstract: The use of service crops is an important tool in soil conservation management, being fundamental in the collection of data to describe early or undesired changes in soil conditions resulting from managed forests, being the study of the biological properties of soils the most sensitive to these variations or disturbances becoming excellent indicators of soil quality for the management of resources in restoration, however, research on this subject is still scarce in Paraguay. The objective of the experiment was to evaluate the biological activity of soils managed with and without the use of service crops in plots intended for forest landscape restoration. It was carried out during 2 years with four soil samplings in the Hernandarias, district near the Tati Yupí Natural Reserve, Paraguay, in four treatments with strips of native species; T1 for timber purposes; T2 for timber purposes + service crop; T3 for energy purposes; and T4 for energy purposes + service crop, where each experimental unit had conservation and harvesting strips. The service crop used was *Cajanus cajan* L. Millsp. Soil samples were extracted from each experimental unit at a depth of 0-20 cm, maintained at a temperature of 4 °C. For the measurement of microbial activity, through respiration, the soil samples were incubated for 7 days at 25 °C, in closed flasks with a NaOH solution for subsequent titration with sulfuric acid. Significant differences were found in the values of respiratory activity in the treatments where the service culture was included, $p>0.05$ by Tukey's test whose values were 0.68 and 0.73 µg $C\text{-}CO_2$/g ss h^{-1} for species with timber and energy purposes, respectively. This shows that the use of service crops contributes positively to the restoration of soil quality.

Soil microbial communities in pure and mixed forests of Oaks and Pines: linking soil microbial data to forest management in the Mediterranean region

T3.11 Forest resilience: the vision from belowground

[5] Centro de Estudos Florestais & Laboratório Associado Terra, Instituto Superior de Agronomia, Universidade de Lisboa, Tapada da Ajuda, 1349-017 Lisboa, Portugal

Abstract: Cork and pine nuts are two of the most valuable non wood forest products of Portugal. The forest tree species that yield these products - cork oak (*Quercus suber*) and stone pine (*Pinus pinea*) - represent approximately one third of mainland Portugal. These species share similar ecological ranges, thus being able to coexist in mixtures. Climate change will likely increase soil degradation by reducing the input of organic matter, overall diversity and exacerbating the already existing desertification processes in the Mediterranean region.
This study intends to understand how forest composition affects soil fungal and bacterial communities and how this knowledge can be used to support forest management decisions under a climate change scenario. For this, we collected soil samples in a north-south ecological gradient including differences in both soil and climatic variables, in Portugal mainland. The plots were organized in triplets (with pure and mixed stands of each species) which were completely characterized in terms of species density, structure, richness and biomass and also tree vitality and health. Soil samples were collected for chemical and physical properties as well as for fungal and bacterial community's characterization using a targeted metagenomics approach based on rDNA amplicon sequencing.
Such an interdisciplinary study will provide valuable information regarding beneficial and antagonistic microorganisms present in the soil, help to explain possible ecological interactions between species in pure and mixed stands with their changing environments and, ultimately, provide guidance for management practices able to preserve soil health status and a sustainable forest production.

The impact of restoration on the activity of microorganisms in European forests

T3.11 Forest resilience: the vision from belowground

Treza Cordaro[1]
[1] Treza Cordaro, KU Leuven, Department Aard- en Omgevingswetenschappen campus Geel, Belgium

Abstract: Forests are under pressure due to climate change and poor management practices. They are experiencing disturbances, loss of biodiversity and soil degradation. However, soil is an important but fragile and nonrenewable component of a forest ecosystem. It encompasses one of the largest carbon reservoirs, containing a significantly greater amount of carbon compared to the aboveground biomass. Therefore, forest restoration is necessary to halt the decline of forests and to reverse soil degradation.

In this study soil carbon and soil biota are being analyzed in 12 European forest areas, selected for restoration in the context of the EU Horizon 2O2O Superb project. These areas reflect the different stress factors faced by forests in Europe, and further include the different biogeographical regions and management practices.

Soil samples were taken to compare soil biota between reference-, degraded-, and restored stands. This was done by taking samples to a depth of 15 cm with fixed depth classes in order to analyze microbial biomass and functional catabolic diversity. The data obtained from the analyses, will enable us to assess the situation of the restoration measures.

We expect that undisturbed forests or forests in a high restoration stage contain a higher activity of microorganisms. Some preliminary results for Romania, where sampling took place in primary, close to nature and highly managed forests, are that primary forests do have more diversity of microorganisms in the 0-5 cm and 5-15 cm soil layer compared to close to nature and highly managed forests. Microbial activity and diversity is higher in forests with predominantly deciduous trees.

Based on the results best practice guidelines for effective implementation and monitoring of forest restoration can be provided.

Tree species effects on stocks and stability of soil carbon: Links to mycorrhizal association and soil biota composition and functioning

T3.11 Forest resilience: the vision from belowground

[5] Institute of Tropical Biodiversity and Sustainable Development, University Malaysia Terengganu, Terengganu, Malaysia

Abstract: Tree species with leaf litter traits driving slow rates of leaf litter decomposition have traditionally been associated with accumulation of higher soil organic carbon (SOC) stocks than tree species with fast litter decomposition rates. This hypothesis has mainly been based on observations of thick C-rich forest floors under tree species associated with ectomycorrhizae (ECM). However, a recent hypothesis suggested that tree species with foliar litter traits conducive to fast decomposition will lead to more pronounced microbial transformation and stabilization of litter C. The latter tree species are often associated with arbuscular mycorrhizae (AM) and may enhance deeper incorporation of C by more active soil fauna communities and by higher belowground rates of litter input. The Danish common garden tree species experiment include ECM and AM tree species that differ widely in traits such as foliar litter chemistry. The experiment has been studied over the last 15 years to document and explain soil C stocks supported by emerging studies of soil biota community composition and functioning.

The six common European tree species formed distinct groups in soil carbon characteristics as well as in soil biota community composition and functioning that partly reflected their mycorrhizal association. Forest floor C stocks were consistent with the traditional perception of slowly decomposing leaf litter in ECM species being conducive to high C stocks. However, an intriguing pattern of higher C stocks in the mineral soil in AM tree species with high litter quality and characteristic soil biota functioning supported the recent microbial stabilization hypothesis and suggested deeper incorporation of C in more stable forms.

Based on new results on microbial, macro- and mesofauna communities and their functioning, and on repeated soil sampling, this talk will revisit the common garden experiments for a synthesis of processes and patterns in organic matter formation that may explain observed patterns in quantity and quality of SOC.

What if we managed forests to sustain soil life?

T3.11 Forest resilience: the vision from belowground

Cindy Prescott[1]
[1] University of British Columbia

Abstract: The last two decades have brought remarkable insights into the exceptional diversity of belowground life in forests, its dependence on inputs from living trees, and its critical importance in generating the many ecosystem services that forests provide. In contrast, forestry policies and practices still reflect an outdated image of forest soils as inert substrates. What if we purposefully managed forests to improve the health and fertility of soil, rather than just mitigate damage? How would we manage forests if our primary objective was to sustain belowground life and the critical ecosystem processes that these organisms mediate? In contrast to the prevailing view of soil organisms depending on dead organic matter generated by trees, recent evidence indicates that metabolites secreted by living tree roots and associated mycorrhizal fungi are essential for sustaining belowground foodwebs. Our view of forest ecosystems needs to recognize the importance of these belowground fluxes from trees, and forestry practices such as clearcut-harvesting, monoculture plantations, and fertilization need to be re-examined through this lens.

T3.12 Forest Restoration Success and How to Achieve it

A Novel Approach for Prioritizing Stepping Stones in Forests to Enhance Connectivity

T3.12 Forest Restoration Success and How to Achieve it

Katharina Lapin[1]
Janine Oettel[1], **Johanna Hoffmann**[1], Martin Braun[1]
[1] Austrian Research Centre for Forests, Department Forest Biodiversity and Nature Conservation, Austria

Abstract: Climate change exacerbates challenges, affecting the range, genetic diversity, behavior, and survival of species. To address these issues, conservation, restoration, and enhancement of ecologically valuable forest areas and their connectivity must be prioritized. Maintaining functional connections between protected areas is essential for promoting gene flow, migration, and recolonization in the face of climate change.

In aiming to implement a conservation program focused on improving forest connectivity, two crucial steps are required. First, suitable areas within forests need to be identified and prioritized. Second, these areas must be selected and established, considering forest ownership and incentive transfer to ensure program success.

In our study, we present a novel approach to identifying and prioritizing stepping stones for preserving connectivity in Austrian forest ecosystems. We combined national and regional biodiversity data to develop a framework that considers structural and functional connectivity metrics. The framework includes four compounded indicator values: Protect Value, Connect Value, Species Value, and Habitat Value. These indicators incorporate information on protected areas, habitat corridors, connectivity areas, species richness, and ecological value. We identified areas with high prioritization values in 25% of the assessed forest area (8,336 km²). The framework provides decision support for managers and conservationists in prioritizing areas for forest habitat connectivity conservation. Accompanying field assessments is essential and should complement the framework's results.

Analysis of canopy cover and grass cover relationship in a Forest Landscape Restoration Plot, Hernandarias, Paraguay.

T3.12 Forest Restoration Success and How to Achieve it

Dahiana Edith Rivas Maqueda[1]
María Laura Quevedo Fernández[1], Lila Mabel Gamarra Ruiz Diaz[1], Lidia Perez de Molas[1], Haroldo Nicolas Silva Imas[2]
[1] Univeridad Nacional de Asuncion, Paraguay
[2] Itaipu Binacional

Abstract: The presence of grasses in Forest Landscape Restoration projects has an impact on the growth and survival of the species of interest, and their control represents a high cost. The objective of the study was to analyze the relationship between canopy cover and grass cover. The experimental plot was set up in the district of Hernandarias, located in the department of Alto Paraná, Paraguay. It covers 5.9 ha and is made up of 5 blocks with 8 treatments, each experimental unit covers 1080 m^2 and has conservation and utilizations strips. Measurements of grass cover (%) were made 18 months after planting, where each unit were sub-divided in 16 units, disregarding the edge. The crown canopy cover (CCC) was estimated considering the measurements made on the x and y axes. Grass and other invasive species control were made in every unit with a canopy cover ≥ 40% and with a height ≥ 30 cm. The results show that treatments 2 and 1 have the lowest grass cover and the highest tree canopy cover; both treatments have Eucalyptus as the tree component. It was observed that the higher the tree canopy cover, the lower the percentage of grasses occurrence, so it is considered that the species with a wide canopy development favours grass control, avoiding the setback of the restoration process and reducing the costs of chemical management.

Analysis of external factors influencing restoration schemes

T3.12 Forest Restoration Success and How to Achieve it

Yitbarek Weldesemaet[1]
Katharina Dehnen Schmutz[1], John Wilson[2], Adrian Evans[1]
[1] Centre for Agroecology Water and Resilience, Coventry University, United Kingdom
[2] South African National Biodiversity Institute (SANBI) & Centre for Invasion Biology (CIB) Department of Botany and Zoology Natural Sciences Building Private Bag X1 Stellenbosch University

Abstract: Ecosystem restoration has been implemented globally, with billions of dollars spent annually for the establishment, associated knowledge, and capacity building. These restorations are expected to address several environmental, social, and economic issues. However, despite the expectations, restoration schemes have failed in several parts of Africa to deliver sustainable outcomes. Studies have tried to assess the factors behind the lack of success and identified technical, ecological, and governance issues. In addition, some of these studies identified spatially and temporally specific mechanisms to improve these internal factors, thereby contributing to the success of restoration schemes. However, restoration schemes still struggle to deliver the expected outcomes despite these efforts. Therefore it is imperative to identify the reason behind restoration schemes' lack of sustainable performance. This identification requires a broad and practical view to provide sustainable solutions to the current inadequacies.

Moreover, identifying spatially and temporally broad and relevant factors will help evolve and function as a sustainable governance mechanism for restoration schemes. In this regard, we identified external environmental factors such as political, economic, social, technological, ecological, legal, and institutional influencing restoration schemes more than the internal technical, ecological, and governance issues. We evaluated the influence of these external environmental factors using the PESTEL analysis tool or framework, taking the case of four African countries (Algeria, Cameroon, Ethiopia, and South Africa). These significant external environmental factors are out of the control and influence of the restoration schemes and hence primarily hinder them in achieving their intended target. Therefore, analysing these factors provides a means to include sustainability in strategic analyses of the restoration schemes because it incorporates the main dimensions of sustainable development: environment, society, and economy. This means restoration scheme stakeholders can analyse these and devise mechanisms to avoid the influence of these factors in their governance practices.

Assessing the recovery in species, size and location diversities of a lowland tropical rainforest by multiple indices at stand and neighborhood scales

T3.12 Forest Restoration Success and How to Achieve it

Runguo Zang[1]
Chaofan Zhou[1]
[1] Key Laboratory of Forest Ecology and Environment of the National Forestry and Grassland Administration, Ecology and Nature Conservation Institute, Chinese Academy of Forestry

Abstract: Tropical forests are rapidly being converted for agricultural use, but abandoned agricultural lands can recover naturally through secondary succession. However, comprehensive knowledges of how species composition, size structure and spatial patterning (represented by species, size and location diversities) change during recovery at multiple scales are still lacking. Our aim was to explore these change patterns to understand the underlying mechanisms of forest recovery and propose corresponding solutions for restoring regrowing secondary forests. Here, twelve 1ha forest dynamics plots (4 plots each in young-secondary forests (YS), old-secondary forests (OS) and old-growth forests (OG) from a chronosequence of tropical lowland rainforest after shifting cultivation) were used to assessed the recovery in species, size and location diversity of trees at stand (plot) and neighborhood (focal tree and its neighbors) scale by using 8 indices. The relative recoveries of YS and OS were quantified by dividing each of the indices in YS and OS to those in OG. Results showed that species and size diversity increased while location diversity decreased with the recovery process. The relative recovery of location diversity was higher than those of species and size diversity in both YS and OS, while species diversity was only higher than size diversity in YS. The relative recovery of species diversity at neighborhood scale was higher than that at stand scale in OS, while there were no differences between scales in size and location diversity. Additionally, using only the Shannon index and Gini coefficient at two scales can provide consistent insights into the recovery patterns of diversity as indicated by the 8 indices. Our study demonstrated that recovery rates of secondary forests relative to old-growth counterparts could be comprehensively quantified using multiple diversity indices in three types at two scales. This quantitative assessment on the relative recovery of disturbed forests could be helpful in applying appropriate management activities and selecting rational approaches to speed up restoration process of degraded forest ecosystems.

Keywords: Secondary forest restoration, Location diversity, Size diversity, Species diversity, Stand scale, Neighborhood scale

Attractiveness of area Exclosures as a Carbon Sinks in Ethiopia

T3.12 Forest Restoration Success and How to Achieve it

Samson Shimelse Jemaneh[1]
[1] EBI

Abstract: Area exclosure in the Ethiopian context can be defined as the degraded land that has been excluded from human and livestock interference for rehabilitation. The primary objective of the research was evaluation of carbon sequestration and economic valuations in particular with the establishment of exclosures. Exclosures of 10, 15, and 20 years old were selected and each exclosure was paired with an adjacent free grazing land. A total of 120 quadrants were sampled using a stratified preferential sampling design technique with flexible systematic model and 180 household respondents were surveyed with multi-stage stratified random sampling procedure incorporating household's survey questionnaires, FGD, and KI discussions. All exclosures displayed higher ECS, and plant species richness, diversity and aboveground standing biomass than the free grazing lands. Differences in ECS between exclosures and free grazing lands varied between 32.96 and 61.0 $tha^{-1}$and increased with exclosure age. Over a period of 20 years, the carbon dioxide sequestered in the investigated exclosures was 223.88 tha^{-1}, total soil nitrogen increased by 2.93 tha^{-1} and additionally available phosphorus stocks amounted to 40 Kg ha^{-1}. Furthermore, the majority of the respondents had positive views on the effectiveness of exclosures. The empirical results from binary logistic regression model showed age, tenure, farm size, off-farm activities and credit access were positive and significant predictors and livestock number is negatively affected the sustainability of exclosure. Our study showed that the establishment of exclosures on degraded free grazing lands in the northern highlands is a viable option to restore vegetation composition, richness, diversity and aboveground biomass. However, economic and social impacts of exclosures should be included in feasibility studies before establishing exclosures. Although our study showed that exclosures are effective to restore ECS, expansion of exclosures would increase grazing pressure on the remaining area. Therefore, the decision to establish additional exclosures should include an economical analysis and evaluation of the social consequences of such a decision. The positive views on exclosures imply that there is a substantial opportunity to mobilize the local communities in the efforts to manage the existing exclosures in a sustainable manner and to establish exclosures in the future.

Biodiversity Islands as a Strategy for Forest Conservation and Restoration

T3.12 Forest Restoration Success and How to Achieve it

[3] Bioren Systems, 16 Andrew Circle, Hampden, MA 01036, U.S.A.

Abstract: To achieve success in forest restoration it is crucial to restore forest biodiversity. Forest biodiversity restoration can be accomplished by restoring or providing additional habitat, creating buffer areas, and establishing corridors that connect forest fragments. As a strategy to contribute to achieving these goals, we propose the implementation of Biodiversity Islands (BI): areas of land with greater diversity than the surrounding areas, where plant and animal species can thrive without interference from human activity. BI constitute genetic, cultural, carbon and nutrient "banks" in the fragmented forest landscape, hosting plants, animals, microorganisms, ecosystems, landscapes and water resources according to their scale. BI are refuges for flora and fauna, serving as sources of propagules and protecting resources from fires, pests and other stresses, providing ecological, economic, and social benefits at the ecosystem, landscape, and global levels. Designs depend on purpose, spatial distribution of reserves throughout the landscape, landscape degradation, species present, and location. BI can exist in a range of human dominated landscapes (natural, rural, urban) and can range from square meters to many square kilometers in size. We provide examples from throughout the world, including case studies for both conservation and production purposes such as tree and vegetation islands, riparian forests and agroforestry systems (AFS). As components of BI, more complex systems, such as multistrata AFS can constitute BI in themselves, while less complex AFS can form part of a buffer area. In all cases, the inclusion of diverse systems within a BI provides greater biodiversity than conventional agriculture or degraded areas. Other BI are relicts from previous land uses and/or are kept by human populations for other purposes while serving a BI objective as well (e.g. sacred forests). In promoting BI, we encourage the application of integrated landscape management and inclusive community led action. BI can be a valuable framing tool for practitioners and policy makers. Possibly the BI principles could be applied more broadly to protect live systems worldwide.

Carbon and conservation trade-offs for restoration in the Brazilian Savannah

T3.12 Forest Restoration Success and How to Achieve it

Maria Luiza Almeida Luz[1]
Oscar Cacho[2], Daniel Moura da Costa Teixeira[3]
[1] Laboratory of Built Environment, Inclusion, and Sustainability (LACIS), University of Brasilia, Brazil
[2] Business School, University of New England, Australia
[3] Department of Economics, University of Brasilia, Brazil

Abstract: The Cerrado biome in Brazil is one of the most biodiverse savannahs in the world, but it is also one of the most threatened biomes due to deforestation and land use change. Given limited resources, it is urgent to understand the trade-offs between ecological and economic outcomes to design prioritization frameworks that can bring economic and socio-ecological objectives together. This study aims to analyze the trade-offs between ecological and economic management objectives to restore habitats and reduce deforestation susceptibility in the Cerrado. Production possibility frontiers and attainment levels were derived for various restoration scenarios and prioritization objectives, including potential profit that could be generated with carbon credits from forest biomass. Modeling was conducted by combining metrics for Fire Risk, Vulnerability of Fauna, Deforestation Susceptibility and Above and Below Ground Carbon into a single shapefile. Priority areas for each objective were identified within the portion of the Central Plateau Ecoregion that occurs in the States of Goiás, Minas Gerais, and the Federal District of Brazil. Results show that few areas have a high potential for maximizing two objectives together. In general, ecological and economic variables have sharp trade-offs, meaning that improving revenue from carbon will reduce the attainment of the ecological variables. We suggest that at a landscape level, ecological priorities could be targeted, while specific sites with high economic potential can be selected for local projects. Regarding the potential of selling carbon credits to fund restoration activities, we discovered that among the restoration methods analyzed, only Natural Regeneration returns a profit, but it is also the method that requires a longer time. Assisted Natural Regeneration and Total Planting are faster methods, but they require additional investments, since relying on carbon credits is not enough to return profits that could fund restoration activities. We suggest that projects should target actions that would increase economic benefits to help fund the restoration together with the carbon revenue. This points to the fact that restoration projects need to consider not only the feasibility of methods but also stakeholders' objectives and demands.

Challenges and opportunities for degraded land rehabilitation in Eastern Amhara; Ethiopia

T3.12 Forest Restoration Success and How to Achieve it

Melese Genete Muluneh[1]
Temima Ibrahim[1], Bantideru Fenta[1]
[1] Wollo University

Abstract: Land degradation is a global issue, with particular severity in developing countries. Despite all rehabilitation efforts, land degradation is continuing with high aggregate rates in Ethiopia. Therefore, this study aimed at assessing challenges and opportunities to rehabilitate a degraded land in south Wollo Zone. A multistage sampling method was used. The descriptive statistics was used to analysis a data. The perception of a problem with land degradation in the research area is held by 97.5% of respondents. Furthermore, even if it takes time, 77.9% of respondents believe that land degradation may be remedied. Soil erosion, deforestation, overgrazing, and decreased land productivity were cited reported as the main types of land degradation in their area, respectively, by about 65.5%, 19.5%, 6.5%, and 4.5 of the respondents. Likewise, 68.5% of respondents stated that rehabilitation practices previously carried out in the study area were not successful. Challenges that contribute to the failure of rehabilitation practice in the study area were lack of follow-up, watering, caring, and protection of the rehabilitated site from free grazing. Besides, low sense of ownership on rehabilitated sites, poor seedling survival, land tenure & institutional problems, socio-economic problems and availability of limited livelihood options and higher degradation level of the site to be rehabilitated were reported as challenges that affect success of rehabilitation measures. Opportunities for the rehabilitation of degraded land, however, include willing of communities to participate, government attention, the involvement of various stockholders, the presence of diversified types of agro-ecologies, multipurpose plants, and sizable degraded areas that can be restored. It is concluded that rehabilitation efforts could not be successful unless those challenges are addressed. Therefore, it is strongly suggested that frequent follow-up, tending operations, control of free grazing, the planting of edible plants for livelihood benefits, and building a sense of ownership will improve the success of rehabilitation practices.

Challenges and Opportunities in Rehabilitation of an Ex-Tin Mine

T3.12 Forest Restoration Success and How to Achieve it

Wai Mun Ho[1]
Rosdi Koter[1], Mohd Zaki Abdullah[1]
[1] Forestry Biotechnology Division, Forest Research Institute Malaysia (FRIM), 52109 Kepong, Selangor, Malaysia

Abstract: Tin mining was a lucrative industry in Malaysia since the late 1800s up to early 1900s due to high demand for tin. Mining of tin ores had promoted rapid economic development but drastically transformed the landscapes of mining areas. These areas were stripped off vegetation and topsoil removed, detention ponds were created and sand barns were heaped. When mining activity ceased with the plunge of tin prices worldwide, ex-tin mines became abandoned and impoverished areas. With no topsoil and organic matter, regeneration becomes impossible especially when there is no seed source in adjacent areas or surrounded by oil palm plantations. Therefore, human intervention is needed to induce or provide a suitable environment to encourage the growth of tropical multipurpose trees especially climax species on tin tailings with cost-effective techniques. Forest Research Institute Malaysia (FRIM) has embarked on the greening of an ex-tin mine in Bidor, Perak since 1996. After 20 years of rehabilitation, the research station was recognised by the Malaysia Book of Records in 2016 as the 'Largest Man-made Forest Established on Ex-Tin Mine'. With suitable techniques in soil amelioration and introduction of fast-growing species as nurse trees, over 60 indigenous tree species including endangered and endemic species can now be found in the research station. In addition, more than 100 bird species had been recorded besides various other animals and fungi. This paper aims to share on the experiences in rehabilitation of an ex-tin mine and outcomes from greening this once barren land.

Choose the trees! Uncovering Farmers' Preferences for Forest Restoration in China through a Choice Experiment

T3.12 Forest Restoration Success and How to Achieve it

Xinran Shen[1]
Jiayun Dong[2], Paola Gatto[1], Francesco Pagliacci[1]
[1] Department TESAF, Land, Environment, Agriculture and Forestry, University of Padova, 35020 Legnaro, Italy
[2] Nanjing Forestry University, College of Economics and Management, China

Abstract: Grain for Green Program (GFGP) is the largest payment for ecosystem services(PES) program in Chinese history, which is aimed at converting marginal croplands on steep slopes into grasslands and forests by afforestation/reforestation activities. The program started in 1999 and it has been running till now. The GFGP covers more than 1500 counties and affects 32 million households. However, it has been criticized for oversimplified design, not engaging local communities in the decision-making, and not customized to local conditions. For example, GFGP only takes tree planting as a project activity and disregard other restoration activities (i.e., tree species diversification, underplanting). To address these concerns, we present a case study to explore more options for PES schemes and farmers' preferences to different forest restoration activities. The study area is in Western China and consists of three villages, which have participated in GFGP before. Respondents are selected using random sampling method. Choice experiment (CE) is applied to understand farmers' willingness to accept PES contracts characterized by different attributes, such as payment levels, length of contract, payment modes, proportion of land involved in the program, and restoration activities. Previous studies have already applied CE to investigate farmers' preferences for PES contracts, but most of them only focus on contracts for tree planting. We aim to fill in the knowledge gap by examining farmers' preferences for other restoration activities. Also, this study adds to the literature about farmers' preferences for environmental programs in a developing country setting, particularly within the current Chinese PES framework. Along with the CE, household survey data are collected, including household demographics, capital assets, and experiences with PES programs. In the experiment, respondents are presented with six choice sets, and each choice set has three alternatives, from which they are asked to choose their preferred one. The working hypothesis is that farmers are more willing to accept short contract length, low proportion of land involved in the program, high payment levels, individual compensation, and different restoration activities. As such, this study can contribute to the PES design, improve the effectiveness of PES programs, and take farmers' preferences into account.

Cloud forest tree regeneration diversity and composition under different restoration approaches: protecting natural regeneration versus tree planting

T3.12 Forest Restoration Success and How to Achieve it

Alma L Trujillo-Miranda[1]
Tarin Toledo-Aceves[2], Fabiola Lopez-Barrera[2]
[1] Yale School of the Environment
[2] Instituto de Ecología A.C.

Abstract: Forest restoration is a key nature-based solution to addressing biodiversity loss and climate change. However, little is known about the effectiveness of different restoration approaches in the recovery of the diversity and composition of old-growth forests. We evaluated the recovery of tree regeneration (seedlings and juvenile) in former cattle pastures after 21 years of natural regeneration (after cattle exclusion) and planting tree native species in comparison to an old-growth tropical montane cloud forest in Veracruz, Mexico. We randomly establish ~ 30 plots per condition. We found a total of 78 species of trees in the regeneration strata. There were no differences in seedling and juvenile´s diversity (Shannon index exponential) between the conditions. The composition of species differed between the two conditions (PERMANOVA). Tree planting presented more similarity (Bray-Curtis) in species composition with the old-growth forest than the natural regeneration (48% and 43% of similitude, respectively). Regarding the dominance and equity of the seedling and juvenile community, most of the species contributed less than 5% to the total abundance in all conditions. In the restoration planting, the late-successional species *Quercus sapotifolia* and *Ocotea psychotrioides* represented 16 % and 8% of the abundance of seedlings. Our results show that while both restoration approaches have favored the recovery of diversity, planting with native species has favored greater recovery of the species composition of the old-growth forest, compared to the natural regeneration. Overall, the results support the potential of different restoration approaches to recover the tropical montane cloud forest landscape.

Combating the Invasion: Native Species Triumph Over Lantana camara

T3.12 Forest Restoration Success and How to Achieve it

Abhishek Kumar[1]
Sanjay Singh[2]
[1] Forest Research Institute
[2] Indian Council of Forestry Research and Education

Abstract: Invasive species have taken a huge toll on our biodiversity, and one such invasive, *Lantana camara* is listed as one of the world's top ten invasive species. Effective management strategies are crucial in controlling this persistent species, which requires continuous vigilance and planned phenological monitoring. We conducted field experiments in Doon Valley to screen potential native species competing with Lantana at different locations. Using the standard BBCH scale, we observed the Phenological Growth Stages of five native species, marking the first time a detailed phenological study using the BBCH scale of these species. Importance Value Index (IVI) and other diversity indexes were calculated for selecting the competitive native species.

Furthermore, we conducted pot and field experiments with these native plants comparing Lantana to study intraspecific and interspecific competition using Relative Interaction Index (RII). They presented a robust competition to Lantana, with *Broussonetia papyrifera, Pterospermum acerifolium, Urtica dioica, Pongamia pinnata*, and *Bauhinia variegata* leading the charge. In addition to the native plants, we also introduced native grass species to the field experiments. Using the seed ball method, we observed the competition from native grass species such as *Penissetum pedicellatum* and *Sachharum spontaneum,* which proved to be strong competitors against Lantana. These findings hold significant implications for policymakers, researchers, and land planners. They offer a roadmap for adopting competitive native species to combat the invasive Lantana, particularly in the Indian Himalayan Region.

Cross-boundary Prioritization and Monitoring of Forest Restoration: Lessons from Longleaf Pine in the Southeastern USA

T3.12 Forest Restoration Success and How to Achieve it

Nathaniel Anderson[1]
John Hogland[1], Joe St Peter[1], Jason Drake[1], Paul Medley[1]
[1] U.S. Forest Service

Abstract: Beginning in 2015, researchers at the U.S. Forest Service and its university and NGO partners began an ambitious collaboration to inventory, map, analyze and monitor critical longleaf pine (Pinus palustris) habitat to prioritize conservation and restoration activities. In large part, this effort was driven by the need to identify the desired restoration endpoints and goals in this important but severely degraded subtropical habitat, and monitor progress toward achieving those goals over time at fine spatial resolution. The team worked to develop and deploy novel remote sensing and statistical techniques and tools to map the extent and condition of longleaf pine ecosystems across the southeastern U.S. states of Alabama, Georgia and Florida. High-resolution geospatial data products were developed using machine learning techniques, including artificial neural networks and decision trees, to model the relationships between forest characteristics measured in field plots and a wide range of spectral metrics derived from a variety of remotely sensed imagery, including aerial photographic imagery and Landsat. Regionally specific models were then used to map forest characteristics at high resolution across large areas. For example, in one study, field plot data was related to normalized Landsat 8 imagery using general linear regression and machine learning models. Multiple raster surfaces of forest metrics, including basal area, stand density, forest type and presence of longleaf pine were created across a 28.8 million acre study area in these three states. The overall accuracy of the eight softmax neural network forest type models ranged between 0.78 and 0.87, averaging 0.83, and 35 moderate resolution (30m) spatially explicit raster surfaces of estimated forest characteristics were integrated with existing vector, tabular and raster datasets to inform and prioritize longleaf forest conservation and restoration efforts. This presentation provides an overview of the effort, which includes multiple interconnected projects and published research studies conducted over more than a decade, and presents lessons learned and recommendations for using remote sensing and advanced inventory techniques to prioritize forest conservation and restoration activities and improve monitoring and verification at various scales.

Effects of a Trench as a Moisture Harvesting Structure to Restore Degraded Land in Southern Ethiopia

T3.12 Forest Restoration Success and How to Achieve it

Hana Habrová[1]
Shiferaw Alem Munie[1], Petr Němec[1]
[1] Mendel University in Brno

Abstract: Knowledge about the biomass productivity of trees planted in a rainwater harvesting structure, i.e., a trench (T), relative to a normal pit (P) on degraded land is scarce. The objective of this study was to compare the effect of T with P on the growth and biomass production of the *Acacia saligna* and *Casuarina equisetifolia* which were planted on degraded land. All the individual stems of both species in the T and P, their diameters at breast height (DBH) and heights in 2016 and 2020 were measured. Species-specific allometric equations were used to quantify the biomass production of the studied species. The t-tests were used for data analysis; both *A. saligna* and *C. equisetifolia* individuals planted in the T had higher DBH and height increments as compared with *A. saligna* and *C. equisetifolia* that were planted and grown in a P. The results revealed significant differences in the mean DBH and height of *A. saligna* and *C. equisetifolia* planted in a T and P ($p < 0.05$). Between 2016 and 2020, the total biomass (TB) of *A. saligna* planted in a T and in a P increased significantly ($p < 0.05$) on average by 25.5 kg/tree and 7.7 kg/tree, respectively ($p < 0.05$). Similarly, the mean TB values of the *C. equisetifolia* planted in a T and a P between 2016 and 2020 increased significantly ($p < 0.05$) by 28.9 kg/tree and 13.1 kg/tree, respectively. Finally, establishing trenches to restore degraded lands was shown to facilitate the growth and biomass production of planted species on degraded land.

Effects of understory invasive plants and native plants on community stability in Benggang ecological restoration of different artificial forests

T3.12 Forest Restoration Success and How to Achieve it

Yuduan Ou[1]
Yushuang Du[1], Liuping Wu[1]
[1] College of Coastal Agricultural Sciences, Guangdong Ocean University, Zhanjiang 524088, China

Abstract: To explore the community construction scheme of Benggang ecological restoration based on nature, four stands (*Pinus elliottii*, *Eucalyptus urophylla*, *Acacia auriculaeformis*, and *Cinnamomum camphora*） were studied for early restoration in Benggang area of Guangdong Sanlinshan National Forest Park, located in the southernmost tip of mainland China. In terms of understory invasive and native species, we conducted the quadrat survey, analyze the community stability of different stands through species diversity, niche width, niche overlap, ecological response and species association index, and optimize understory plant allocation. The results were showed as follow: (1) Among the four stands, the number of species, diversity index and niche width of understory invasive in *Eucalyptus urophylla* stand was the lowest, and the niche overlap between understory invasive plants and native plants was also the lowest. (2) The future development trend of the understory plant community was the best in *Pinus elliottii* stand, followed by *Eucalyptus urophylla* stand. The average rate of the positive development of *Pinus elliottii*, *Eucalyptus urophylla*, and *Cinnamomum camphora*, the three stands was higher than the negative development, except for *Acacia auriculaeformis* stand. (3) The interspecific associations of the understory plants of the four stands were small (OI≤0.5), and most of them were negative associations, and the communities were in an unstable stage. (4) The pattern of community allocation can be optimized as: *Eucalyptus urophylla*-*Dicranopteris Dichotoma*-*Rottboellia Linn*-*Miscanthus Sinensis*, *Pinus elliottii*- *Miscanthus Sinensis*-*Imperata Cylindrica*-*Blechnum Orientale*, *Acacia auriculaeformis*-*Miscanthus Sinensis*-*Blechnum Orientale*-*Rhodomyrtus Tomentosa*, *Cinnamomum camphora*-*Rhodomyrtus Tomentosa*-*Rottboellia Linn*-*Mallotus Paniculatus*. Therefore, when planting fast-growing trees to rapidly afforest for early restoration in Benggang area, we can give priority to stands with abundant understory native plants and few understory invasive plants (such as *Eucalyptus urophylla* stand). Positive associated understory native plants can be select for understory plant community allocation, so as to effectively resist understory invasive plants and form stable progressive understory plant community.

Enabling conditions for Forest Landscape Restoration in Mozonte, Nicaragua-A community forestry perspective on FLR

T3.12 Forest Restoration Success and How to Achieve it

Ivania Cornejo[1, 2]
[1] Technische Universitat Dresden
[2] International Union of Forest Research Organizations, ind. member

Abstract: Mozonte, in northern Nicaragua is a landscape with important presence of indigenous community as owners of around 23 thousand hectares of land and with a recognized governance structure. This thesis explores enabling social, policy and environmental conditions for FLR in the community of Mozonte via in-depth interviews with stakeholders, participatory P/RRA workshops and secondary data. Given the importance of the community and the overlapping set of conditions that favors FLR and community forestry (CF), a CF perspective is emphasized. The results showed that the community have motivations for FLR, relating restoration as solutions to many of their socio-environmental issues and expecting economic, environmental and social benefits as: water security, improved local climate, diversified income, and the enhancement of cultural and timber values. Proposed restoration interventions were agroforestry systems, reforestation of riparian zones and critical areas for watersheds, coffee zones, and the formalization of a community reserve.

Major challenges found were a complex land tenure context and a set of favorable policies that however, lack an effective implementation and enforcement. Coffee farms in the north, as land-use change driver, their associated bad practices and impacts on water were a high concern expressed by people. Forest fires are another important threat to FLR in Mozonte, but they offer the opportunity to expand and strengthen effective institutional coordination, an enabling condition for both FLR and CF. Potential synergies among FLR and CF such as linking FLR with food security and formalizing management of a community reserve in Cerro Guásara have a positive perspective. Despite limitations, these results can be a tool for the community and potential partners to advance FLR strategies and community forestry in Mozonte.

Explore Before You Restore: Incorporating Complex Systems thinking in Ecosystem Restoration

Abstract: The global movement for ecosystem restoration has gained momentum in response to the Bonn Challenge (2010) and the UN Decade on Ecosystem Restoration (UNDER, 2021-2030). While several science-based guidelines exist to aid in achieving successful restoration outcomes, significant variation remains in the outcomes of restoration projects. Some of this disparity can be attributed to unexpected responses of ecosystem components to planned interventions. Given the complex nature of ecosystems, we propose that concepts from *Complex Systems Science* (CSS) such as regime shifts, ecological resilience, and ecological feedbacks, should be employed to help explain this variation in restoration outcomes. Our framework, Explore Before You Restore, illustrates how these concepts impact restoration outcomes by influencing degradation and restoration trajectories.

Additionally, we propose incorporating CSS concepts into the typical restoration project cycle, and suggest that they are explicitly included in the guidelines to improve restoration outcomes.

Exploring the Path to Forest Restoration through International Forest Aid in Asia

T3.12 Forest Restoration Success and How to Achieve it

Seongmin Shin[1]
Eun Soo Kim[2], Mi Sun Park[2, 3]
[1] Department of Global Development, College of Agriculture and Life Sciences, Cornell University, Ithaca, New York

[3] Institutes of Green Bio Science and Technology, Seoul National University, Pyeongchang, 25354, Republic of Korea

Abstract: As a response to the extensive forest degradation across Asia, forest restoration has been actively integrated into Official Development Assistance (ODA) projects. This study aims to understand the evolving trends and priorities in Asian forest restoration-related ODA projects. By synergizing the systematic review and topic modeling techniques, we offer an in-depth examination of the status, predominant themes, and trajectories of forest ODA and the global community's response to forest restoration in Asia. This study includes statistical data from the OECD Development Assistance Committee (DAC) from 1998 to 2021. Our analysis reveals that an upward trend in multi-country projects in Asia since 2010 is identified. Although a substantial percentage of the Asian forest ODA funds are directed towards China and India, the initiatives show a wide geographical distribution across numerous countries. Our text mining approach revealed four dominant themes in Asian forest ODA: "Reforestation and Disaster Management," "Social Forestry," "Landscape Management," and "Production and Industry." Frequency and time-series analysis indicates a gradual shift from the "Social Forestry" theme to "Landscape Management" and "Production and Industry" themes. This shift reflects a more holistic and integrative approach to forest ODA in Asia, accommodating various socio-economic and ecological considerations. Our findings have significant implications for designing future projects, including topic selection and regional prioritization. The insights could prove instrumental in integrating forest restoration strategies in forest ODA, paving the way for a more efficient approach to global forest restoration, addressing multifaceted goals from social, economic, and ecological perspectives, and further contributing to improved local livelihoods, better governance, and sustainable development.

Floristic Composition ,Structural Diversity under Passive and Active Restoration of Biodiversity Hotspots in Kakamega-Nandi Forest Ecosystem, Kenya

T3.12 Forest Restoration Success and How to Achieve it

Abstract: Restoration of degraded landscapes is emerging as a global conservation priority. Opinion is divided, however, whether active restoration is a better approach than passive interventions in regard to ecological outcome. We assessed the variation in woody species composition and stand structure in a degraded forest site in western Kenya where both tree planting and natural regeneration had been applied for four years. The site was protected from repeat incidences of disturbance using enclosures. Natural regeneration registered a significantly higher woody species richness (36.75±6.97) than active restoration (12.75±1.75) four years later. Similarly, natural regeneration had a higher Shannon-Wiener diversity index (3.05±0.72) than active restoration (2.32±1.26). Woody stem density was significantly higher under natural regeneration (21,789±7,087 stems ha^{-1}) than active restoration (13,118±1,857 stems ha^{-1}) even though up to 10,000 seedlings per ha were planted at the beginning of the study in active restoration plots. Mean sapling height was higher under natural regeneration (2.60±0.31 m) than active restoration (1.38±0.30 m). The diameter size-class distribution for saplings ranged between 2.1cm and 15.0 cm in natural regeneration plots, and below DBH level and 10.0 cm in the planted plots. The results suggest that natural regeneration may be superior to active restoration in rehabilitating degraded landscapes in the humid tropics where repeat incidences of disturbance are under control. The long-held view that active restoration leads to greater woody species diversity and stand structure may have been spurred by the fact that ecological restoration interventions are often carried out in open sites that are exposed to continual incidences of disturbance, which tends to hamper the recruitment and survival of natural regrowth.

Functional traits to predict financial value of enrichment planting in degraded tropical forests

T3.12 Forest Restoration Success and How to Achieve it

Abstract: A global push to increase reliance on sustainable renewable materials is expected to increase the demand for tropical timber. However, sustainable production of tropical timber, especially high-value tropical hardwoods, remains a challenge for the global wood product supply chain. Restoration of degraded lands through enrichment planting of native tree species could provide a solution, but the financial viability of thousands of native tropical tree species remains largely unknown. Therefore, we evaluated how the financial viability of 22 tree hardwood species native to northern Borneo in enrichment plantings of a degraded forest in Sabah, Malaysia, varied based on their plant functional trait composition. Partial least square models showed high internal rate of return (IRR) values to be correlated with low leaf calcium, magnesium and nitrogen content, and leaf pH and specific leaf area. All considered conservative trait values. Therefore, our results did not support our hypothesis regarding the trait-IRR relationship, based on the plant economic spectrum, i.e., high financial value was not predicted by acquisitive traits. Additionally, we found that high IRR was achieved by species that could concurrently maintain a high growth and survival rate. Our results show that enrichment planting for high value hardwood production in degraded forests can be financially viable, to different degrees depending on the species, and that conservative traits are linked to high financial value.

Integrated approaches for restoring degraded landscapes and enhancing the resilience of inhabitants

T3.12 Forest Restoration Success and How to Achieve it

Niguse Hagazi[1, 2]

Abstract: Abstract Landscape restoration interventions have been priorities to combat land degradation in Ethiopia. This paper presents important learned lessons from the integrated landscape interventions implemented at Gergera watershed in Tigray, Ethiopia to restore degraded landscapes and enhancing the resilience of inhabitants.

We will present principles and steps to be followed in the process of implementing a successful landscape restoration intervention. Community led restoration with shared goals and vision and intervention priorities was the main landscape restoration approach introduced to the experimental watershed.

This approach with multiple interventions provide a multitude of benefits in a short to longer time scale, such as improved household food security, diversifying income sources, rehabilitating abandoned lands, improving feed, fodder availability, improving environmental quality. Degraded hillsides and gullies and farmland expected to be abandoned in 2-3 years due to gully formation were saved and restored through planting economically and ecologically important plants supported with physical structures. A gully as wide as 120 meters and 6-25 meters in depth converted from threats to opportunities and become sources of income for women and youths. Water availability was improved due to reduced runoff and increased irrigation, drinking water for livestock and humans. Restoration impacts have brought a mindset-shift that degraded lands can be restored and used to improve the livelihood of the community. Quality planting materials availability, integrating landscape restoration with livelihoods improvement and incentives to grow trees in farms and landscapes are key success factors for an effective, inclusive, and sustainable landscape restoration and in creating functional agroforestry practice.

We, therefore, recommend integrated watershed and/or landscape restoration practices should be guided through developing a community led vision and intervention priorities with appropriate socioeconomic and restoration packages and incentives in Ethiopia and beyond.

Key words: Land degradation, climate change, restoration, community, livelihood, green jobs

Learning from 25 years of operational restoration and research in the INIKEA – Sow-a-Seed rainforest restoration project

Abstract: The INIKEA Sow-a-Seed project in Sabah, Borneo, was launched in 1998 to rehabilitate 18,500 hectares of tropical rainforest degraded by logging and later by fire. Sabah Foundation, The Swedish University of Agricultural Sciences, and IKEA built the project from the ground, including basic infrastructure, roads, nurseries, and housing for employees and families, and last but not least, developing knowledge. We used a range of restoration techniques depending on the level of degradation; In the moderately to highly disturbed areas, climber cutting, weeding, and selective girdling of pioneer Macaranga trees was repeated several times during ten years, while in the least disturbed areas, we made a one-time treatment consisting of climber cutting. Enrichment planting was also done in the moderately disturbed areas when few non-pioneer species were present. In total, we planted 5 million trees from 90 species. Here we summarize five key lessons learned after 25 years. 1) The restoration project created a valuable natural resource. 2); The selection of tree species can now be adjusted to the aim of the restoration; 3) Planted trees contribute to stand development in highly disturbed areas, but if resources are limited, ANR alone can often be sufficient to boost recovery; 4) Tree diversity matters for broader biodiversity; 5) Genetic variation of native trees is a neglected potential for native reforestation.

Mobile and web applications to involve the public in scouting and monitoring for forest health

T3.12 Forest Restoration Success and How to Achieve it

Margaret Staton[1]
Noah Caldwell[1], Abdullah Almsaeed[1], Ellen Crocker[2]
[1] Department of Entomology and Plant Pathology, University of Tennessee, Knoxville, TN, USA
[2] Department of Forestry and Natural Resources, University of Kentucky, Lexington, KY, USA

Abstract: Engaging the public in research has benefits to forest research projects, including increased geographical scope, more frequent data points, and earlier detection of forest health problems. Building a research program with non-professional scientists requires an easy-to-use platform to guide new participants to successfully contribute useful information. We have designed a series of mobile and web applications to facilitate public science and will focus on two case studies. TreeSnap is a mobile phone application that engages the public in scouting for trees affected by insects and diseases, including North American ash, chestnut, hemlock, and elm. Volunteers can use the free app on Android or Apple phones to provide GPS locations, images, and characteristics to tree research programs. In contrast to other reporting apps, we increase the utility of the collected data by asking a set of customized questions for each species, such as a list of signs of emerald ash borer for ash trees and presence of cones for hemlocks. Scientists can use the TreeSnap website to sort and filter trees, download user observations, and contact individual users. With over 2000 active users and over 16000 tagged trees, TreeSnap is an important resource for scientists to find lingering trees that may harbor genetic resistance. We are actively seeking new partners to expand TreeSnap. A second new software system is in development to support plot monitoring. Research for forest health often needs data taken over years to record tree survival, changes in species composition, growth rates, and more. Our app will enable participants to work within a custom plot monitoring system set up by a partner scientist, with the ability to define plots then take regular data measurements. The first plot monitoring protocol is for hemlock species threatened by hemlock woolly adelgid. Users will report on infestation levels, canopy health, and tree survival. We welcome the opportunity to provide this software to other groups who have plot monitoring needs. Our 6 years of experience building apps that connect forest research programs to the public has proven that excellent, easy-to-use software paves the way for useful data and participant satisfaction.

Non-timber forest products management as a forest restoration strategy, based on a successful case of community forest management in Petén, Guatemala

T3.12 Forest Restoration Success and How to Achieve it

Juan Pablo Rodriguez Garavito[1]
Roger Villalobos Soto[1], Alejandro Imbach[1], Fernando Carrera[1]
[1] Centro Agronómico Tropical de Investigación y Enseñanza (CATIE)

Abstract: Non-timber forest products are an important part of many cultures and societies, providing food, medicines, fodder, aromatic products, bushmeat and honey. The Maya Biosphere Reserve (MBR) is one of the most successful cases of Community Forest Management, thanks to the forest concessions given to communities at the end of the 1990s, after the peace process in Guatemala. In the 1960s, the extraction of xate (Chamaedorea spp.) began with a largely artisanal process, but today it employs thousands of people and brings in thousands of dollars annually. On the other hand, ramón (Brosimum alicastrum Sw.) is one of the multi-purpose tropical species. It is currently in increasing demand as it is on the list of "superfoods" and is sought after for the development of food supplements. The main objective of this research was to systematise experiences on the use of xate leaves and ramón seeds in the communities of Uaxactún and Carmelita, in order to obtain lessons learned. The research approach was qualitative, with deliberate sampling and snowballing, seeking theoretical saturation of information. The methodological tools were literature analysis, interviews, ethnographic methods and focus groups. This work provides knowledge on the management, conservation and restoration practices developed in the concession areas of the villages of Uaxactún and Carmelita in the MBR; thanks in large part to the commercialisation of these two products. Eighteen technical and socio-economic bases were identified that have favoured the results of the concession process, after more than 20 years of accumulated experience. These bases are expected to become principles for similar initiatives and projects in tropical America.

Piloting Aerial Seeding in Restoration of Degraded Landscapes: Preliminary Results from Maasai Mau Forest in Kenya

T3.12 Forest Restoration Success and How to Achieve it

Jane Njuguna[1]
STEPHEN KIAMA[1], John Kigomo[1], James Maua[1], Magrate Kaigongi[1], Charles Koech[1], Stanley Nadir[1], Michael Muganda[1]
[1] Kenya Forestry Research Institute

Abstract: Aerial seeding technology has big potential for restoring large areas of degraded landscapes including forestlands as it is fast and cost-effective and has the capacity to cover inaccessible and rugged terrains. The technology was piloted on the abandoned and degraded area of Maasai Mau Forest in Kenya covering 3,600 ha using three thousand six hundred (3,600 kg) seed of fifteen indigenous tree species suitable for the area in November 2019. The objectives were to evaluate the success rate of the technology by assessing; density of tree seedlings emergence and establishment, relative success of individual tree species used in the restoration effort and factors for success. The results would inform the recommendation of the technology for widespread use in restoring millions of hectares of degraded lands to achieve the country's commitment to restore 5.1 million hectares of degraded lands by 2030. Assessments are conducted annually for all parameters. Data was collected using circular plots of 0.03 ha which were randomly distributed across very steep, steep and flat sites within selected blocks in the aerial seeded areas. Germination was recorded on nine tree species after nine months but at significant densities and establishment levels between species and across topographical zones. An average of 570 ± 313 seedlings per hectare was recorded accounting for 6.8% of the seeding rate of 8,409 seeds per hectare. The study identified *Dombeya torrida* and *Croton macrostachyus* exhibiting high seedling frequency and abundance among the fifteen species seeded. However, with time, the thickness of undergrowth vegetation and human activities seemed to reduce species performance. Performance of *Dombeya torrida* and *Croton macrostachyus* indicate that they are fast growers and may be good colonizers of degraded forestlands. We conclude that aerial seeding has fairly good success rates and may be used to restore degraded landscapes in Kenya.

Post-fire restoration: Can we learn from restorations already carried out in the past?

T3.12 Forest Restoration Success and How to Achieve it

Abstract: Forests acting as carbon sinks play a key role in mitigating climate change due to the storage of carbon in their biomass and soils. Nevertheless, this natural process can be reversed due to disturbances such as wildfires, droughts, pests and diseases. Emissions from organic matter burning in vegetation, litter, or even in the mineral soil can be significant depending on the conditions of the fire severity. In addition, in the context of climate change we are currently suffering, the size of fires, the length of the burn season and the emissions can be increasing every year. As a consequence, restoration projects in the affected areas are the key to reverse the ecosystem degradation and avoid the carbon losses.

Post-fire restoration efforts typically involve a collaborative effort between government agencies, conservation organizations, and local communities. There are different types of post-fire restoration actions, such as reforestations, soil stabilization, fuel reduction, habitat restoration or water quality improvement. These processes can take many years and require many resources. However, on one hand, there is a lack of knowledge in the indicators of success or failure of these restoration actions; and, on the other, it takes many years to know if the restoration action has been a success or not.

With this situation as a starting point, in the context of the SUPERB Project we have collected the existing information of post-fire restoration projects that have been carried out in the past or were currently being carried out. We worked in two ways: from an online questionnaire and an exhaustive bibliographical review. This information allowed us to create a database with work done, success/failure indicators, actions to avoid, etc. We are presenting a first approach of the success vs failures indicators observed, that would very useful when carrying out of projects and future post-fires restoration actions.

Relationship between specific leaf area and survival of forest species in a landscape restoration experiment trial in Hernandarias, Paraguay

T3.12 Forest Restoration Success and How to Achieve it

Alexander Fleitas[1]
Maria Laura Quevedo Fernandez[1], Lila Mabel Gamarra Ruiz Diaz[1], Lidia Perez de Molas[1], Haroldo Nicolas Silva Imas[2]
[1] Universidad Nacional de Asunción, Paraguay
[2] Itaipu Binacional

Abstract: The correct selection of species in an active restoration process is a determining factor for the future success of the project. In order to optimize the selection of these species, different criteria are used, one of which is the adaptability of the species to the conditions prior to intervention. According to this, the objective of the study was to evaluate the relationship between specific leaf area (SLA) and the survival of the species used under the conditions of this trial. The methodology consisted of evaluating the survival of 30 forest species at 18 months after planting, without considering their replacement, in the Atlantic Forest ecoregion of Alto Paraná (Dinerstein et al., 1995), in the experimental plot of Itaipu Binacional in Hernandarias, Paraguay, which had 8 treatments and 5 blocks, distributed in a randomized block design . Additionally, 5 leaves from 5 individuals per species were collected, processed using ImageJ software, and then placed in an oven for 72 hours at a temperature of 60°C to obtain dry weight. The samples were weighed on a precision balance of 0.0001g to determine the dry weight. Using these data, SLA was estimated using the variables of dry weight and leaf area for each species, and their relationship with survival was evaluated through a simple linear regression analysis. The statistical analysis confirmed a relationship between SLA and survival with an R2 value of 0.42, and species with lower SLA indicated a higher percentage of survival. Therefore, they could serve as a parameter for selecting more efficient species in terms of their survival for any restoration project in the Atlantic Forest ecoregion of Alto Paraná, always considering the necessary functional diversity.

Restoration from even-aged conifer plantation toward mixed forest by planting broad-leaved tree at line cutting sites in Mt. Fuji, central Japan

T3.12 Forest Restoration Success and How to Achieve it

Takuo Nagaike[1]
[1] Yamanashi Forest Research Institute

Abstract: Transforming from pure and even-aged forests toward mix and uneven-aged forests is a central topic of forest management science. In Japan, most of coniferous plantations is pure and even-aged. The silvicultural technique to ecological restore such plantations is still under developing. I studied the growth and mortality of planted broad-leaved tree at line cutting sites in an even-aged conifer plantation. I would like to answer the following question: what factors affecting the growth and mortality of the planted seedlings at line cutting sites? The study site is located at 1600m in elevation at the west slope of Mt. Fuji and a 44 years old plantation (*Abies veitchii*) subject to line cutting (10-m width) in 2005. In 2007, broad-leaved saplings (*Acer palmatum*, *Alnus hirsute*, *Fagus crenata*, *Prunus jamasakura* and *Quercus crispula*) were randomly planted at line cutting sites and a permanent plot (1.06ha) was established. Every planted broad-leaved tree was protected by plastic tube from serious browsing by sika deer (*Cervus nippon*). Height and mortality census for planted broad-leaved trees was carried out in 2010, 2016 and 2023. After 2007, *Larix kaempferi* was naturally and successfully regenerated. I applied regression tree analysis to clarify the effects of distances from the nearest planted and naturally regenerated conifer (*L. kaempferi*), size of planted broad-leaved saplings and the nearest trees on growth and mortality of planted bread-leaved trees. For growth, *A. palmatum*, *A. hirsute*, and *P. jamasakura*, which were better growth species, was affected by distance from planted conifers, while *F. crenata* and *Q. crispula,* which were less growth species, was affected by distance from naturally regenerated conifers. Thus, to accomplish making mixed and diverse forests, careful management which considered species growth traits should be necessary.

RESTORATION POTENTIAL OF DEGRADED FOREST USING NATIVE SPECIES IN THE SOUTHERN REGION OF PENINSULAR MALAYSIA

T3.12 Forest Restoration Success and How to Achieve it

Rosdi Koter[1]
Faridah Ahmad Azam[1], Nur Sarah Nabila Ahmad Azian[1], Dasrul Iskandar Darus[1], Amir Saifuddin Kassim[1]
[1] Forestry Biotechnology Division, Forest Research Institute Malaysia (FRIM), 52109 Kepong, Selangor, Malaysia

Abstract: The federal government funded the restoration, reclamation, and rehabilitation of degraded areas (3RSM) programme managed by the Forestry Department Peninsular Malaysia (JPSM). The programme aimed to restore the forested land using native species. The establishment of a native species required a suitable silviculture regime. This study aims to assess the survival and growth performance of *Shorea roxburghii* planted on degraded forest land in the 3 sites with 4 spacing types of Southern region of Peninsular Malaysia. *S. roxburghii* was chosen as a pilot plant due to the availability of seeds yearly. Based on growth performance analysis, the average height of the seedlings increased gradually, averaging about 1.5 to 3 meters annually, with a better survival rate (>80%). The *S.roxburghii* was well adapted and performed well in its growth. Based on the results of this study, *S.roxburghii* is a promising native species and has the potential to be planted as potential species to help rehabilitate the degraded forest.

Keywords: *Shorea roxburghii*, native tree species, degraded forest, growth performance

Scarabaeidae family as an indicator for the early evaluation of restoration success with nucleation techniques

T3.12 Forest Restoration Success and How to Achieve it

Belén González Garcete[1]
Lourdes González Soria[1], Fernando Cubilla[2], Carlos Aguilar[2, 3]
[1] National University of Asuncion, Faculty of Agricultural Sciences, Forestry Engineering Career, Forestry and Biodiversity Area
[2] Universidad Nacional de Asunción, Facultad de Ciencias Exactas y Naturales, Department of Biology, FACEN Zoological Collection.
[3] National Museum of Natural History of Paraguay

Abstract: The beetles of the family Scarabaeidae, a group of insects widely studied as ecological indicators of anthropogenic disturbances, because many of these species depend on native forests, are highly sensitive to disturbance processes such as fragmentation and forest transformation (Gardner et al. 2008). Using these aspects, the general objective of the research was to characterize the contribution of the Scarabaeidae family to the early evaluation of riparian forest restoration processes. The study area is located in the district of Minga Guazu, department of Alto Parana, Paraguay, in an area of forest production with *Eucalyptus* sp. for firewood. It consists of an area of nine hectares, subjected to active restoration with nucleation techniques, which in turn is divided into four subplots with the same treatment, of which three are being monitored. These three subplots have cores composed of 10-20 individuals of native forest species (fourteen in total). For the collection of Scarabaeidae a pitfall trap type was applied, based on Aguilar (2010) and López (2010), where the baits were (a) bovine intestine and (b) pig feces; the traps were placed in ten cores, distributed in the three subplots and monitored every 24 hours, during 3 days, after their installation. Identification was carried out at the National Museum of Natural History of Paraguay. Eleven individuals of 6 different species were collected, all copro-necrophages, among which *Coprophanaeus cyanescens* and *Dichotomius nisus* stand out, indicating the improvement of soil fertilization and aeration, as well as the presence of large mammals, since they depend on them as their main source of food (Nichols et al. 2009).

Simple innovations to scale assisted forest restoration: the promise of improving outcomes with cost-efficient low-tech approaches

T3.12 Forest Restoration Success and How to Achieve it

Leland Werden[1]
Rebecca Cole[1], Thomas Crowther[1]
[1] ETH Zürich, Department of Environmental Systems Science, Switzerland

Abstract: To rapidly regenerate the world's forests it is imperative that we test and evaluate as many promising restoration approaches as possible. To pinpoint cost effective approaches that may facilitate scaling global forest restoration efforts, we systematically reviewed and quantified the ecological outcomes of a suite of emerging low-tech restoration techniques (hereafter 'simple innovations') with potential for landscape-scale implementation in areas that are slow to recover naturally. We reviewed approaches that have facilitated forest, woodland, and/or mangrove recovery while also decreasing implementation costs, offsetting costs of interventions, leveraging underutilized resources, and/or efficiently restoring natural processes. The simple innovations reviewed were: alternative propagation (e.g., direct seeding), applying biowaste, applying biochar, mixing native and exotic/economic species, mixed plantings, soil microbiome amendment, and spatially patterned planting. For these topics, our initial searches identified 6,456 studies from which fully reviewed all that met our inclusion criteria (field studies conducted in biomes dominated by woody vegetation that included empirical recovery data or data on implementation costs; N = 342). We extracted ecosystem recovery data for all studies that compared a given simple innovation to business-as-usual approaches (N = 143) and implementation costs from all studies that included them (N = 17). The simple innovations evaluated generally had either higher (48.5%) or the same (37.7%) mean ecological recovery values, and rarely had lower recovery values (13.8%; Fig. 1a), when compared to business-as usual controls; emphasizing that these simple innovations may have tremendous capacity to improve restoration outcomes, especially with respect to aboveground biomass/carbon accumulation (N = 63) and plant growth (N = 61). While these innovations have high potential to improve restoration outcomes, we found that they are rarely evaluated at scale and have mostly been tested in the tropics. Thus, we outline strategies to rapidly assess their efficacy, while championing the importance of capacity-building and knowledge-sharing networks in facilitating broader discussions of restoration best practices. Meeting ambitious global terrestrial restoration targets will be incredibly challenging, we argue that we already have many of the tools and the groundswell of support that we need to drive this movement forward.

Structured monitoring is needed to quantify success in forest restoration and deliver global climate and biodiversity goals

T3.12 Forest Restoration Success and How to Achieve it

Alexandre Changenet[1]
Alex Bush[2], **Ruben Valbuena**[1]
[1] SLU, Umeå, Department of forest remote sensing
[2] Lancaster University

Abstract: Ambitious international policy targets have reinvigorated the global ecosystem restoration agenda, to reduce biodiversity loss and restore ecosystems. Yet, the consistent failure to deliver previous goals should serve as a warning. Targets need to be underpinned by a consistent system for monitoring, reporting and verification (MRV) of restoration gains.

Here, we describe an MRV system to consistently define the biodiversity and ecosystem services (BES) gained within a landscape through restoration actions. This MRV-BES system forms the basis of our outcome-based accountability framework that can enable high performing restoration projects to be financially rewarded for their bundled BES gains, and for the confidence with which gains meet expectations. The performance of any restoration project would be evaluated by the similarity of their BES measurements against reference trajectories that approximate the spectrum of development and target state of sites in that landscape. At the same time, project should achieve additionally evaluated by their dissimilarity to counterfactual models approximating the ecosystem development spectrum had no restoration occurred.

We exemplify the MRV-BES framework, with the pioneer work carried out within SUPERB (Systemic solutions for upscaling of urgent ecosystem restoration for forest related biodiversity and ecosystem services), a H2020 ecosystem restoration project part of the EU Green Deal. We monitored several restoration projects across Europe to establish the sequence of ecological changes we would expect restoration sites to follow toward reference ecosystems (reference trajectory). We have combined high-throughput taxa identification (automated acoustic recording, eDNA data) with remotely sensed data (airborne LiDAR, multispectral imaging) to link changes in BES to characteristics of forest ecosystem structure. The reference trajectories can then be used to evaluate the performance of restoration projects in the same landscapes.

We show our framework has the potential to incentivize investments in restoration projects using cost-effective monitoring methods. Ultimately, this work can help reverse the loss of biodiversity by informing the decisions of forest managers.

The nurse shrubs' Role in the Soil Enhancing in reclaimed opencast coal-mines: interactions with Grazing

T3.12 Forest Restoration Success and How to Achieve it

[1] Área de Ecología, Dpto. Ciencias Agroforestales, Instituto Universitario en Gestión Forestal Sostenible (iuFOR), E.T.S. de Ingenierías Agrarias, Universidad de Valladolid, Campus La Yutera, Avda. Madrid 50, 34004 Palencia, Spain
[2] Área de Edafología y Química Agrícola, Dpto. Ciencias Agroforestales, Instituto Universitario en Gestión Forestal Sostenible (iuFOR), E.T.S. de Ingenierías Agrarias, Universidad de Valladolid, Campus La Yutera, Avda. Madrid 50, 34004 Palencia, Spain

Abstract: Native shrubs play a vital role in facilitating the establishment of oak seedlings in opencast coal mines, with greater relevance in Mediterranean areas. Thus, we hypothesize that nurse shrubs in mining areas can enhance edaphic properties by mitigating the negative impacts of trampling and grazing by the ungulates. For that, we evaluate the combined effects of nurse shrubs (plots with and without shrubs) and grazing (plots with and without fences to prevent browsing and trampling) on soil properties in a reclaimed coal mine in Northern Spain.

Regarding chemical soil properties, higher values of electrical conductivity, K^+, cation exchange capacity, and C/N ratio beneath the shrubs were described. Similarly, total organic matter, total N, total organic C, total P, available P, and Mg^{2+} levels were higher under shrubs, but only with grazing. On the other hand, pH and Ca^{+2} levels were higher outside the shrubs, but Ca^{+2} only without grazing. In grazed areas, Na^+ levels decreased under shrubs.

Among physical properties, bulk density increased, and porosity decreased exclusively in grazed plots. In contrast, sand content increased under shrubs within the grazed plots, while clay content decreased in those areas. In addition, ungrazed areas showed the highest water holding capacity and available water.

Overall, our findings indicate that shrubs have a direct positive impact on soil fertility, particularly in grazed areas, as nurse shrubs and grazing exhibit synergistic effects. Furthermore, they indirectly contribute to the improvement of physical properties by mitigating the adverse effects of grazing, specifically soil compaction, through the reduction of trampling by livestock and wild ungulates. Hence, these results highlight the significant role of nurse shrubs in soil amelioration, facilitating the establishment of plants in reclaimed mines, thereby offering substantial implications for the restoration of pastures and forests.

Trends, challenges, and drivers of land cover change in community-based mangrove restoration (CBMR): A case study from Sucre, Colombia.

Abstract: Mangrove forests offer an array of ecosystem services to coastal communities. Mangrove restoration can be a crucial strategy to contribute to the recovery of mangrove ecosystem functionality and services in sites where they have been degraded. One of the approaches for restoration is community-based mangrove restoration (CBMR). In this study, we combine two methods to investigate CBMR in Sucre Province (Colombia), where promising restoration sites for annexation to the Blue Carbon National Program exist. First, we will use Q-methodology to map the main mangrove management stakeholders' discourses. Second, we will map Sucre's mangrove forest extent from 1984 to 2022 using remote sensing techniques. The Q-methodology results will identify mangrove management stakeholders' perceptions of trends and challenges in mangrove restoration management in Sucre. The remotely-sensed verification will complement these perceptions by examining the context of restoration sites through a temporal analysis of mangrove cover supported by existing literature. Finally, this study aims to contribute to understanding whether and how CBMR enables socio-ecological transformations and to inform complex decision-making and policy-making processes for mangrove conservation and livelihood improvement.

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Agroforestry-based Forest Landscape Restoration in Timor-Leste: Challenges and Opportunities

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Yustina Artati[1]
Himlal Baral[1], Kishor Bhatta[1], Shyam Paudel[2], Agus Maulana[1]
[1] Center for International Forestry Research (CIFOR)
[2] CTA United Nation Environment Program (UNEP), Ministry of Natural Resources and Environment, Vientiane, Lao PDR

Abstract: Timor-Leste is the newest country and one of the least developing countries in the Southeast Asia region. The country has been facing multidimensional challenges in land governance leading to deforestation, land degradation, and poverty. Further, Timor-Leste is also prone to climate change effects including unpredictable rain, storm wind, flooding, and drought. Agroforestry is a viable option to balance poverty alleviation and ecological functions of the forest and lands in Timor-Leste. The study presents the challenges and opportunities of agroforestry-based reforestation to improve ecosystem services of degraded landscapes and alleviate poverty in Timor Leste. The study reveals agroforestry has been traditionally practiced in different forms including alley cropping, tree border, alternate row, and irregular patterns. Further, agroforestry initiatives have been conducted with support from different international donors in almost whole municipalities. Agroforestry practice has the potential to increase the diversity of trees on farms which potentially improves ecosystem services and soil health. It also potentially generates income through the production of food crops and employment opportunities for the young generation of the local population. As the main livelihood sources for the rural population rely on land-based resources, therefore the improved income and livelihoods from their lands potentially will encourage forest to expand agricultural land. However, the lack of capacity and knowledge on improved agroforestry systems for both farmers and extension workers is one of the constraints in promoting agroforestry for the restoration of degraded landscapes in the country. Lack of financial access is also another challenge to sustain agroforestry. Economic return from planting trees is long-term while landowners demand fast cash flow to fulfill daily needs. Land tenure insecurity has discouraged private sectors from investing in large-scale agroforestry. The study suggests that a direct incentive is necessary to promote agroforestry for landscape restoration, in addition to land tenure security. Capacity building to extension workers and intensive assistance to farmers, as well as market accessibility are required to foster agroforestry in Timor-Leste. Further, establishing a community-based monitoring system is necessary to generate information on the progress of agroforestry such as potential carbon sequestration and food crop productivity needed by market or investors.

Assessing subtropical forest ecosystems' response to climate extremes by using dynamic process network and eddy covariance observations

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Rong Yu[1, 2, 3, 4]

Abstract: The recent IPCC AR6 synthesis report confirms the significant impact of human activities on global warming, leading to an increase in the frequency and severity of extreme climate events. Subtropical ecosystems in East and Southeast Asia monsoon region, which contribute approximately 8% to the world's forest net ecosystem productivity, are also under significant pressure due to these climate extremes. This study seeks to assess the responses of subtropical forest ecosystems to three primary types of climate extremes, i.e., droughts, heatwaves, and extreme rainfalls.

We propose to utilize eddy covariance observations and high-resolution satellite data collected from three representative subtropical ecosystems in the region, i.e., a Moso bamboo forest, a Lei bamboo forest, and an evergreen broadleaf forest. The Dynamic Process Network approach, based on information theory, has been demonstrated as a robust method for investigating and assessing ecosystem functionality using high-frequency observations. Additionally, the Cumulative Power Law Model will be employed to evaluate these ecosystems' sensitivity to climate extremes in the region. This proposed research is expected to enhance our understanding of the complex responses of subtropical ecosystems to climate change.

Climate change on subtropical cloud forest and restoration strategies: a case study on the endangered beech forest in Taiwan

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Huan-Yu Lin[1]
Tze-Ying Chen[1], Chang-Fu Hsieh[2], Hsin-Chi Li[3]
[1] Department of Forestry and Natural Resources, National Ilan University, Taiwan.
[2] Institute of Ecology and Evolutionary Biology, National Taiwan University, Taiwan.
[3] National Science and Technology Center for Disaster Reduction, Taiwan

Abstract: The directional range shift, including the poleward and upward migration of tree species under global warming, is an issue of growing concern for natural resource management. Mountain regions have a dramatic climatic gradient, so species can approach a temperature-suitable habitat in a very short distance. However, the accompanying interspecific competition, substitution, and progressive replacement of forest communities may also occur. Cloud forests on tropical and subtropical islands have been proven to be one of the most vulnerable ecosystems to climate change. The montane cloud beech forest in Taiwan, which is predominantly dominated by the glacier-relict species of *Fagus hayatae*, was projected to suffer severe impacts with a 92.90% habitat loss under a medium stabilization scenario (RCP 4.5) or 99.23% under a high emission scenario (RCP 8.5) based on an intact historical and future climate database developed by The Taiwan Climate Change Projection Information and Adaptation Knowledge Platform (TCCIP).

In Taiwan, *Fagus hayatae* is mainly distributed in the northeast mountains and exposed to the winter monsoon to meet its cool-temperate ecological requirements. All populations currently inhabit isolated mountain tops and ridges from 1,000 to 2,000m asl. Our model simulations revealed that the fragmented and ridge-top habitats impose strong limitations on their migration and lead to a high extinction risk. Long-term field surveys from a series of permanent forest plots from 1,000 to 1,800m elevation also support the model projection. The low-elevation populations exhibited an unstable size-class distribution compared to high elevations, and a cascade-like population decline was triggered by extreme climatic events such as typhoons.

To mitigate the impact of climate change on the endangered *Fagus* forest, several conservation strategies have been implemented, including (1) Annual monitoring by drone to detect the mortality of adult trees; (2) The establishment and identification of genetic variation for each relic population; (3) Assisted propagation from seed collection and preservation, as well as air layering for adult trees in the wild; and (4) Assisted migration by using *Fagus* saplings to accelerate the regeneration of thinned-out plantations along projected migration corridors.

Determinants of Public Participation in Watershed Management: An Application of the Institutional Analysis and Development Framework

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Daile Zeng[1]
Boya Chen[2], John Innes[1], Juliet Lu[1], Jingxin Wang[3], Yancun Yan[1], Guangyu Wang[1]

[2] Department of Statistics, University of British Columbia, Vancouver, BC, Canada
[3] School of Management, Yale University, New Haven, USA

Abstract: Increasingly, adaptive processes and decentralization are vital aspects of watershed governance. A significant gap exists in our understanding of the factors that facilitate public participation in China. In this study, we combine the Institutional Analysis and Development framework with multiple models and ordered probit regression to investigate empirically the determinants of willingness to participate (WTP) and actual participation of the public in integrated watershed management (IWM) planning and implementation activities. Data derived from questionnaires are used to define stakeholders' perceptions of IWM. The sustainability of the regional conservation plan is primarily based on the satisfaction of citizens with management performance. Considering the importance of the terrestrial-aquatic interface for watershed integrity, we also investigated the effectiveness and appropriateness of riparian forest management. We find that individual environmental intention and behavior are influenced by biophysical conditions, rules-in-use, socioeconomic characteristics, and interactional capacity, to varying extents. The results of this work reinforce the necessity for an integrated and holistic approach to regional watershed resource management. The results also show that information-sharing significantly improves the WTP and actual public participation in IWM. Interpersonal communication and cross-reach support in an interactional capacity are also significantly correlated with WTP, while the overall performance of governance and inappropriate forest practices influence intention and behavior. Participants were more inclined to engage in river basin activities if they had previously observed poor forest management behavior (e.g., burning slash and shrub, clear-cutting, logging within a riparian zone, herbicide and pesticide use). The biophysical conditions and socioeconomic characteristics of the watershed do not markedly affect WTP but shape actual participation behavior. These findings provide workable insights into the social and institutional factors that shape the participation by individuals in watershed governance as it moves towards a decentralized and sustainable future.

Developing tools for evaluating forest degradation under climate change: case studies from East and South-East Asian evergreen broad-leaved forest

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

ANIL SHRESTHA[1]
Gladys Guo[1], Hoang Van Sam[2], Bui Manh Hung[2], Phan Quoc Dung[2], Gunagyu Wang[1]
[1] Faculty of Forestry, University of British Columbia, Vancouver, Canada
[2] Vietnam National University of Forestry, Hanoi, Vietnam

Abstract: The degradation of tropical forests contributes to global greenhouse gas emissions including loss of biodiversity, ecosystem services and consequently negative impact on wellbeings and livelihoods. Thus, monitoring forest degradation is the key for developing forest restoration plans, policies, and actions. However, monitoring forest degradation is understudied and poorly understood, mainly because most of the programs focused on deforestation, which is easier to monitor. Few monitoring tools that existed mostly focused on larger spatial scale, in contrast, most of the forest restoration programs took place at smaller scale. In addition to this, the existing monitoring tools almost disregard the climate change complexity that will eventually impact success of forest restoration tropical forest. To address these issues, we develop forest degradation monitoring tools as measured by criteria and indicators related to biophysical attributes of forests that consider local climate change. In this presentation, we will introduce the tools and discuss the application of tools under climate change including associated challenges and opportunities with case studies from evergreen broad-leaved forest across East Asia and Southeast Asia. We hope these tools will help practitioners to evaluate forest degradation at a local scale and develop effective restoration plans and actions for recovery of degraded forest.

Development of standard nursery growth media for enhanced domestication of East African sandalwood in Kenya

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Riziki Mwadalu[1]
Mary Gathara[1], Mohamed Elema[1], Peter Gachie[1], Florence Towett[1], Mercy Rutto[1]
[1] Kenya Forestry Research Institute

Abstract: Tree nurseries play a vital role in afforestation and reforestation programmes across the globe. The quality of planting stock leads to successful field establishment and growth performance thus leading to high yield. The need to domesticate *Osyris lanceolata* (East African Sandalwood), which is a threatened species, has increased the demand for quality Sandalwood seedlings in Kenya. The population of this species had dwindled over the years due to over-exploitation from the natural ecosystem due to its commercial potential. Wild-harvested Sandalwood from Kenya is illegally poached and smuggled mostly to India as a substitute to the Asian Sandalwoods as an ingredient in the multimillion dollar cosmetic, perfumery and flavour industries. For successful domestication of the species, there is need to develop appropriate nursery growth media for production of quality seedlings. Currently, there is no standard nursery growth media for propagation of the species. As such, a nursery experiment was established to evaluate sandalwood growth performance under different ratios (v/v) of forest soil, manure and sand. The study was set using randomized complete block design with 5 treatments, each replicated thrice. The ratios used were: 5:1:1+NH (control), 5:1:1+H, 4:1:1+H, 3:1:1+H and 2:1:1+H with "NH" representing non-hosted seedlings while "H" represented hosted seedlings. The seedlings were hosted with *Acacia polyacantha* except the control. The results show 5:1:1+H had the best seedling growth in terms of height and collar diameter at the end of the experiment (19.23cm and 2.74mm, respectively); 123.3% and 87.7% higher than the control, respectively. In terms of shoot and root biomass, 5:1:1+H had the highest biomass (1.80g and 0.44g per seedling, respectively); this was >150% higher than the control. The highest sturdiness quotient (SQ) was observed in 5:1:1+H (8.53) while the lowest SQ was recorded in 2:1:1+H (5.92). There were no significant differences in root/shoot ratio of sandalwood seedlings raised from different soil mixtures ($p<0.23$). The highest seedling survival rate of 88.9% was recorded in 5:1:1+H while the lowest was recorded in 5:1:1+NH (62.2%). The treatment of 5:1:1+H is the most appropriate for production of quality sandalwood seedlings to enhance domestication of the species.

Diverse approaches to forest landscape restoration in mainland Southeast Asia.

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Natasha Han[1]
James Bampton[1]
[1] World Wide Fund for Nature - Greater Mekong

Abstract: Forest landscape restoration (FLR) represents a cost-effective, long-term, and sustainable nature-based solution to address adverse impacts of degradation. It aligns with national and international priorities, including climate change mitigation, livelihood improvement, and biodiversity conservation. Economic analyses confirm that long-term benefits of FLR outweigh initial investments. However, countries in the Greater Mekong Subregion (GMS) exhibit divergent priorities and approaches, impeding the required scale of FLR implementation to reverse historical and ongoing degradation.

WWF actively engages in diverse FLR approaches within the GMS tailored to contextual factors and aligned with the UN Decade on Ecosystem Restoration. Their aim is to generate benefits for both nature and people within local and global landscapes. I propose to present the comprehensive range of activities undertaken by WWF, demonstrating clear objectives and effective monitoring mechanisms.

In Myanmar, WWF supports Assisted Natural Regeneration and firebreaks to restore local territories of the Karen in the Tanintharyi region. These efforts integrate indigenous peoples and local community knowledge and practices to restore ecosystem services. Food production within restored forests encourages wider adoption of FLR.

FLR349 in Thailand employs an agroecology lens to address the expansion of monoculture maize agriculture, which has led to extensive deforestation and degradation, particularly in the Northern watershed areas. This model promotes sustainable agriculture based on the agroecological concepts of "Three Forests, Four Benefits" under the "Sufficiency Economy Philosophy" of His Majesty King Bhumibol Adulyadej, Rama IX of Thailand.

The Community-based Forest Restoration and Management for Livelihoods program in Lao PDR targets villages with degraded forests in and around the Xe Sap National Protected Areas. This inclusive approach embraces natural forest restoration and management and supports climate-resilient livelihoods. WWF Laos is piloting a wildlife recovery assessment tool with Mekong Timber Plantations to explore how private concession-based timber plantation companies can contribute to FLR.

WWF supports the Vietnamese Government through various approaches including restoring natural forests to enhance climate resilience and diversifying commercial plantations through extended rotations. Additionally, each location is analyzed to highlight successful strategies and challenges overcome to derive lessons for scaling up these approaches and implementing FLR initiatives in similar situations to amplify impact.

Ecological restoration and environmental impacts caused by construction activities

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Yan Zhang[1]
Tingning Zhao[1], Guangyu Wang[2], Jingjing Feng[1]
[1] College of Soil and Water Conservation, Beijing Forestry University, Beijing 100083, PR China
[2] Faculty of Forestry, University of British Columbia（UBC）, Vancouver, Canada

Abstract: This paper presents the natural hazards caused by human activities i.e. surface mining and highway construction in Beijing mountainous area. The exploitation of large open pit mines and the construction of highways have caused severe disturbance to land and vegetation. This kind of disturbance causes a series of problems, for example, serious loss of water and soil, geologic hazards like landslides and collapses, which affect the ecological and living environment. The reconstruction of the vegetation ecosystem is the key to improve soil condition. Therefore, soil and water conservation measures should be designed reasonably according to the features and physical truths of a project or an engineering. And engineering measures and vegetation measures should be combined for protection. In order to improve the fraction of slope surfaces' coverage and plant roots' ability to reinforce soil, deep-rooted and local plants should be widely used and shrub proportion should be increased appropriately. Among the ecological measures for greening in rock slopes in mountainous areas, the use of geogrids with embedded ecological bags results in the minimum runoff volume, while the use of geogrid chambers leads to the minimum sediment yield. Among the ecological protection measures for slopes in mountainous areas, the runoff volume and sediment yield are the lowest when geogrid chambers are used. In plain areas, the runoff volume and sediment yield of trapezoidal hollow hexagonal brick greening measures are both lower than those of hollow hexagonal brick greening measures. Based on the effectiveness of different ecological protection measures in reducing runoff and sediment, the optimal ecological protection measures should be selected for vegetation restoration on various typical slopes to ensure the best control of soil erosion. The ecological restoration and afforesting goal whose premise is to achieve slope stability will be finally achieved and plant community which is in harmony with the surrounding environment will be formed so that the aim to prevent soil and water loss will be reached.

Effect of Prolonging Nursery Lifespan on Survival Rate of out planted Tree Seedlings

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

[2]Mekelle Agricultural Research Center

Tigray Agricultural Research Institute (TARI)

**Email of corresponding author: kiroskey@gmail.com*

ABSTRACT

The most challenging issue for rehabilitation of degraded lands in Tigray mostly is attributed to poor survival rate of planted seedlings. Therefore, the objective of this research was to evaluate the survival rate of planted seedlings through prolonging the nursery lifespan of seedlings which ensures the vigorosity of the seedlings to withstand the moisture stress of the areas. The treatments were seedlings of three, five, seven and nine month's nursery lifespans. The tree species considered for this study were *Moringa stenoptella; Jatropha curcas, Leucaena leucocephala and Ziziphus spina Christ* that poorly survives in the area were selected and subjected to the different treatments (nursery lifespan). The spacing between blocks, plots and plants were four, three, and two meters respectively with RCBD design. Plantation pits were prepared two weeks ahead of plantation for moisture retention. The required post and pre plantation management activities were equally applied to all treatments and species. Data such as plant height and survival rate have been collected for a year at different months. Analysis of variance (ANOVA) was employed to see if there was a mean difference between the treatments. LSD mean separation was employed to compute for multiple comparisons or post hoc tests. Prolonging the nursery lifespan of the seedlings has brought a significant effect on both survival rate and plant height. However, the tree species didn't consistently respond to the treatments (lifespan). Some tree species increase their survival rate with increasing nursery lifespan while, others, not. The best survival rate of tree species was identified at five months nursery lifespan except for Jatropha which consistently increases its survival rate with increasing nursery lifespan. In general, prolonging only the seedlings nursery lifespan may not be enough for improving the survival rate, but also needs to add fertilizer at the expense of prolonging the seedlings nursery life span.

Key words: *Nursery lifespan, survival rate and prolonging*

Forest landscape restoration measures as a cost effective solution for climate change mitigation and adaptation in India

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

V.P. TEWARI[1]
[1] President, International Society of Tropical Foresters India Chapter, Lucknow, India

Abstract: Global deforestation and forest degradation have led to massive loss of biodiversity. Hence, it is important not only to protect but also restore the forest ecosystems. Forest biodiversity protection, biomass production and climate change mitigation and adaptation are some of the important key motivations for forest restoration.

Tree-based landscape restoration is a widely accepted cost-effective measure to combat climate change. India's commitment of Nationally Determined Contribution to the Paris Agreement is to sequester additional 2.5 to 3 billion tons CO_2 equivalent by 2030 through increased forest and tree cover and this ties in with the Bonn Challenge commitment to restore 21 mha of deforested and degraded lands by 2030 (now increased to 26 mha during UNCCD COP 14 meeting held in Sept. 2019) as well as the SDGs. This commitment can only be met if existing forests are protected and improved and tree cover is extended by 25 to 30 mha.

The main objectives of the Forest Landscape Restoration (FLR) in India is to reverse the process of degradation of forests & improve its productive potential, improve the regeneration of native flora & enrich the biodiversity, and enhance biomass production, carbon stocks & incomes of the rural households.

For a successful FLR works in India, focus needs to be on proactive involvement of communities and local people, better coordination among the various government agencies and departments for effective implementation of project activities, robust Institutional mechanism, and continuous fund flow and support to sustain the activities and keep the restored areas intact.

Here, we present how India can achieve the NDC and Bonn Challenge through forest landscape restoration. Potential to increase forest and tree cover and the carbon sequestration that can be achieved has been discussed. This will support planning for landscape restoration through the past and on-going initiatives which identifies different types of interventions implemented.

Forest Restoration under Climate Change in Southeast Asia: Innovative Tools, Models, and Approaches

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Guangyu Wang
Kalifi Ferretti-Gallon[1], James Douglas Langston[1], Kebiao Huang[2], Hongbo Zhai[2], Futao Guo[3], Guibin Wang[4]

[3] College of Forestry, Fujian Forestry and Agriculture University, Fujian, China
[4] College of Forestry, Nanjing Forestry University, Jiangsu, China

Abstract: Forest restoration is gaining increasing attention at international and national levels. However, identifying forest degradation, particularly at smaller scales, remains a challenge due to diverse drivers and site-specific factors. Existing frameworks for identifying forest degradation are useful on a larger scale, but a framework that incorporates local knowledge is needed for smaller-scale assessments. In this research, we propose a new mechanism called the Degradation and Restoration Assessment Mechanism (DReAM) that facilitates the identification of forest degradation and opportunities for restoration in landscapes. The DReAM framework is based on an iterative process that incorporates input from local knowledge-holders and established regional expertise. It provides a comprehensive approach to understanding forest degradation and monitoring restoration progress. We tested the utility of the DReAM mechanism in multiple sites across the Lancang-Mekong Region, including Cambodia, Laos, Myanmar, Thailand, and Vietnam. Through the application of the DReAM mechanism, we derived a set of appropriate criteria and indicators for identifying degraded forests. These criteria and indicators can serve as guidelines for developing effective rehabilitation approaches. Importantly, the DReAM mechanism is designed to be accessible and applicable to any individual or group interested in identifying forest degradation or assessing rehabilitation efforts.

Integrating technology and community management for forest and water resource management for climate adaptation: Lessons and approaches

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Ajith Chandran[1, 2, 3]
[1] Chair, Water Working Group, Institute of Engineering and Technology (IET), India
[2] Forestry Expert, WASCA II Project, India
[3] Managing Director, Development Interlinks International Pvt Ltd, India

Abstract: Context:

Climate change poses significant challenges for forest and water resource management, necessitating the integration of technology and community management approaches. This abstract presents key lessons and approaches from the Water Security and Climate Adaptation in Rural India (WASCA) project, which aims to enhance climate adaptation in forest and water resource management.

Topic of Study:

This study focuses on the integration of technology and community management for climate adaptation in India's forest and water resource management, drawing lessons from the WASCA project.

Methods:

The WASCA project utilised advanced technology and community-based management strategies to address climate-related challenges. Remote sensing, geographic information systems (GIS), and hydrological modelling were employed to assess the impacts of climate change on forests and water resources. Community engagement and participatory approaches were adopted to foster local ownership, knowledge sharing, and resource mobilisation. Adaptation strategies were implemented in collaboration with local communities, including afforestation, reforestation, sustainable water management practices, and capacity-building programs.

Main Results:

Technology integration provided valuable data and insights, enabling evidence-based decision-making and planning. It facilitated accurate monitoring of changes in vegetation cover, hydrological patterns, and water availability, helping identify vulnerable areas, prioritising adaptation measures and water budgeting. Community management played a pivotal role in ensuring the effectiveness and sustainability of interventions. This collaborative approach fosters social cohesion, empowering communities to take ownership of climate adaptation efforts. Despite its many successes, there are challenges in integrating forest management at the institutional level.

Conclusions:

The findings from the WASCA project demonstrate that integrating technology and community

management is a promising approach for climate adaptation in forest and water resource management in India. The combination of advanced technology and community engagement enhances the accuracy and relevance of adaptation measures. Moreover, it strengthens social resilience and supports sustainable livelihoods. Policymakers and practitioners should consider these lessons to develop context-specific adaptation strategies, recognising the importance of community participation and traditional knowledge in climate adaptation efforts. By integrating technology and community management, India can effectively respond to the challenges of climate change and ensure the resilience of its forest and water resources to benefit local communities and the environment.

Physiological and ecological responses of moso bamboo of different ages to summer drought stress

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Tingting Mei[1]
[1] Zhejiang A&F University

Abstract: Bamboo is known for its fast growth rate and carbon sequestration capabilities, making it an important part of the forestry carbon sequestration. However, due to the climate change, extreme high temperatures and droughts are becoming more frequent, posing a threat to the health of the forests and the carbon sinks they carry. This study aims to investigate drought resilience of Moso bamboo by simulating drought conditions in Lin'an, Zhejiang, and monitoring the physiological response of new and old Moso bamboo culms to the drought. We found that moso bamboo shows different drought resistance strategies at different ages: (1) Under summer drought stress, soil microbial diversity and root infection rate of arbuscular mycorrhizal fungi decreased significantly in moso bamboo forest, especially in new bamboo. Adult bamboo transferred more nutrients to fungi to maintain water uptake ability by reducing root fungal infection rate decline. (2) Stem hydraulic structure and sap flow monitoring revealed age-related differences in water use of moso bamboo. New bamboo had higher transpiration, photosynthetic capacity and xylem water transport capacity than old bamboo. Under drought stress, water consumption of both decreased significantly, but new bamboo still maintained higher transpiration. Continuous heat and drought damaged photosynthetic capacity and hydraulic structure of new bamboo due to insufficient water support. However, old bamboo started water-saving mode in the early stage of drought and performed better than new bamboo in terms of stomatal control of transpiration and nocturnal water recharge capacity. (3) Drought reduced leaf photosynthesis, but increased isoprene release. Moso bamboo increased carbon investment in drought defense. This study revealed the different drought resistance strategies of moso bamboo at different ages. Adult bamboo relied more on symbiotic fungi to maintain water uptake ability, while new bamboo maintained higher transpiration and photosynthetic capacity but suffered more damage under heat and drought stress. Old bamboo adopted a water-saving mode and performed better than new bamboo in terms of stomatal control and nocturnal water recharge. Our findings provide new insights into the physiological and ecological responses of moso bamboo to drought stress and have implications for its sustainable management and conservation.

Study of Genetic Diversity in An Effort to Save The Genus of Dacrydium (Lamb.) in Kalimantan Indonesia

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Siti Soebagiyo[1]
Paul JA Kessler[2], Sapto Indrioko[3], Mohammad Naiem[3]
[1] Faculty of Forestry Instiper Yogyakarta Indonesia
[2] University Leiden, The Netherlands
[3] Forest Tree Improvement Laboratorium Faculty of Forestry, Universitas Gadjah Mada Yogyakarta, Indonesia

Abstract: The tropical coniferous genus *Dacrydium* is widespread in Kalimantan, Indonesia. Four species can still be found in Borneo. Locally known as *Alau*, this genus thrives in a range of habitats from heath to deep-peat forests, especially in Central Kalimantan. This genus is threatened by logging, fires, and forest conversion for other uses. The objectives of this study were to investigate the genetic diversity of *Dacrydium* in the study area which is a large unified diverse landscape.. Our research was conducted in a heath forest located within PT Taiyoung Engreen logging company in Gunung Mas District, PT Dasa Intiga in Kapuas District, and a deep-peat swamp forest located in Sebangau National Park in Palangkaraya District. The four species that are suspected to exist in Kalimantan, namely *Dacrydium beccarii* Parl.; *Dacrydium pectinatum* de Laub., *Dacrydium elatum* (Roxb.)Wall. ex Hook. and *Dacrydium xanthandrum* Pilg. were met in various abundances. Isoenzyme markers were applied to analyze the genetic diversity of *D. beccarii* and *D. pectinatum* using 20 samples per species from each site.

The results showed that *D. beccarii* and *D. pectinatum* have a large number of missing alleles, rare alleles, and individual alleles, which are found in different species in the three research sites; all show their owngenetic peculiarities. That makes it necessary to develop a strategy to protect the alau quite locally , Especially *D. pectinatum* is of high concern as it is quite threatened. *D. beccarii* and *D. pectinatum* have similar total heterozygosity (H_T) namely 0,686 and 0,700. Most the genetic diversity of both species 71,1% and 0,65% present within the population, and the fixation index (FIS) values close to zero -0,021 and 0,187, which means both species has a tendency to random mating. It is necessary to implement a strategy for saving Dacrydium. This can be implemented from our research site. Actions will include the translocating of individual seedlings between research sites where each has a private allele with different advantages to be planted in all original habitat to increase genetic variation, and establish demonstration plots to safeguard genetic variation (diversity), and additionally carry-out genetic enrichment planting, especially for *D pectinatum*.

Sustainable Forest Ecological Restoration in the Context of Corporate Social Responsibility

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Damrong Pipatwattanakul[1]
[1] Kasetsart University, Faculty of Forestry, Thailand

Abstract: In 2013, an eco-centric Corporate Social Responsibility (CSR) initiative called the Khao Huai Mahat Forest Restoration project was launched through the collaboration of four organizations: GC, Kasetsart University, The Air and Coastal Defense Command, and The Konrakpa Club under Charklookya-Huai Mahat community. With a ten-year timeframe, the primary objectives of the project included restoring the degraded forest, improving the economic and social well-being of the surrounding communities, raising awareness about environmental protection and forest conservation, and safeguarding the only forest area within the Map Ta Phut Industrial Estate in Thailand.

Khao Huai Mahat was once a thriving forest ecosystem that provided essential ecological services, including high-quality water, NTFPs and a rich source of medicinal plants for the community's livelihood. However, due to decades of forest exploitation for agricultural practices and frequent fires, the forest area has deteriorated. To address this issue, a project master plan was formulated with three main activities: restoration, construction of weirs, and fire protection measures. These initiatives aim to enhance water absorption, increase biodiversity, and contribute to mitigating climate change. The local community has shown strong support for these activities and recognizes the significance of the project.

To facilitate monitoring and decision-making, a digital platform has been established, capturing baseline information and documenting implemented activities. Biodiversity monitoring was the key indicator, while the growth of planted trees and the functionality of weirs are monitored annually. The project has received certification from the Thailand Greenhouse Gas Management Organization as a Low Emission Support Scheme, highlighting the project's contribution to greenhouse gas storage and sustainability.

Despite the potential for projects to exceed initial timelines, the 400-hectare ecosystem of Khao Huai Mahat serves as a testament to the transformative power and impact of community-driven initiatives. The project exemplifies best practices and a robust corporate social responsibility (CSR) model, emphasizing the crucial role of community involvement in restoring forest ecosystems.

The Untapped Potential of Bamboo Forests for Carbon Offset in Mitigating Climate Change: A Comparative Study with Tree Forests

T3.13 Forest restoration under climate change in Southeast Asia: innovative tools, model, and approaches

Chunyu Pan[1, 2]
Guomo Zhou[2], Anil Shrestha[1], Guangyu Wang[1, 2]
[1] Faculty of Forestry, University of British Columbia
[2] State Key Laboratory of Subtropical Silviculture, Zhejiang A&F University

Abstract: In light of the increasing deforestation rates and climate change challenges in Southeast Asia, this study examines innovative strategies for forest restoration, focusing on the carbon sequestration potential of bamboo and tree forest Afforestation/Reforestation (AR) projects. Employing a global empirical analysis, we compare the carbon sequestration capacity of these two types of forests in diverse climatic and geographical conditions. This investigation uses Landsat remote sensing data to analyze five tree- and five bamboo-AR projects, certified by the Verified Carbon Standard (VCS), Chinese Certified Emission Reduction (CCER), and the Fujian Forestry Certified Emission Reduction (FFCER), providing a comprehensive perspective on these forests' potential in carbon offset schemes. Additionally, a detailed case study conducted in Tongshan County, China, further illuminates our understanding by utilizing LiDAR data to compare the carbon sequestration performance of a bamboo afforestation project with a tree afforestation project. This ground-level analysis offers insight into the adaptability and sustainability of these forest types within a rapidly changing climate. This research scrutinizes the advantages and limitations of remote sensing technologies like Landsat and LiDAR in accurately assessing and monitoring AR projects, potentially guiding the development of more advanced and effective tools for forest plantation projects. Through this analysis, we present evidence-based recommendations to enhance the design, implementation, and monitoring of forest carbon offset projects. These findings are essential to contribute significantly to the ongoing discourse on sustainable forest management, particularly in regions experiencing ecological degradation under climate change. By spotlighting the untapped potential of bamboo forests, this research proposes a broader, more innovative approach to forest restoration in Southeast Asia, thereby setting a precedent for similar endeavors worldwide.

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Agility in changing environments: how genomic and enviromic technologies transformed a Eucalyptus globulus tree improvement program

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Andrew Callister[1]
Ben Bradshaw[2]
[1] Treehouse Forest Research, Check, Virginia, USA
[2] Australian Bluegum Plantations, Albany, Western Australia, Australia

Abstract: Physical and economic environments are changing rapidly and with increasing uncertainty. Agility is now a fundamental requirement of tree improvement programs globally, demonstrated through sensitivity, flexibility, and responsiveness to sudden changes in breeding or deployment objectives. Thankfully, advances in genomics, enviromics, and phenomics have provided tools to help meet this challenge.

Australian Bluegum Plantations (ABP) conducts an advanced-generation *Eucalyptus globulus* breeding program, which we present as an example of how adoption of genomic and enviromic technologies can deliver greater agility in response to changing climatic and market demands. Application of genomic tools has been foundational to the transformation of ABP's program, to correct identity errors in the pedigree and orchards and increase breeding value accuracy through single-step genomic BLUP (ssGBLUP). Races and landraces are accommodated in ssGBLUP as 'metafounders' and the optimisation of this process has helped classify pedigree founders from unknown origins into genetically similar groups. ssGBLUP facilitated the joint analysis breeding populations from ABP and a collaborator. This has crucially increased our flexibility via improved genetic diversity. The power of ssGBLUP was leveraged with factor analytic analysis to calculate genotype-environment interaction. Enviromic characterisation of 33 trial sites using 145 environmental variables then enabled identification of five deployment zones based on envirotypes. Mapping of these new deployment zones using predicted climates has revealed the dominant envirotypes expected in future decades. Selection and breeding for survival and growth in these environments is now underway.

Agility in the ABP program is also achieved through sublining and integration of breeding and deployment activities. Breeding and deployment populations are divided into non-exclusive sublines based on suitability to envirotype, wood properties, and disease resistance. This approach provides a framework for flexibility and responsiveness to changing market or environmental demands which can be applied to new objectives that emerge from the bioeconomy sector. By deployment of control-pollinated families, parents from particular sublines can be paired to produce seedlots for different combinations of traits and environments. Selection for reproductive attributes is practiced with each new introduction of seed orchard clones. Active program developments include genomic and marker-assisted selection and rapid phenotyping methods.

Assessing adaptability and resilience of pure species and clones of Eucalyptus grandis and Eucalyptus camandulensis in planted forests

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Mitchel Oluoch[1]
Joram Mbinga[1], Joyce Okumu[1]
[1] Kenya Forestry Research Institute

Abstract: Assessment of resilience and adaptability of clones of the marketable tree species- *Eucalyptus grandis* on high potential highland areas and *Eucalyptus camandulensis* for low potential areas is key towards addressing climate change adaptation and mitigation. This study explores the need to sustain quality timber supply towards bio-circular economy and use of clones plantations. The research focused on three main objectives of; One, to assess survival of pure species and clone hybrids. Two, assessing the recovery and resilience pure species and clone hybrids within blocks in Turbo. Three, to model the potential of clones from low and high potential zones as future resilient crosses. The research data was collected within Turbo through total enumeration. There were six (6) blocks of thirty four (34) treatments of fifteen clones of *Eucalyptus camandulensis and Eucalyptus grandis* of GC03, GC785, GC514, GC167, GU7, GC796, GC642, GU8, GC522, GC10, GC12,GC584, GC14, GC15, GC581,18 pure and one local *Eucalyptus grandis*. Inventory of the stands was by the tree height and diameter at breast height(DBH). Annual rainfall and temperature ranges were acquired and minimal and optimal weather conditions were calculated. Data analysis included; survival and abundance of pure species and clones within the years, comparison of annual volume of the stands within years of optimal and minimal rainfall and temprature, modelling on future performance of pure species and clones. Tentative results show high survival of pure species of *Eucalyptus grandis* at the first five years with an average of >50% trees present in the blocks compared to clones on this site similarly to abundance of pure species to stand density. Recovery of the clones after minimal weather conditions was low compared to pure species. Response in terms of volume accumulation of clones; GC514, GC581 and GC796 was significant than the other clones likewise to significant performance of EG6, EG10 and EG3. The results suggest adaptive climate-smart breeding methods and growing of resilient clones and species within planted forests towards climate change mitigation and livelihood improvement. The study was limited to research conducted within a high potential forestry area, replicates of the clones for wider sites should be considered.

Assessment of bud flush and damage in young Norway Spruce trees through airborne high-resolution multispectral images

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Louisa Eurich[1]
Sara Lopez Fernandez[2], Johannes Wiesenberg[2], Andreas Helmersson[3], Malin Elfstrand[2], María Rosario García-Gil[4], Eva Lindberg[1]
[1] Department of Forest Resource Management, Swedish University of Agricultural Sciences, Umeå, Sweden
[2] Department of Forest Mycology and Plant Pathology, Swedish University of Agricultural Sciences, Uppsala, Sweden
[3] Forestry Research Institute of Sweden (Skogforsk), Ekebo, Sweden
[4] Umeå Plant Science Centre, Department of Forest Genetics and Plant Physiology, Swedish University of Agricultural Sciences, Umeå, Sweden

Abstract: Scandinavia is facing climate changes with a predicted increase of mean temperature between 2-4° C, which is expected to result in longer vegetation periods and consequently increased tree growth. This might lead to an increased risk of frost damage to newly sprouted buds as the timing of bud flush will change and temperature might backlash during spring.

Studies of one-year-old Norway spruce (*Picea abies*) seedlings suggest a strong correlation between early bud flush and frost damage. Bud flush and hardiness have been assessed for adult Norway spruce plantations. However, the effects on planted and established young spruces is yet to be described. The classical way to gather data on bud flush is manual assessment. As an alternative, Remote Sensing technology has been proven feasible to score bud flush in conifers with the advantage of scoring more trees in shorter time with lesser resources.

This study aims to provide data for the bud flush of young spruces derived from multispectral high-resolution drone images. The genotype of the spruces is known at individual tree level. The data was collected during spring 2023 and data collection will be repeated in the following years. Bud flush is estimated from the spectral values of the tree crowns using manual assessment of the bud flush in a subset of the trees as training data. To ensure capturing a high level of variation in bud flush phases, images were taken before the vegetation period and up to twice a week during the period with most rapid bud flush. In a second step, multispectral high-resolution images will be used to assess the damage on the new shoots later in the vegetation period. During the session, the results from the first sampling season will be shown and discussed in relation to the genetic variation and the risk of damage.

Breeding Against Spring Frost? - Heritability of Spring Frost Tolerance in Norway Spruce (Picea abies)

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Tuuli Aro[1]
Biyue Tan[2], Vaughan Hurry[1]
[1] Umeå Plant Science Centre (UPSC), Department of Forest Genetics and Plant Physiology, Swedish University of Agricultural Sciences, 901 83 Umeå, Sweden
[2] Stora Enso, Sweden

Abstract: Climate change is challenging the traditional breeding objectives, since future tree species will face more diverse abiotic and biotic pressures that require higher plasticity and adaptive potential. The boreal forest biome is predicted to shift towards an earlier start of the thermal growth season by the end of this century. Rising temperature is advancing the bud break and dormancy release in coniferous species, thereby increasing the risk of frost damage in newly developed buds due to early frost backlashes. Norway spruce, a dominant boreal conifer species, has high ecological and economical importance in Nordic countries, but is also vulnerable for early frost events.

The aim of our study was to investigate the heritability of spring frost tolerance in Norway spruce and whether the variation of frost tolerance in the Swedish Norway spruce breeding population could be used for genomic selection. To that end, the correlation between frost tolerance and vitality, height and timing of budburst were analysed.The spring frost tolerance was assessed in 3 consecutive springs in young Norway spruce stance in Northern Sweden. Freezing tolerance was measured by an electrolyte leakage assay of newly emerged buds from 38 Norway spruce families. Spring frost tolerance, bud burst timing, height and vitality were used as traits in the narrow-sense heritability and genetic correlation analyses. Finally, breeding values of the field population are predicted with a genomic selection model.

Our narrow-sense heritability estimations indicate variation of spring frost tolerance (0.35) in the Swedish Norway spruce population. Frost tolerance also showed moderately negative correlation (-0.568) to budburst timing and low negative correlation (-0.262) to vitality. Our study suggests that the Swedish Norway spruce breeding population accommodate variation of spring frost tolerance in newly developed buds. We believe that frost tolerance trait could be incorporated in the Norway spruce breeding programs to improve frost tolerance of the Norway spruce seedlings especially in the frost prone areas.

Development of a genomic selection method for silver birch - a commercially important boreal forest tree species

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Kalle Leppälä[1]
Juha Immanen[2], Kaisa Nieminen[1, 2]
[1] The Organismal and Evolutionary Biology Research Programme, University of Helsinki, Finland
[2] Natural Resources Institute of Finand

Abstract:
Due to changing climate and rapidly northward moving ecological zones, broadleaved hardwood species are becoming ever more economically and ecologically important for boreal forests. To facilitate the adaptation of forests to climate change, we will need detailed knowledge about the mechanisms controlling carbon sequestration in hardwood biomass.

For an enhanced carbon sink effect, we are developing a genomic selection method for silver birch (Betula pendula) breeding. Birch is among the most fast-growing, widely distributed and economically important boreal hardwood trees. Additionally, under greenhouse conditions, flowering can be induced in trees as young as two years of age. The shortened generation time raises the possibility of speed breeding: growing several early flowering generations in succession with genomic selection, allowing faster genetic and phenotypic change. Our program will speed up breeding by selecting the best trees for breeding crosses through early phenotyping of trees and apply the long-term (10–20 years of growth) field testing on the trees only a only after several successive generational crosses.

Many quantitative traits are expected to be under stabilizing selection: phenotypes differing too much from the optimal range are selected against. Therefore, we expect effect alleles of the same sign to be negatively correlated. Such prior assumption influences the genetic relationship matrix used in genomic prediction - typically such a matrix implicitly assumes the random effect sizes are independent of the linkage structure. The tendency of linked alleles having the opposite signs can be included as a new parameter and estimated along with the variance components.
We compare a number of genomic methods on their ability to predict tree growth from the sequence data, as measured by the predictive ability. To supplement the classic BLUP, we introduce a matrix parameter describing the tendency of alleles with opposite signs to be linked.

Development of Drought Tolerant Indigenous Trees for Enhances Productivity and Adaption to Climate Change in Kenya

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Abstract: Drylands of the world-over are more affected by impacts of climate change. In Kenya, arid and semi-arid lands (ASALs) occupy over 80% of the land area and are increasingly being recognized as the new frontier for afforestation programs. National Forestry Program (NFP) and Kenya's Strategy for Achievement of 30% tree cover by 2032 have recognized drylands as key targets area for afforestation using tree species such as *Acacia tortilis* and *Melia volkensii*. Acacia is widespread in ASALs of Africa and the Middle East and has been overexploited for charcoal production. Similarly, Melia, an important endemic and high valued tree species growing in the ASALs of eastern Africa has been over-harvested for timber. The two species have been are targeted for breeding. Projects on 'Development of Drought tolerant Trees for Adaption to Climate Change in Drylands of Kenya' and 'Capacity Development Project for Sustainable Forest Management in Kenya' are a pioneer multidisciplinary initiatives implemented from 2012 to 2021whose overall goals were to promote quality plantations of indigenous species in the ASALs through: breeding drought tolerant trees for increased productivity and adaptation to climate change; development of quality seed/seedlings supply system; and creating awareness of drylands forestry using improved drought tolerant germplasm. The project's had four main synergetic discipline-oriented components: (a) Molecular component to determine inter and intra population genetic variation; (b) Tree breeding component to select Candidate Plus Trees (CPTs), establishing seed orchards; seed stands and progeny trials for continuous improvement and phenology studies (c) Drought tolerance component to develop drought tolerance indices and (d) Extension component through farmer forestry field schools to upscale adoption of improved germplasm in target Counties and establishment of improved seed/seedlings supply system. 100 CPTs each of Melia and Acacia were selected from various populations by considering qualitative and quantitative traits. To harness the outputs from the work, breeding toward second generation improvement have continued through a Project on 'Strengthening Community Resilience to Climate Change through Landscape Restoration and Sustainable Forest Management in Kenya' since 2022. The findings that has been obtained over the years are useful for guiding tree breeding and forest restoration programs.

Development of genomic selection model in Norway spruce based on genomic and epigenomic markers associated with wood quality and disease resistance

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

[3] LUKE, Natural Resources Institute Finland

Abstract: The genetic and epigenetic basis of wood development and disease resistance to the pathogenic fungus *Heterobasidium parviporum* have been studied in Norway spruce (*Picea abies* L. Karst.) using 620 trees, including 218 half-siblings from 17 families (currently used in breeding programs) and 402 seedlings presumably representing unrelated trees from natural stands in Finland. They were genotyped via exome-capture sequencing using both untreated and treated with bisulfite. After filtering based on sequencing depth, quality, and missing data, 79,293 high quality single nucleotide polymorphisms (SNPs) were identified and used for genome-wide association studies (GWAS) that included phenotypic traits related to growth and disease resistance, taking also into account the confounding effects of genetic structure and kinship in the mixed linear model (MLM). In total, 472 SNPs were associated with height, while 2,225 and 2,146 SNPs were associated with the length/width ratio of necrosis in phloem and xylem measured after infection with *H. parviporum*, respectively. The same individuals were also sequenced and epigenotyped after treating the targeted exome with bisulfite (so-called targeted-bisulfite sequencing). In total, 21,161 single methylation variants (SMVs) were identified after filtering based on depth and quality. These epigenomic markers were used for epigenome-wide association studies (EWAS) with the same phenotypic traits and resulted in 70 SMVs associated with height, and 172 and 158 SMVs associated with phloem and xylem necrosis, respectively. Both genomic and epigenomic data obtained have been used then for development of a new genomic selection (GS) model following regression model approach to predict breeding values of each individual from the 17 half-sibling families. The model has been then tested and validated by using the 402 individuals from natural populations. The identification of epimarkers emphasizes the role of epigenetic regulation in the expression of the phenotype in Norway spruce, and the importance of the use of both genomic and epigenomic factors for improving our overall understanding of the mechanisms controlling crucial adaptive processes. In addition, this allows the development of more effective strategies for both conservation and breeding programs in tree species.

Does conifers genomic selection need a whole-genome level imputation step? A case study in Norway spruce.

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

[2] Forestry Research Institute of Sweden(Skogforsk)

Abstract: In conifer breeding, so far as we know, we usually use a few thousand to a hundred thousand SNPs based on exome capture, genotyping by sequencing (GBS), and SNP array genotyping platforms to study the efficiency of genomic selection. In our study, we want to validate whether imputing the current relatively sparse SNPs to a whole genome-level, based on a species range-wide genome imputation panel, will improve genomic selection. In our current Swedish Norway spruce breeding program, we have re-sequenced more than 1000 range-wide samples and genotyped ca. 600 individuals for each of 20 populations using a 50k SNP array across Sweden. We are planning to build a whole-genome level imputation panel and validate if we could use the imputation panel to improve the efficiency of our genomic selection.

Effect of population structure in genetic evaluation of growth and wood properties in Norway spruce and its implications in breeding programs

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

[4] RISE Built environment, Växjö, Sweden
[5] Natural Resources Institute Finland (LUKE), OULU, Finland

Abstract: It is well known that the geographic ranges of tree species have expanded and contracted several times during glacial and interglacial periods. Norway spruce (*Picea abies*) is a dominant conifer species of major economic importance in northern Europe. The recent analysis of genome-wide data revealed demographic movements, followed by secondary contacts, resulted in division of Norway spruce into seven genetic clusters.

A large-scale Norway spruce breeding program initiated in Sweden during the last century. The current breeding populations of Norway spruce in southern Sweden has a heterogenous background, composed of both local and the recently introduced materials from the seven P. *abies* genetic clusters (population structure).

The main objective of this study was to assess effect of population structure as a fixed effect in quantitative genetic evaluation of growth and wood properties, using about 6000 increment-cores collected in two open-pollinated progeny trials of Norway spruce in southern Sweden.

Genetic parameters for growth, Solid- and fibrewood, chemical and resin characteristics as well as genetic correlations among these traits were estimated in five different model scenarios, including:

1. No population
2. All populations
3. Most northern populations
4. Central populations
5. Most southern populations

Narrow-sense heritability (h^2) estimates and genetic gains were highest based on model one, while such estimates decreased significantly in model two, particularly for growth and density related traits. This implies that when the effect of population structure is ignored, the estimated genetic parameters for such traits can be biased, and therefore, the obtained genetic gains are inflated. Similarly, we have observed that additive genetic correlations among traits vary in five tested scenarios. For instance, the unfavourable genetic correlation between density and growth-related traits were higher in northern populations, compared to the southern and central ones.

Overall, findings of our study suggests that population structure and genetic background of breeding materials may have major influence for genetic improvement and delineation of Norway spruce breeding populations as well as selection of trees for industrial purposes.

Genetic background of early flowering in Betula pendula for the successful development of efficient and rapid breeding.

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Giovanni Bozza[1, 2]
Mateusz Liziniewicz[2]
[1] Sveriges lantbruksuniversitet (SLU)
[2] Skogforsk

Abstract: Information on flowering genetics and flowering variability is important for the development of breeding programs. The importance of these will increase when breeding by means of genomic selection method will be implemented into operational breeding. This study aimed to evaluate the genetic background of early flowering in Betula pendula.

The project aimed to quantify the genetic parameters of early flowering in two genetic progeny trials located in southern Sweden. Both trials were planted in 2014 and consisted of offsprings from 19 full-sib families. The parents of the families came from the elite silver birch population in southern Sweden. There were around 20 - 70 plants per crossing in both trials. During three observation seasons, the occurrence of male and female flowers was registered. The number of flowers was quantified subjectively using a simple four-stage scale from 0 (no flowers) to 3 (many flowers). Height, diameter, and quality traits were also collected.

Nine years after planting, there were on average around 20% of trees having male flowers. In one family, flowering frequency exceeded 50%. The female flowering was much less frequent with an average of less than 10%. Out of the 19 families, only 10 families had an individual with female flower. Flowering frequency was slightly higher in the northernmost experiment and there was a positive correlation of transfer distance (distance between experiment location and parental origin) and male flowers production.

The male flowers started to be produced earlier than females' flowers. There was also a great genetic variation in the ability to produce male and female flowers in early years after planting. Nine-years results also indicate a positive effect of northward transfer on the frequency of trees producing male flowers. There is no such indication for female flower production. These results indicate that flowering ability must be considered in selection to facilitate the performance of crosses in new generations and for the deployment of the results through seed orchards. The indication of positive effect of transfer might be considered when new seed orchards are planned for establishment.

Integrating environmental gradients into forest tree breeding: genomic norms of reaction in maritime pine

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Abstract: Global warming threatens the productivity of forest plantations. Traits targeted by forest breeding programs are mostly final growth traits of the trees (height, circumference). However, such phenotypes are very integrative: the final growth traits are the results of multiple years of growth in interaction with an evolving environment. To tackle these interactions and to propose new breeding strategies ensuring resilience of forest trees in the coming years, individual genomic reaction norms were modelled. Random regression models were used to fit wood ring series, reflecting the longitudinal phenotypic plasticity of tree growth, according to various environmental gradients. The predictive performance of the models was considered to select the most relevant environmental gradient, namely a gradient derived from an ecophysiological model and combining trunk water potential and temperature. Even if the genotype ranking was preserved over most of the environmental gradient, strong genotype x environment interactions were detected in the extreme unfavorable part of the gradient, which includes environmental conditions that are very likely to increase in the future. Combining genomic information and longitudinal data allowed to predict growth in unobserved environments: considering an equivalent phenotyping effort, the cross-validation scenarios led to predictive performances ranging from 0.25 to 0.59 highlighting the importance of phenotypic data allocation. Genomic reaction norms are useful for the characterization and prediction of the function of genetic parameters and facilitate breeding in a climate change context.

Is gridling a method to increase seed production in silver birch seed orchards? - Effect of girdling on male and female flower formation.

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Giovanni Bozza[1, 2]
Mateusz Liziniewicz[2]
[1] Sveriges lantbruksuniversitet (SLU), Alnarp, Skåne, Sweden
[2] Skogforsk, EKEBO, Skåne, Sweden

Abstract: Silver birch is considered a species that might mitigate problems that have occurred in the silviculture of coniferous species in Sweden. Thanks to the breeding program initiated in the late 1980's current birches are producing from 15% to 20% more volume and are of significantly better quality. Currently, the main obstacle to using more birch in operation forestry is the access to well-performing seedlings due to the low production of seeds.

Last years, a decrease in volume of seed production has been observed in Swedish birch seed orchards. In greenhouse seed orchards, the production of seeds and their quality dropped abruptly. In addition, great clonal variability in the setting of flowers and consequently seeds production has been observed. Thus, the higher demand for plants on the market cannot be covered.

The girdling treatment, also called partial ring-barking, is the complete removal of the bark and a portion of the cambium layer from around the circumference of either a branch or trunk. It has been found for other species that girdling can increase the abundance of flowers.

The aim of this project was to evaluate the effect of girdling on flowering abundance in silver birch. The hypothesis in the study was that applying girdling treatments would increase the abundance of flowering on girdled branches.

The experiment has been started in a clonal archive in southern Sweden. Seventeen genotypes with three ramets each were subjected to three girdling treatments removing 25%, 50% and 75% of tree branch circumference. Treatments were applied to branches of similar size. Two branches have been treated on two-time occasions (in mid-May and mid-June). Two branches were considered untreated control. The number of buds, male and female flowers was counted, and branches length and diameter were measured before and after treatments in two following growing seasons to quantify the most optimal girdling regime to increase seeds production of silver birch. Here we present the results after the first observation year.

Landscape breeding: A new paradigm in forest tree management

Abstract: In conventional forest tree breeding, tree selection follows a recurrent scheme with repeated rounds of crossing, testing and selection, the so-called breeding cycle. This is a long process sustained by costly logistical and organizational commitments and constrained by factors such as the experimental size of the test trials, the accuracy of the measurements, and the ability to model individual genetic effects across sufficient environments. The genomic revolution opened the possibility to develop molecular tools to infer accurately the realized proportion of the genome shared among individuals - the pedigree. In conifer trees, this is the bases of an alternative approach to crossing-based conventional breeding, the so-called Breeding without Breeding. Originally, this approach was proposed to circumvent artificial mating, but it remained constrained by the need for establishing structured open-pollinated (OP) trials at a limited number of environments. Recent developments in remote sensing technology offer high-throughput, accurate, and spatially explicit means for tree phenotyping that can operate at large landscape scales and thus account for climatic variables, water, and soil data, among other variables to model ecological or environmental zones. Furthermore, remote sensing phenotyping also allows assessing a myriad of tree properties otherwise difficult or impossible.

We havee developed a digitized tree breeding strategy that overcomes the limitations of conventional breeding. Landscape Breeding aims to accelerate forest tree improvement by operating directly on commercial forests and accounting for climatic and environmental variables. Norway spruce, the most economically important species in Sweden and model system in conifer genomics, is our study case.

New method to study drought stress in Norway spruce seedlings using high-throughput plant phenotyping integrated with metabolomics and transcriptomics

Abstract: Drought stress is a major constraint limiting the distribution of Norway spruce (*Picea abies* (L.) H. Karst.). Provenance trials, a common approach to assess adaptive variation among populations, are limited due to the finite number of sites and seed sources involved, as well as their labour-intensive nature. Here, we present a novel multi-sensor high-throughput plant phenotyping (HTPP) approach and protocol to assess the drought stress adaptation potential of Norway spruce provenances at the most critical life stage of the tree, the seedling stage. Two climatically contrasting Norway spruce provenances were studied by HTPP while exposed to 21 days of drought stress under controlled conditions. Multivariate analyses of data derived from the HTPP platform show that the HTPP approach allows the estimation of more than 50 phenotypic traits (chlorophyll fluorescence, RGB and hyperspectral related traits) to differentiate early and late drought stress responses between populations. We further linked the phenotypic data to needle metabolomics, transcriptomics and stem anatomy. Consistent with the phenotypic results, we observed significant metabolic changes towards the later stages of drought stress (e.g. increase in zeaxanthin associated with photoprotection via non-photochemical quenching), with each provenance exhibiting a distinct metabolic signature under both well-watered and drought-stressed conditions. Analysis of the mRNA-Seq data revealed over 4000 differentially expressed genes, the majority of which were shared between the two populations. A small proportion of genes were provenance-specific, consistent with the differences observed between the two provenances in the phenomics and metabolomics datasets. Finally, stem anatomical differences were identified between drought-stressed seedlings and control plants, and the proportion of specific stem tissues such as xylem was differentially affected on the studied provenances, which may have implications for future wood production. In conclusion, our study highlights the relevance of the HTPP approach and introduces a standardised HTPP protocol for evaluating drought stress adaptation in Norway spruce seedlings, which can potentially be extended to other tree species. By integrating different -omics approaches, we have gained a deeper insight into the mechanistic basis driving phenotypic responses to drought stress, providing a basis for further research and potential strategies to mitigate the adverse effects of drought.

Norway spruce somatic embryogenesis in Finland to enhance bioeconomy using genetically wide material

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Saila Varis[1]
Mikko Tikkinen[1], Sakari Välimäki[1], Jaanika Edesi[1], Tuija Aronen[1]
[1] Natural Resources Institute Finland (Luke), Vipusenkuja 5, FI-57200 Savonlinna, Finland

Abstract: Somatic embryogenesis (SE) has been recognized to have vast potential to produce improved reforestation material. Yet only a few commercial applications have been reported in conifers. Recent developments in Norway spruce (*Picea abies* (L.) H. Karst.) SE in Finland e.g. high initiations rates, high recovery from cryopreservation, short in vitro germination have developed into a SE pipeline, which can be applied to genetically wide materials. This development has led to construction of SE technology platform and research greenhouse spaces located in Savonlinna.

Current cryostorage at Luke exceeds 5000 Norway spruce genotypes from elite crossings of tree breeding program. Luke registered the first SE derived Norway spruce basic material for forestry in 2017. The basic material (named as Laukansaari) includes 12 full-sib families of progeny tested plus trees. Propagation pilots have been carried out since 2018 (over 170 000 germinants sold). In a Public Private Partnership (2021-2023) project realized with commercial partners, two more basic materials are registered, SE knowhow is transferred to partners, and selection based on root rot resistance marker PaLAR3 is applied in SE. No trade-off between resistance locus PaLAR3B and somatic embryo production ability has been observed.

Field tests of SE material have been established and they are maturing, and the first preliminary results are available after growing season 2023. To decrease production cost of somatic plants, we have developed a robot prototype (patent pending) for in vitro germination in collaboration with South-Eastern Finland University of Applied Sciences. Robot selects, classifies, orients and plates good embryos to germination, stacks, and changes full plates to empty ones.

Population Structure and Genetic Diversity in Eucalyptus pellita Based on SNP Markers

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Chubiao Wang[1]
Jianzhong Luo[1]
[1] Research Institute of Fast-Growing Trees, Chinese Academy of Forestry, Zhanjiang 524022, China

Abstract: Context:
At present, there is little research on molecular breeding of E. pellita. With the development of technology, whole genome resequencing based on single nucleotide polymorphism (SNP) markers to improve related traits of E. pellita is an important direction of selective breeding.
Aims:
The aim of this study was to develop SNP markers for E. pellita genome, and to identify its population structure, genetic diversity and population differentiation.
Methods:
In this study, the genetic diversity of 1st generation 196 E. pellita families from 23 geographically defined was assessed using 1,677,732 SNP markers identified by whole genome resequencing.
Results:
SNP annotation showed that the ratio of non-synonymous to synonymous coding mutations was 0.83. Principal component analysis (PCA), phylogenetic tree and population structure analysis permitted the families to be categorized into three groups. Genetic relationship analysis showed that IDN was closely related to PNG. Genetic diversity analysis showed that the mean values of He, PIC, I and H were 0.2502, 0.2027, 0.3815 and 0.2680, respectively. The results of genetic differentiation (Fst) showed that PNG region was divided into two groups (PNG1 and PNG2), the Fst (0.172) between QLD and PNG2 region was higher than QLD and PNG1, and the Fst (0.024) between IDN and PNG1 is smaller than IDN and PNG2.
Conclusion：
This study has a certain reference value for genetic identification, population origin, germplasm preservation and breeding of E. pellita, and also provides a basis for subsequent association analysis to explore excellent alleles and introduction.

Progress of genomic selection in Swedish Norway spruce and Scots pine national breeding program

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Harry Wu[1]
Zhiqiang Chen[1], Henrik Hallingbäck[2], Mari Suontama[2], Adam Klingberg[2], Tomas Funda[1], Maximiliano Estravis Barcala[1], Rajiv Chaudhary[1], Edward Carlsson[2]
[1] Swedish University of Agriculture Sciences
[2] Skogforsk

Abstract: Since the first publication of genomic selection concept in trees in 2010/11, genomic selection using cross-validation were studied in a dozen of commercially important conifer species. SNPs from low density array, exome sequencing, GBS and more recently from medium-density SNP-array were used for genomic selection. Also genomic selection from cross-validation were effective, with an average efficiency about 90%, relative to phenotype selection. The genomic selection across breeding populations and across generations are much lower based on simulation and real data. By developing two 50K SNP-arrays using whole genome re-sequencing in Norway spruce and Scots pine, we studied genomic selection (1) across generations using models based on parental population (F1) only for selection at F2 and F3 populations, (2) across breeding populations with or without genetic connections between them and (3) using GWAS to enhance genomic selection efficiency. Possible causes of low cross-population and cross-generation genomic selection efficiency are studied and the proposed mitigation strategies including re-sequencing of parental population are presented. Several case studies of genomic selection in Norway spruce and Scots pine are presented.

Spatial transcriptomics reveals developmental patterns in the tissues of vegetative and reproductive buds of Norway spruce.

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Nathan Zivi[1, 2]

[3] KTH Royal Institute of Technology, School of Engineering Sciences in Chemistry, Biotechnology and Health (CBH), Department of Gene Technology, Solna, Sweden

Abstract: Vegetative and reproductive development in Norway spruce (*Picea abies*) is difficult to study. Trees are tall, have long juvenile periods, and infrequently produce female cones. Additionally, there is a lack of genetic studies and a massive, 20Gbp, and not thoroughly annotated genome. To best manage our forestry resources and seed orchards, a systematic understanding of development is key to ensure productivity, biodiversity, and climate change preparedness. We performed a spatial transcriptomic experiment on early developing buds (representing female cones, vegetative growth, and a naturally occurring, early female cone producing mutant) at 3 time points in the fall to investigate bud development. The buds ranged in size from meristems to fully formed buds with recognizable tissues and organs.

With spatial transcriptomics, thin tissue sections are taken from each bud and are placed on a specially designed microscope slide to collect and record the location of each mRNA molecule within a section. When the transcriptome from the sections is clustered, the visually identifiable tissue patterns also appear in the clusters. We grouped the clusters into 4 tissue domains: pith, vascular, lateral organ primordia, and lateral organ differentiated. The top genes in each tissue domain are characteristic of the tissue. For example, upregulated genes in vascular tissues are involved in the transport of sugars, hormones, and water. Examination of genes expressed in female organs revealed many genes related to female development, like the recently published *PaSPL1* transcription factor (TF). This TF helps regulate the reproductive shift and cone-setting in Norway spruce and is only expressed in female buds and female parts of mutant buds. Some genes have a temporal pattern, like those linked to cold acclimation being mainly expressed late in the fall. Others have a strong spatial pattern, like the YABBY TFs, that are expressed in lateral organ tissue domains and regulate abaxial-adaxial development. In order to easily visualize these expression patterns, a shiny app was developed that shows exactly where and when in each bud section a specific gene is expressed.

Speed-breeding – Accelerated breeding for improved hardwood growth and quality

T3.14 Forest Tree Breeding in the Context of Climate Change and Bioeconomy Development

Juha Immanen[1, 2]
[1] Luke
[2] University of Helsinki

Abstract: It is difficult to exaggerate the role of trees and forests in the mitigation of climate change:
trees are elementary both as essential long-term carbon sink and as raw material for the bioeconomy. By accelerating tree breeding, the aim of our project is to both mitigate the effects of climate change and facilitate the adaptation to them.
By developing an accelerated breeding program for silver birch (Betula pendula), one of the most fast-growing, widely distributed, and economically important boreal broadleaved tree species, we will facilitate the production of improved hardwood genotypes for silviculture purposes. Based on the fact that silver birch flowering can be accelerated under greenhouse conditions, and already 2-year-old seedlings can be induced to flower, our program will speed up breeding by selecting the best trees for breeding crosses through early phenotyping of 1-year-old trees and apply the long-term (10-20 years of growth) field testing on the trees only a only after several successive generational crosses. ‘
Since we are working on Finland’s current silver birch breeding population, our results can be directly implemented in breeding and silviculture of silver birch. The best speed-bred genotypes can be directly incorporated into an ongoing traditional birch breeding program. Furthermore, they can also be clonally micropropagated for silviculture purposes. Our speed-breeding project is complementary to an ongoing project exploring the genetic basis of carbon sequestration in silver birch, with the aim to develop a genomic prediction method for genome-assisted tree breeding.

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Assessing the Land Cover from the Canadian Wetland Inventory Map (CWIM) Using Field Data from Eastern and Central Canada

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

[5] Canadian Wildlife Service, Environment and Climate Change Canada, Sackville, New Brunswick, Canada

Abstract: Mapping the land cover, including forests and wetlands, for a vast country like Canada is a big challenge. One option is using satellite images. A wetland map was produced by applying the Random Forest classifier to Sentinel-1 and-2 imagery in Google Earth Engine. The resulting map is known as the 10 m Canadian wetland inventory map (CWIM). This paper aims to assess the accuracy of the map by comparing the map with ground-truth data collected from ground-truth sites of four study areas in Canada. These areas include 951 sites in New Brunswick, 309 sites in Nova Scotia, 1088 sites in northern Québec and 848 sites in northern Ontario. For each study area, the map accuracy was computed regarding validation accuracies. The overall validation accuracy of the CWIM was between 41% to 55%. We also compared the area of each class to those extracted from previous regional maps. In all four regions, the area of bogs was underestimated, but the area of fens was overestimated. The area of swamps was underestimated in the New Brunswick and Québec areas but overestimated in the two other regions. The marsh areas were underestimated in the Nova Scotia area but overestimated elsewhere. The area of the Water class was underestimated in the Northern Ontario and Northern Québec areas but overestimated in the two other regions. We suggest that the misclassifications occurring with the CWIM could be reduced by: 1. increasing the amount of geographically-representative ground-truth data; 2. defining more wetland classes based on spectral characteristics; 3. including digital elevation models and associated metrics to the classification; 4. including satellite imagery acquired at different water levels and/or different seasons, and; 5. using imagery-derived vegetation indices that do not have spectral saturation such as NDVI. Given the limitations of the CWIM, caution should be used when applying this map to regional applications that require high accuracy

Choice of CO2 equivalent metrics influences risk of CH4 emissions associated with wetland restoration

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Abstract: Several international climate agreements emphasize the potential of natural ecosystems - including wetlands - to remove CO_2 from the atmosphere. However, wetlands play a dual role in the radiative forcing of climate, affecting the atmospheric burden of both CO_2 and CH_4. The cooling effect of wetland CO_2 sequestration can be offset by wetland CH_4 emissions. To assess the climate footprint of wetlands on a comparable basis, the wetland GHG fluxes need to be normalized to CO_2 equivalent (eq) value using CO_2-eq metrics. The reporting of CO_2-eq GHG fluxes has been standardized using the Global Warming Potential (GWP) in the policy world and the sustained global warming potential (SGWP) within the wetland community. However, CO_2-eq metrics that equate GHG fluxes using a single factor can be misleading as the climate impact mechanisms of CO_2 and CH_4 differ markedly. An alternative is the dynamic GWP* that captures the effects of changes in CH_4 fluxes instead of the magnitude of CH_4. We used the GHG perturbation model to simulate wetland radiative forcing and temperature change associated with wetland state conversion over 100 and 500 years based on a synthesis of published carbon fluxes values. We then calculated GWP, SGWP, and GWP* CO_2-eq GHG fluxes. The dynamic GWP* captured initial cooling and warming period associated with drainage and restoration, respectively, while the static S/GWP did not. Intact wetlands with low methane fluxes continue to serve as carbon sinks and deliver cooling effect on the climate. Draining wetlands with low methane flux will shift wetland systems to carbon sources, resulting in consistent warming impact. Conversely, draining wetlands with medium or high methane fluxes had an initial cooling effect given reduced CH_4 emissions, followed by a sustained warming effect. The climate benefits of restored wetlands depended on their ambient CH_4 emissions, with the climate benefit lag period longer with higher CH_4 emissions. Based on our radiative forcing model and GWP*, we argue that protecting and restoring wetlands are important nature-based climate solutions (NbCS), and that warnings to not restore wetlands due to the risk of greater CH_4 emissions are unjustified in the context of their role as NbCS.

Climate benefits of rewetting forest wetlands recovers slowly over decades and is lowered by groundwater fluctuations

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Jesper Christiansen[1]
Rachel Burns[1], Klaus Steenberg Larsen[1]
[1] Department of Geoscience and Natural Resource Management, University of Copenhagen, Denmark

Abstract: Rewetting of drained forest plantations on organic soils is crucial for restoring biodiversity in forests worldwide and is also seen as an effective climate mitigation strategy. However, there is a lack of comparative analyses on post-rewetting greenhouse gas emissions and field measurements of the actual effects of rewetting on gas exchange. Additionally, the assumption that rewetting will immediately restore the pre-drainage functionality of organic soil is questionable, given the significant alterations in soil hydrology, biogeochemistry, and microbial dynamics caused by drainage.

Here, we present a quantitative analysis of literature data on methane (CH_4), nitrous oxide (N_2O), and carbon dioxide (CO_2) net fluxes from rewetted fen soils in temperate forest wetlands in Europe and North America. Secondly, we provide field measurements of greenhouse gas fluxes and hydrology from a rewetted site in Gribskov, Denmark's third-largest forest.

The literature data analysis reviews current knowledge in the field and establishes relationships between soil hydrology metrics and emissions of CO_2, CH_4, and N_2O from drained and rewetted forest peat soils. The analysis reveals that rewetting reduces overall emissions, with CO_2 being the primary driver of soil greenhouse gas budget before and after rewetting, followed by CH_4. The literature data also suggest that emission reductions occur gradually over decades, indicating that beneficial climate effects cannot be expected immediately after rewetting.

Our field measurements investigate the relationship between short-term (<1 year) hydrological and climate variability after rewetting and soil fluxes of CO_2, CH_4, and N_2O. Using a novel automated system called SkyLine, we collected over 22,000 flux measurements for each gas over a three-year period, coupled with groundwater levels and climate variables. The data clearly demonstrates that hydrological and climatic variability plays a crucial role in determining emissions of all gases post-rewetting. Thus, different relations between CO_2/CH_4 and groundwater levels for cold and warm periods and under specific hydrological conditions, N_2O emissions may also become significant in rewetted peat soils.

In summary, our data emphasize the importance of considering different temporal scales of greenhouse gas fluxes in rewetted organic forest soils when assessing the climate mitigation potential of rewetting and to derive reliable emission factors.

Designing nature-based solutions for ecosystem services: a decision support system for forests and wetlands in the Brenta river area (Italy)

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Mauro Masiero[1]

[3] Consorzio di Bacino del Brenta

Abstract: The assessment of environmental and resource costs (ERC) associated with integrated water management systems is mandated by the European Union (EU) Water Framework Directive, with the aim of identifying effective measures to reduce, mitigate, and compensate for these costs. Nature-based solutions (NBS), including forests and wetlands, are increasingly recognized as cost-effective approaches to achieving water-related targets while providing additional benefits such as biodiversity enhancement, carbon sequestration, and recreation opportunities.

This paper, developed within Life Brenta 2030 project, focuses on the case study of the Brenta river area (Northern Italy), supplying approximately 35.5 million m^3/year of drinking water, primarily from underground water. The middle course of the river falls within the EU Natura 2000 Network of protection areas and faces challenges arising from intensive farming practices (irrigated crops and livestock) and other economic activities, as well as recreational practices, resulting in trade-offs between water and nature resource management, and socioeconomic needs.

To address ERC associated with water management, a set of NBS has been preliminarily identified through collaboration with local experts and stakeholders. The identified NBS - namely wetlands, forest infiltration areas, and transitioning to organic and conservation farming practices - aim to improve water table recharge and water quality while providing additional ecosystem services such as carbon sequestration and biodiversity conservation.

To assess the suitability, effectiveness, and efficiency of the proposed NBS, an integrated approach is adopted. A decision-support system is developed, considering the targeted challenges, expected outcomes, and budget constraints to identify the optimal combination of solutions. The approach combines an extensive literature review of the targeted NBS, the development of suitability maps based on a spatial analysis of biophysical and socioeconomic features within the case study area, and a cost-benefit analysis applied to various scenarios characterized by different levels of NBS blending.

Our research aims to contribute to the advancement of knowledge in the field of NBS for integrated water management, providing policymakers, scientists, and practitioners with practical approaches and tools to support the selection of NBS. Furthermore, it contributes to global and regional targets outlined in the UN Agenda 2030 and the EU Nature Restoration Law.

Evaluating the GHG balances of drained and restored peatland forests in boreal Sweden

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Cheuk Hei Marcus Tong[1]
Matthias Peichl[1], Mats B. Nilsson[1], Hjalmar Laudon[1], Järvi Järveoja[1]
[1] Department of Forest Ecology and Management, Swedish University of Agricultural Sciences, 910 83 Umeå, Sweden

Abstract: Rewetting of drained peatland forests potentially reduces carbon dioxide (CO_2) emissions but also re-establishes the emission of methane (CH_4), thus the impact of rewetting on the net greenhouse gas and carbon balance remains uncertain. In this study, we compared fluxes of CO_2 and CH_4 based on eddy covariance measurements for a drained nutrient-poor peatland forest and a nearby rewetted peatland in boreal Sweden for two years after rewetting. The rewetted site was a net carbon source to the atmosphere (86 ± 5 g m^{-2} yr^{-1}) for both years, relative to the drained forest which was a net carbon sink (-98 ± 20 g m^{-2} yr^{-1}). The carbon budget was dominated by CO_2 flux in both rewetted (NEE = 71 ± 4 g m^{-2} yr^{-1}) and drained forest (NEE = -167 ± 30 g m^{-2} yr^{-1}) areas. The CO_2 component fluxes of ecosystem respiration and vegetation uptake (GPP) was 65% and 79% lower at the rewetted site than in the drained forest. In the second year after rewetting, the GPP increases by 26% in response to vegetation recovery, resulting in a 47% smaller net source of CO_2 from the site. While CH_4 emission remained small (< 0.80 g m^{-2} yr^{-1}) at the drained forest for both years, it increased substantially in the rewetted site from the first (2.8 ± 0.1 g m^{-2} yr^{-1}) to the second year (4.3 ± 0.2 g m^{-2} yr^{-1}) after rewetting.. Overall, our study highlights that rewetting of drained nutrient-poor peatland forests may considerably increase GHG and C emissions during the initial years. However, long-term observations under various site conditions are warranted to better understand such effects on the GHG balance.

Guiding restoration of drained peat soils aiming for minimum GHG-emissions

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate
Åsa Kasimir[1]
Amelie Lindgren[1]
[1] Department of Earth Sciences, University of Gothenburg, Sweden

Abstract: Wet ecosystems have over millennia accumulated carbon as peat due to anaerobic conditions. In the recent past (c. 150 years), Swedish mires and swamp forest ecosystems have been drained for agriculture and forestry reasons. After drainage soil decomposition increases releasing CO_2 as well as N_2O, where these soils contribute 1/5 of the Swedish greenhouse gas emissions (GHG). Emissions can be avoided by rewetting, and the soil may again become a carbon sink. However, there is a risk of large CH_4 emissions from rewetted peat soils which may have negative climatic effects in the short term. We have compiled measurement data into emission factors in a guidebook, written in Swedish, to guide management and restoration into different low GHG options. We have also identified the land categories where rewetting is critical for climate mitigation purposes. These are:

- Agricultural organic soils
- Forest on drained peat in temperate climate

Aiming for minimum GHG emissions the soil water level should preferably be aimed at a water level between 5 to 30 cm below the soil surface, avoiding visible water due to a risk of CH_4. It may be challenging to reach a steady high water level through rewetting, especially if the land is forested. Besides ditch blocking, thinning or removal of all trees is often needed to be able to reach a preferred water level. Swamp forests are however possible if enough water is added laterally. Depending on the site conditions, different land use and ecosystems may follow upon restoration, like;

- Grassland
- Wet meadow
- Fen
- Swamp forest

In an expected drier climate, farmers could be persuaded to rewet soils if able to continue grass production, with the added benefit of reducing drought stress in the landscape. Rewetting is also on the political agenda, why we in the guidebook show how decisions to rewet certain land categories may impact the radiative forcing from managed peatlands over the next 100 years.

Impact of rewetting on the carbon balance of a drained nutrient-poor peatland forest in Northern Sweden

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Alexander Pinkwart[1]
Matthias Peichl[1], Mats B. Nilsson[1], Hjalmar Laudon[1], Järvi Järveoja[1]
[1] Swedish University of Agricultural Sciences, Dept. of Forest Ecology and Management, Umeå, Sweden

Abstract: Natural peatlands represent a small but important long-term carbon sink. For forest management approximately 1.5 to 2.0 million hectares in Sweden were drained over the past century. The Nordic countries have therefore identified peatland restoration as part of its strategy to reduce greenhouse gas (GHG) emissions in the land use sector. However, while peatland restoration may lead to reductions in CO_2 emissions from drained peatlands, rewetted peatlands show initially higher CH_4 emissions. Most empirical evidence in the boreal zone was obtained from sites in Finland, while data is lacking in Sweden. In our study, we investigate the spatial variability of GHG exchange before and after peatland rewetting, determine the biogeochemical factors that govern these variations and examine the overall impact of rewetting on the GHG balance of a drained peatland forest in boreal Sweden. We use the manual closed-chamber method to measure the soil-atmosphere fluxes of CO_2 and CH_4 along six transects at the Trollberget rewetted peatland forest near Vindeln, Sweden. The rewetting actions at the site were carried out in November 2020 and a drained section has been kept as control near the outlet of the mire. We observe higher CH_4 emissions and lower CO_2 emissions compared to drained conditions, however, no significant change in the net soil-atmosphere C exchange within the initial years following rewetting.

Inland Freshwater Wetlands as a Nature-based Solutions (NbS) to Mitigate Global Climate Change: Opportunities, Challenges and Way Forward

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Laxmi Kant Sharma[1]
Shubham Kumar[1]
[1] Department of Environmental Science, School of Earth Sciences, Central University of Rajasthan, Bandarsindri-305817, Rajasthan (India)

Abstract: Reducing or eliminating human-caused emissions of carbon dioxide is fundamentally required. This will help mitigate climate-related risks and keep the increase in global mean surface temperature to less than 2 degrees Celsius. The sequestration of carbon by natural ecosystems is an emerging and cost-effective Nature-based Solutions (NbS) that can help accomplish the goal of carbon neutrality and minimize the annual additions of atmospheric carbon. Over the course of the past two decades, a wide range of colour-based descriptors has emerged as a means of characterizing the one-of-a-kind qualities, specialized roles, and distribution of organic carbon. The inland freshwater wetlands hold a large amount of stored carbon that is very significant to address the global phenomena of climate change. Here, we performed a systematic review-based analysis of inland freshwater wetlands in order to highlight the status of stored carbon and its potential role in mitigating global climate change. We estimated that the global carbon storage from major inland freshwater wetland ecosystems is approximately 519 Pg C. Significant amounts of carbon stored in peatlands, wetlands, and natural freshwater marshes are 465.1, 40.8, and 13.1 Pg, respectively. At the same time, these ecosystems are one of the major sources of natural greenhouse gas (GHG) emissions like methane, carbon dioxide and nitrous oxide if not properly managed. Along with it, the loss of areal extent at an alarming rate is also a thrust issue that needs to be addressed by restoring and developing inland wetland ecosystems. Therefore, these natural ecosystems have a huge potential to be NbS under the proper management conditions.

Moist humus forms and the soil water balance of forest ecosystems in Northwestern Germany

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Tina Frank[1]
Hans-Jörg Brauckmann[1], Gabriele Broll[1]
[1] University Osnabrueck, Institute for Geography, Germany

Abstract: The indicator function of humus forms can make an important contribution to the further development of monitoring methods for the evaluation of soil ecological properties in moist forest stands. In the BioFeuchtHumus project, the moist humus forms (aerohydromorphic humus forms) are considered in particular. These occur in mixed oak forests with the soil type Stagnosol in the lowlands of Northwestern Germany. Moist humus forms are particularly sensitive to climate change due to their dependence on precipitation and evapotranspiration. In the BioFeuchtHumus project, measurements of soil water tension and temperature are carried out directly at the boundary of mineral soil and organic horizons in the selected forest areas in the lowlands in order to record the influence of water in the organic horizons. For this purpose, 56 study sites were selected, and soil sensors (Tensiomarks) were installed to measure the soil water tension at 8 microsites in three different depths at each site.

The results of the soil water tension support the findings of the morphological classification of the moist humus forms which occur at the study sites. Typically, it also becomes apparent that soil water tension fluctuates over the course of the year. Especially in the winter months, the sites are waterlogged up to the organic layer (pF = 0). In the summer months of August and September, the sites reach pF values of >4.2.

Special classification features typical for moist humus forms are identified. Additionally, the correlations between humus forms and the soil parameters pH, C_{org}, N_t are important to characterize moist forest stands in Northwestern Germany. Further, the expected effects of climate change on the soil water balance and on the distribution patterns of moist humus forms can be better predicted. This will also provide information on the future functionality of today's moist forest ecosystems, which is of great importance for forestry practice with regard to necessary and sensible adaptation measures to climate change.

New AI maps as decision support tools for multifunctional management of forested wetlands

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Anneli M. Ågren[1]
William Lidberg[1], Hjalmar Laudon[1], Siddhartho S. Paul[2], Yiqi Lin[1], Florian Westphal[3], Olivia Andersson[1], Eliza Maher Hasselquist[1]
[1] Department of Forest Ecology and Management, Swedish University of Agricultural Science (SLU), Sweden
[2] Department of Agronomy, Purdue University, USA
[3] Department of Computing, School of Engineering, Jönköping University, Sweden

Abstract: Understanding how to manage the 1.2 million km of Swedish ditches dug to drain forests to increase their productivity is one of the biggest challenges facing forest managers. Here, we apply two recently AI-developed maps; a detailed peat map developed with machine learning and a ditch map developed using deep learning to better understand the effect of ditching on the entire Swedish landscape. These maps were based on high-resolution (1-2 m) digital elevation models generated from aerial laser scanning and surpassed the quality of previous maps. The new peat map had a recall of 80 % compared to the previously available map of peat in Sweden (70%). Furthermore, we automatically mapped 82% of the ditch networks, in comparison to 9% on current topographic maps. Combining the new maps with field data from the National Forest Inventory we found 4 126 sites within 100 m from a ditch. This allowed us to investigate the effect of the historical ditching of forested wetlands and how drainage has affected soil properties, tree stands and plant diversity across Sweden. A recent meta-analysis found that the water table drawdown of a ditch decreases exponentially with distance from the ditch. Based on this, we hypothesized that soil properties and vegetation around ditch networks would also change exponentially with distance to the ditch. In short; on drained wetlands bulk density, N, pH, and Al increases while C:N-ratio, C, K, Mg, and Mn decreased towards ditches. For trees; average height, basal area, total volume, birch volume, total growth, spruce growth, and birch growth increased towards ditches. We found a decrease in wetland mosses and an increase in forest mosses and broad-leafed grasses toward ditches, however, the Shannon-Hill diversity index was higher towards ditches. We are now developing a decision support system for multiple purposes (timber, hydrology, biodiversity).

Regional scale effects of wetland restoration on aquatic carbon

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Marcus Wallin[1]
Alberto Zannella[1], Karin Eklöf[1]
[1] Swedish University of Agricultural Sciences

Abstract: Wetland restoration (WR) is currently made in Sweden to reduce carbon dioxide emissions, improve biodiversity, and mitigate hydrological floods and droughts. However, limited information exists regarding the effects of WR on other ecosystem services such as aquatic carbon export. An emerging issue from a water quality perspective is the brownification of many surface waters caused by increasing dissolved organic carbon (DOC) concentrations. Also, stream networks are strong emitters of greenhouse gases (GHG), and where wetlands are a main source for downstream emissions. Literature on WR effects on surface water DOC and GHG is scarce and with divergent results. Hence, science-based knowledge is urgently needed to make well-founded decisions about WR efforts, including an aquatic C perspective. In this study, WR effects on aquatic C have been explored across the forested landscape of Sweden by sampling 33 restored and 33 non-restored wetlands that have historically been drained. The wetlands were selected to cover a large latitudinal gradient as well as differences in nutrient status. Wetland outlets were sampled in spring and autumn 2022 for a full set of water chemistry variables, and with particular focus on DOC and GHG. Independent on season, DOC and GHG concentrations were significantly higher in the outlets of restored than non-restored wetlands, and the difference was especially pronounced in northern Sweden. These results will contribute to improve our understanding on how WR affects the landscape C balance and the quality of surface water resources.

Trade-offs between freshwater biodiversity and the local communities' livelihood: Insights from freshwater ecosystems in Democratic Republic of Congo

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Bila-Isia Inogwabini[1]
[1] School of Management, Catholic University of Congo

Abstract: Democratic Republic of Congo (DRC) is among the most diverse countries in the world both biological and culturally. The country holds a large assemblage of biodiversity that includes a multiplicity of habitat types, different fish, mammal, bird and plant species, etc. Multiple habitat types, comprising mountain forests, lowland forest, northern and southern savannahs and lakes and rivers that form freshwaters habitats, provide multiple ecological services that benefit to local communities at different scales and different ways. However, DRC is also among those whose human populations are increasing at an alarming pace. This situation makes it difficult to accommodate both the need for preserving the country's important biodiversity while also addressing human needs, given the country's poverty levels. This presentation focuses on freshwater ecosystems and presents how valuable these are to support the livelihood activities to sustain local economy. Using field examples from the Lake Tumba Landscape (Western DRC), the talk with present some methods that have been applied to bring communities to agree on taking action to preserve not only the freshwater biodiversity but also the essential ecological functions that are beneficial to themselves and the wider community.

Tree dynamics in rewetted genuinely wooded peatlands in Southern- and Central Finland

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Otto Liutu[1]
[1] University of Helsinki, Faculty of Agriculture and Forestry, Finland

Abstract: This thesis was a part of the RESPEAT project (PI Kari Minkkinen), which aims to assess the climatic impacts of boreal peatland rewetting. The project is a joint effort by the University of Helsinki and the Finnish Meteorological Institute. I investigated the impact of rewetting on tree mortality in genuinely wooded peatlands, such as swamps and wooded bogs in Finland. I examined the effects of site fertility, tree species and the years since rewetting on tree mortality.

I conducted tree measurements in 14 different rewetted peatland sites. I set up 54 circular sample plots in the 14 sites. I estimated the volume of standing and fallen trees with a diameter greater than 7 cm. The sample plots were placed in genuinely wooded sections of the rewetted peatlands, and their fertility levels were categorized according to the Finnish classification system: herb-rich type (Rhtkg, n=15), *Vaccinium myrtillus* type (Mtkg, n=24), *Vaccinium vitis-idaea* type (Ptkg, n=8), and dwarf-shrub type (Vatkg, n=7).

Based on the results, site type had a statistically significant effect on the proportion of the dead tree volume of the total tree volume. A linear mixed model, controlling for peatland type, estimated the following dead tree volume proportions for different peatland types: Rhtkg 32.8% (standard error ±5.8%), Mtkg 15.9% (±4.7%), Ptkg 10.9% (±7.8%), and Vatkg 7.3% (±8.4%). The number of years since rewetting did not appear to have a cleat effect on the proportion of dead trees, but the sample size was too small to draw conclusions.

Picea abies displayed the highest mortality, especially in herb-rich peatlands, where 49% of spruce volume was dead. In other site types, the proportion of dead spruce was only slightly higher than that of birch (approximately 13%). *Pinus sylvestris* also had the highest proportion of dead tree volume in herb-rich peatlands (22%), and the proportion of dead tree volume decreased gradually with decreasing site fertility, reaching only 8% in dwarf-shrub peatlands. This reduction is probably partly due to the larger total volume of pines in the poorer site types. For *Betula pubescens* the proportion of dead volume was approximately 10% regardless of site type.

Will wetland restoration cause elevated methylmercury in surface waters?

T3.15 Forest Wetlands as Nature Based Solutions for Water, Biodiversity and Climate

Karin Eklöf[1]

Abstract: Sweden has extensively drained forest wetlands over the last 150 years to improve forest productivity. However, this action had severe environmental consequences, affecting biodiversity, and carbon and water retention. There is a strong societal interest in restoring drained wetlands and reversing the negative impact caused by previous drainage. However, a key question is whether it's possible to fully achieve the many societal and environmental benefits associated with natural wetlands or if restoration efforts will induce other environmental risks.

One potential risk is increased formation of MeHg when water-saturated soils become reduced and thus favorable for specific groups of anaerobic microorganisms capable of methylating Hg. Flooding of soils may also release legacy Hg from soil to water environments, increasing also total Hg (THg) concentrations in water. Earlier studies have shown soil inundations to caused elevated MeHg concentrations in water and aquatic biota, but it is less known where and how wetlands can be restored to reduce the risk of elevated MeHg in water.

Here we include a set of 33 restored wetlands and close-by references, i.e. non-restored drained wetlands, from north to south of Sweden. The sites encompass variation in landscape factors and wetland design factors. Samples were collected in the outlet of the wetlands during seasonal campaigns in spring and autumn of 2022. During one campaign we also sampled runoff water from beaver ponds to be compared with restored wetlands. Two of the restored wetlands were included in the Trollberget Experimental Area (TEA), where sampling was done on a monthly basis 2 years before and 2 years after restoration.

THg concentrations were elevated in restored wetlands compared to references, both in the spatial sampling sites and in the TEA sites. In the TEA sites, the concentrations of THg more than doubled after wetland restoration. The concentrations of MeHg did increase in one of the TEA sites, but not in the spatial sampling sites. Instead, MeHg concentrations increased in the beaver ponds. These results indicate that restoring drained wetlands did not promote the formation of MeHg to the same extent as inundation of other terrestrial soils, including upland soils, by beavers.

Abstract: Governments and markets worldwide have grappled with mobilising stakeholders and resources to restore degraded landscapes and foster sustainable livelihoods. This study explores the potential of socially innovative forest and landscape restoration (SIFLR) driven by organised landscape stewardship groups, including local communities, rural workers, women, and youth, to address these challenges. By harnessing social innovations, SIFLR can effectively enhance the resilience of livelihoods and the invaluable contributions of nature to society, benefiting governments, markets, and communities alike. Through a comprehensive content analysis of 64 Brazilian policy documents, we identified a total of 102 policy instruments that possess the potential to support SIFLR initiatives. However, these policies were found to be dispersed within a complex organisational structure, characterised by weakened governance mechanisms and limited experimentation by local actors. This situation underscores the need to bridge the policy gap and strengthen governmental support for SIFLR in Brazil. Based on this analysis, we propose three key strategies to broaden Brazilian government support for SIFLR: 1) Reconnecting politics to existing environmental policies and laws: By aligning political agendas with established environmental frameworks, policymakers can integrate SIFLR objectives into existing policy instruments, fostering coherence and synergy between different levels of governance. 2) Bringing decision-making closer to local needs through landscape governance: Encouraging decentralised decision-making processes that involve local communities, stakeholders, and institutions can enhance the relevance and effectiveness of SIFLR initiatives. Such an approach empowers local actors to address specific landscape challenges and enables context-specific interventions. 3) Establishing a a robust legal framework to enable innovation and science structures, that support local civil society, is crucial for driving social-ecological innovations. This framework should encourage experimentation, knowledge-sharing, and collaboration among diverse stakeholders, fostering adaptive management approaches. By implementing these strategies, Brazilian policymakers can effectively bridge the policy gap, creating an enabling environment that supports and promotes socially innovative approaches to forest and landscape restoration. This comprehensive approach holds great potential for enhancing sustainable livelihoods, bolstering nature's contributions to people, and achieving long-term environmental and socio-economic benefits for Brazil.

China's ecological protection redline: A solution for future socio-ecological adaptation

T3.16 Fostering modern forest and landscape restoration based on climate-smart use of forest genetic resources and innovation: from policy to practices

Hongge Zhu[1]
Menghan Zhao
[1] Northeast Forestry University, Agricultural and forestry economic management, China

Abstract: Continuing environmental degradation globally has led to many countries strengthening their systems of protected areas. The 10th Convention on Biological Diversity (CBD) in 2010 set global targets for the areal extent of protected areas (PAs) that were partially met in 2020. However, a more ambitious target is needed to halt ongoing global biodiversity loss. To supplement its growing system of PAs, the Chinese government has adopted a strategy of Ecological Conservation Redlines (ECRs). ECRs are designed to be integrated and scientifically sound, providing a systemic management mechanism. The goal of ECRs is to support the formation of a comprehensive ecological conservation system to ensure effective conservation of the most ecologically valuable and fragile ecosystems. However, ECRs not only involve the area but also the degree of protection, which poses challenges in balancing ecological protection and economic development, overlapping with farmers' living space, ecological vulnerability, and poverty. Therefore, it is necessary to clarify the degree of protection of ECRs, establish clear negative lists for industrial admission, and plan the future development direction and spatial layout of ECRs to connect with the value of ecological products and become a mutually beneficial entity. The implementation of ECRs can provide a valuable example for improving the adaptability of society and ecology in global forest management.

Delivering diversity for resilient restoration outcomes; Opportunities and Innovations

T3.16 Fostering modern forest and landscape restoration based on climate-smart use of forest genetic resources and innovation: from policy to practices

Chris J Kettle[1]
[1] Alliance of Bioversity International and CIAT, CGIAR

Abstract: Global commitment to forest and landscape restoration are accelerating and attracting more interest from impact investors the private sector and philanthropists. A growing body of work highlights a complete mismatch between national commitments to restoration and capacity on the ground to deliver the billions of seeds, seedlings and planting material that will lead to climate resilient restoration, deliver local benefits, in terms of livelihoods and food security and enhance biodiversity outcomes. I present a summary of recent work to evaluate regional seed systems for native tree genetic resource. I will introduce innovations in species site matching and digital solution to improve the supply chain in genetic resource delivery and incentivize farmers to increase native trees in landscape restoration and agroforestry. Finally, I will discuss how new AI and machine learning can be applied to improve restoration outcomes.

European examples of Forest and Land Restoration innovative approaches to degraded and devastated forests

T3.16 Fostering modern forest and landscape restoration based on climate-smart use of forest genetic resources and innovation: from policy to practices

Jacopo Giacomoni[1]

[8] Office national des forêts (ONF)
[9] University of Copenhagen (UCPH)
[10] European Forest Institute (EFI)

Abstract: Forest and Landscape Restoration (FLR) interventions are becoming more and more important to speed up and support the recovery process of degraded and devastated forests (e.g. forests damaged by extreme events such as floods, landslides, wildfires, pest and disease outbreaks, windstorms, etc.). FLR interventions can consist in active forest management operations that might benefit from the use of artificial regeneration that relies on Forest Reproductive Material (FRM). The use of proper and adequate FRM and the design of management practices that consider genetic diversity is crucial to support ecosystem restoration while promoting biodiversity and the resilience of the full forest ecosystem.

We worked together with operators managing FLR interventions, some of them partners in an EU Horizon Europe project (OptFORESTS – 101081774), to explore innovative approaches that embed a holistic approach, considering the technical feasibility, ecological effectiveness, economic viability and institutional practicability for improving biodiversity and ecosystem services (ES). European examples of evolution-oriented management of declining forest stands, and forest biodiversity restoration interventions are studied with the aim to identify suitable management options and develop FLR strategies to halt forest decline and biodiversity loss, and to favor forest resilience in a context of changing climate.

Our examples aim to stimulate the attention of scientists, technicians, policy makers and the society, promote the discussion and raise awareness on the role of Forest Genetic Resources (FGR) in facing the challenges of FLR interventions in a context of climate change. Furthermore, we aim at underlining the importance of considering stakeholders as active and essential part of the social-ecological system to be restored.

Expert panel; comments from Robin Chazdon

T3.16 Fostering modern forest and landscape restoration based on climate-smart use of forest genetic resources and innovation: from policy to practices

Robin Chazdon[1]
[1] Tropical Forests and People Research Centre, University of the Sunshine Coast

Abstract: I will contribute to the panel with comments on the previous presentations and lightning talks. I will emphasize areas of my expertise, which include tradeoffs between economic development and ecosystem services and governance aspects in the context of forest and landscape restoration. Nature-based solutions, such as forest and landscape restoration, must consider genetic resources as they influence both social and ecological outcomes of forest restoration. Ensuring the genetic diversity of trees is important for resilience to climate change, but may entail more costs and expertise involved in collecting genetic material and selecting genotypes that perform well in different locations. Involving local communities in seed collection of trees for restoration can support livelihoods and build social and human capital that strengthen restoration efforts.

Exploring forest genetic resources' contribution to forest restoration initiatives in terms of ecosystem services in Europe: a preliminary assessment

Abstract: Aiming to restore 20% of the EU's land areas by 2030, the European Union Nature Restoration Law will require unprecedented efforts by the forest-related community in Europe, including conservation and sustainable use of Forest Genetic Resources (FGR). Forest and Landscape Restoration (FLR) is expected to create better forest landscapes that will provide ecosystem services (ES) flows, benefiting society. Nevertheless, the role of FGR in providing ES in this context and their associated values are still poorly considered within existing research.

To fill this gap, within the framework of the EU-funded Horizon Europe project OptFORESTS, we assess the role and value of FGR diversity in terms of ES supply vis-à-vis the challenges posed by climate change through an extensive literature review and an expert-based approach via Delphi method. FGR can be framed within the most common existing ES classification systems both as a service themselves - provisioning (e.g., seed collection from natural stands, tree selection for breeding, etc.), regulating (e.g., gene pool protection contributing to biodiversity conservation) and cultural (e.g., research and education) - and as a catalyst for additional services spanning various ES categories.

Most of the existing studies on FGR and ES focus on provisioning services, namely on wood production in both quantitative (tree growth and yield) and qualitative terms, thus emphasizing an increased capital value associated with the use of improved FGR. Moreover, the scope of existing European research is mainly concentrated in the Nordic countries (Scandinavia and Finland) and limited to a few economically important species (notably *Pinus sylvestris* L.), while there are no comprehensive studies assessing ES delivered by FGR across different species and regions in Europe.

Our research aims to analyse and systematize findings from existing literature on FGR and ES, and

to complement it via tailored expert-based assessments about the present and expected future value of a selected pool of FGR-related ES, thus investigating the points of view of experts from different fields/domains across Europe.

By doing so, our paper aims to provide policymakers, scientists and practitioners with useful insights supporting the selection of FGR for future FLR projects and initiatives.

Forest landscape restoration governance: social networks and institutional arrangements in three Brazilian watersheds

T3.16 Fostering modern forest and landscape restoration based on climate-smart use of forest genetic resources and innovation: from policy to practices

Cristina Adams[1]
[1] Institute of Energy and Environment (IEE), University of São Paulo (USP)

Abstract: Forest landscape restoration (FLR) is a long-term process that takes place in private and public lands and generates private and common goods and services. In Brazil, several FLR initiatives are being planned and implemented to help the country achieve its Nationally Determined Contributions (NDCs) to the Paris Agreement. In order to achieve its goals, FLR involves multiple stakeholders with different interests and represents a challenge from the governance perspective. In socioecological systems, social actors interact through formal and informal coordinated networks, exchanging information, engaging in social learning, synthetizing and mobilizing knowledge and innovating. The properties of governance networks (size, number and type of connections, structure of the network) can influence the outcomes of governance processes. We used social network analysis to identify key stakeholders, analyze patterns of inter stakeholder connections and the flow of information, knowledge, seeds and seedlings in three Brazilian landscapes undergoing FLR (Paraíba do Sul, Doce, and Itaúnas-São Mateus watersheds). Our goal was to investigate how actors innovate by organizing themselves and cooperating to meet the challenges of FLR governance. Data gathering included a literature and document review, 59 semi-structured interviews with key stakeholders, participatory workshops, and social network mapping. Thirty-eight recent (2000-2019) FLR initiatives were identified, involving more than a hundred different stakeholders in each landscape, organized in networks responsible for FLR planning, project implementation and monitoring. The comparative analysis showed a diversity of governance arrangements in the three landscapes. Critical aspects identified included monitoring, extension services and financing FLR. Common to the three landscapes was the connection between the water management and FLR agendas, and the appropriation of existing institutions designed at the landscape level for water management governance as a strategy to accelerate and upscale forest restoration.

Governance aspects fostering or hindering forest and landscape restoration's social innovation potential

[6] Etifor - Valuing Nature

Abstract: Restoring degraded landscapes to either increase the supply of ecosystem service or to secure their provision in the context of climate change has become one of the premises of several policies within the European Union Green Deal initiative. The Nature Restoration Law and its proposed directions is an ambitious one, and thus needs a wide support from not only decision makers, but the public and landowners as well.

Having a broad consensus is one of key elements needed for a policy or a program to be successful, and that is why we have designed a set of participatory workshops to be implemented ahead of different nature restoration actions being implemented in six protected areas of forested landscapes throughout Slovenia. Project ZAGON (Norway Grants) is designed to develop and test innovative governance approaches, where aspects of climate change, provision of ecosystem services, and stakeholder engagement are to be integrated into management of protected areas, with a focus on restoring ecosystems. Those approaches are being implemented in a variety of management documents (plans, guidelines, positions, etc.), which are relevant for each protected area within the project.

Participatory workshops in local environment are proving to be a rich source of information, especially in terms of (1) relevant local challenges related to nature restoration (affecting farming and forestry activities, urbanization and pollution), and (2) potential solutions provided by local stakeholders (drivers of change in ecosystems and ecosystem services, responsibility attached to those drivers, means to control drivers of change, desired future trajectories, etc.). However, involving local people into innovation of governance of protected landscapes is not only providing data, but also strengthens connection among locals and managers of the protected areas and gives people a chance to have their say. Both are essential not only to develop a relevant governance approach reflected in a management plan, but also to build an environment for its successful implementation.

Key lessons learnt is to approach local people with challenges that are relevant for them, to ensure that they feel free to speak out, and to pinpoint how restored nature will be an asset in future.

Revisiting tropical forest and landscape restoration governance in fragile countries: Ethiopia's Tigray as a case

T3.16 Fostering modern forest and landscape restoration based on climate-smart use of forest genetic resources and innovation: from policy to practices

Tewodros Tadesse[1]
Sara TewoldeBerhan[1], Emiru Birhane[1], Meley Rannestad[2], Tigist Araya[1], Aster Gebrekirstos[3]
[1] Mekelle University
[2] Norwegian University of Life Sciences (NMBU)
[3] World Agroforestry Center (ICRAF)

Abstract: Introduction/Background

With growing armed conflicts and associated factors like weak institutions in Sub-Saharan Africa (SSA), deforestation, and consequently loss of important ecosystem services is a great concern in the region. In conflict zones such as the one observed in Tigray, some belligerents intentionally destroyed ecosystems and governance institutions. Inherently, the conflict itself also fostered institutional decay of resource governance systems. Despite the Tigray region in northern Ethiopia gained international recognition for its efforts in forestland rehabilitation and landscape restoration, these conflict-induced forces combined to significantly harm the forest governance systems. Understanding the mechanisms of forest governance in a conflict environment and how these governance systems evolve in conflict environments helps better understand the mechanisms through which the overall process of rehabilitating and restoring forests can be facilitated.

Objectives: The objective of this paper is to analyze the impact of the war on formal and indigenous governance systems of forests and natural resources.

Methodology: the study employed desk review of over 50 documents, discussion with 10 experts, focus group discussions across several conflict areas, survey of forest communities, on-site visits to damaged sites and documentation from 12 sample sites. The collected data were analysed using content analysis.

Result: As a result of the decades-old efforts before the war, restoration and rehabilitation of environmental resources using indigenous management systems was scientifically documented. These documented results point to the decent success of such governance systems in promoting sustainable use of environmental resources. In this regard, Tigray's governance systems for environmental rehabilitation and restoration were acknowledged. During the war, the restored areas and governance institutions (formal institutions, indigenous governance, belief and management systems) were intentionally destroyed, which affected the effectiveness of communities to use, protect and conserve environmental resources.

Implication/conclusion: With decades-old centralized management, in Tigray, a mix of centralized and local institutions working in harmony was documented to be more effective in addressing the resource management challenges. The war destroyed these with grave consequences to the environment and the evolution of forest governance systems in the regional context, which still require in-depth studies.

Keywords: damage; ecocide, governance, recovery, rehabilitation, War, Tigray, Ethiopia

The transformational potential of community forestry and traditional forest-related knowledge for climate-resilience

T3.16 Fostering modern forest and landscape restoration based on climate-smart use of forest genetic resources and innovation: from policy to practices

Monica Gabay[1]
[1] Ministry of Environment and Sustainable Development - Argentina

Abstract: This contribution to the round table will comment on previous talks based on my expertise on forest governance, community forestry and traditional knowledge. The Kunming-Montreal Global Biodiversity Framework recognizes the stewardship role of Indigenous Peoples and local communities regarding biodiversity conservation and sustainable use. My participation will highlight the transformative potential of community forestry and traditional knowledge to catalyze forest landscape restoration and build resilience to climate change. A session description is already available, so there is no need to repeat it.

Unlocking Green Growth: Boosting the European Forest Tree Nursery Sector

Abstract: The use of proper forest reproductive material (FRM) is vital for maintaining high-quality forest biodiversity and enabling sustainable forest management and wood production. However, various challenges affect forest nurseries and impede the provision of adequate FRM in Europe. The topic of FRM is generally of low priority among policy-makers and forest managers, leading to underinvestment in FRM production, resulting in inadequate supply and poor quality of FRM. Other obstacles include limited availability of certified FRM sources, legal constraints in transfer among countries, as well as environmental and biotic factors like climate change and the introduction of novel pests. Moreover, market-based hurdles, such as insufficient demand, financial constraints, and inadequate pricing mechanisms further compromise the availability and quality of FRM.

Over the last two decades these challenges have been exacerbated by wage and labor force disparities due to cost constraints at nurseries and narrow time constraints in grant schemes. Current information largely focuses on national or regional conditions while a comprehensive and systemic analysis of these problems across the European forest tree nursery sector is lacking. A better understanding of the structure, economic framework conditions and needs of the European forest tree nursery sector is thus of particular importance.

We conducted a comprehensive survey of the European forest tree nursery sector including an investigation of perceived challenges and trends in seed sourcing, market framework conditions, demand structure, the perceived impact of EU policies on the sector as well as barriers and needs for future collaboration. The survey is part of an in-depth analysis of the sector aggregating EU member state in four regions.

Our analysis contributes to a better understanding of impediments on provision with FRM, provides suggestions for expanding the European capacities in FRM production and examines pathways of

potential cooperation between nurseries thus being an important contribution to implementation of the European Green Deal.

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

A crossroad of post-glacial migration haplotypes of Tilia cordata at Lithuania

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Darius Kavaliauskas[1]
Darius Danusevicius[1], Virgilijus Baliuckas[1], Ruta Kembryte-Ilciukiene[1]
[1] Faculty of Forest Science and Ecology, Agricultural Academy, Vytautas Magnus university

Abstract: We used five chloroplast microsatellite markers to study postglacial migration haplotypes of Tilia cordata in Lithuania. We sampled and genotyped 266 adult trees of Tilia cordata in natural forest stands with dominance of Tilia cordata in Lithuania. We constructed microsatellite markers identifying the postglacial migration haplotypes of Tilia cordata based on the NCBI GenBank accessions submitted by Semerikova et al. (2019). The genotyping revealed presence of four main European postglacial migration lines of Tilia cordata: (a) a western haplotype from the Balkan refugium (t5/Hap5/H4 notations from different studies), presently common in south-western Europe and in southern Lithuania; (b) an eastern haplotype from the Balkan refugium (t1/H3), presently common in south-eastern Europe (Ukraine, southern Russia) and in eastern Lithuania; (c) a haplotype from the Italian refugium (t3, Hap 1-3, H6) common in northwestern Europe and most common in Lithuania, (d) a north-eastern refugium (centered at about present-day eastern Ukraine), which presently is common in western Russia and north-eastern Lithuania. Such haplotypic diversity is favorable reserve of genetic diversity for a sound spreading of Tilia cordata that has notably intensified in the Baltic region over the last decade. The visual abstract is given below.

AI-Assisted Object Detection for Biodiversity Assessment in Forest Ecosystems

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Ahmad Athif Mohd Faudzi[1, 2]
Uswah Khairuddin[1], Hazlina Selamat[1], Zool Hilmi Ismail[1], Mohd Ibrahim Shapiai[1], Wicknewary Ratnam[2]

[2] Akademi Sains Malaysia

Abstract: This study highlights the potential of artificial intelligence (AI) in supporting forest policy and planning by facilitating biodiversity assessment through object detection techniques. Specifically, we focus on two aspects: leaves detection for flora analysis and insect and vertebrate detection for fauna analysis. Advancements in computer vision and AI algorithms have opened up new possibilities for automated identification and monitoring of forest flora and fauna. Leaves detection plays a crucial role in understanding the composition and health of forest ecosystems. By utilizing AI algorithms, leaf identification can be automated, enabling efficient and accurate species classification, disease detection, and overall ecosystem assessment. It's started by digitizing the leaves from herbarium using scanners and hi-def scanners. Similarly, AI-based object detection techniques can aid in identifying insects and vertebrates in forest habitats. By analysing images or video footage captured from camera traps, AI algorithms can detect and classify various species, allowing for population estimation, habitat mapping, and ecological research. This information is vital for forest management and conservation efforts. Furthermore, in the context of forest canopy analysis, drones equipped with AI-powered systems can provide valuable insights. By capturing high-resolution imagery and using AI algorithms for canopy identification, it becomes possible to estimate forest parameters like canopy cover, canopy height, and species distribution, aiding in forest inventory and planning. Additionally, legged robots equipped with AI-enabled algorithms can be utilized to measure the diameter at breast height (DBH) of trees. These robots can autonomously navigate forest terrain, detect tree trunks, and accurately measure their dimensions, enabling efficient forest inventory and growth monitoring. The adoption of AI systems in Precision Biodiversity could foster responsible research and innovation that respects these diverse perspectives. By doing so, we can envision a future where AI systems contribute to improved forest management, conservation, and sustainable utilisation.

Ash tree genomics - providing solutions to global pest and pathogen threats

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Abstract: Ash (*Fraxinus*) is a broadleaved tree genus of major importance in the Northern Hemisphere, encompassing species of ecological, economic and cultural significance. Since the 1990s, the survival of global ash populations has been threatened by invasive pest and pathogen outbreaks. The first draft genome for an ash species was released just over 10 years ago, in response to an urgent need for genomic resources to help to tackle the ash dieback disease epidemic in Europe. Our recent research has encompassed the generation of improved genomic resources for European ash (*F. excelsior*), comparative genomic analyses including the majority of diploid taxa in the genus *Fraxinus*, and population genomics for individual ash species, in efforts to better understand the basis of susceptibility to ash dieback disease and the equally damaging emerald ash borer. This talk will present results outlining the latest developments in our understanding of the genomic basis of susceptibility and the evolutionary response to these threats, and highlight the broader implications for the health and resilience of forest ecosystems under increasing biotic and abiotic stress.

De novo assembly of the Ulmus minor genome

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Jorge Pallares-Zazo[1]

Abstract: Elm populations in Europe and North America suffered a severe decline during last century, whose main agent was a clade of tree pathogens of the genus *Ophiostoma*, responsible of the Dutch elm disease (DED). It is estimated that only 1% of the ecosystems formerly dominated by elms remain. To the date, detection of disease resistant lingering elm genotypes has been the most successful action for elm recovery. However, current molecular knowledge of the species remains oddly scarce to allow the development of specific genetic tools to cope with the disease. The absence of a reliable reference genome limits in-depth genetic conservation and evolutionary studies, gene expression analyses and modern genomic-assisted breeding approaches. Here, we present a high-quality *de novo* genome assembly of an Iberian *Ulmus minor* resistant genotype, as a state-of-the-art resource to pursue new approaches against DED.

This work delves into the specific assembly techniques for this species genome, which is large, highly repetitive and highly heterozygous, features shared with some other forest tree genomes. To tackle these challenges, different sequencing technologies and assembly software were combined to generate the final assembly. Wengan ultrafast assembler was used to decide the combination of sequencing reads and their parameters in an optimal fashion for the assembly methodology, which allowed efficient use of time and computational resources. Once decided, the hybrid software MaSuRCA assembled the Illumina and PacBio reads, the latter previously corrected and trimmed with Canu. The polishing of the assembly was repeated in successive phases using Polca software. Haplotype refinement was performed using purge haplotigs software. PacBio Hi-Fi data were then integrated to the resulting assembly to improve continuity and quality; and finally, by using Hi-C data, the pseudo-chromosomes were obtained. Annotation of the repetitive content reported that more than 70% of the genome corresponds to repeat elements predominantly the retrotransposons of the *Gypsy* and *Copia* families. By using retrotransposons and highly conserved protein sequences, phylogenetic studies were performed.

This *Ulmus* reference genome represents a substantial leap forward, not only to help tackling DED, but also as a due resource for the research in Ulmaceae and Urticalean rosid genomics.

Dendrogenomics - a new interdisciplinary approach to study genetics of adaptation and individual tree response to biotic and abiotic stresses

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Konstantin Krutovsky[1]

[1] Department of Forest Genetics and Forest Tree Breeding, Faculty of Forest Sciences and Forest Ecology, Georg-August University of Göttingen, Büsgenweg 2, 37077 Göttingen, Germany

Abstract: Dendrogenomics is a new interdisciplinary field of research that integrates dendrochronology, dendroecology, dendroclimatology, genetics and genomics. This novel approach allows joint analyses of dendrological and genomic data and opens new ways to study temporal dynamics of forest treelines, to delineate spatial and temporal population structure and to decipher individual tree response to the abiotic and biotic stresses and to evaluate the adaptive genetic potential of forest tree populations. These data are much needed for prediction how climate change will shape distribution of boreal forest species and for mitigation of negative climate change effects. It will be presented how an association analysis of the variation of individual dendrophenotypes, reflecting the individual response of a tree to stress, with variation of a large number of DNA markers identified genome-wide via genotyping-by-sequencing (GBS) allows to locate genome regions and genes whose variation is associated with variation of important adaptive traits using as examples the studies of Siberian larch and Siberian stone pine populations.

Digital Twin with Artificial Intelligence and Data Science for Precision Biodiversity

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Nurfadhlina Mohd Sharef[1, 2]

[2] Academy of Sciences Malaysia, Malaysia

Abstract: Malaysia is committed to conserving its biological diversity, promoting its sustainable use and ensuring fair and equitable sharing of the benefits arising out of the utilization of biological resources. Therefore, one of the national flagship projects is tapping into artificial intelligence (AI) which has emerged as a powerful tool in various scientific disciplines, including forest biometry. AI models are used for predicting forest-related variables such as tree species classification, biomass estimation, growth prediction and stand prescription. Furthermore, AI will be used with remote sensing data, such as satellite imagery and LiDAR, to provide a comprehensive view of forest dynamics at various spatial and temporal scales. The project focuses on the development of a digital twin system for precision biodiversity that allows ecology monitoring, analysis, prediction, and simulation for the purpose of biodiversity management. As AI models advanced, researchers shifted their focus toward understanding the underlying processes driving forest dynamics through descriptive, predictive, and prescriptive analytics. Therefore, the interpretability and explainability of AI models became critical to gaining insights into the relationships between different variables and their impact on forests for supporting proactive forest strategies (digital twin). The pilot implementation is in Pasoh Reserve Forest, a nature reserve located about 8 km from Simpang Pertang, Malaysia, and around 70 km southeast of Kuala Lumpur. It has a total area of 2,450 hectares, with a core area of 600 ha surrounded by a buffer zone. We have developed a framework for stand prescription and biodiversity analytics dashboard. A national alliance on biodiversity evaluated the framework and the system is aimed to be used by several entities such as the Forest Research Institute Malaysia, departments of forestry and Ministry of Natural Resources, Environment, and Climate Change. The digital twin system is hopeful to facilitate further discovery in biodiversity research and increase the efficiency of forest management.

DNA GENOTYPING REVEALS STRONGLY DIFFERENTIATED GENETIC GROUPS WITHIN NATURAL POPULATIONS OF SCOTS PINE IN NORTHERLY FORESTS

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Abstract: Earlier phenology observations in natural stands of Scots indicate that the mating among the trees within the stands may not be random but rather clustered into groups with synchronized flowering. In our study we tested this hypothesis by genotyping 890 mature trees of Scots pine in six natural populations of Scots pine located in different parts of Lithuania. We considered the level of population differentiation as a point of account for estimating the differentiation strength of the within population genetic groups. We used 11 genomic SSR markers to genotype the trees selected at a fine grid within ca. 2 ha sampling areas within each population (ca. 150 individuals per population). The STRUCTURE Bayesian clustering revealed two to six distinct genetic groups within the populations. These genetic groups were spatially intermixed. Genetic differentiation indexes among the within-population genetic groups were almost 10-fold greater (D_{est} = 0.012-0.081) than the differentiation indexes between the populations (D_{est} = 0.003). Our results indicate that there is a markedly stronger structure of genetic variation within populations than between populations of Scots pine in large forest tracts of northerly Europe, which presumably contributes to most of genetic variation residing within populations. It is likely that mating of individuals within Scots pine populations is not completely random but rather is stratified into genetic clusters. Our study provides a new approach and novel key insights into fine-scale genetic structuring within Scots pine populations. It has implications for population genetics studies, and conservation and sustainable use and management of forest genetic resources (FGR) for the most stand forming, wind pollinated monoecious tree species.

Evaluation of Ion Torrent-based Variant calling for the analysis of tree NGS data by validation against the common variant calling algorithms

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Cesare Garosi[1]
Donatella Paffetti[1], Salvatore Conti[2], **Cristina Vettori**[1, 3]

Abstract: Next-generation sequencing (NGS) has revolutionized plant research in many ways, including new high-throughput genotyping methods. Genotyping by sequencing has been proven to be a robust and cost-effective method capable of producing thousands or millions of SNPs in many species. Undoubtedly, the greatest barrier to its wider use is the challenge of data analysis. With the advancement of technology in recent years, different sequencing technologies (Ion Torrent, Illumina, and PacBio) have emerged, resulting in different methods to obtain reads and thus different data types. Frequently applied pipelines often start with the pre-processing of sequence reads, followed by the alignment (mapping) of these reads to a reference sequence. Finally, the identification (calling) of sequence variants is performed based on alignments. Each of these three steps can be carried out by various alternative programs using different algorithms, which influence the accuracy and sensitivity of the resulting variant set. Genomic variants like single nucleotide variants (SNVs) or small insertions/deletions (InDels) can be inferred by variant callers based on sequence read alignment. Popular variant callers like SAMtools/BCFtools, CLC-GWB, FreeBayes, GATK, LoFreq, SNVer, VarDict, and VarScan use a variety of different approaches to call variants. Consequently, resulting variant sets differ depending on the employed methods (Bayesian, likelihood, or machine learning), which come with strengths and weaknesses concerning the identification of specific variant types. As shown in recent comparative studies, despite the undoubted performance, there are no software that, with equal analysis efficiency, can be used to complete all the tasks to be done for genomic variant analysis. The purpose of this study is to analyse the performance of a direct pipeline, based on Ion Torrent technology, that allows obtaining genomic variant analysis (SNVs, MNVs, InDels) as a direct sequencing output, without the use of external software: *Torrent suite software*. In this study, we compared the performance of Torrent suite's direct variant calling pipeline with the most commonly used pipelines on target sequencing data from 18 genomic regions of *Fagus sylavtica* L. genome in 7 Italian populations. Our results demonstrated variant calling efficiency comparable to the various workflows that are commonly adopted by the scientific community.

Expansion of black poplar genetic resources to ensure sustainability and stability of carr and riparian forests

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Petra Štochlová[1]
Kateřina Novotná[1], Kateřina Podrábská[1], Hana Drahošová[1], Vladimír Zýka[1], Daniel Zahradník[1], Dita Šetinová[1], Veronika Strnadová[1], Marek Štochl[1], Karel Černý[1]
[1] Silva Tarouca Research Institute for Landcape and Ornamental Gardening, Publ. Res. Inst.

Abstract: Riparian stands are irreplaceable part of the nature that is nowadays threatened by human activity but much more by invasive pathogens that reduce populations of key species (ash, elm, alder) rapidly resulting in significant changes in the composition and structure of these stands with impact on whole ecosystems. One of the possible solutions could be the substitution of these species for black poplar (*Populus nigra*, PN) in suitable condition for its growth. PN is an autochthonous European woody species that is endangered not only in the Czech Republic. This species is easily crossed with non-native poplars. This endangers the gene pool and, moreover, obtained hybrids have bad technical and ecological properties. Another risk is fragmentation of the population that can lead to inbreeding.

In the last century more than 200 trees from different parts of the Czech Republic were selected for in situ or ex situ conservation. From that time some of them died. To get better situation of black poplar populations and also the riparian stands, the project focusing on the black poplar conservation and its application in water management and forestry was financially supported by the Ministry of Agriculture of the Czech Republic (project QK22010142). The main aims are i) identification of residual trees of black poplar; ii) selection of genotypes that meet the desired characteristics and their species purity is confirmed with DNA markers; iii) propagation of them and iv) specification of factors to successful reintroduction of the species to riparian forests.

During the recons mainly the residues of local populations have been found. Only the small part of the identified trees is healthy. More than one half of identified trees is older than recommended coppice age for poplars. In the surroundings of the most identified trees there is presence of other poplars (mostly *P. ×canadensis*). Negative effect of inbreeding on seed germination and growth characteristics was observed in trials.

The identified trees enlarge the PN genetic resources. The obtained findings have important implications for reintroduction of PN into riparian forests and can help to assist its self-reliant and long-term survival in landscape.

Exploring the genomic and metabolomic bases of differential pollution symptoms in fir trees from a peri-urban forest under chronic ozone exposure

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Abstract: Urbanization modifies both ecosystem conditions and evolutionary processes. Such changes include air pollution, mostly in the form of tropospheric ozone (O_3), which leads to urban and peri-urban forest decline. Such is the case of fir (*Abies religiosa*) forests in the peripheral mountains west of Mexico City (CDMX), which have been severely affected by O_3 pollution since the 1970s. We developed a participatory monitoring system with local community members to record ozone damage and other morphological traits in trees within these forests. We observed that more than thirty-five percent of the trees ($n = 1,765$) had ozone damage, with younger trees having a lower percentage of foliage damaged by ozone than older trees ($p < 0.0001$). Interestingly, we also observed some young individuals with low O_3—related damage within a zone of great O_3 incidence; these trees were smaller than symptomatic individuals of the same age, and might be reflecting rapid tolerance/adaptation to this pollutant. We observed significant differences between asymptomatic and damaged plants using histological, metabolomic and transcriptomic methods. For instance, we observed thicker epidermis and more collapsed cells in the palisade parenchyma in needles from symptomatic than from asymptomatic individuals; such differences increased with needle age. Furthermore, damaged individuals had lower concentrations of various terpenoids and differentially expressed genes related to carbohydrate metabolism, plant defense, and gene regulation, when compared to asymptomatic trees. Landscape genomic analyses finally revealed significant spatial and environmental components acting on heritable variation, which could explain the development of putatively tolerant phenotypes. Such elements may provide the raw material for future forest survival and could set the bases for possible genome-guided forest management. Involving the local community in pinpointing mature asymptomatic individuals and use them in reforestation is thus of high priority.

Genetic diversity and population structure of African sandalwood (Osyris lanceolata) in Kenya: implications for conservation

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

John Ochieng Otieno[1, 2]

[3] UK Centre for Ecology and Hydrology, Bush Estate, Penicuik, Midlothian, EH26 0QB, UK

Abstract: Abstract

African sandalwood (*Osyris lanceolata* [Hoscht. & Steud.]) is a multipurpose and drought tolerant, African tropical tree species of *Santalaceae* family. The species is valued globally for it has important ornamental, medicinal, and economic value. The population of *O. lanceolata* is declining in Africa due to overexploitation and increased demand for its essential oil and other products, but information on population dynamics across its entire range of distribution is limited. In this study, the genetic variation and population structure were evaluated for 288 individuals from 10 discrete Kenyan populations based on 10 polymorphic SSR primers. The total number of alleles detected was 178 with a mean of 7.10 alleles per locus. The average observed heterozygosity (*Ho*) across all loci varied from 0.112 to 0.815. The gene diversity among the loci ranged from 0.226 to 0.869. There was strong genetic differentiation among populations (F_{ST} = 0.250), likely resulting from low gene flow (*Nm* = 0.79). The polymorphism information content (PIC) ranged from 0.896 to 0.968, with an average of 0.931, which indicated that the markers were highly informative. Analysis of molecular variance (AMOVA) indicated that the principal molecular variance existed within populations (62%) rather than among populations (38%). A high level of genetic diversity was inferred from the genetic diversity parameters (*He* = 0.587, *I* = 1.302 and *PPL* = 97 %).). Multivariate analyses with the unweighted pair group method with arithmetic mean (UPGMA) and principal coordinate analysis (PCoA) grouped the 228 individuals into two major groups, which was also supported by the Bayesian STRUCTURE analysis. This is the first study of the genetic diversity and population structure of *O. lanceolata* using SSR markers in Kenya. The microsatellite markers developed in this study will be useful for future breeding programs and genetic studies aimed at developing conservation plans. We recommend both *in situ* and *ex situ* conservation strategies to protect the species from population decline and further genetic diversity loss.

Keywords: *Osyris lanceolata*; genetic diversity; microsatellites (SSR); population structure

Genetic Diversity and Prediction Mapping of Pyracantha crenulata in Northwestern Himalayan Region of India

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Haripriya Kavidayal[1]
Hukum Singh[1], Harish Singh Ginwal[1]
[1] Genetics and Tree Improvement Division, Forest Research Institute P.O. I.P.E., Kaulagarh Road, Dehradun – 248 195 (Uttarakhand), India

Abstract: *Pyracantha crenulata*, an evergreen and perennial shrub, is a socio-economically important and underutilized forest genetic resource of the northwestern Himalayan region of India. The population of *P. crenulata* is declining due to the human-driven activities leading to habitat destruction. The present study was carried out in the Indian Himalayan State of Uttarakhand to analyze the genetic diversity within and among the populations and to predict the potential occurrence of *P. crenulata*. Total genomic DNA was extracted from the leaves using the modified CTAB method. The genetic variation in four natural populations of *P. crenulata* was analyzed using 13 ISSR markers. A high genetic diversity was recorded in the sampled populations (h = 0.223; I = 0.337) as well as at species level (h = 0.3174; I = 0.4821). Besides, high level of genetic differentiation (G_{st} = 0.295, *PhiPT* = 0.271) with the low gene flow ($N\text{-}_{m}$ = 0.191) among the populations were detected. Two significant clusters were separated by the UPGMA-based dendrogram, revealed that the populations are also geographically diverse. Bayesian model based clustering method was employed to assess the genetic population structure and detect gene pools which revealed that the populations were clustered according to their geographical distribution. This study will provide adequate information on genetic and geographical variability in *P. crenulata*, contributing to evolutionary dynamics, plant breeding, efficient use of germplasm resources, and plant conservation. Further, species mapping and prediction modelling would be an effective tool in species restoration, management, conservation, and utilization planning under the threats of human and climate change scenarios.

Genetic Resource Conservation Value and Climate Change Adaptation Potential of Old-growth vs Second-growth Populations of Keystone Eastern White Pine

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Om Rajora[1]
[1] Faculty of Forestry and Environmental Management, University of New Brunswick, 28 Dineen Drive, Fredericton, New Brunswick, E3B 5A3 Canada

Abstract: Conservation, sustainable management, and climate adaptation of genetic resources of keystone forest trees are essential for their forest ecosystem stability, functioning and provisioning of ecosystem services because many faunal and floral associations depend on the existence of keystone forest tree species. Biodiversity, especially genetic diversity, provides the foundation of ecosystem resilience, stability, and functioning. Whether old-growth forests have higher genetic diversity and effective population size, consequently higher genetic resource conservation value and climate adaptive potential than second-growth forests, remains an unresolved issue. We have tested the hypothesis that old-growth forest tree populations have higher genetic diversity, effective population size (N_e), climate adaptive potential and genetic resource conservation value and lower genetic differentiation than second-growth forest tree populations, employing a keystone, long-lived and extensively logged conifer, eastern white pine (*Pinus strobus*). Genetic diversity and population structure of old-growth and second-growth populations of eastern white pine (EWP) were examined using microsatellites of the nuclear and chloroplast genomes and SNPs in candidate nuclear genes putatively involved in adaptive responses to climate and underlying multilocus genetic architecture of local adaptation to climate in EWP. Old-growth and second-growth EWP populations had statistically similar genetic diversity, inbreeding coefficient and inter-population genetic differentiation based on nuclear microsatellites and SNPs. However, old-growth populations had significantly higher chloroplast microsatellites haploid diversity than second-growth populations. Old-growth EWP populations had higher coalescence-based historical long-term N_e than second-growth EWP populations, but the linkage disequilibrium-based contemporary N_e estimates were statistically similar between the old-growth and second-growth EWP populations. Analyses of population genetic structure and inter-population genetic relationships revealed some genetic constitution differences between the old-growth and second-growth EWP populations. Overall, our results suggest that old-growth and second-growth EWP populations have similar genetic resource conservation value. Because old-growth and second-growth EWP populations have similar levels of genetic diversity in genes putatively involved in adaptive responses to climate, old-growth and second-growth populations may have similar adaptive potential under climate change. Our results could be generalized across boreal and temperate conifer forest trees. Our study contributes to addresses a long-standing issue, advances research field and knowledge about conservation and ecological and climate adaptation of forest trees.

Genomic Insights and Sustainable Propagation Strategies for the Conservation and Enhanced Saponin Production of Oplopanax elatus

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Yu Wang[1]
Xin Wang[1], He Zhang[1], **Yuhua Li**[1]
[1] Northeast Forestry University

Abstract: *Oplopanax elatus* Nakai, a small thorny shrub belonging to the Oplopanax genus in the Araliaceae family, holds considerable significance in Eastern Asia as an ethnomedicinal plant. The plant's therapeutic value stems primarily from the abundant lupane-type triterpenoid saponins found within its leaves and roots.The survival and propagation of wild *O. elatus* present significant challenges due to its specific habitat requirements. With a considerably narrow natural distribution range and low germination rate, along with over-harvesting by humans, the plant's population is sparse. These factors have led to its classification as an endangered species and its recognition as a nationally protected species in China. To sustain the utilization of *O. elatus* resources, we have developed an in vitro propagation system using its adventitious roots, supplemented by a suspension culture system for its expedited propagation. To decode the biosynthetic mechanism of lupane-type triterpenoids, we performed genome sequencing of an allotetraploid *O. elatus* individual from China. The resulting de novo assembly is 1.45 Gb, with a contig N50 of 6.3 Mb, spanning across 24 chromosomes and comprising a total of 61,842 annotated genes. Employing an agrobacterium-mediated transient expression assay in *Nicotiana benthamiana*, we identified multiple enzymes, including 5 oxidosqualene cyclases (OSCs), 6 cytochrome P450-dependent monooxygenases (P450s), and 9 UDP-glucosyltransferases (UGTs), involved in *O. elatus* saponin biosynthesis. The present study offers crucial resources for the future genetic improvement of *O. elatus*, particularly in enhancing saponin production. Moreover, it establishes the groundwork for the sustainable exploitation of lupane-type triterpenoids via large-scale root cultivation, thereby contributing to conservation efforts.

Geographical patterns of forest genetic diversity to tackle conservation needs: insights from genomics approaches

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Anna-Maria Farsakoglou[1]
Ivan Scotti[2], Bruno Fady[2], Filippos Aravanopoulos[1]
[1] Laboratory of Forest Genetics and Tree Breeding, School of Forestry and Natural Environment, Aristotle University of Thessaloniki, Thessaloniki, Greece
[2] INRAE, Ecologie des Forêts Méditerranéennes (URFM), Avignon, France

Abstract: Advanced DNA sequencing technologies have expanded our ability to estimate genetic diversity and differentiation parameters genome-wide, and to address crucial biological questions concerning conservation and the fate of forest tree populations in the face of strong environmental change. Here, we estimate geographical patterns of genome-wide genetic diversity in five European conifer species (*Abies alba*, *Pinus cembra*, *P. halepensis*, *P. nigra*, *Taxus baccata*) that cover different geographical ranges and ecological requirements. For each species, 9-15 populations (19-25 trees per population) were used for Allegro-SPET genotyping to produce several thousand SNPs (ranging from 7k to 17k after filtering). *Pinus nigra* and *P. halepensis* showed a clear East-West geographical pattern in genetic structure, while the remaining three species had either weak geographical subdivisions, or no structure. A bioinformatics pipeline was constructed, using R and UNIX environments, to automatically analyse the data with three different types of datasets (all SNPs, 1 SNP/Contig, Haplotype Phasing) and estimate genetic parameters, such as expected (H_s) and observed (H_o) heterozygosity and the inbreeding coefficient (F_{IS}). The spatial structure of each species was investigated using the ConStruct R package. Values of the diversity statistics were regressed against geographical coordinates (while controlling for genetic structure), revealing those that showed statistically significant geographical patterns. Consistent trends with longitude and latitude were observed for both measures of mean and standard deviation of the genetic diversity parameters. Genetic diversity and inbreeding values at the genome-level presented an overall trend towards higher values in the south-east and lower values in the north-west. The geographic patterns of the estimated genetic parameters not only revealed significant trends, but also effectively highlighted populations with original gene pools. Our approach opens the way to more efficient *in situ* conservation and sustainable forest management decisions, especially in non-model, large genome conifer species, and when sampling effort is increased.

Geospatial population mapping and genomic research advancement in vulnerable Dalbergia latifolia

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Maneesh S. Bhandari[1]
Rama Kant[1], Shailesh Pandey[1], Tushal K. Srivastava[1], Rajendra K. Meena[1], Harish S. Ginwal[1]
[1] ICFRE-Forest Research Institute, Dehradun, Uttarakhand, India

Abstract: *Dalbergia latifolia* (Family: Fabaceae) is considered vulnerable (VU A1cd Ver. 3.1) to extinction according to the IUCN Red List. The heartwood is very hard, weighing about 850 kg m^{-3}, used to make premium-quality furniture, paneling, and veneers. It is distributed predominantly in deciduous forests of the Asian, African, and American subcontinents and has gained acceptance as an agroforestry tree variety, possessing luxury wood traits. The *D. latifolia* population and ecological distribution are scarce in the wild, and there is limited availability of baseline genetic information and genomic data. Surveys were conducted in the northern, central, and southern Indian forest divisions to reveal their population structure and generate geo-tag maps for exotic and indigenous ranges. There are 50–80 trees, with an average of ~35 showing a restricted distribution of *D. latifolia*, with plantation forests comprising more than 200 trees. The tree height (5–40 m; av=~25 m) and girth at breast height (0.15–5.40 m; av=~0.65 m) data across different divisions, it was noted that fruiting occurs non-synchronously and location-specific. In the genomic data analysis, low-depth next-generation sequencing (NGS) of *D. latifolia* yielded 13.33 Gb raw data with 21x coverage on the Illumina high-throughput platform. The developed *de novo* assembly has a total read length of 8,88,65,132 with ~619 Mbp genome size covered in 4,45,006 contigs, with an average size of 150 bp. Assembly has N50 and L50 values of 2,873 and 50,876, respectively. Through MISA, a total of 1,05,226 SSRs were identified in 4,45,006 contigs with 66,407 designed SSRs. Di-nucleotide SSRs were the most abundant motif 69.31%, followed by tri- 27.57%, tetra- 2.47%), penta- 0.48%), and hexa-nucleotide 0.17%) repeats. Furthermore, BUSCO analysis revealed ~67% completed and single copy expected gene content of a genome assembly. The contigs were used to predict genes using Augustus, which showed 1,25,658 for each protein, CDS, and mRNA. KEGG and COG annotations were obtained by submitting the protein sequences of each sample to KAAS and WebMGA, respectively. Overall, research work enriched *D. latifolia* basic knowledge of germplasm availability and applied biotechnological aspects for long-term tree improvement to fulfil the timber demand across the globe.

Inferring molecular signatures of climate adaptation in Santalum album (Indian sandalwood) using landscape genomics approach

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Modhumita Ghosh Dasgupta[1]
Eswaran Muthulakshmi[1], Thangaraj Karthick[1], Aiyar Balasubramanian[1], Suma Arun Dev[2], Swathi Balakrishnan[2], Kandasamy Ulaganathan[3]
[1] ICFRE-Institute of Forest Genetics and Tree Breeding, Coimbatore, Tamil Nadu, India
[2] Kerala Forest Research Institute Peechi, Kerala, India
[3] Centre for Plant Molecular Biology, Osmania University, Hyderabad, Andhra Pradesh, India

Abstract: Natural selection is the driving force in determining the genetic makeup of populations over time, resulting in locally adapted genotypes with higher relative fitness in their resident environment. Identifying, monitoring and managing this locally adapted genetic variation is essential for conservation and genetic improvement programs. *Santalum album* L. (commonly known as Indian sandalwood) is one of the most over exploited tropical tree species due to its use in fragrance and essential oil industries and is an invaluable commodity in international trade. The species is approaching commercial extinction due to illegal harvest, lack of natural and artificial regeneration, habitat loss and sandal spike disease, resulting in erosion of gene pool and reduction in genetic diversity in the natural populations. However, understanding on genetic basis of adaptation is presently limited in sandalwood. Hence, a study was taken up to infer the adaptive potential in the species; document geographical patterns of genome-wide variations and predict environmentally adaptive alleles. Twenty three natural populations spanning 7 Indian states were surveyed and inter population variations in leaf functional traits, biochemical traits and leaf spectral indices were recorded. Low depth whole genome sequencing in 29 individuals predicted 1.1 million polymorphic SNPs and structure analysis revealed that natural population from Thiruvannamalai (Jawadhu hills) in Tamil Nadu was distinct from other populations. Mantel test and correlogram provided an evidence of a weak but significant correlation between genetic and geographic distances. Concurrently, outlier analysis predicted 667 outlier SNPs which were correlated with 19 bioclimatic variables. Association analysis predicted significant correlation of 667 outliers distributed across 57 scaffolds of *Santalum album* genome with 18 climatic variables with a p-value less than 0.001. Functional annotation of the environmentally associated outlier loci revealed that genes like HMG-CoA synthase from sesquiterpene pathway, strictosidine synthase, transcriptional regulator SLK2, RNA binding protein 18, heat stress transcription factor B-2a-like protein (*HsfB2a*), ubiquitin ligase SUD1 and zinc finger protein ZAT10 may govern climate adaption in sandalwood. Interestingly, ZAT10 harbored maximum outlier SNPs and was associated with several climatic variables. Overall, the study improves the current understanding on genomic basis of local adaptation in sandalwood.

Natural variation in birch as an untapped resource for tree research

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Kaisa Nieminen[1, 2]
[1] Natural Resources Institute Finland (Luke), Finland
[2] University of Helsinki, Finland

Abstract: We are currently developing on a novel resource for forest tree genetics. Our focus is on silver birch (*Betula pendula*), one of the most fast- growing, widely distributed, and economically important boreal hardwood trees. Silver birch has a small (440 Mbp; sequenced, assembled and annotated) diploid genome. Furthermore, birch flowering can be accelerated under greenhouse conditions, and already 2-year-old seedling can be induced to flower. We have thus far sequenced ca. 400 genotypes from both natural and breeding populations, and have been able to identify that over 10% of the annotated genes have potentially deleterious mutations (e.g. an early *STOP* codon) in the annotated genes (in a heterozygous state). We will cross-breed the trees that harbor these heterozygous mutations in the same gene, and/or back-cross the progeny trees from the mutants to their parent through an accelerated flowering approach. Our first goal is to verify this approach through producing homozygous mutant lines for known regulators of e.g. tree architecture, where we will be able to phenotype the branching pattern already in young trees. The opportunities are nearly unlimited, we may e.g. produce trees with a higher carbon sequestration effectiveness (through modified stomatal conductance), or trees producing less pollen allergens. Our ultimate aim is to develop a genetic tree resource similar to Arabidopsis, where people can order for their gene in interest a homogygous loss-of-function mutation genotype.

New Ideas on Genetic Conservation and Sustainable Management of Southeast Asia's Valuable Tropical Rainforests

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Wickneswari Ratnam[1]
[1] Academy of Sciences Malaysia

Abstract: The timber industry in Southeast Asia is a major contributor to regional economy but the connection between scientific research and application and development of policy is weak. Knowledge on the evolutionary biology of tropical rainforest trees and how management systems interact with these natural dynamics is critical for sustainable forestry. Understanding the historical dynamics of climate change, anthropogenic threats to genetic viability and the important role of wildlife in maintaining genetic diversity will promote a deeper appreciation of not only the economic value of forests but also their mystery and intangible values. Advanced intelligent systems, drone technology, 5G collars and sensors, and blockchain are some of the high-end advanced technologies that can be deployed for precise monitoring and predicting impacts of climate change and anthropogenic threats for timely mitigation measures.

Phylogenomic analyses shed new light on the spatiotemporal evolution of global larches: implications for the dynamics of boreal forests

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Xiao-Xin Wei[1]
Xiu-Fei Qiu[1], Yan-Yan Liu[2], Ge Wu[1], Cong-Hui Xu[1], Xiao-Yan Xiang[3]

[3] College of Life Sciences, Anqing Normal University, Anqing 246133, China

Abstract: Global warming is already causing significant impacts on forest ecosystems, threatening the ecosystem integrity and their component species. However, given the complex interactions between biotic and abiotic factors and migrational lags of forest trees, projecting the dynamics of forests is very challenging. Therefore, to understand the long-term dynamics of modern forests, knowledge of past forest changes is very essential to inform current predictions and conservation options. In this study, we reconstructed a highly resolved and robust phylogeny of *Larix*, a keystone genus of the boreal forests, using plastid genomes and 1301 orthologous genes (OGs) generated from transcriptomic data. On the basis of a solid phylogenetic framework, we investigated the spatiotemporal evolution of global larches and the determinants of species diversification. In sharp contrast to previously a genetic divide between the New World and the Old World or a morphology-based dichotomous classification of sects. *Larix* and *Multiserialis*, our results demonstrate a deep split between the high-latitude circumboreal and low-latitude QTP larches. Within each lineage, two geographically distinct clades were further resolved. Biogeographical analyses suggest that *Larix* might have an origin of Eocene high-latitude uplands in North America, and at the end of Eocene, it has expanded into the two sides of Beringia. Global climate deterioration starting from the late Eocene onwards, especially the sharp shift from greenhouse to icehouse climate at the Eocene–Oligocene Transition and the uplift of QTP played an important role in shaping its large-scale geographical pattern and species divergence. The evolutionary differences among the three keystone conifer genera (i.e., *Larix*, *Abies* and *Picea*) of boreal forests were also discussed, providing some clues of the origin and dynamics of the boreal forests. The proto-boreal forest probably had a relative old origin, at least prior to the early Miocene. As global temperature continuously declined, the composition of the proto-boreal biome was gradually winnowed and altered, resulting in the extant young and depauperate boreal forests. This work also confirms the significance of a robust phylogeny in study of evolutionary biogeography and accurate species delimitation and conservation.

Reference based genome assembly and comparative genomics in Calamus brandisii for identification of gender linked polymorphisms

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Muneera Parveen Abdul Bari[1]
Suma Arun Dev[2], Sarath Paremmal[2], Sreekumar V.B.[2], **Modhumita Ghosh Dasgupta**[1]
[1] ICFRE - Institute of Forest Genetics and Tree Breeding, Forest Campus, R.S. Puram, Coimbatore Pincode-641002, India
[2] Forest Genetics and Biotechnology Division, Kerala Forest Research Institute, Peechi P. O, Thrissur, Kerala 680653, India

Abstract: *Calamus brandisii* is an endangered rattan species indigenous to the Western Ghats of India. It is extensively extracted in the furniture and handicraft industries owing to its strength, durability, and elasticity. The dioecious nature and longer flowering time limit conservation in rattans. Hence, the development of markers for early gender detection in seedlings can facilitate and ensure viable populations for *in-situ/ex-situ* conservation. Presently, there are no reports of sex chromosomes or gender-specific genes in *C. brandisii*. Hence, the present study aimed to conduct comparative genomics between the male and female genomes of *C. brandisii* to identify polymorphism in gender-specific genes. The raw data of ~99 Gb and ~120 Gb was generated and reference-based male and female genome assemblies were ~1.96 Gb each with 5109 and 5112 scaffolds respectively. The haploid genome size predicted for male and female genomes was ~691 Mb and ~884 Mb respectively. The female genome had higher GC content (39.07%), heterozygosity rate (1.18%), and repeat elements (36.09%) when compared to the male genome. The male and female genomes were predicted to contain 39,276 and 47,949 protein-coding genes respectively. The male genome assembly was mapped to the female genome as a reference to predict the polymorphisms between the genomes. The variant calling predicted a total of 12,476,774 SNPs and 707,542 InDels across the genomes. Further, a total of nine gender-determining genes were mined from the draft genomes and sequence alignment predicted a total of 106 SNPs and 16 InDels in *TPP*, *NAC*, *KAS-III*, *FCMO*, *FCMO-3*, *ET01*, *YABBY*, *EST,* and *LOG*. The gender-specific variations in *Flavin-containing monooxygenase* (*FCMO*) and *FCMO-3* were validated in a limited number of male and female plants of *C. brandisii.* The identified gender-specific markers will aid in early gender determination for efficient restoration of the species and science-based conservation programmes. Future studies on the gender-biased genes linked to floral development will help to unravel the molecular mechanisms of dioecy in rattans.

Study of genetic diversity of forest trees in Czech Republic by microsatellite markers

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Pavlína Máchová[1]
Helena Cvrčková[1]
[1] Forestry and Game Management Research Institute, Strnady 136, 252 02 Jíloviště, Czech Republic

Abstract: With consequence of climate and environment changes are gaining importance one of the priority tasks under state forest policies of the Czech Republic, which is conserve biodiversity in forest ecosystems while promoting the principles of sustainable management. Determination of genetic variability in ecologically and economically valuable stands and populations is essential for the possibility of fulfilling this goal and international obligations. The Simple Sequence Repeats (SSR) method of DNA analyses were used to determine the genetic variability and diversity of selected forest tree species populations (Scots pine, Norway spruce, European beech, silver fir etc.) in the Czech Republic. PCR were optimized with the selected polymorphic specific primers. The data from fragmentation analyses were processing by the statistical programs (GenAlEx, Structure etc.) to obtained genetic characteristics, especially an overview of the level of genetic diversity, heterozygosity, genetic differentiation genetic compositions and genetic distance between forest tree species populations. Based on analyses of nuclear microsatellite loci, a relatively high degree of diversity was shown in the monitored populations of forest tree species. The representation of heterozygotes in the populations ranged from 56 to 82%. Spruce populations appeared to be the most polymorphic and differentiation between ecotypes was detected, too. The differentiations between the populations were not negligible and thus indicate the structuring of valuable regional populations. Significant differences between populations of individual species were manifested in the frequency of representation of specific alleles. The genetic distances in the evaluated populations of Norway spruce and white fir corresponded approximately to the geographical distances. For the other observed species, the dependence between genetic and geographical distances was low or very low for European beech, oaks and Scots pine. The Scots pine marginal populations located on serpentines was clearly separated by the others. The genetic diversity of forest trees is crucial for adaptation of forest to climate change and for sustaining forest ecosystems. Knowledge based on DNA analyses regarding the variability of genetic resources will contribute to the quality of the reproduction material and to creating optimal species composition in forests.

Supported by the Ministry of Agriculture of the Czech Republic (Institutional Support MZE-RO0123).

The central-periphery hypothesis as applied to some European forest tree populations

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

FILIPPOS ARAVANOPOULOS

[3] 3Institute of Plant Breeding and Genetic Resources, Hellenic Agricultural Organization (ELGO), 57001, Thessaloniki-Thermi, Greece

Abstract: According to the central-periphery hypothesis, marginal populations should be less genetically diverse and be more genetically differentiated, than core ones. Regarding forest trees, this pattern has generally been considered as the norm. Nevertheless, there has been an accumulating line of evidence suggesting that an increasing number of species do not follow this model. In this work, several results are presented that consider the amount and structure of genetic diversity in marginal forest tree populations of south-eastern Europe *vis-à-vis* central European populations, for *Abies alba*, *Alnus glutinosa, Betula pendula, Fagus sylvatica, Quercus petraea, Picea abies* and *Prunus avium*. These results are largely non-concordant with the central-periphery hypothesis. The roles of historical events, such as glacial - interglacial cycles, long-term rotations of migrations cycles, position of refugial and post-glacial range expansion areas, and of different species characteristics (gymnosperms vs. angiosperms, stand-forming vs. scattered, temperate vs. boreal, hybridizing vs. non-hybridizing), in shaping extant genetic diversity and structure, are examined . Discussion focuses both concerning the results observed and in terms of the application of the hypothesis in general.

Understanding genetic correlations and trade-offs of fire adaptive traits in a Mediterranean conifer: key for more resilient management strategies

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Ruth C. Martín-Sanz[1, 2]

[3] Institute of Forest Sciences (ICIFOR-INIA), CSIC. Madrid, Spain

Abstract: Life history theory assumes that there are trade-offs between life functions, expressed as costs in terms of survival, growth, and reproduction. Both individual tree and population fitness depend on different characteristic interactions, which are also highly dependent on the environment. Genetic correlations measure the shared genetic effect between two traits in a given population, but they can differ depending on multiple factors such as population, environment, age, selective pressure, etc. Genotype-environment interactions may also influence the expression of trade-offs since the magnitude of plasticity may be heterogeneous among different traits and, therefore, correlations among traits may disappear or even change sign depending on the context. In recent years, there has been a growing interest in fire adaptive traits in forest species, mainly due to the new conditions of fire frequency and intensity in many parts of the world. Different studies have shown that fire adaptive traits vary among species under different fire regimes. However, there are hardly any studies carried out on forest genetic trials with a genetic structure as suitable as provenance-progeny trials. Our previous studies using provenance-progeny common garden experiments of *Pinus halepensis* have shown the existence of genetic variation within populations with moderate heritability for serotiny degree. Moreover, we found trade-offs between serotiny degree and bark thickness, since the first is associated with abundant post-fire recruitment and the second with greater survival of adult trees in the face of low-medium intensity fires. In addition, we found that these key fire adaptive traits are environment-dependent: low water availability decreases both serotiny degree, bark allocation, and absolute bark thickness in *P. halepensis*. Our objective is to (1) determine whether there are genetic correlations among fire adaptive traits on this species, and with other vital traits, and (2) verify if these traits respond equally or with changed-sign among and within provenances of *P. halepensis*.

WILDOBST: Using Genetics to Inform Conservation

T3.17 Genomics of Keystone and Underused Forest Genetic Resources for Their Climate Adaptation, Resilience, Conservation and Sustainable Management

Lila Afifi[1, 2]
Katharina Lapin[1], Karin Tremetsberger[2], Heino Konrad[1]
[1] Department Forest Biodiversity and Nature Conservation, Federal Research & Training Center for Forests, Natural Hazards & Landscape, Vienna, Austria
[2] Institute of Botany, Department of Integrative Biology and Biodiversity Research, University of Natural Resources and Life Sciences, Vienna, Austria

Abstract: As climate change progresses, so does our need to bolster forest resilience in order to lessen the burden of climate change in the future. So too, does our need to maintain the genetic diversity of drought resistant species capable of acting as ecosystem anchors. The WILDOBST project focuses on understanding just that: the genetic diversity and connectivity of scattered Rosaceae trees that are projected to expand their range as climate change continues. The focal species of this project are Sorbus torminalis, S. domestica, and Pyrus pyraster, all of which are light-dependent, tolerant species with high economic and environmental value. However, all of these species currently exist in Austria in small, scattered populations and are never the dominant forest species. With such a scattered distribution it is unlikely that the functional connectivity of these species is adequate to maintain healthy genetic diversity levels into the future. In this project we analyzed the genetic diversity, population structure, gene flow, and spatial genetic structure of each of the three species in order to understand not only the levels of structural and functional connectivity that exist across Austria but also to identify which populations may be of higher conservation priority. Using the insights from this analysis we will be able to provide more targeted conservation and management plans for foresters and forest owners across Austria with applications across the broader European region.

T3.18 Improving biosecurity measures to better protect forests

Detection of viable Phytophthora and other oomycetes from soil using eRNA and its potential use a diagnostic tool

T3.18 Improving biosecurity measures to better protect forests

Rebecca McDougal[1, 2]
Preeti Panda[2, 3], Renelle O'Neill[1], Darryl Herron[1, 2], Simon Bulman[2, 3]

[2] Better Border Biosecurity (B3), New Zealand
[3] The New Zealand Institute for Plant and Food Research Ltd., Lincoln, New Zealand

Abstract: High-throughput DNA sequencing (HTS) of environmental RNA (eRNA) can provide information on soil communities that differ from those observed with environmental DNA (eDNA). RNA has a very short half-life compared to DNA and is found in living and active organisms, whereas DNA can persist in environmental samples long after an organism has died. In this way, eRNA gives a snapshot of the living organisms in an environment which may be more biologically relevant than relying on eDNA. In a warming climate it has been predicted that fungal pathogens will increase in prevalence, including soil-borne pathogens. Detection of soilborne pathogens is hampered by inefficient and often ineffective diagnostics which rely heavily on soil baiting, can take weeks to perform, and do not provide an accurate diagnosis when unculturable organisms are involved. These essential tools underpin current and future biosecurity systems. In this study comparative eDNA/eRNA HTS approach was employed to determine the diversity and viability of *Phytophthora* species and other oomycetes following fumigation of a *Pinus radiata* nursery bed. These results were compared to those from soil baiting. We found that the detected oomycete populations differed between eRNA, eDNA and soil baiting. Notably, some *Phytophthora* were detected in the eRNA samples that were not detected in the eDNA. In addition, this study revealed that soil fumigation was not completely effective at eliminating oomycetes from nursery soil. This work demonstrated the utility of eRNA for identifying viable oomycetes in environmental samples. This will be expanded upon to develop new and much needed tools for soil diagnostics. Innovate new tools will contribute to earlier detection and improved risk assessment of pathogens leading to better outcomes for healthier forests.

Emerging pathogens in urban forests in Germany causing an increased safety risk due to stem and branch cankers

T3.18 Improving biosecurity measures to better protect forests

Kathrin Blumenstein[1]
Yasin Korkmaz[1]
[1] Chair of Pathology of Trees, Institute of Forestry, Faculty of Environment and Natural Resources, University of Freiburg, Bertoldstr. 17, 79098 Freiburg, Germany

Abstract: Raising temperatures, less precipitation, and more extreme weather events cause trees to suffer from stress, such as drought. While the trees invest their energy in compensating for suboptimal conditions, they weaken the host tree, making it more susceptible to pest and pathogen infections.

On the other hand, insects, invertebrates, and microorganisms are emerging in areas with warmer climates, finding ideal conditions to infest and infect host trees that are too weak to defend themselves, thus becoming highly susceptible.

Starting early in 2023, red-colored bleeding cankers have been detected in various cities in Germany, primarily affecting plane trees. The symptoms of the stem and branch cankers are caused by a combination of bacteria and fungal pathogens originating from warmer climate areas, insects and invertebrates. Plane trees in urban areas undergo regular pruning measures, and observations suggest a correlation between these cuttings and increased bleeding. Raising awareness about the importance of using disinfected pruning tools may be crucial in preventing the further spread of these symptoms.

Additionally, there has been a concerning increase in stem cankers among urban tree species such as Yew Tree, Maple, Beech, and Horse Chestnuts in recent years. Wood density measurements have linked decay to the canker symptoms. The isolated fungi belong to atypical genera in relation to their corresponding host trees, indicating a broadening infection spectrum of fungal species expanding into new areas.

From a safety standpoint, close monitoring is crucial for identifying initial indications of fungal infections, as fungi often remain latent within their hosts and are not visible from the outside, posing a safety risk. When environmental conditions change, their lifestyle switches to pathogenic, and they begin to degrade the wood inside their hosts. Only in the later stages do cankers appear in the stem, indicating the unstable condition of the host trees.

These findings underscore the importance of closely monitoring urban forest trees to identify potential safety risks in a timely manner.

Landscape configuration matters in the spread of invasive tree pests

T3.18 Improving biosecurity measures to better protect forests

Manuela Branco[1]
Pedro Nunes[1], Christelle Robinet[2], José Carlos Franco[1], Mario Santos[3], **Luis Bonifacio**[4], Inge van Halder[5], Hervé Jactel[5]

[4] INIAV, Portugal
[5] INRAe, BIOGECO, Pierroton, Bordeaux, France

Abstract: The risk posed by invasive pest species is so great for the vitality and functioning of forest ecosystems that makes it urgent to study all the measures to prevent their introduction to new areas or limit their spread. While the initial stages of invasion are particularly targeted by biosecurity measures, the epidemic propagation phase is often less well addressed. And yet a better understanding and prediction of the behaviour and rate of spread of invasive species is invaluable in predicting areas at risk of invasion, optimising the application of surveillance tools and trying to slow their spread. Simulation models are used for these purposes, often based on reaction-diffusion principles, but they rarely take into account the structure and composition of the landscapes crossed by the invasive species. We hypothesised that the proportion of host and non-host plants and their spatial distribution could either speed up or slow down the invasive species spread. We tested this hypothesis on two cases in Europe: the pinewood nematode and its insect vector *Monochamus galloprovincialis*, and the African citrus psyllid *Trioza erytreae*. By using mark-release-recapture data experiments and spread models, we were able to compare spread rates in homogeneous and heterogeneous landscapes. For *M. galloprovinciallis*, the results obtained showed that the presence of patches of non-host tree species, slowed down their flight dispersal and increased their risk of mortality. We also found that isolated host trees in urban and peri-urban areas were likely used as stepping-stones by the African citrus psyllid, accelerating its dispersal. These results suggest that explicitly considering the effects of the distribution of host and non-host trees on insect dispersal in the landscape can improve our understanding of processes and the accuracy of range expansion models, making them more useful for the monitoring and control of invasive tree species.

The challenge of managing an alien invasive forest insect pest-a successful case of classical biological control in Croatia

T3.18 Improving biosecurity measures to better protect forests

Dinka Matosevic[1]
Nikola Zoric[1]
[1] Croatian Forest Research Institute, Jastrebarsko, Croatia

Abstract: Classical biological control against invasive forest pests is sustainable pest management solution in large natural forests and protected forest ecosystems. Introduction and use of classical biocontrol agent *Torymus sinensis* (Hymenoptera; Torymidae) for control of invasive sweet chestnut gall wasp *Dryocosmus kuriphillus* (hymenoptera; Cynipidae) is one of recent examples of effective strategy to control a highly invasive forest pest in Europe. *T. sinensis* is a univoltine, host specific parasitoid, phenologically synchronized and morphologically adapted to *D. kuriphilus*. *T. sinensis* has good dispersal ability, builds up populations quickly and effectively controls the pest already few years after the release. Seven years after first releases and natural dispersal in Croatia, we have evaluated the impact of this classical biocontrol agent on invasive population of *D. kuriphilus*. *T. sinensis* has shown traits of very effective biocontrol agent: the methods for raising and release are not difficult to apply, it disperses very quickly when released, it lowers the population of its host for more than 90% in only few years, suffers no bottleneck -induced founder effect phenomenon and leads to recovery of chestnut vigour and yield in natural sweet chestnut forests. Seven years after first releases, an ecological equilibrium between the pest and classical biocontrol agent has been reached. In the last few years mismatch between *T. sinensis* adult emergence and the gall formation on chestnut trees has been observed that has been caused by warmer winter temperatures caused by climate change. This has caused resurgence of insect pest infestations and absence of parasitoid regulation.

Using reproductive ecology to guide the selection and release of biological control agents within forest ecosystems

T3.18 Improving biosecurity measures to better protect forests

Josephine Queffelec[1]
Martin Lukas Seehausen[2], Kevin Dodds[3], Bernard Slippers[4], Jeremy D. Allison[1, 5]
[1] Natural Resources Canada, Canadian Forest Service, Canada
[2] CAB International, Switzerland
[3] USDA Forest Service, Forest Health Protection, USA
[4] Forestry and Agricultural Biotechnology Institute, South Africa
[5] Department of Zoology and Entomology, University of Pretoria, South Africa

Abstract: Classical biological control is defined as the intentional introduction of predatory and parasitic alien species to control invasive organisms. Even though classical biological control has been a popular regulation tactic for decades, the success rates of these programs is not showing significant increase. In fact, many introduced agents either never establish, or fail to regulate the target population. In plants, reproductive biology is recognised as a reliable predictor of establishment capacity as it influences generation time, genetic diversity, or the capacity of single individuals to start new populations. As such, reproductive biology is regularly considered for risk assessment and management of invasive plants. However, while insects exhibit a wide range of reproductive traits (i.e., embryogenesis, sex determination, reproductive parasites, mating behaviors or mate choice strategies), the effects of these strategies on establishment and spread are still misunderstood. The BIOCAT2010 database is the largest database of information on biological control programs globally. By cross referencing information available in the database on the establishment success of biological control agents with information available in the literature regarding their reproductive traits, we aim to construct a predictive framework to guide the selection and release of insect biological control agents in forest ecosystems.

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

A global alliance for assisted natural regeneration: generating and sharing knowledge, advocacy, and technical support

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Robin Chazdon[1, 2]
Carlos Alberto de Mattos Scaramuzza[3, 4], Mariana Oliveira[5]
[1] Tropical Forests and People Research Centre, University of the Sunshine Coast, Queensland, AU

[3] Department of Geography and Environment, Pontifical Catholic University of Rio de Janeiro, Brasil
[4] International Institute for Sustainability, Rio de Janeiro, Brasil
[5] World Resources Institute, Brasil

Abstract: The Assisted Natural Regeneration (ANR) Alliance[1] was created in 2022 to stimulate wide adoption and provide technical and policy guidance for ANR as a low-cost and effective restoration practice in rural communities across the world. Although ANR has strong links to agriculture, forestry, conservation, climate change mitigation and adaptation and sustainable development, it is not formally integrated into these sectors and lacks adequate financial support from donors, investors, and governments. Currently, the ANR "community" is highly fragmented across disciplines, sectors, and geographic regions with no unifying support platform. The ANR Alliance is an international and multisectoral coalition to promote the exchange of knowledge and experiences between countries, regions and stakeholders to support the technical and political adoption of ANR as a strategic restoration methodology aligned with sustainable development**,** integrated landscape management and forest landscape restoration. The governance structure includes membership of individuals, organizations, and partnerships with other networks. The ANR Alliance provides a vehicle to identify and address key challenges and opportunities, synthesize information and propose solutions and actions at subnational, national and international scales and to raise awareness of issues of common interest within regions and around the world. The ANR Alliance is composed of three regional nodes in Asia-Pacific, Africa, and Latin America-Caribbean, global leadership with support of regional co-leaders team and an administrative secretariat hosted by World Resources Institute, Colombia. A series of virtual workshops held in 2023 engaged 130 ANR stakeholders, including implementers, practitioners, researchers, and decision-makers. Regional workshops provided input for a five-year action plan under participative development orientated to explore window opportunities and overcome challenges. The ANR Alliance will collaborate with other networks, restoration and nature-based solutions initiatives that intersect in their focus on ANR. Activities organized by the ANR Alliance will include presentations at international, national and subnational conferences, workshops, webinars, synthesis workshops for working groups, training opportunities, fundraising support, R&D coordination, cost-benefit analysis, development of an ANR hub and document archive, policy briefs and blogs, and study tours.

[1] Support for initiating the ANR Alliance was provided by a grant from the Norway Climate Fund to World Resources Institute

A mix of active and passive restoration improves early-stage succession after forest fire in Brandenburg, Germany

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Katrin Fröhlich[1]
Johanna Gaber[1], Somidh Saha[1]
[1] Karlsruhe Institute of Technology, ITAS, 76133 Karlsruhe, Germany

Abstract: Climate change is leading to an increase in forest fires in Germany. Restoration of disturbed areas and forest stands is equally affected by climate change impacts and land use intentions. As functioning forest ecosystems also mitigate the effects of climate change, restoration of a value-creating forest stand becomes a challenge. To date, fire-damaged forest stands in Germany have been actively and artificialy restored, primarily through full clearing, leaving a completely empty area. With application of such fully active and artificial approaches foresters and land-owner intend to increase control over future forest structure. However, since these areas are particularly exposed to extreme weather conditions and erosion, the success of regeneration and target tree plantings is at stake. To improve reforestation of fire-damaged forests, knowledge of the processes of early succession and the effects of different restoration measures on plant communities in temperate forests is needed. Early successional communities set the basis for forest regeneration and are formed by both mosses and herbaceous plants that pioneer in fire-damaged areas, followed by pioneer tree species like poplar trees. In order to investigate short term effects of artificial and natural restoration practices on early stage succession, we studied plant communities that underwent passive, purely active (full clearing), and combined restoration actions three years after a forest fire in Brandenburg, Germany. Our inventory of early successional plant communities revealed the effects of applied restoration measures on the respective communities. Diversity and abundance of vegetation increased from active (artificial) to passive (natural) restoration approaches in fire-damaged forest stands. Nonmetric multidimensional scaling indicated an increase in vegetation diversity and from active to passive restoration gradient. Furthermore, examination of the functional characteristics of the vegetation layer in areas under combined restoration revealed particularly short-lived herbaceous species that can be used for topsoil regeneration but also for the introduction of target tree species. Overall, we conclude that a combination of active and passive restoration measures, such as partial clearing and site preparation in small-scale sections, can mitigate vegetation diversity loss while promoting restoration success.

Advances in fostering natural regeneration in the Eastern Brazilian Amazon

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Joice Nunes Ferreira[1]
Danielle Celentano[2], Andreia Pinto[3], **Mariana Oliveira**[4], Robin Chazdon[5]

[5] Tropical Forests and People Research Centre, University of the Sunshine Coast, Queensland, Australia

Abstract: Naturally regenerating forests are a promising strategy for large-scale restoration of tropical areas in the Brazilian Amazon, given its high natural propensity for regeneration and low intensity of land use following recent deforestation. By 2019, 7.2 million ha of secondary forests (≥ 6 years old) regrew following land abandonment and poor management across the Brazilian Amazon, of which 5.2 million ha are on land unsuitable for agriculture. Regenerating areas are often cleared within 5–10 years of regrowth, emphasizing the urgent need to strengthen protection.

Recent actions and articulations demonstrate some progress towards the valuation of secondary forests as a restoration strategy in the Eastern Brazilian Amazon. Pará state, which holds 42% of Amazonia's secondary forests, passed two pieces of legislation to protect regenerating forests in more advanced stages of succession. In 2020, Pará launched the Amazônia Agora State Plan (PEAA), with an aim of net zero greenhouse gas emissions. To meet this target, the State of Pará is following a strategy to regenerate 5.65 million ha of secondary forests, along with a reduction in deforestation. A state plan is being designed to guide forest restoration more broadly. Opportunities for protecting natural regeneration from the rules set by the national forest legislation are advancing slowly in most Amazonian states.

New programs led by NGOs focus on capacity building, material support, and technical assistance to help landowners and communities apply assisted natural regeneration toward deficits in legal reserves and permanent protection areas in compliance with national policies. The FloreSer Platform mapped secondary forests in the Amazon to guide decision making, the multi-institutional Alliance for Restoration in the Amazon is conducting a social network analysis of restoration, and WRI Brazil is offering field-based training workshops with Landless Movement (MST) settlements provide technical assistance on how to manage regenerating vegetation and agroforestry in their land holdings. Imazon's Floresta para Sempre project supports family farmers in southeast Pará with agroforestry and implementation of assisted natural regeneration approaches for environmental and productive restoration. The ANR Alliance aims to promote wide implementation of ANR interventions across Amazonia and globally through integrating practice, policy and scientific research.

Drivers of colonization, species richness, and structural variation during the initial three decades of natural forest colonization in abandoned soils

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Nané Køllgaard Pedersen[1]
Sebastian Kepfer-Rojas[1], **Inger Kappel Schmidt**[1]
[1] University of Copenhagen

Abstract: Natural colonization of abandoned agricultural soils has been proposed as a cost-effective strategy for simultaneously mitigating the climate crisis, restoring ecological integrity, and promoting the re-establishment of native biodiversity. The success and speed at which forests develop in the presence of land-use legacies are highly variable, and empirical knowledge on the drivers of the initial phase of temperate forest colonization in a range of site conditions is lacking. We analyzed and compared drivers of the initial three decades of natural forest colonization in 33 afforestation sites laid out between 1990 and 2018, in Denmark. We analyzed how the age of colonization, size of the area, soil type, topography, and abundance of neighboring woody vegetation influenced woody vegetation cover, species richness, and variation in vegetation structure of the colonizing woody species. We found that woody vegetation cover, species richness, and structural variation increased significantly with time since abandonment. Woody vegetation cover was significantly higher in sites with abundant neighboring vegetation and on loamy soils compared to sand or clay. Woody vegetation cover tended to be higher in sites with sloping terrain. Species richness increased significantly in sites with loamy or clay soil and sites with sloping terrain. After accounting for the other drivers, none of the elements were influenced by the size of the area. The results suggest that time since abandonment, neighboring mature

woody vegetation, soil and topography are key drivers of the different elements of

colonization. This knowledge can be used to prioritize areas for natural regeneration.
The presentation will suggest active afforestation methods and designs depending on if the aims are production, stability or biodiversity.

Effect of selective cutting on natural regeneration of oak in mixed structurally complex forest in southern Sweden

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Nora Pohl[1]

[3] Norwegian Institute for Nature Research, NINA, Songsveien 68, 0855 Oslo, Norway

Abstract: There is a worldwide crisis regarding biodiversity loss and ecosystem degradation, with serious implications for the capacity of biodiversity to meet increased needs of resilience and ecosystem services in the future. Oak-dominated and mixed oak forest are widely distributed across Eurasia and North America. However, despite their importance as foundational species for many ecosystems, oak dominance is declining worldwide. One of the main explanation for the decline in oak forests is failure in oak regeneration and its inability to grow and reach into the overstory. So far, research has focused on influences of e.g. browsing and fire on the early stages of natural regeneration. Thus, there is a knowledge gap regarding the stand structures and light conditions necessary for the regeneration layer to develop into the canopy. We analysed stand structural complexity in mixed oak-dominated forests across Southern Sweden with regards to change in light availability, competition of surroundings and the recruitment of the natural regenerated oaks into the canopy. For this, twelve experimental sites in 60-80 years old, mixed broadleaved forests were used. They all originated from abandoned pastures and at each site, one treatment (selective cutting) and one control plot (no intervention) were installed. The treatment was carried out in winter 2016/2017 in one hectare plots, and about 25 % of the basal area was removed. Early results suggest that selective cutting enhances the recruitment of seedlings and small diameter oak trees while larger oak trees are unaffected. Additional analyses will enable us to answer questions concerning the most favourable stand structures to sustaining growth and recruitment of natural oak regeneration into the canopy. Further, results of this research will be foundational to develop practical guidelines for managing stand structures to create and sustain critical, oak-dominated habitats valued for biodiversity conservation.

Effects of Land Restoration Activities on Productive Land Access and Women's Participation in Rural Kenya

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Yoonho Cho[1]
Jeongeun Son[1], Yaeji Hwang[1]
[1] World Vision Korea

Abstract: The aim of this study is to assess the extent to which households have adopted a wider range of land restoration and management practices as a result of the rural Kenyan project. In addition, it aims to determine whether households that have implemented a greater number of land restoration and management activities have better access to productive land and higher levels of women participation compared to households that have implemented fewer activities.

We used repeated cross-sectional data collected from the rural Kenyan project to investigate the relationship between participation in training programs, awareness of climate change risks, 9 types of land restoration and management activities, household income, women's involvement in household and community, and access to productive lands among beneficiary households. Multiple linear regression analysis was conducted to test the association between those variables.

During the project, 250 community members, including 43 female-headed households and 207 maleheaded households, participated in land restoration and management activities such as tree planting, FMNR, invasive species removal, bare land rehabilitation, and agroforestry.

At the endline, 77.05% (n=141) of households had at least one member trained in land rehabilitation and management, compared to 18.38% (n=25) at the baseline. The training program focused on land rehabilitation and management activities, including FMNR, agroforestry, and women's participation. On average, program participants adopted three types of land rehabilitation and management activities, improving from 1.58 types at the baseline. Additionally, 42.3% of the land was productive or undergoing restoration, up from the baseline value of 29.79%. The women's participation score increased from 2.95 (in-house) and 2.58 (in the community) to 3.11 and 2.89, respectively.

A multiple regression analysis considered factors like the household head's gender and educational background, household size, climate change awareness, training program participation, agricultural income, women's involvement, and access to productive land. The analysis revealed that training program participation and types of land rehabilitation and management activities were significant factors contributing to increased productive land and women's participation score.

The results of this study could help NGOs and policymakers in developing and implementing effective approaches to tackle climate change and land degradation in rural Kenya.

Effects of reforestation and site preparation methods on early growth and survival of Scots pine (Pinus sylvestris L.) in south-eastern Poland

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

[1] Department of Forest Protection, Institute of Forest Sciences, Warsaw University of Life Sciences, Poland
[2] Department of Silviculture, Institute of Forest Sciences, Warsaw University of Life Sciences, Poland

Abstract: Successful tree regeneration is a key process in ensuring forest sustainability and one of the most crucial investments made in silviculture. This study compared the effects of three reforestation methods (planting, direct seeding, and natural regeneration) and three mechanical site preparation methods (double mould-board forest plough (FP); active plough (AP); and forest mill (FM)) on biometric parameters, survival, and density of Scots pine (*Pinus sylvestris* L.) seedlings in the first 4 years of growth in a clear-cut area in south-eastern Poland. Planted seedlings were higher, thicker in root collar, and had higher survival rates after the fourth growing season than trees from natural regeneration and direct seeding. Site preparation methods did not affect the density of planted seedlings. After natural regeneration and direct seeding, seedling density was lower and less homogeneous (plots with no seedlings) in FM soil preparation in comparison to other methods. The survival of pines in all reforestation methods was not affected significantly by site preparation methods. Our results indicate that the best mechanical site preparation method for planting is FM, as this is the one that least disturbs the soil environment. For direct seeding the best results were achieved after AP preparation. Natural regeneration of Scots pine was most effective after FP use, and in relatively wet years also after AP use.

Effects of thinning on growth and regeneration in threatened and socio-ecologically important southern African woodland ecosystems

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Werner Mbongo[1]
Magnus Löf[2], Ben du Toit[1]
[1] Department of Forest and Wood Science, Faculty of AgriSciences, Stellenbosch University, Private Bag X1, 7602 Matieland, South Africa
[2] Department of Southern Swedish Forest Research Centre, Faculty of Forest Sciences, Swedish University of Agricultural Sciences, P.O Box 190, SE-234 22 Lomma, Sweden

Abstract: The application of silviculture can contribute to the growth and productivity of forests and woodlands. Yet, active silvicultural practices are largely absent in southern African woodlands despite continuous decline and degradation. The absence of silvicultural practices is a consequence of a lack of knowledge and understanding of the growth patterns of these species-rich, and structurally diverse woodlands. Effects of an important silvicultural practice, namely thinning, on the growth and regeneration of socioeconomic and ecologically important woodland ecosystems in northern Namibia were investigated along a precipitation gradient. The thinning considered all wood utilization needs and encompassed all tree species and sizes. Growth and regeneration responses to thinning are assessed through measurements and statistical analyses of stem diameters at breast height of all trees equal to or larger than 5 cm, and the total number and heights of seedlings, saplings, and stump sprout shoots of the thinned-out (cut) trees.

Stand basal area growth increments correlated with rainfall. Growth responses to light and heavy thinning were more pronounced at the site with higher initial relative stand density, correspondingly averaging 24.0 – 52.6% more than the stand basal area growth increments of non-thinned stands. Tree recruitment represented an average of 27.2% of stand basal areas, of which 35.1 and 47.1% are correspondingly from light- and heavy-thinned stands in contrast to 17.8% from non-thinned stands. All cut tree species coppiced, with over 70% of all stumps having coppice shoots already on the first growing season following thinning implementation, averaging 5.3 shoots per sprouting stump. Height growth of coppice shoots averaged 50.2 and 64.4 cm annually for light and heavy thinning respectively. Seedling regeneration pattern was comparable across sites, abundantly pronounced in the 0 – 0.5 cm height class in the second and third growing seasons, averaging 49% more seedlings than in the first growing season. The amount of seedling regeneration in the 0 – 0.5 cm height class shows abundant regeneration patterns in light- and heavy-thinned stands, averaging 22 – 34 % more seedlings than in non-thinned stands. This intensive utilization-oriented thinning yielded encouraging results in these woodlands without compromising forest integrity but rather stimulating abundant coppicing and recruitment.

Forest regeneration after stand-replacing disturbances in the Italian Alps: regeneration dynamics and innovative approach for artificial restoration.

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Davide Marangon[1]
Claudio Betetto[1], Emanuele Lingua[1]
[1] University of Padova, dep TESAF

Abstract: Recently, we are witnessing changes in disturbance regimes mainly driven by climate change, that expose the ecosystems to compound or cascading disturbances. Alpine forests are highly sensitive, and such modifications affect forest ecosystem dynamics, structure, species composition, and consequently the provision of forest ecosystem services. It is thus important to restore as soon as possible the forest cover. In this scenario natural regeneration is considered the key factor in restoring forests: it covers large areas and is cost-effective. In some situation, it can be hard for natural regeneration to establish in short time. It is therefore important to deeply understand natural regeneration dynamics and drivers to create the best situation for regeneration to establish.

In this contribution, we analyzed the drivers of natural regeneration after stand-replacing disturbances in the Italian Dolomites. We focused on the role of site characteristics, soil cover, and deadwood in creating favorable microsites for regeneration establishment. Post-disturbance management strategies have been included in the analysis. The results show a negative correlation between the elevation and the seedlings' presence, as well as the increase in the distance from the green islands. High percentages of deadwood soil cover have a mulching effect lowering seedling establishment, while a high number of wood debris increases seedling occurrence. At microsite scale deadwood contributes to more favorable conditions for regeneration establishment, decreasing soil temperature and increasing the survival of planted seedlings. Deadwood presence moreover contributes to protect seedlings from browsing.

Understanding the drivers of natural regeneration in damaged stands helps define where the regeneration could have a better chance to establish. This information is valuable to decide the intervention strategies to mitigate the impact of natural disturbances on alpine forests. As a real case of an application, we present case studies from the project LIFE VAIA: the aim is to reduce the impacts of windstorms on forest and local communities, restoring damaged areas by implementing agroforestry practices (berry cultivation and bee breeding) within the afforestation sites. The restoration protocol is based on the concepts of applied nucleation and assisted regeneration, providing space to natural regeneration dynamics within the pilot site areas.

Gap-based Silviculture in Temperate Secondary Forests: From Standard to Application

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Deliang Lu[1, 2]

Abstract: Forest gaps, characterized as small- to medium-scale disturbances, are prevalent in forest ecosystems and play significant roles in driving forest dynamics. Due to their widespread occurrence, forest gaps have been used as a crucial silvicultural approach in forest restoration for several decades, including natural forest protection projects in China, close-to-nature silviculture or continuous cover forestry in Europe, and ecosystem management in North America. We systematically studied the temperate secondary forest in Northeast China, which originated from severe deforestation before the 1950s. Our study mainly focused on four aspects: (1) establishing objective standards for gap-related profiles; (2) quantifying the 3-D structure of forest gaps and the light environment within them; (3) examining natural regeneration and succession patterns and dynamics of main tree species after gap formation; and (4) assessing the potential for converting larch plantations into mixed stands through gap treatments. Various methodologies, including permanent plot monitoring, large-scale inventory, terrestrial laser scanning, and remote sensing imagery, were used during the study. Our research findings will advance gap-based silviculture and provide practical management guidance for restoring temperate secondary forests.

Guideline for the restoration of degraded and damaged forests in Germany with natural regeneration of pioneer tree species

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Katharina Tiebel[1]
Antje Karge[1], Sven Wagner[1]
[1] TU Dresden - Chair of Silviculture

Abstract: Large-scale damage of forests due to biotic and abiotic disturbance events have many negative ecological consequences for the forest ecosystem. The forest loss lead to the decoupling of water and nutrient cycles, the drastic alteration of habitats and species communities, and the reduction of functional processes and ecosystem services. Pre-forest structures of ecologically important pioneer tree species, which occur naturally as a result of succession processes, are able to mitigate the negative effects within short periods. They are also able of increasing the performance of degraded sites.

For this reason, a practical guideline was developed to help foresters to assess the probability of intense and vital regeneration of damaged areas by pioneer tree species *Alnus glutinosa*, *Betula pendula*, *Populus tremula*, *Salix caprea*, *Pinus sylvestris* and *Larix decidua* based on site conditions and regeneration ecology requirements. For site conditions, the most important parameters are information on the location, shape, size of the damaged area, climatic conditions, soil properties, previous stocking trees and seed tree locations. Regarding regeneration ecology requirements of the pioneer tree species, information on age and vitality of seed trees as well as species-specific knowledge on seed production, mast years, seed dispersal distances, seed longevity and microsite requirements are crucial parameters. Only on the basis of these parameters it can be assessed whether a specific damaged area can be completely or partially successfully natural regenerated or whether it needs support by artificial regeneration.

For example, *Betula pendula* trees can produce 0.6 to 10 million seeds depending on mast years and non-mast years. Seeds can be dispersed over 40 to 360 m depending on relief, wind direction and strength, whereas *Salix caprea* can produce high seed amounts of more than 22 million seeds more or less annually, which are dispersed over 200 m to 3 km regardless of wind direction, strength and relief. *Betula pendula* is able of building up a soil seed bank of up to 13 years, whereas *Salix caprea* can only regenerate from annual seed rain. *Betula pendula* seedlings proved to be significantly more drought stress resistant in the first year of growth than *Salix caprea* seedlings.

Modelling changes occurring in secondary succession silver birch stands (Betula Pendula roth.) on post-agricultural lands in central Poland

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Karol Bronisz[1]
Michał Zasada[1], Mike Strub[2], Chris J. Cieszewski[3], Szymon Bijak[1], Rafał Wojtan[1], Marta Aleksandrowicz-Trzcińska[1]

[3] University of Georgia, Athens, GA, USA

Abstract: Because of socioeconomic changes in Central Europe, many farmers abandon their farms, which subsequently are overgrown by forest pioneer tree species, such as silver birch (Betula pendula). Despite the significant scale of this phenomenon, its impact and future scope are unknown; therefore, research studying the production capacity of the young birch stands growing on post-agricultural lands is vital. We intend to develop a whole-stand model for the new young birch stands encroaching on agricultural areas. The model will help to predict future growth and yield of the new birch populations based on their stand-level attributes. The data for the proposed model development comes from 120 pure silver birch stands growing on former agricultural lands in central Poland. We have performed no silvicultural treatments preceding the plot measurements. Stands' ages vary from 1 to 19 years. Each plot is about 200 trees and their sizes vary from 4 to 731 m2, depending on stand age and density. Because of the relatively simple structure of young silver birch stands, we used the whole stand model approach to describe the dynamics of the pioneering birch ecosystems. The main state variables are dominant height and number of trees per hectare. The interim sub-models cover the competition index, the development of quadratic mean diameter, volume, and the aboveground biomass based on biomass expansion factors. We test several functions in model development and evaluate the results using such fit statistics as the sum of square residuals (SSE), residual mean square error (RMSE), mean error (ME), and coefficient of determination (R2). Validation of the model is based on repeated K-fold cross-validation. We have carried all analyses out in R software.

Natural regeneration of main forest species in Romania: approaches, best practices, limits

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Valeriu-Norocel Nicolescu[1]
Cornelia Buzatu-Goanță[2]
[1] Transylvania University of Brasov, Faculty of Silviculture and Forest Engineering, Brasov, Romania
[2] Banat's University of Agricultural Sciences and Veterinary Medicine "King Michael I of Romania", Faculty of Horticulture and Forestry, Timisoara, Romania

Abstract: Romanian forests (about 6.6 milion hectares) are dominated by broadleaves (74% of total forest area, of which European beech *Fagus sylvatica* cover 32%, and oaks - predominantly sessile oak *Quercus petraea* and pedunculate oak *Q. robur* - cover 18%), found predominantly in mixed stands. Conifers cover 26% of national forestland, of which Norway spruce *Picea abies* (19%) and silver fir *Abies alba* (5%) are the most important forest species, and are found in both mixed and pure stands.

Over 90% of Romanian forests are regenerated naturally by seed (high forests), and only about 5% of them (forests of black locust *Robinia pseudoacacia*, native poplars *Populus* spp., native willows *Salix* spp., and alders *Alnus* spp.) are treated as coppice and regenerated by stump stools or root suckers. Less than 5% of the forests (with Norway spruce, pines *Pinus* spp., and European larch *Larix decidua*) are regenerated artificially by planting, after small-scale (maximum 3 hectares) clearfelling. On a small scale (when the natural regeneration by seed is not complete or enrichment of regeneration with non-existing valuable species, predominantly native, is targeted), planting is complementary to natural regeneration.

The natural regeneration by seed is achieved mostly through silvicultural systems providing the establishment of main forest species under shelter (e.g., single-tree and group selection system, irregular shelterwood system, uniform and group shelterwood system).

Based on such background, the paper will show the main features of natural regeneration of most important forest species in Romania, focusing on both advantages of this regeneration method as well as the specific challenges such as rare seed years (case of pedunculate oak), high competition of admixed and competitive tree species, threatening the survival and early growth of most important ones, low inner accessibility of stands, increasing the logging damages to the established regeneration, shortage and high cost of labour for silvicultural interventions in young stands, etc.

Natural regeneration of Quercus via a multi-phased shelterwood in eastern upland hardwood forests, USA

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Callie Schweitzer[1]
Jared Calvert[1], **Stacy Clark**[1], Jacob Royse[1]
[1] USDA Forest Service

Abstract: The Heathy Forests Restoration Act of 2003 spurred a long-term study in the Cold Hill area of the London Ranger District on the Daniel Boone National Forest (DBNF), KY. USA. This study included regeneration and intermediate stand treatments to assess silvicultural prescriptions designed to curtail susceptibility and vulnerability of *Quercus*-dominated stands from spongy moth and *Quercus* decline. One treatment targeted recruitment of natural *Quercus* reproduction using a multi-phased shelterwood. In 2006, midstory stems of non-desirable species in six stands were deadened with an herbicide to improve understory light conditions for *Quercus* growth. Ten-years post-treatment, competitive *Quercus* reproduction, those 1.2 m tall up to 3.8 cm DBH, increased to 66 stems per ha. In this same size class *Acer rubrum*, a less-desirable species, increased to over 114 stems per ha. We did a pre-harvest "site preparation for natural regeneration" treatment in 2019 (cut-surface herbicide treatment of *Acer rubrum* stems) prior to a commercial harvest in 2020 that retained 5.7 square m of basal area per ha. *Quercus* reproduction two growing seasons post-harvest release showed significant increases in stem densities across all reproductive size classes, from 1,1105 stems per ha to 3,436 stems per ha, but the largest stem sizes were only 58 stems per ha. Concurrent increases in *Acer rubrum* occurred, and competitive *Acer rubrum* dominated the reproduction cohort at 197 stems per ha. Applying these intensive prescriptions at the stand-level is predicated on plot-level studies that showed promise for *Quercus* reproductive success. However contemporary upland hardwood stands in the eastern United States have remained undisturbed for over 50 years, creating closed-canopy conditions, and promoting the establishment of a robust mesophytic understory, including *Acer rubrum*. Sustaining *Quercus* dominance in these forests will require herculean efforts.

Naturally regenerating the primary southern pines of the United States

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Don Bragg[1]
John Willis[1], **Ajay Sharma**[1]
[1] U.S. Department of Agriculture, Forest Service, Southern Research Station

Abstract: While many see forestry in the southeastern United States as driven by large-scale plantings of loblolly pine (*Pinus taeda*), most pine-dominated forests in this region are still regenerated naturally. Over a century of work has been dedicated to the development of naturally regenerated silvicultural systems for the four primary southern pines (loblolly, longleaf (*Pinus palustris*), shortleaf (*Pinus echinata*), and slash (*Pinus elliottii*)). While the earliest such investigations included both even- and uneven-aged silviculture, by the mid-20th century interest focused more on even-aged systems to better accommodate the relative shade intolerance of southern pines and landowners' desire for higher stocking levels. The success of these silvicultural systems suggests a high degree of functional similarity among southern pines; however, decades of research have identified important differences in life history traits that strongly influence treatment effectiveness. For example, seedling establishment of all southern pines generally improves following prescribed fire due to the creation of favorable seedbeds. Yet southern pine response to fire in the early developmental stages varies widely due to differences in early growth strategy such as the grass stage in longleaf pine and shortleaf's ability to resprout. Such differences contribute to varying patterns in post-fire stand development, which has important implications for southern pine overstory recruitment, restoration success, and delivery of desired ecosystem services. Moreover, subtle-to-pronounced differences in the susceptibility of southern pines from regeneration to maturity to biotic pests and abiotic disturbances produce important management considerations across a range of scales. This paper reviews the processes that affect natural regeneration of the primary southern pines including silvics, forest threats, and treatment responses. Collectively, this information gathered from observation, trial-and-error experiences, and controlled experiments across the southeastern US can inform forest managers and landowners about potential options and alternatives to more costly and resource-intensive approaches to artificial regeneration.

Passive and active afforestation of degraded mine lands – towards succession to naturalization of ecosystem

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Abstract: With the current discussion on biodiversity and the restoration of ecosystems (Proposal for a Regulation of the European Parliament and of the Council on nature restoration, 2022/0195 (COD)), as well as the assessment of the response of forest ecosystems to climate change it is important to consider different scenarios for ecosystem restoration on degraded land and large scale disturbance. An additional issue is the role of the forest ecosystem in increasing retention at the risk of drought. In human-made forest management dynamic and spontaneous succession are still being discussed. From one point of view, post-mine and post-industrial sites are the consequences of civilization development and using fossil fuels in the energy mix, but on the other hand, these areas are connected with total deforestation and extreme changes of water availability and site conditions. Therefore, post-mine sites can be a case study for assessing the dynamics of regenerated ecosystems and the ecosystem's reaction to environmental stress and climate change. We present various aspects of active and passive restoration with the role of succession in the reclamation of mine sites and forest ecosystem restoration.

Patterns and dynamics of land change in swidden systems across highland forest-agriculture frontiers in Laos, Southeast Asia

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Abstract: Swidden—the cyclical practice of land clearing, cropping, and leaving fallow for forest recovery—is an integral land use in the highlands of Southeast Asia, a region also identified as the leading global hotspot of highland forest loss. While it is generally understood that swidden is being increasingly replaced by cash crops (e.g., tree plantations), the actual extent of this process has been difficult to determine owing to challenges in the detection of swidden, a highly spatiotemporally dynamic form of land change. As a result, our understanding on the effects of this regionwide sedentarization of agriculture on the sustainability of highland forests remains limited. This is a problem because different post-swidden land uses can have varied environmental consequences, not just for highland systems, but also the lowland agrarian populus who depend on water regulation from the highlands. Here, we leverage on an existing land cover dataset to investigate the dynamics of swidden replacement in Laos, a developing country with the largest rural population in SE Asia where swidden remains widely practiced. By applying a rule-based classification to constrain our analysis to areas where at least one swidden cycle was observed, we found that from 1990–2020, the total area of swidden-affected forest in Laos was 7,147 km^2. Of this amount, 37.2% (2,660 km^2) remained under swidden (stable) while the remaining 62.8% (4,487 km^2) were eventually replaced by other land uses. Over time, the annual area of swidden replacement increased at an exponential rate, with more than half (52.2%) of total swidden replacement occurring in the last 3 years (2017–2020). The overall contribution of tree plantations was much lower than expected (<5% of total), and the vast majority of replacement (95.5%) involved a permanent conversion into non-forest types. Annual replacement area by non-forest increased throughout the 30-y period, whereas replacement by tree plantations only increased after 2003. Overall, our findings provide weak evidence for tree plantation establishment as a key driver of swidden replacement in Laos. More research is needed to accurately determine the various land use trajectories driving swidden replacement, in Laos, and the wider SE Asian region.

Potential salt tolerant species for degraded land restoration

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Abstract: Expansion in the areas affected by salinity is predicted in the coming decades with areas under the risk of salinization through 2079–2099 being the drylands of south America, southern Australia, Mexico, south-western United States, and south Africa. Reclamation of such lands through planting of salt tolerant species is not only a cost-effective strategy but would also ensure the long-term biodiversity of the area. Species selection is curcial because introducing alien species to the ecosystem would be harmful, with native species preffered due to their adaptability and economic value to the local community. The aim of this work was to determine such salt tolerant species estimated through spatial inverse distance weighted (IDW) interpolation. Ground truth salinity data was obtained from the WoSIS (World Soil Information Service) soil profile database (https://www.isric.org). To isolate species growing in salinity affected areas, multiple plant databases were combined to form a database with over 10000 unique species. Spatial surface of salinity distribution and used to extract EC_e values at the median geolocations of the species. Based on the predicted salinity levels, species at high and severe levels were classified based on their presence in locations with EC_e of more than 8 and 16 dS m^{-1}, respectively. Through this procedure, we isolated 261 species as being present in at least highly saline environments, out of which 208 species had either salt tolerant mechanicms such as salt glands or were salt tolerant. Out of these 261 species, 4 in Africa (*Geranium lucidum*, *Guibourtia coleosperma*, *Moringa ovalifolia*, and *Catophractes alexandri*), 23 in Asia (*Syzygium oblatum*, *Tamarix passerinoides*, and *Heliotropium bacciferum*), 38 in Australia (*Acacia saligna*, *Allocasuarina huegeliana*, and *Acacia scirpifolia*), 101 in Europe (*Salvadora persica*, *Vachellia tortilis*, and Tamarix nilotica), 53 in North America (*Carex strigosa*, *Chaenactis douglasii*, *Stipa speciosa*, and *Deschampsia flexuosa*), and 4 in South America (*Casimiroa edulis*, *Colletia spinosissima*, *Pinus nelsonii*, and *Pyrus nivalis*). Confidence interval around the predicted ECe values of the potential salt tolerance of such species could be quantified to determine their maximum level of tolerance. Additionally, dosage response experiments should be carried out on such species.

Practices and guidelines to restore evergreen forests in Kenya: after changed fire regimes, degrading uses, and introduced tree species stands

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Margaret W Mugure[1]
Coert J Geldenhuys[2]
[1] Kenya Forest Service, Nairobi, Kenya
[2] University of Pretoria, Department of Plant and Soil Sciences, c/o Forestwood cc, South Africa

Abstract: Natural evergreen forest systems in Africa have developed various strategies over millennia to recover from diverse types of natural disturbances at various scales and regimes. Such systems in most cases provide more cost-effective recovery with higher biodiversity, productivity, and diverse resource use value than artificial planting systems. The natural forest systems have canopy tree species that range from fast-growing, strongly light-demanding, early regrowth species to slower-growing, shade-tolerant species in the more advanced stages. They also vary in their fruit-seed dispersal strategies. Such characteristics contribute to a succession of species from the early to advanced recovery stages, and in use value. Forestry plantations and most invasive introduced species represent the tree species of the early recovery stages.

We present concepts for restoring such evergreen forest from three case studies and indicate how thousands of local rural resource users could form part of and benefit from such recovery actions. In the Ngong Forest Reserve people settled in dense numbers at the base of Ngong mountain. This reduced the incidences of fires from the lowlands, causing development of natural forest tree species in former wooded grassland, that are used for firewood and poles by the surrounding people. The Chapalungu forest in Bomet County was cleared/destroyed by locals during 'political' interferences, leaving only few scattered trees with hanging beehives (by local believes/myths such trees may not be cut). This concept is used to restore this forest. The natural Karura forest within Nairobi city is surrounded by planted trees of introduced tree species. A combination of resource use by adjacent rural people with planting clusters of useful indigenous tree species can be used to restore and expand the Karura natural forest system.

In the three cases, resource use through selective stem thinning (of suppressed stems of light-demanding tree species) and branch pruning of remaining stems, as in plantation forestry, is advocated. Where necessary, group-felling can be applied to facilitate better regeneration of secondary natural forest species to speed up the recovery process. Forest landscape restoration is synonymous with active resource use, to the benefit of both the forest recovery and resource users.

Promotion and management of mixed natural regeneration in single layer Scots pine forests

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Franka Huth[1]
Alexandra Wehnert[1], Janosch Heinermann[2], Sven Wagner[1], Uta Berger[2]
[1] TU Dresden, Institute of Silviculture and Forest Protection, Chair of Silviculture, Germany
[2] TU Dresden, Institute of Forest Growth and Forest Computer Sciences, Chair of Forest Biometrics and Systems Analysis, Germany

Abstract: In the pure Scots pine stands of the Northeast German Lowlands, the establishment of naturally regenerated mixed tree species is of particular importance to strengthen these forests against damaging abiotic and biotic factors in the future. But mixed tree species have been removed over the decades, and establishing natural mixed regeneration is proving to be a major challenge. This is especially true for the mostly poor sites with low water supply. Our research project investigates the development and growth of naturally regenerated mixed tree species considering: (a) pine canopy, (b) associated vegetation, (c) competition among regeneration plants, and (d) local precipitation. For this purpose, we recorded all tree positions of pines in the upper stand and of all regenerating tree species. We conducted intensive growth and quality measurements on the regenerating trees to document their growth and development potential. In addition, to understand the influences of microclimate on regeneration, precipitation was recorded on a 1 m x 1m grid.

The spatial distribution of seed trees results in area-specific proportions of regenerated tree species with densities ranging from 3,200 to 32,700 per hectare. In all nine study sites, Scots pine, sessile oak, and European beech were the most common tree species in the regeneration layer. In dense pine stands, the proportion of pine in the regeneration layer was less than 5 %, whereas this canopy effect was low for beech and oak regeneration density. The results of the spatial point pattern analyses illustrate the species-specific and distance-dependent effects of old-growth pine and precipitation amounts on regeneration plants. The spatial statistical analyses also show greater intraspecific aggregation of regeneration with increasing age. Tree species-specific analyses of annual shoot length increment demonstrate the direct influence of stand basal area as a regulating variable and the influence of precipitation. In years with particularly low precipitation, annual growth of regeneration plants is significantly reduced. The absolute differences in increment result in competitive shifts, which are of additional importance for silvicultural planning.

quaxnat - An R package for estimating regeneration potential based on forest inventory and remote sensing data

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Maximilian Axer[1]
Robert Schlicht[2], Sven Wagner[2]
[1] Northwest German Forest Research Institute
[2] Technical University Dresden

Abstract: Nowadays, the integration of natural regeneration is an important goal in the restoration of degraded forests. Regional and local information on the dispersal potential of tree species is insufficient so far. Therefore, a potential analysis of natural regeneration for concrete areas is to be developed as a basis for silvicultural decisions on forest restoration.

Data basis for the determination of the regeneration potential are inventory data of the permanent forest inventory. Remote sensing data are used to determine the distance to the nearest potential seed tree. Meanwhile, high-resolution remote sensing data sets with tree species detection are available for Germany and worldwide. Thus, there are valuable information for the position of seed trees of the respective species.

The dispersal potential of tree species can be estimated using a quantile regression. The regeneration densities are used to parameterise the dispersal potential of a tree species as a function of the distance to the nearest seed tree. With the help of a quantile regression, a statistical relationship between the distance and the potential natural regeneration density can be derived. Spatial predictions for natural regeneration potentials can be calculated using the fitted models for the dispersal potential of the tree species. These potentials can be compared with forest restoration activities to identify rationalization potentials through the use of natural regeneration. In this way, limited funds, staff and resources can be used for artificial regeneration where no natural regeneration is expected.

The R package *quaxnat* offers the possibility to determine a dispersal potential for certain tree species and to calculate spatial predictions of the dispersal potential. The presentation will introduce the methodological approach and give a first introduction to the R package.

Rehabilitation of post-extraction cutaway peatlands – the role of natural regeneration

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Meshack O Moranga[1]
Dr. John Devaney[1]
[1] National University of Ireland, Maynooth

Abstract: Globally, wetland ecosystems (permanently or seasonally flooded habitats) make a disproportionally high contribution to ecosystem services. Yet, up to 50% of all wetlands globally have been lost or degraded since 1900 due to human activities. For example, Ireland's intact peatland area has declined from 1,200,000 hectares to approximately 100,000 hectares in the last century, primarily due to industrial-scale harvesting of peat. However, the last two decades have seen increased recognition of the need to rehabilitate Ireland's peatlands, particularly to restore their status as a carbon sink to aid climate change mitigation efforts. In peatlands where industrial extraction of peat has ceased, without intervention, these degraded bog ecosystems can rapidly transition to wooded landscapes due to the natural regeneration of fast-growing native trees. The overarching aim of this project is to assess the factors contributing to the successful natural regeneration of native forests on post-extraction peatlands. Earth Observation techniques have been used to quantify the area of natural forest development on post-extraction peatlands in Ireland over the last two decades. In addition, an ex-situ experiment is set to assess the role of seed input, soil moisture and nutrient status, and microclimate on the early establishment and growth of naturally regenerating native forests on post-extraction peatlands. Ultimately, this project will inform future peatland restoration and rehabilitation approaches in Ireland and beyond.

Remedy Towards Poor Natural Regeneration: Best Practice strategy for on-ground action for Forest Sustainability

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

PRODYUT BHATTACHARYA[1]
[1] University School of Environment Management, GGS Indraprastha University,New Delhi-110078

Abstract: India is the 10th highest forest cover country in the world, followed by the SFM principles in last 2 decades. In the past seven decades since independence, India has shown remarkable progress in key development areas, but still, about 250 million people depend on forest resources for livelihood and income generation. The current forest cover of India is 7,13,789 square kilometers which is 21.72% of the geographical area of the country and the per capita forest cover is less than 0.058ha. There is a very low capacity of natural forest regeneration, only about 42 % due to severe biotic pressure in the form of overgrazing, firewood and fodder collection and illicit felling, forest fire, invasion of weeds, climate vulnerability and pressure on land diversion for development purpose. Most natural forests have a limited number of potential seed-producing trees. The quality of the country's forest in terms of average productivity, per capita availability, growing stock, and forest composition have declined in the past three decades. To restore ecosystems resilience and increase the forest cover in the country, afforestation and tree plantation activities have been given high priority but the implementation result is far below the target to achieve an additional 5 million ha of forest and non-forest land plantation in the Green India Mission (GIM). All 29 states and union territories of India make a reasonable effort towards afforestation activities under various programs and schemes of line Ministry such as the Mahatma Gandhi National Rural Employment Guarantee Scheme, National Compensatory Afforestation Fund (CAMPA), National Bamboo Mission, Sub-Mission on Agroforestry, etc. towards responding to climate change.

This paper argues for major efforts required towards an innovative mechanism for *in situ* natural regeneration initiative which is much more cost-effective and practical for the country. A multi-prong strategy gives more emphasis on reducing the drivers of degradation and restoring degraded forest lands by strengthening participatory forest management. By strengthening age-old practices of joint forest management which assisted natural regeneration, enrichment plantation, contour trenching, native tree seed dissemination, soil, and improved water conservation practices with people's participation against millions of hectares of new plantation every year.

Restoration of degraded tropical forests by assisting natural regeneration of valuable plant species in the North of Vietnam

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Van Anh Thi Nguyen[1]
Sven Wagner[1]
[1] Chair of Silviculture, Institute of Silviculture and Forest Protection, TU Dresden, 01737 Tharandt, Germany

Abstract: Tropical forests are important terrestrial ecosystems in the world. They are not only the home of many species of plants and animals, but also a huge carbon reservoir. The loss and degradation of tropical forests lead to negative impacts on biodiversity, environment and climate. In Vietnam, there are about 14.7 million ha forests (covering about 42.0% of the area), but they are mainly secondary and poor forests (accounting about 67% of natural forest area). The restoration of these forest areas is becoming an urgent issue in government's policy. The structure of forests has been changed by humans, the ecological and biodiversity functions have been reduced. However, in the degraded forests remnants of mature trees are often left. Our concept of restoration in these secondary forests relies upon these remnants left as a source of natural regeneration. *Erythrophleum fordii* Oliver (ironwood) is a valuable timber species and widely distributed in the north of Vietnam. Our research focused on disentangling the main factors effected to natural regeneration of *E. fordii* species aiming to restore degraded tropical lowland forests in the North of Vietnam. The natural regeneration of this valuable species is impacted by the distance to the conspecific adult trees and percentage of ground cover. By taking maximum distance to source tree remnants into account and carefully manage cover of competing ground vegetation in the surrounding of naturally established seedlings, this species can have an increased proportion in the next generation improving the value of the secondary forests.

Strategies and experiences in increasing the rodent-mediated early regeneration of Pinus koraiensis in restoring temperate secondary forests

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Qiaoling YAN[1, 2]
Jing WANG[1, 3]
[1] Qingyuan Forest CERN, National Observation and Research Station, Liaoning Province, Shenyang 110016, China
[2] Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang 110016, China
[3] School of Life Sciences, Zhengzhou University, Gaoxin District, Zhengzhou, Henan Province 450001, China

Abstract: Korean pine (Pinus koraiensis) is the constructive tree species in the primary broad-leaved Korean pine forest (BLKPF) in Northeast China. Due to long-term destructive disturbances, Korean pine has basically disappeared and the BLKPF has degraded into a secondary forest. There are natural regeneration obstacles of Korean pine due to the limitation of seed sources in secondary forests. In addition, after the cones of P. koraiensis mature and fall off, they must rely on rodents to achieve seed regeneration. However, due to the difficulty in tracking the seed dispersal and subsequent regeneration process by rodents, the mechanism of rodent-mediated seed regeneration barriers is unclear. Therefore, it is urgent to adopt artificial regulation methods (such as changing forest structure, increasing artificial regeneration methods, etc.) to promote rodent-mediated early regeneration of Korean pine in order to restore secondary forests.

By conducting field investigations with infrared cameras, we tried to reveal the reciprocal antagonistic relationship between rodents and P. koraiensis under the coupling of source restriction and forest structure. In the forest treated with gaps, the relationship between selection of spatial sites for animal storage/feeding of Korean pine seeds and the composition and distribution of understory vegetation was determined through ground based LiDAR scanning. Direct sowing and planting seedlings were conducted in gaps and thinning plots to clarify short-term response of rodent-mediated artificial regeneration to forest structure.

The results showed that the lack of P. koraiensis provenance caused a 17% increase in the proportion of rodents feeding on seeds, and the mutual relationship between animals and P. koraiensis tended to be antagonistic. Forest gaps and thinning changed the canopy structure, understory vegetation composition, and spatial distribution characteristics, which has a negative effect on the animal-mediated seed regeneration process. Therefore, there are serious obstacles to seed regeneration of Korean pine, and even by regulating the stand structure, it is not possible to accelerate its rodent-mediated seed regeneration. However, without considering economic costs, short-term results indicated that forming large forest gaps or 50% thinning treatment, and planting 3-year-old seedlings were the most effective ways to promote the replenishment of Korean pine in secondary forests.

The impact of restoration approach on diversity of vascular plants, bryophytes, lichens and soil fungi in birch stands on previous agricultural land

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Tea Tullus[1]
Reimo Lutter[1], Arvo Tullus[2], Reeno Sopp[1], Marju Kaivapalu[1], Katri Ots[1], Maris Hordo[1, 3], Kristjan Täll[1], Mari-Liis Siller[1], Aivo Vares[1], Kalle Karoles[1], Hardi Tullus[1]
[1] Chair of Silviculture and Forest Ecology, Institute of Forestry and Engineering, Estonian University of Life Sciences, Estonia
[2] Department of Botany, Institute of Ecology and Earth Sciences, Faculty of Science and Technology, University of Tartu, Estonia
[3] Chair of Forest and Land Management and Wood Processing Technologies, Institute of Forestry and Engineering, Estonian University of Life Sciences, Estonia

Abstract: Restoring forests on previous agricultural land can rely on passive or active restoration. We compared the impacts of restoration approach (passive = natural regeneration *vs*. active = plantation establishment) on different biodiversity groups in 21-28-year-old birch (*Betula pendula* and *B. pubescens*) stands (n=22) on former agricultural land in Estonia, using birch stands (n=11) on native forest land as a reference group. We further analysed the effects of past land use (field, grassland, forest), and soil, stand and landscape variables on biodiversity. In addition, we evaluated whether the recovery of forest understory follows similar pathways in passively and actively restored stands, based on data of two monitorings with 8-year interval on permanent plots.

Altogether 33 shrub layer, 182 field layer, 70 bryophyte, 63 lichen species and 2830 soil fungal OTUs were recorded in 33 stands. Restoration approach impacted the richness of shrubs and bryophytes that were higher in naturally regenerated stands than in plantations. At the same time the richness of field layer and lichens as well as the diversity of soil fungi were related to other environmental factors. PERMANOVA analyses and NMDS ordination based separately on vascular plant, bryophyte, lichen and soil fungus data revealed compositional differences between naturally regenerated stands, plantations and native forests. However, the effect of previous land use (agriculture vs. forest) was clearly stronger than the effect of restoration approach. The results of repeated understory monitoring revealed that the recovery of forest understory took place in similar ways in plantations and naturally regenerated stands as the numbers of herbaceous and bryophyte forest specialists slowly increased in both stand types. The overall share of forest specialists in composition was continuously low forming 12.4% of herbs and 31.1% of bryophytes in plantations and 20.8% of herbs and 25.0% of bryophytes in naturally regenerated stands.

To conclude, we found that fast-growing birch plantations and naturally regenerated stands harbour similar richness of several biodiversity groups, at the same time showing clear compositional differences from native forests due to agricultural legacy.

The interplay between the importance of natural regeneration in regular forest management and knowledge of the ecological processes underlying it

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Sven Wagner[1]
Franka Huth[1]
[1] TU Dresden, Chair of silviculture

Abstract: Based on the life cycle and its stages, we aim to provide an overview of studies and case studies that highlight past research successes and current research needs in the field of natural regeneration. Our focus is to establish direct links from phase-specific regeneration research to concrete measures of practical forest management.

Using two very contrasting characteristics of forest trees - pioneers and shade tolerants - as examples, we show the effects of flowering frequency, seed set, seed dispersal ability, seed bank ecology, and seedling development of tree species on restoration success. The examples show that both traits may vary in how well they are adapted to given restoration conditions. However, it appears that ecologically and economically valuable shade-tolerant tree species generally suffer more from a lack of source trees near restoration sites and their seeds and seedlings are more susceptible to predation than those of pioneers are. Pioneers, on the other hand, often fail to colonise a particular site because of the harsh climatic conditions their germinating seeds and germinants are not adapted to, while their seedlings are often very resilient once established. This phase-specific example of sensitivity to climatic conditions, such as moisture deficits that hinder seed germination, could lead to major problems in the near future due to climate change.

Forest management may well aim to create the appropriate favourable environmental conditions for the diverse tree traits, which would increase the success of restoration efforts through natural regeneration.

The potential use of natural regeneration for restoring temperate rainforests in Chile: examples from Patagonia, Chile

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Jan Bannister[1]
Osvaldo Vidal[2], Manuel Acevedo[1], Rodrigo Morales[3]
[1] Instituto Forestal de Chile
[2] Universidad de Magallanes
[3] Universidad Austral de Chile

Abstract: According to the 2020 updated Chilean NDCs, Chile is committed to plant 200.000 ha of planted forests by 2030, 35% of then with native species. However, if restoration focus is placed only on artificial regeneration, at current plantation rate (<1,000 ha/year) this commitment is hard to meet. Nowadays, in the Chilean temperate bioclimatic region, probably the place with greatest potential for ecological restoration in the country, there are only ~100 restoration initiatives, most of them using artificial regeneration and developed on a small scale (<10 ha), and with evaluations of early performance in terms of survival and early growth, considering in best cases the first 5 years since plant establishment. This situation contrasts with the over 2 million hectares of second-growth forests that naturally regenerated after anthropogenic and natural stand-replacing disturbances the last century in the same region. This can be seen as an indicator of the resilience of these forests if we give them the option to regenerate on their own. In this study, we discuss the potential use of natural regeneration (NR) for restoring temperate rainforests in North-Patagonia, Chile, showing examples of forest restoration after anthropogenic fires, conversion to grasslands, and high-grading practices. We emphasize the need of promoting NR in sites beneath a nurse canopy or closed to remnant trees, and of complementing NR with artificial regeneration in order to foster natural succession in open places or away from remnant seed sources. Also we highlight the need of evaluating restoration success by integrating the study of structural, compositional and functional aspects of ecosystem integrity in restored areas. Applied research on these topics will give guidance to restoration practitioners as to how to restore temperate rainforests and how to evaluate restoration success. It will also allow us to know if during the UN decade of ecosystem restoration, we are only summing area with established trees or if we are really restoring functional forests for the future decades.

The surrounding landscape as a modulator of forest ecosystems developing through natural colonization in former cropland

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Sebastian Kepfer-Rojas[1]
David B. Byriel[1], Nané K. Pedersen[1], Anna K. Zimmerman[1], Davide Barsotti[1], Micaela Y. Rosas[1], Inger K. Schmidt[1]
[1] Department of Geosciences and Natural Resource Management, University of Copenhagen

Abstract: The area of abandoned agricultural soil has increased in Europe and it´s projected to keep increasing in the future. With the ongoing biodiversity and climate crisis, it is expected that a large fraction of this abandoned land will be converted into forest.

Natural colonization and regeneration are considered cost-effective methods to create and restore forests. Although multiple benefits to biodiversity are expected from these methods, other ecosystem functions as carbon sequestration, might not be as efficient when compared to forest plantations. A reason for this might be that natural colonization is in some cases slow and even arrested due to biophysical legacies in the soil and the characteristics of the surrounding landscape.

Although there is some evidence of this on the vegetation layer, it is unclear how forest communities from the different compartments of the forest develop in naturally colonized areas on how landscape vs stand factors interact to influence this development.

We used a research platform of 10 sites in Denmark, each consisting of 4 land use types: natural colonization (NC), planted beech forest, mature beech forest, and agricultural field, where the natural colonization and the plantation forests are all ca. 30 years old. Within this platform, we investigated the insect, soil-borne microbiome and vegetation biodiversity using eDNA and conventional methods. We complemented this with information on the forest structure measured with LiDAR. Additionally, we characterized the surrounding landscape deriving metrics of fragmentation, composition and quality.

Moreover, we supplemented this with information from the Danish National Forest Inventory to explore a wider range of stand and landscape conditions and to explore the interactive effect of them on the development of forest´s diversity, structure and function.

We will compare how the different forest communities and functions develop under natural colonization and forest plantations and will examine the degree to which these responses are mediated by the surrounding landscapes. We will identify trade-offs and synergies between biodiversity and ecosystem functions that can inform spatial prioritization planning.

Using natural regeneration to restore native forests from Pinus radiata plantations in south-central Chile: Effects of different harvesting treatments

T3.19 Increasing the potential of natural regeneration in restoring degraded forest and deforested lands around the world: concepts, strategies, experiences and guidelines

Klaus Kremer[1]
Jürgen Bauhus[1]
[1] University of Freiburg

Abstract: In south-central Chile, there has been a significant expansion of commercial plantations of *Pinus radiata* in the past few decades, often at the expense of natural vegetation. In accordance with recent commitments to certification programs, forestry companies have initiated efforts to restore the native ecosystems replaced through plantations of exotic tree species after 1994. The spatial extent of required restoration, encompassing hundreds of thousands of hectares, increasingly unfavorable and unpredictable climatic conditions, and a lack of suitable planting stock, have led to rising costs and uncertainties associated to planting. Yet, most research on reforestation and afforestation in this region has focused on artificial regeneration. Thus, the understanding of natural regeneration processes for restoration purposes is limited. We conducted a large-scale experiment in mature *P. radiata* plantations of the Nahuelbuta Coastal Range. Our aim was to assess the effect of different harvesting treatments (clearcut, strip-cutting, and unharvested control) on the development of natural regeneration of native tree species. These treatments were replicated across three sites at varying altitudes on both the western and eastern slopes of the Coastal Range. We employed 4 indicators to analyze the development of natural regeneration, which was monitored on multiple permanent plots per treatment over a two-year period: 1) basal area of saplings (>50 cm height), 2) maximum sapling height, 3) frequency of plots with free-growing regeneration, and 4) species diversity. Although treatment effects varied among sites, the clearcut generally resulted in the highest increase in saplings basal area, followed closely by the strip-cutting. A similar pattern was observed for the frequency of plots with free-growing regeneration, while the strip-cutting exhibited the highest increase in maximum height and species diversity. Despite the higher growth of native tree species in the clearcut, this treatment also showed the highest increase in basal area of *P. radiata* saplings, which may eventually outcompete native species. Thus, if clearfelling is chosen to initiate restoration with naturally regenerated native species, effective control measures must be implemented to manage the competing *P. radiata* regeneration. Alternatively, strip-cuttings appear to be a promising option for a restoration approach requiring less intervention in the regeneration layer.

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

A new index for assessing forest biodiversity based on tree-related microhabitats and forest inventory variables

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

[3] Department of Agricultural, Environmental and Food Sciences, University of Molise (UNIMOL), Via F. De Sanctis, Campobasso (CB), Italy

Abstract: Hosting over half of worldwide biodiversity, forests are one of the biodiversity richest terrestrial ecosystems. The increasing pressure of society for even more services, fostered the depauperation of this ecosystem, resulting in a loss of biodiversity. To preserve forest biodiversity, different agreements have been implemented, but monitoring forest biodiversity under human strong pressure represents a critical challenge. In the last years, different biodiversity indicators were developed for forest diversity monitoring, among which tree-related microhabitats (TreMs). Defined as well-delineated structures occurring on living and standing dead trees, created by biotic or abiotic events, TreMs received great attention in the last decades as key elements for the indirect assessment of forest biodiversity. TreMs and habitat trees, i.e., living or standing dead trees with at least one TreMs, constitute a particular substrate or life site for species and become increasingly important as conservation elements of forest biodiversity in regularly managed forests. Despite there are several studies focusing on the abundance and diversity of TreMs in different forest categories and forest management systems, studies on their spatial distribution within forest stands are still missing.

This study aims to introduce a new biodiversity index, based on the occurrence, diversity, and spatial distribution of TreMs. The index was tested in 109 marteloscopes belonging to the Integrate network. The index was calculated at different levels of TreMs hierarchical typology (i.e., type, form, group), highlighting its suitability to be implemented at different levels of investigation. To verify its robustness, the index was compared with the two indices often used for the assessment of forest biodiversity, such as the Shannon diversity index and the Clark and Evans aggregation index, highlighting similar patterns.

Considering the importance of TreMs for assessing multi-taxon forest biodiversity, and the possibility to introduce TreMs as an attribute to monitoring through the national forest inventory, the index represents a very suitable tool for assessing forest biodiversity throughout forest ecosystems. From the practical point of view, it can drive silvicultural interventions to retain habitat trees ensuring an appropriate spatial distribution.

Adapting forests to climate change: evaluating opportunities and risks of non-native tree species on ecosystem services

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Abstract: Forestry is facing unprecedented challenges due to increasing climate change threats and disturbances. Particularly, economically important tree species are being lost and it is often unclear if native or non-native tree species (NNT) can be used as alternatives. The choice of tree species for climate-smart forests should not only take productivity, carbon sequestration and economic efficiency of forests into account, but also forest biodiversity and the provision of other ecosystem services. Using species distribution models of native and NNT as well as data from the Austrian forest inventory, we modelled the provision of various ecosystems services of Austrian forests under current and future climate conditions and by applying various species selection scenarios. The ecosystem services encompass the productivity of forests, their protective function against avalanche and rockfall events, as well as their resistance to wildfire. Five different species change scenarios were evaluated: (1) no tree species change, (2a) replacement of lost species with native tree species which are climatically most suitable, (2b) replacement of coniferous with native coniferous trees and deciduous with native deciduous trees, if appropriate; (3a) replacement of lost species with non-native trees if they show a higher suitability to future climate; (3b) replacement of coniferous with non-native coniferous trees and deciduous with non-native deciduous trees, if appropriate. The results indicate that relying solely on native species would result in a decline in both productivity and biodiversity in terms of tree species composition. This negative impact can be mitigated by increasing the proportion of NNT. However, it is important to note that the selection of native or NNT has a lesser effect on the protective function of forests. Depending on whether productivity, the protective function (ecosystem service) or tree species diversity (biodiversity) are considered, different species selection scenarios can be recommended. Accordingly, a good balance of tree species is of particular importance in order to be able to meet the different requirements of climate-smart forests. Especially in the protection forest, different aspects are important than in production forest. Our results provide a knowledge basis for Austrian forest owners/managers to make decisions on a sustainable choice of tree species.

Assessing the impact of biodiversity indicators' scale and management diversification on biodiversity connectivity patterns.

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Juliette Hunault-Fontbonne[1]
Kyle Eyvindson[1, 2]
[1] Faculty of Environmental Sciences and Natural Resource Management, Norwegian University of Life Sciences, Campus Ås, Norway
[2] Natural Resource Institute Finland (LUKE), Bioeconomy and Environment Unit, Laatokartanonkaari 9, 00790 Helsinki, Finland

Abstract: Biodiversity and ecological concepts are becoming an increasingly important component of forest planning. However, central concepts in ecology, such as spatial and temporal connectivity, are often neglected in forest planning studies. To appropriately incorporate biodiversity protection into forest planning, we therefore need to quantify how forest management practices impact connectivity patterns.

Biodiversity models used in forest planning often rely on broad-scale objectives that may ignore local specificities important for connectivity. Additionally, the traditional monospecific even-aged management applied in European boreal forests is another obstacle to habitat connectivity.

Our study investigates the impacts of (1) using local indicators in biodiversity objectives and (2) diversifying management on habitat connectivity. We simulated the development of a small, forested landscape in Norway as a case study. To investigate the impact of shifting biodiversity objectives from the global to the local scale, we defined two scales for biodiversity indicators: broad- and fine-scale. For broad-scale, biodiversity objectives are set at the landscape level, using indicators based on biodiversity policy in Norway. For fine-scale, biodiversity objectives are set at the stand level based on the conditions and biodiversity status at the beginning of the planning period. Through multi-objective optimization, we identified optimal prescriptions for increasing levels of management diversity, going from homogeneous to heterogenous treatments in terms of rotation ages, harvest and thinnings intensities, and types of regeneration. We then compared the impact of the optimal prescriptions on spatial and temporal connectivity to define which combination of scale and diversification results in the highest connectivity in the landscape.

Our preliminary results suggest that a combination of fine-scale biodiversity objectives and high diversification level will result in a higher spatial and temporal connectivity. However, this leads to a reduction in the net present value and timber extracted from the forest. We anticipate that our results will be valuable to determine the degree of indicators specificity and management diversification required for biodiversity policies to efficiently promote habitat connectivity.

Balancing biodiversity and recreation – the public's perspective

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Marcel Hunziker[1]
Boris Salak[1], Johanna Trummer[1], Tessa Hegetschweiler[1]
[1] Swiss Federal Institute for Forest, Snow and Landscape Research WSL

Abstract: Managing forests for society requires knowing and incorporating the perceptions, attitudes, and preferences of the local population. Among the cultural ecosystem services provided by forests, aesthetics and recreation belong to the most important ones in Switzerland. The urban populations' need for easily accessible forests for outdoor recreation makes management of these forests for recreation indispensable, and inadequate visitor management can cause conflicts between recreation and biodiversity, e.g., reduced biodiversity due to trampling of soil and vegetation. On the other hand, results from the Swiss Sociocultural Forest Monitoring WaMos – conducted as a representative online survey focusing on the relationship of the population to the forest – show that awareness concerning the general decline in biodiversity has grown over the last years and that the Swiss population has an increasingly positive attitude towards the ecological function of our forests. Consequently, acceptance of nature conservation measures in forests is high. Nevertheless, confronting forest visitors on-site with forest management aimed at enhancing biodiversity sometimes provokes contradictory reactions. A study concerning the attractiveness of various forest management forms revealed that different stages of coppice-with-standards – managed to enhance biodiversity – received lower ratings than other management forms, even compared to even-aged high forest consisting of a monoculture of coniferous trees. Forest management in multifunctional forests with recreational areas has to consider visitors' needs and preferences to avoid a lack of understanding, protests and (often unintentionally) damaging behaviour.

Co-creating forest management plans for better accommodation of biodiversity and a landscape perspective.

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Anna Karlsson[1]
Vilis Brukas[1], Ola Eriksson[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Sweden

Abstract: Landscapes worldwide have become fragmented and degraded, posing a threat to biodiversity and ecosystems. In Sweden, companies or private forest owners orientated towards timber production for commercial purposes own most of productive forest. Thus, exclusive reliance on increased areas of set-asides for enhancing the status of forested landscapes would be costly and require an elaborate process to acquire acceptance. Rather, there is a need for approaches integrated into standard procedures for forest management and planning. The forest management plan (FMP) plays a vital role in Sweden's forestry, serving as an instrument for generating and implementing forest management alternatives. To effectively balance diverse objectives and consider different management options, including aligning estate management with landscape features, the current FMPs require improvement. Additionally, there is a need for advancing the planner's core capacity from production-oriented technical expertise to a wider skill-set, while matching the owner's multi-dimensional needs.

To address these needs, our study goes through three phases. First, we will conduct ethnographic observations of planning operations followed by semi-structured interviews with forest planners to examine their motivations, expertise, and planning procedures, including the accustomed ways to integrate the landscape perspective in FMPs. Second, we will create a low-cost, standardised method to assess how estate management affects landscape values. Finally, we are going to co-design novel planning procedures and pilot them on selected forest estates.

To achieve better consideration of biodiversity and multitude of ecosystem services in FMPs, we intend to produce procedural guidelines, a prototype plan that includes landscape features, and a training module for planners. Our approach is based on knowledge co-creation between scientists, forest planners and owners, enhancing the likelihood of practical implementation on a broader scale.

Development of plant and fungal communities after afforestation on agricultural soils – highlights form three chronosequences in Denmark.

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Davide Barsotti[1]
Karelle Rheault[1], David Bille Bryel[1], Sebastian Kepfer Rojas[1], Inger Kappel Schmidt[1]
[1] Department of Geosciences and Natural Resource Management, University of Copenhagen, Copenhagen 1017, Denmark

Abstract: The ongoing afforestation in North European countries like Denmark is often limited to agricultural soils. The creation of forested areas has the potential to foster rich and resilient ecosystems, providing services and habitats for specialist species. However, biodiversity recovery in forests planted on agricultural soils is hindered by land use legacies and fragmented landscapes.

This study investigates the drivers of biodiversity recovery in afforested agricultural land from the perspective of plants and fungi, in order to guide management choices and suggest new options tailored to the constraints of these habitats.

We studied three chronosequences in Denmark spanning 60 years of afforestation with three different tree species, surveying the vegetation and sequencing microbial DNA. The space for time substitution sampled in 2021 was supplemented with vegetation and soil surveys taken 20 and 10 years ago. We explored the effects of soil and tree development, tree species, forest structures, management, connectivity, and the influence of the communities on one another. We then modeled the impacts of these factors on forest specialists and the whole communities, using distinct models for variables describing the environment and management choices.

We found that plants and fungi respond to different aspects of forest development: the plant communities are shaped by light availability and disturbance, while fungi respond more strongly to soil development and tree species. Furthermore, structural heterogeneity, canopy cover, and vicinity of the reference forest drive the abundance of forest specialists. In the chronosequence, however, communities did not develop to resemble the old forest reference. Indeed, while many forest plant species appeared, only those with long-range dispersal capability colonized the plantations; on the other hand, soil physicochemical properties did not fully approach the reference, possibly producing the difference found in the fungal communities.

We, therefore, confirm that forest structural diversity and connectivity can promote potential biodiversity, but a lack of seed sources, dispersal limitation, and lingering soil legacies affect the establishment and recovery of specialist communities. Furthermore, we highlight the different needs of plants and fungi, remarking on the strength of the long-term effects of agriculture and the importance of assisted dispersal to overcome landscape barriers.

Effects of habitat tree retention on adjacent regeneration growth in continuous cover forests in Central Europe

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Rose-Marie Oksanen[1]
Jürgen Bauhus[1]
[1] Albert Ludwig University of Freiburg

Abstract: Habitat tree retention, a relatively recent but widely applied practice in temperate European forests, involves the permanent preservation of mature trees during the course of harvesting. The aim of habitat tree retention is to enhance biodiversity, maintain ecosystem functionality, and provide resources for a wide range of species in production forests. Retention of habitat trees benefits a range of forest-dwelling species. However, our current understanding about the effects of habitat tree retention on wood production and other ecosystem functions is rather limited, especially in Central European continuous-cover systems. Without this information, the costs and benefits of retention cannot be calculated and the tree growth of production systems cannot be accurately modeled. The goal of this study was to measure the effect of retained habitat tree groups on the surrounding regeneration and regrowth stands. We analyzed data from ca. 120 habitat tree groups in the state forests of Baden-Württemberg Germany. All stands were dominated by European Beech and Silver Fir. The surrounding regrowth was measured by means of linear transects into all four cardinal directions. Here we show how diversity, growth and quality of surrounding regrowth and regeneration changes with distance from habitat tree groups and how it is influenced by microclimatic effects, hemispheric direction, tree species traits (e.g. shade-tolerance), and condition of the habitat tree groups (size, vitality, density) and of the surrounding matrix. Our results are directly relevant to integrative forest management, by providing an evidence-base for synergies and trade-offs between biodiversity conservation function and other ecosystem functions of habitat trees.

Employing a dynamic approach for habitat tree selection in temperate forests of Europe

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Andreea Spînu[1]
Jürgen Bauhus[1]
[1] Chair of Silviculture, Faculty of Environment and Natural Resources, University of Freiburg

Abstract: Selection of living habitat trees in the multiple-use forests of temperate Europe is commonly done on the basis of their tree-related microhabitats (TreMs). TreM occurrence is largely determined by the dimension, vitality and species identity of the habitat tree. Thus, TreM assemblages and associated forest-dwelling species will be affected by changes in tree attributes such as those driven by increasing rates of climate change-related disturbances and tree mortality. So far, retention forestry approaches have been rather static, not considering the temporal dynamics of habitat trees and their TreMs.

Based on data describing TreMs borne by functionally-different trees, we provide the first evidence-base for dynamic habitat tree selection in temperate forests. We compared the TreM abundance and richness on trees with contrasting life-history traits: lifespan, growth and wood decay resistance. To identify how TreMs are changing over time, we estimated the rates of TreM persistence and loss based on longitudinal data from repeated inventories and employing methods of survival analysis and generalized linear mixed models. Further, we described how TreMs change after tree death by comparing their occurrence on dead and living trees.

Our analysis showed that pioneer tree species developed TreMs quicker than longer-lived tree species. Tree species such as *Populus* and *Betula* play an important role in accelerating habitat restoration. We also highlighted that living habitat trees had distinct TreMs, not found on deadwood. Even though overall TreM abundance and richness increased over time on living habitat trees, individual TreMs on those individuals were at risk of being lost. While dead habitat trees cannot substitute the habitat functions of living broadleaved trees, they complement them. The overall stand-level TreM diversity can increase, in particular through decayed, large snags.

Considering the temporal development of TreMs on functionally-different habitat trees can support a more continuous provisioning of resources for species that depend on them. We emphasize the importance of an abundant and stable supply of TreMs, in order to decrease the risk of losing rare TreM types over time.

Enhancing multifunctionality in European boreal forests: the potential role of Triad landscape functional zoning

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Clemens Blattert[1, 2, 3]

[5] Natural Resource Institute Finland, Helsinki, Finland

Abstract: Land-use policies strive to enhance the sustainable use of natural resources. The Triad approach has been suggested to balance the social, ecological, and economic demands of forested landscapes. The core idea is to enhance multifunctionality at the landscape level by allocating landscape zones with specific management priorities, i.e., production (intensive management), multiple use (extensive management), and conservation (forest reserves).

We tested the efficiency of the Triad approach and identified the respective proportion of above-mentioned zones needed to enhance multifunctionality in a Finnish forest landscape. Through a simulation and optimization framework, we explored a range of scenarios of the three zones and evaluated how changing their relative proportion (each ranging from 0 – 100 %) impacted landscape multifunctionality, measured by various biodiversity and ecosystem service indicators.

The results show that maximizing multifunctionality required 20 % forest area managed intensively, 50 % extensively, and 30 % allocated to forest reserves. In our case study, such landscape zoning represented a good compromise between the studied multifunctionality components and maintained 61 % of the maximum achievable net present value (i.e., total timber economic value). Allocating specific proportion of the landscape to a management zone had distinctive effects on the optimized economic or multifunctionality values. NPV was only moderately impacted by shifting intensity of management from intensive to extensive, while multifunctionality benefited from less intensive and more diverse management regimes.

This is the first study to apply Triad in a European boreal forest context, highlighting the usefulness of this approach. Our results show the potential of the Triad approach in promoting forest multifunctionality, as well as a strong trade-off between net present value and multifunctionality. We conclude that simply applying the Triad approach does not implicitly contribute to an overall increase in forest multifunctionality, as careful forest management planning still requires clear landscape objectives.

Enhancing tree diversity for the mitigation of climate change-induced phenological mismatch between breeding birds and prey in temperate forests

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Min-Su Jeong[1]
Eunjeong Kim[1], Hankyu Kim[1], **Chang-Yong Choi**[1]
[1] Seoul National University

Abstract: Climate change has caused a phenological mismatch between consumers and prey, reducing prey availability andhence leading to fitness consequences and their ecological service. In this study, we aimed to understand how the phenological mismatch on diet use and reproductive output of a forest songbird (Varied Tit, *Sittiparus varius*) were affected by the peakedness of caterpillar availability in temperate mixed deciduous forests with different vegetation covers. With two-year data collected in five plots across elevational gradients, we analyzed the change in in body conditions of nestlings and in two stable isotope values (δ13C and δ15N) of their blood samples related to the degree of phenological synchrony and peak season of caterpillar availability (peak prey season). We found that the peak prey season extended as the tree diversity increased in the forest. The higher δ13C values of nestlings with later peak timing indicated that their parents might feed less caterpillar which is the key prey of forest birds, and the δ15N significantly changed with the degree of synchrony only when the peak prey season was shorter. The nestling conditions decreased over the breeding season when the peak prey season mismatched. Consequently, these findings suggested that the effect of phenological mismatch on forest songbirds' prey use and reproductive output would be mitigated by a more extended peak prey season, which may be achieved by improving tree diversity in temperate deciduous habitats. Given the abundance and distribution of Varied Tits, forest managements enhancing the tree diversity may mitigate the negative impacts of phenological mismatch on ecological services of the most commont forest bird (such as seed disperser, insect pest control, etc.) through the improvement of prey-consumer interactions in the temperate forest ecosystem.

Forest and forest landscape planning and restoration for integrated multi-functional capacity in Swedish Ecoparks

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Johan Svensson[1]
Anne-Marit Hekkala[1], Wiebke Neumann[1], Paulina Bergmark[1], Bengt Gunnar Jonsson[1], Joakim Hjältén[1], Peter Bergman[2], Malin Norderman[2]
[1] Swedish University of Agricultural Sciences, Department of Wildlife, Fish and Environmental Studies
[2] Sveaskog

Abstract: Swedish forestry relies on simultaneous realization of wood biomass production and environmental goals as reflected in the principles of sustainable forest management. To achieve this, operationally, tactically and strategically, forestry planning relies on four management-goal classes; PG – wood biomass production with general conservation consideration, PE – as the previous but with enhanced conservation consideration, NM – nature conservation with management, and NF – natural development without management. The two former classes focus on wood biomass production whereas the two latter strictly on nature conservation. This classification system is applied on 22 million ha forestland in Sweden. Following long-term intensive forestry systematically across the Swedish forest landscape, however, the outcomes for nature conservation, socio-cultural and other environmental values are deficient, as recently concluded in the evaluation of the national sustainable forestry environmental criteria. Thus, the needs for advancing restoration and multi-functionality in forests and forest landscapes are well established but also urgent to act upon. Applying 37 Ecoparks ranging from the subalpine and north boreal to the south nemoral on the Swedish State forest company Sveaskog holdings, this study aimed for exploring the extent to which these management-goal classes promote integrated multiple use planning. The Ecoparks, covering in total about 250,000 ha whereof 180,000 ha forestland, are areas where Sveaskog apply a higher nature conservation ambition than elsewhere in managed forest landscapes. We found that the Ecoparks provide extensive restoration opportunities favoring nature conservation, mainly within the PE and NM management-goal classes. We also found, however, that that many multiple-use values, e.g., reindeer husbandry and recreational values, are not reflected in the classification system. We conclude that a classification system that accommodate the sustainability principles needs to integrate values beyond wood biomass production and nature conservation, and that restoration, including also specific management favoring multiple-use values, needs to be better reflected. Hence, there is a need to revise the management-goal classification system for Swedish forests and forestry. Based on our findings, we propose and discuss an alternative system that include wood biomass, multiple-use and nature conservation oriented goals, with restoration embedded to secure forest conditions that better facilitate multiple-use capacity and hence sustainable forestry.

Forest Biomass for Energy: A Systems Assessment of Sustainability of the Strip Cut Forest Harvest Method

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Kirsten Stephan[1]
Jamie Schuler[1], Charlene Kelly[1], Christopher Lituma[1]
[1] Division of Forestry and Natural Resources, West Virginia University, USA

Abstract: Despite the interest in increasing forest bioenergy use, gaps remain in the understanding of how much, how often, and in which spatial pattern forest biomass can be removed from a site before it begins to adversely affect forest ecosystem resources. In this study, woody biomass yield, soil fertility, and the abundance and diversity of herbaceous plants and birds were quantified in a replicated design (n=3 sites) with Cut strips of different widths, Residual strips left between the Cut strips, and an uncut Control in a temperate, deciduous forest in the central Appalachian Mountains in West Virginia, USA. In 2020, at each of the three sites, stripcutting removed woody biomass from three, 30-m long Cut strips. Cut strips varied in width (2.4 m, 3.7 m, or 4.9 m – allowing one to two passes of harvesting equipment). Trees in the Cut strips were 6 years old (a prior cutting had occurred in 2014); in the Control and in Residual strips (2.4 m wide), trees were 17 years. Biomass yield differed significantly between the strips of different widths, with 0.046 t (dry weight) ha^{-1}, 0.31 t ha^{-1}, and 10.4 t ha^{-1} harvested from the 2.4-m, 3.7-m, and 4.9-m strips, respectively. Soil fertility, assessed via Soil Organic Matter content at 0–10 cm depth, ranged from 22% to 28% but did not differ between Cut strips, Residual strips, and the Control. In the herbaceous layer (vascular plants <1 m height), leaf area (LA), species richness (R), and Shannon diversity (H) tended to be higher in Cut strips regardless of width than in the Control. Comparing the Cut strips of different widths, no statistically significant differences in LA, R, or H, respectively, were detected. An edge effect also benefitted the herbaceous layer in Residual strips. Avian abundance and diversity were greater in the vicinity of stripcut sites than in the surrounding forest matrix. Thus, stripcutting, in lieu of pre-commercial thinning, appears to be suitable to produce woody biomass when strips are at least 4.9 m wide while simultaneously benefitting the herbaceous and bird communities without short-term deleterious effects on soil fertility.

Framing European forest management terms and definitions for effective forest biodiversity studies

Abstract: Plenty of forest classifications are inconsistently used in forest biodiversity studies. This hampers their comparability, and makes the assessment of forest management effects on biodiversity highly context-dependent. Improving the comparison of European forest biodiversity studies is pivotal for the implementation and monitoring of sustainable forest management policies and retrospective meta-analyses. Recent attempts to standardize forestry definitions mostly used a top-down approach, regardless of the information reported in scientific articles and of the perspective of forest biodiversity experts. With this contribution, we aim to define a common standard for silvicultural operations and types of vegetation to adopt in forest biodiversity studies coupling a novel bottom-up and a top-driven review process. The work results from the networking activities of the COST Action “BOTTOMS-UP” (CA18207), which gathered and standardized data on multiple taxonomic groups, forest structures and management from European forests in a single harmonized platform. We highlight strengths and weaknesses of the silvicultural and vegetation information provided in biodiversity monitoring studies. Most recent studies based their conclusions on the analysis of the relationships between forest biodiversity and a given management regime or silvicultural system. While quantitative data on forest biomass and dominant tree species are frequently reported, specific information on silvicultural activities and vegetation composition is often lacking, superficial, or based on broad and heterogeneous classifications. We propose to: i) increasingly pay attention on the terminology used in research projects dealing with forest management and biodiversity; ii) use a common set of terms and data classification; iii) integrate specific terminologies with in-depth descriptions and ancillary data. The proposed standard could be adapted to other continents’ requirements and extended to other types of interventions in forests, bridging the gap between practice and science.

How integrated forest management caters to recreationists

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Jakob Derks[1]
Georg Winkel[1], Rik De Vreese[2], Lukas Giessen[3]
[1] Wageningen University
[2] European Forest Institute
[3] TU Dresden

Abstract: Integrated forest management (IFM) mainly revolves around the combination of production and conservation targets within a single area. The related forest management measures, such as the promotion of natural regeneration, selective harvesting and a continuous forest cover, do however also provide additional positive externalities, like aesthetically pleasing forest stands. The COVID-19 induced lockdown provided a prime example of this. Using long-terms visitor counts as well as hundreds of on-site interviews in the Kottenforst near Bonn, Germany, we studied forest visitors'perceptions of the forest and its management before and during the pandemic - when we identified a tremendous boom in forest visits.
One of the focal points of the study was the impact of various forest magament measures that compose IFM and how they affected the attitudes of the interviewed recreationists. IFM turned out to be a key factor in the high appreciation of the forest landscape, but the results also showed that the interviewees were generally not aware of the active management behind it. The selected forest stands were broadly perceived as being natural, despite their long and ongoing managment. IFM thus shows a potential to not just safeguard ecological processes and habitats in management forests, but also to cater to the ever evolving expectations of an increasingly urban populace.

Impacts of future forest use on biodiversity, ecosystem services and climate

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Abstract: We aim to identify pathways of sustainable future forest management that develops the bioeconomy and multifunctional forests by mitigating climate change, delivering non-woody ecosystem services and preserving biodiversity. This will be based on analyses of synergies and trade-offs among alternative uses of forest biomass for Sweden the coming 30 and 80 years. Our methodological approach is to simulate many forest management alternatives for the national forest inventory plots and then apply multi-objective optimization to identify future pathways that fulfil objectives to be specified for the Swedish forest. This optimization will concern harvest level, ecosystem services, biodiversity and climate chance mitigation, the latter based on life-cycle assessment. In the work, we will further utilize models for different non-woody ecosystem services and a wide range of species representing different organism groups. I will present our starting work on joint optimization of objectives on these wide-ranging responses of forest biomass use. In the presentation, I aim to answer these questions: How should we manage and harvest the Swedish forest to make red-listed species increase with 50%, retain current levels of non-woody ecosystem services and obtain maximal climate change mitigation? This will consider both the alternative of storing carbon in the forest or substituting fossil-based products for bio-based products. Will the management be different if the time horizon is year 2050 or 2100? Moreover, can we reach the 50% increase of red-listed species and what will be the effect on climate if we apply BAU forestry and today's protection for conservation versus if we apply forestry according to the EU Biodiversity Strategy (10% strict protection and 20% closer to nature forestry)?

In times of change: Water and forest policy integration in Germany

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Sabeth Häublein[1]
[1] Chair of Forest and Environmental Policy, ALU Freiburg

Abstract: Worldwide we are facing an increased frequency of disturbances related to global warming. Drought and its consequences have led to water scarcity and forest cover losses, floods have caused many casualties and polluted water bodies further reduce access to clean water resources. Water ecosystem functioning is highly dependent on forests, as especially forest biodiversity is crucial for a sustainable provision of high quality freshwater. It is thus, that throughout the last decade the interlinkages between water and forest has gained increasing attention in the scientific debates, commonly referred to as the water-forest-nexus. In order to govern these interlinkages and develop integrated water forest management approaches, scholars call for cross-sectoral policy integration. Policy integration is understood here as the joint development of policies across sectors. In the case of water and forest interlinkages, scholars deem it crucial that representatives of both sectors jointly engage in the development of policies that manage disturbances like drought, low water quality, and flood events. In our research we follow the implementation of water-forest policy integration by analyzing the respective sectors of Germany. In Germany, institutional and ideational policy integration of water and forest sectors were previously observed as low. With the publication of the German National Water Strategy in March 2023, however, forest concerns are for the first time integrated into water policy making. Our research aim is thus to analyze the corresponding policy change, which we deem necessary for the development of integrated management practices. Via a discursive-institutional analysis, we identify causes for the (late) implementation of water forest policy integration. The analysis is based on policy documents as well as expert interviews and follows the question how policy integration between the German water and forest sectors has entered the policy debates.

Managed forests and their ecological integrity: a case study in Central Mexico

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Martha Azucena Rendón-Pérez[1]

[1] Colegio de Postgraduados

Abstract: Timber production is not the only forest management objective to fulfill today; essential to sustainable use are also the conservation of biodiversity and the provision of other ecosystem services and functions. In this study, we set up and applied an index of ecological integrity (IEI) as a tool to assess the integrity status of managed ecosystems in a mountainous area of central Mexico. The study area had four vegetation associations: three under timber harvesting (with *Pinus montezumae*, *P. patula* and *P. pseudostrobus,* respectively) and one as a conservation area *(Pinus-Quercus*). The structure, composition, and function of these temperate forests were assessed at 79 sites using 20 indicators, corresponding to three ecological attributes: landscape, vegetation, and soil. The IEI was built to assess sites in the categories of excellent, good, fair, and low condition. The highest IEI value found was for the conservation area, within the excellent category, while the harvesting zones were classified as excellent (*P. patula)* and good *(P. montezumae* and *P. pseudostrobus)*. The IEI allowed for the characterization of the associations under management and the identification of indicators that required intervention or further research to maintain the IEI in an acceptable category. A baseline of knowledge was generated for the study area, and can be useful as a guiding sustainable forest management and harvesting practices.

Natura 2000 hemi-boreal forests in Lithuania – finding favourable management strategies towards meeting long term conservation aims

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Gediminas Brazaitis[1]
Vitas Marozas[1], Žydrūnas Preikša[1], Silvija Šaudytė-Manton[1], Birutė Valatkienė[2]

[2] Environmental Projects Management Agency under the Ministry of Environment of the Republic of Lithuania

Abstract: Natural habitats are protected, but management recommendations are still missing: the practises vary from strict conservation to business as usual in various European countries. Long term conservation is challenging for forest habitats, most of stands have even-aged structure, low tree species diversity, are vulnerable to damages and natural development often tends unfavourably. Hemi-boreal conditions require specific forest management.
The proposed concept of forest habitat management is based on division of habitat types into two categories: (I) Unique, not abundant and sensitive habitats; (II) Wider spread and typical habitats for the region. Management planning for category I habitats should be limited to stand level (conservation management, forest protection and growth measures); category II – planning expanded to a whole protected area by imitating natural forest dynamics that provide wider platform for silviculture manipulations. To achieve favourable status of forest habitats at protected area level the overall stand age structure of habitats should be considered.
The aim of the *conservation measures* is to obtain or/and maintain favourable conservation status of habitat. Applicable to all habitat types. They include stand management by cuttings and other necessary actions: invasive species control, forest density and structure management, undergrowth limitation, inhibition of unfavourable succession, prescribed burning, hydrological regime restoration, etc.
Planning *landscape natural dynamics imitation cuttings* must be undertaken on a whole protected area. As a safeguarding mechanism, it is required to exclude 30% of the most valuable habitats for the patch conservation management level, the remaining 70 % are subject to cuttings. It is based on natural forest disturbances of a habitat type and depends on typical disturbance characteristics and includes single tree (<0.05 ha) cuttings, small gaps (<0.25 ha) and large gap formations (0.25-1.0 ha). Large gap formations are applicable only if new patches of that habitat type were developed and identified at the level of the whole area of conservation.
Forest protection and growth measures can be applied under critical situations at limited extent. Measures should support or improve long term favourable habitat conservation status, not contradict defined protection goals, positively affect habitat. It includes stand sanitary control, thinning, reforestation and wildlife damage prevention.

Prediction of tree-related microhabitats across the European forest ecosystems to support the integrative forest management approach

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Abstract: Silviculture has traditionally been considered the science of growing and taking care of forests to promote high-quality timber production. However, over the years, there was an overall increase in awareness of the multifunctional role that forests play in human well-being, providing several ecosystem services. Among others, the conservation of biodiversity is considered of vital importance for which numerous forests are recognized as protected areas (e.g., strictly forest reserves and national parks), leaving the remaining forests for harvesting activities. The integrative forest management approach was introduced to balance timber production and the conservation of biodiversity of forests that are managed for commercial purposes. In light of this, tree-related microhabitats (TreMs) have gained attention over the past decade as a multi-taxonomic biodiversity indicator for retaining structural elements, such as habitat trees.

This study aims to predict TreMs across European forests exploring the existing relationships with dendrometric and topographic variables. Based on the European Integrate Network of marteloscopes, several generalized linear (or mixed) models were run to predict the occurrence, abundance, and richness of TreMs in different forest types.

Findings highlight the usefulness of TreMs as indicators of multi-taxonomic biodiversity, representing a suitable tool for assessing forest biodiversity and promoting integrated forest management. The predictive models can be tested with the forest inventory attributes to extend the assessment of potential biodiversity throughout European forests.

This study provides significant insights to promote the retention of high-value habitat trees, highlighting the need for developing a biodiversity-smart forestry toolkit, which can result strongly important for the management of forests within the Natura 2000 network.

Production forests in a changing climate - Balancing biodiversity and ecosystem services

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Adam Felton[1]
Salim Belyazid[2], Jeannette Eggers[3], Eva-Maria Nordström[3], Karin Öhman[3]

[3] Department of Forest Resource Management, Swedish University of Agricultural Sciences

Abstract: Climate change adaptation and mitigation strategies (CCAMS) are changes to the management of production forests motivated by the need to mitigate climate change, or adapt production forests to climate change risks. Fennoscandia is employing CCAMS with unclear implications for biodiversity and forest ecosystem services (ES). Here we report our findings from the SPARC project, in which we synthesized the outcomes of 54 published scientific reviews and evaluated the potential for balancing biodiversity conservation with a range of provisioning, regulating and cultural ES when adopting CCAMS relative to standard forestry practice. The CCAMS assessed were the adoption of i) mixed-species stands, ii) continuous cover forestry, iii) altered rotation lengths, iv) conversion to introduced tree species, v) logging residue extraction, vi) stand fertilization, and vii) altered ditching / draining practices. There were clear differences in the consistency of different CCAMS with their capacity to enhance the habitat provision of production forest stands and landscapes. As importantly for CCAMS uptake, CCAMS that had more synergistic outcomes with biodiversity goals have the potential to provide comparable or increased levels of biomass production or soil carbon sequestration. These CCAMS can also provide for a broader range of additional ES delivery than CCAMS incurring trade-offs with biodiversity. Nevertheless, there were no silver bullets. The adoption of specific CCAMS entails a suite of implications for biodiversity, biomass production, and stand recreational and aesthetics values, as well as highly specific trade-offs and synergies with respect to which abiotic and biotic disturbance risks are reduced or enhanced. Balancing these outcomes and making necessary trade-offs creates challenging conditions for decision-makers when choosing between alternative forest management strategies. Thus, there is a need for effective planning among decision makers and stakeholders to develop and implement landscape-scale CCAMS strategies that better integrate potential synergies and minimize trade-offs when balancing biodiversity and ES outcomes.

Simulating forest dynamics during field marteloscope exercises to analyze the effects of silviculture on ecosystem services and biodiversity

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Abstract: Marteloscopes are forest plots used to teach tree marking and to discuss silvicultural strategies. They are popular with forestry professionals, students and the general public as tools that make silvicultural concepts concrete and stimulate discussion among participants. This is particularly the case in mixed continuous cover forestry and in situations of trade-offs between ecosystem services. Several computational tools have been developed to represent the forest plot before and after harvesting and to compare the markings of different groups of participants. We present here a complete processing chain that allows to simulate in the field with the Samsara2 simulator on the Capsis platform not only the proposed field marking, but also successive silvicultural interventions consistent with the field marking, and the stand evolution over 50 years. We present an application of this process on a marteloscope designed to raise awareness of the effects of silviculture on wood product supply, biodiversity conservation and carbon sequestration. We also show the economic consequences of different strategies for the forest owner, which could provide a basis for thinking about payments for ecosystem services. We discuss initial feedback from participants on the educational value of this approach and future developments towards the inclusion of other ecosystem services and the evaluation of silvicultural strategies in relation to climate change.

Strategic management of the portfolio of forest ecosystem services in public forest enterprises in Slovakia

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Alex Bumbera[1]
Daniel Halaj[1]
[1] Technical University in Zvolen, Faculty of Forestry, Department of Forest Economics and Management, T. G. Masaryka 24, SK-96001 Zvolen

Abstract: The work identifies the difference between the current and future strategic management of the forest ecosystem services (FES) portfolio in Slovakia's public forest enterprises. We chose public forest enterprises in Košice, Banská Štiavnica, Kremnica, and Bratislava. These enterprises represent examples of the best practices in providing cultural services within the individual regions of Slovakia. The current portfolio of forest ecosystem services was analysed using a marketing decision-making model (BCG matrix). The input data were revenues for individual forest ecosystem services of respective companies. The content analysis of the interview was used to evaluate the future position of forest ecosystem services in companies' portfolios over the horizon of 10 years. Structured interviews were conducted with managers of selected forest enterprises. Currently, the portfolios of all companies are unbalanced due to the dominant position of revenues for provisioning services (especially wood production). Revenues for provisioning services account for 67-99%, cultural 0.33-32%, and regulatory and maintenance services 0-1.84% of total revenues. Revenues for regulatory and maintenance services are realized as compensation for the limitation of regular economic activity or finances to support non-production services. Company managers are of the opinion that no significant changes will occur in the next ten years. Enterprises will apply a combined management approach, and revenues for provisioning services (wood) will form the primary source of income. Cultural services will be provided similarly to today, while their financing will depend on the revenues from selling wood assortments again. At present, the exception is the public forest enterprise in Bratislava, which partially balanced its portfolio with the financial support of the city budget. Based on the content analysis of the interview, we can label the managerial approach of FES management in Bratislava enterprise as close to nature management.

Keywords: forest ecosystem services, urban/public forest enterprises, portfolio, BCG matrix, future

The ecological value and ecosystem services of young native woodlands

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Kate Harrington[1]
Jane Stout[1], Fraser Mitchell[1]
[1] School of Natural Science (Botany), Trinity College Dublin

Abstract: Ireland has an ambitious afforestation programme aimed at increasing forest cover. While the overall forestry programme is still primarily focused on timber production, with conifer plantations remaining central to its delivery, recent targets include a significant proportion of native woodland afforestation. In addition to increased standard payments, landowners are now also being incentivised to plant native woodland for ecosystem service payments from public and private sources. Ecological structure and condition attributes for mature native woodlands are well established, however these do not represent the potential ecological values of immature woodlands which may align more with those of open habitats. There is a need for data to inform relevant indicators of ecological value of young woodland sites and to understand how these change as the woodlands develop. This presentation will describe the results of field research carried out in 2022 and 2023 in planted native woodland sites in Ireland aged between 2 and 20 years old. Data on the structure and flora within 100m^2 plots across a range of woodland sites were collected, and pollinating insect surveys were carried out at a subset of these sites. Based on the results of these surveys, we will discuss what factors may be driving the diversity and composition of species in the young woodlands, which aside from age may include former land use, management approaches or landscape influences. We will also explore how ecological data can be transformed into ecosystem service metrics. The success of native woodland establishment in Ireland is often summed up as 'the right tree in the right place', and so the implications of this research for current approaches to planting and management will be highlighted. The work forms part of the ongoing multidisciplinary FOREST project, which is aiming to explore different perspectives on the values of extending Irish forest networks with native species. Afforestation has consequences for environment, people, and economies, but is often only assessed through a single lens. Drawing on research from other team members, we will also touch on the broader challenge of evaluating trade-offs between the environmental, economic and social consequences of native woodland afforestation.

The response of forestry organisations to long-term and short-term factors influencing forest management

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Milan Sarvaš[1]
[1] National Forest Centre - Centre of Transfer of Knowledge and Forest Pedagogy

Abstract: Forests and their management are currently facing major challenges, in particular climate change, which is having a significant and long-term impact on forests. Other long-term factors include changing preferences in the use of ecosystem services of temperate forests. In Slovakia, society has begun to prefer the environmental and social functions of forests. In addition to these long-term factors, forest management is also affected by sudden changes such as the COVID 19 pandemic, the war in Ukraine and the rise in energy prices. The impact of these factors on the change in the organisation of work in forestry organisations was evaluated through a questionnaire survey in Slovakia. Interim results showed that forestry entities have not experienced changes in the forestry labour market caused by the above-mentioned factors, nor are they preparing changes in job positions. The forestry sector remains in the traditional management mode, where the priority is sustainable forest management, with a substantial part of the income based on the production of wood raw material. The forestry sector is not actively responding to the changes, not only at the organisational level, but also in the training of employees to faced these changes.

To Manage Or Not To Manage? Evaluating the Impact of Management on Ecosystem Function in European Forests Through Satellite Remote Sensing

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Jonas Simons[1]
Bart Muys[1], Ben Somers[1], Koenraad Van Meerbeek[1]
[1] KU Leuven

Abstract: Forest management affects forest health and the provisioning of multiple ecosystem services, including carbon sequestration and biodiversity conservation. However, current scientific evidence concerning these relationships is not unequivocal, mainly due to a lack of unconfounded observational comparisons between managed and unmanaged forests. This gap in the literature, along with evolving societal expectations of our forests, poses great challenges for forest managers: How can we ensure biodiversity conservation within our European forests? And how can this conservation goal be integrated with economic (bioeconomy, timber…) and environmental (carbon sequestration, water regulation, soil protection…) goals that are expected of our forests? How can we simultaneously ensure our forests' resilience in the face of climate change? Within the Horizon Europe INFORMA project, we address these questions in three phases. In the first phase, the need for unconfounded observational comparisons between managed and unmanaged forests is addressed through the creation of the INFORMA Forest Management Platform. The Platform is a database of clustered forest patches across Europe comparing managed (including a management gradient) and unmanaged forest patches, excluding confounding variables (soil, topography, climate, species etc.) as much as possible. In the second phase, satellite remote sensing data are used to compare ecosystem functioning between these managed and unmanaged forest patches. Spatial General Linear Mixed Models (sGLMM) are employed to analyze the data. In the third phase, the stability of forest ecosystem functioning for both managed and unmanaged forests is addressed. Here, we will present the methodology behind the development of the INFORMA Forest Management Platform and discuss its potential for future forest management research within Europe. Furthermore, we will discuss the first results of the sGLMM by reporting on the differences in gross primary production and forest structural diversity between managed and unmanaged forests, as well as their stability. Lastly, we will reflect on the perspectives of the INFORMA Forest Management Platform for research relevant to EU policy.

Tree species selection has a major impact on understory vegetation species abundance and composition

T3.20 integrated forest management in temperate and boreal forests - balancing biodiversity and ecosystem services

Ola Langvall[1]
Maria Lundgren[1]
[1] Swedish University of Agricultural Sciences, Unit for Field-based Forest Research, Siljansfors Experimental Forest

Abstract: Tree species composition and performance in the boreal forest is greatly formed by local climate, soil and water conditions. For the understory vegetation, not only these abiotic factors are important for the structure and composition, but also the selection of the overstory tree species has a great influence.

We hypotetised that the selection of the overstory tree species has a major impact on the understory vegetation on the same site, over long time.

In two long-term forest experiments in a boreal forest area, established in 1964 and 1968, respectively, five tree species, Scots pine, Norway spruce, Silver birch, Russian larch and European larch, was planted in monocultures with similar abiotic conditions. Each species were treated with thinnings for best practice for wood production. In 2021 and 2022, understory tree numbers and size, as well as the number of species and coverage of other vegetation was assessed in all plots.

The number of understory trees and their species composition varied significantly, depending on the overstory tree species. The ground floor vegetation was influenced in a similar way. The number of species found under the different tree species were quite equal, but species composition and coverage was significantly different. The extremes were in the Norway spruce and Silver birch plots, where the former had a higher number of moss and lichen species, while the latter had a higher number of herbaceaus species.

The differences could possibly be explained by the different biomass production levels, silvicultural treatments, below-canopy light conditions and the amount and quality of the litterfall, that the tree species produce.

The conclusion of the study is that we can greatly choose to form the understory in different directions, depending on the choice of tree species in the forest.

T3.21 Legacy tropical forest data: current status, uses, and securing them

Acquisition and use long-term observational data on forest dynamics to assess the impact on climate change in tropical seasonal forests in Thailand

T3.21 Legacy tropical forest data: current status, uses, and securing them

[3] Tohoku Research Center, Forestry and Forest Products Research Institute, Morioka, Japan
[4] Japan International Forestry Promotion and Cooperation Center, Tokyo, Japan
[5] Hokkaido Research Centre, Forestry and Forest Products Research Institute, Sapporo, Japan

Abstract: Forest dynamics have been observing since 1992 to the present, to assess the impact of climate change, established in a long-term monitoring site in dry seasonal forest Kanchanaburi, western Thailand.

Tree census have been carried out and the dominance of the understory vegetation type recorded at natural, secondary forest and site after slash-and-burn at 20x20m unit established in 4ha research plot each in a long-term monitoring site. Soil survey were also conducted.

Mixing with several bamboo species are characterized in the forest in this region, and gregarious flowering of three bamboo species occurred, followed by rapid changes in the vegetation type in the understory were observed during this period.

With regard to the mitigation function of forests in climate change, the contribution of bamboo biomass in carbon storage has been determined, and carbon dynamics have been assessed by observing carbon fluxes at a tower and soil respiration. It is also characterized by extreme dryness and frequent wildfires without rainfall in a dry season from November to March. So, there is no nutrient and water supply from the soil to the plants and then different mechanism of material cycling from the rainy season was also clear.

Furthermore, long-term observations have shown that the frequency and intensity of wildfires varies with the topography and associated environmental inclinations. This mechanism may be one of the factors defining the mixed distribution of some of the bamboo species characterized in the forest in this region. Recent climate change has altered the frequency and intensity of rainfall in Thailand, which may affect the distribution of bamboo in the future. Therefore, research is currently focused on this aspect, together with an assessment of the function of silicon on wildfire tolerance by species.

Thus, long-term observations in tropical seasonal forests contribute not only to the scientific clarification on forest dynamics, but also to new issues such as the evaluation of the impact of climate change on carbon dynamics. We would like to continue long-term observations to accumulate data, and we would like to research with researchers to publish and utilize the data to clear the new issues.

Dendrometric evaluation of Khaya grandifoliola C. DC. as a function of phosphorus doses in Brazilian Cerrado

T3.21 Legacy tropical forest data: current status, uses, and securing them

Glauciana Ataíde[1]
Aline Vasconcelos[2], Bianca Trindade[1], Renato Castro[1], Igor Cavaglieri[1], Cristiano Meira[2], Mayra Fraga[2]
[1] Federal University of São João del-Rei (UFSJ), Department of Forestry, Brazil
[2] Federal University of São João del-Rei (UFSJ), Department of Agricultural Sciences, Brazil

Abstract: *Khaya grandifoliola* C. DC. is a tree of African origin belonging to the botanical family Meliaceae, popularly known as African mahogany. It is a species that has been standing out in forest plantations in Brazil, of great importance due to its high value in international trade and relatively fast growth. For plants to develop and express all their productive potential, a correct supply of nutrients is necessary. In Brazil, African mahogany is generally planted in acidic and nutrient-poor soils, such as Cerrado soils, making fertilization an essential practice for higher yields. In this context, this work aimed to evaluate the growth of *K. grandifoliola* plants in soils of the Brazilian Cerrado as a function of phosphorus (P) doses at planting. The experiment was carried out at Fazenda Espanha, located in the municipality of Pompéu, in Minas Gerais, Brazil, at latitude 19º 13' 28" S and longitude 44º 56' 07". Four doses of phosphorus applied in the planting were evaluated: 150, 200, 300, and 400 kg.ha^{-1}. The experimental design was randomized blocks, with eight replications. Every 180 days after planting, the height and diameter of the plants were measured, as well as the nutrient content in the soil and leaves. Plants subjected to the highest P dose (400 kg.ha^{-1}) showed the highest growth rates for all analyzed variables, as well as higher P levels in the soil in the 0-20 and 20-40cm layers. On the other hand, the lowest P rates used (150 and 200 kg.ha^{-1} a) resulted in lower P availability in the soil, negatively affecting plant development. Thus, for the initial growth of *K. grandifoliola* plants in the condition studied, in Brazilian Cerrado soils, the application of 400 kg.ha^{-1} of P in the planting is recommended.

Efforts to publish East African tropical forest insect data currently under the custody of Kenya Forestry Research Institute

Abstract: European explorers first undertook surveys of flora and fauna in Eastern Africa in 1862. The specimens they collected were housed in museums in Berlin, Vienna, London and Brussels. Germany then took control of contemporary Burundi, Rwanda and mainland Tanzania in 1891, which was followed by about 25 years of effective land tenure. German foresters made scientific contributions including extensive inventories and utilitarian assessments of native trees in addition to aggressive testing and distribution programs for mostly exotic tree species. They were also concerned with the protection of forest plantations and reserves from destructive agents. These colonial scientific interests were transferred to the British who later occupied Kenya, Uganda and Tanzania. By 1948, the East African Agriculture and Forestry Research Organization was formed with its headquarters in Muguga, Kenya to consolidate such past research efforts. During the post-independence era, these research interests were managed by the East African Community but it broke up in 1977 and Kenya Agricultural Research Institute (KARI) became its successor in Kenya. The Forestry Department of KARI evolved into the more specialized, independent Kenya Forestry Research Institute (KEFRI) in 1986. KEFRI subsequently holds over 50,000 analog records of insects on paper and associated specimens collected over time from Eastern Africa. These are preserved in an Insect Reference Collection as dried, pinned specimens or in industrial alcohol. KEFRI commenced efforts in 2016 to convert analog records of the collection into digital formats that can be widely shared electronically under creative commons licenses. Staff are trained in using SPECIFY software and about 1000 records are ready for uploading. The Institute registered in 2021 as a data publisher in the Global Biodiversity Information (GBIF) platform (http://ipt.kefri.org/ipt/). Future plans are to publish occurrence lists and data using the GBIF IPT. Other associated knowledge products include e-posters and training videos codifying tacit knowledge and curation skills necessary for the maintenance of the physical specimens. This collection holds valuable material for morphological and genetic, taxonomic identification with application in integrated pest management and advancement of restoration of tropical forests in response to climate change.

Key words: historical data, tacit knowledge, digitization, IPM

Progress in locating legacy tropical data and related resources

T3.21 Legacy tropical forest data: current status, uses, and securing them

Sheila Ward[1]
Jenny Wong[2, 3], Gillian Petrokofsky[4], Hans Juergen Boehmer[5]
[1] Mahogany for the Future, Inc, Puerto Rico, USA
[2] Wild Resources Ltd., United Kingdom
[3] Bangor University, Department of Forestry, United Kingdom
[4] University of Oxford, Long-Term Ecology Lab, United Kingdom
[5] Leibniz University, Institute of Geobotany, Germany

Abstract: Imagine information 100 years old or more, sitting on a multitude of old shelves or in filing cabinets all over the world, in print format and many, sometimes obsolete digital formats. Imagine that this hidden information could be critical for managing natural resources now and in the future, including under climate change. Such is the case with legacy tropical forest datasets. We have been on the search for these datasets and funding for their recovery for several years. These datasets are held by academic institutions, government agencies, international development agencies, and private individuals around the world. Without appropriate curation, the future of these data is precarious.

Recently the effort expanded to include related information. Living legacy tropical foresters are another endangered resource, some of whose careers can stretch back to the colonial era. Interviews have been conducted with several on their experiences and bodies of work. There are also numerous publications related to tropical forestry that are available only in paper or microfilm/microfiche. These include bulletins and reports from the colonial era and early development projects in various countries. With the help of university interns, the online library catalogues of the University of Oxford (former home of the Oxford Forestry Institute), and the British Library have been perused for these bulletins and reports. To date, over 2000 titles for about 200 countries have been compiled. We are now working to locate electronic versions of these publications.

The next step is to obtain funding for digitizing these datasets and related resources. We are getting interest from different foundations. This help may plant the seeds for attracting other resources. The goal is to get these datasets and important publications broadly available and used in restoration and management efforts.

TraitDivNet: an open global network advancing knowledge on above and belowground ecosystem functioning

T3.21 Legacy tropical forest data: current status, uses, and securing them

Blanca Luz Caleño Ruiz[1]
Carlos Perez Carmona[1], Enrico Tordoni[1]
[1] University of Tartu, Institute of Ecology and Earth Sciences, Estonia

Abstract: To understand ecosystem functioning, the use of plant traits related to their growth, resistance, and reproduction (e.g., height, stem density, leaf and root thickness, size of seeds) allows for defining how plants respond to competition, disturbances, and environmental conditions, which ultimately affects ecosystem processes (e.g., water and nutrient cycling, decomposition, pollination). There is a wide variety of studied traits following different sampling methodologies and focused on characterizing functions of aboveground organs, although they interact with belowground structures and both influence ecological processes. However, available information for belowground traits is particularly scarce to draw a complete picture of plant functions across the globe, which limits understanding of ecosystem functioning at large scales.

Considering this information gap, we promoted a global network to create an extensive trait database using standardized methods, a wide variety of dominant species, and the ten most informative traits to improve the knowledge on above and belowground plant functions and how they affect ecosystem processes under future climatic change. We developed a detailed protocol with a global standardized methodology using 10x10 m plots in natural and seminatural ecosystems to measure six aboveground (leaf area, specific leaf area, leaf nitrogen, seed mass, specific stem density, and total height) and four belowground traits (root diameter, specific root length, root tissue density, and root nitrogen) for the 20 most abundant vascular plant species. We included soil sampling to measure soil texture, nutrients, and microbiota and registration of coordinates, vegetation characteristics, human management regime, and topography.

Currently, we have a global network of more than 200 plots distributed worldwide, but some regions of Africa, Southeast Asia, and South America need to be represented, whereby we encourage potentially interested colleagues to join our initiative. We will use this information to describe the function of different plant communities and to predict how projected climate change may influence it and affect global ecosystem processes. We expect that our results contribute to a complete view of how different plant organs interact and affect critical processes in the atmosphere and soils that ensure habitats for all organisms worldwide.

Unearthing Past Sundaland's Legacy: The Savanna Corridor of Belitung Kerangas Forest, Indonesia

T3.21 Legacy tropical forest data: current status, uses, and securing them

Dina Oktavia[1]
Santi Dwi Pratiwi[2]
[1] Department of Transdisciplinary, Graduate School, Universitas Padjadjaran. Jl. Dipati Ukur No, 35, Bandung 40132, West Java, Indonesia
[2] Department of Geosciences, Faculty of Geological Engineering, Universitas Padjadjaran. Jl. Ir.Soekarno Km. 21, Jatinangor, Sumedang 45363, West Java, Indonesia

Abstract: Sundaland heath forest (Kerangas forests) hold significance within tropical ecosystems as they fulfill crucial roles in biodiversity conservation, climate change mitigation, and the provision of valuable ecosystem services to local communities. During the Last Glacial Maximum, the Kerangas forest was situated within the tropical grassland. Thus, this ecosystem possesses distinct characteristics such as acidic and nutrient-deficient sandy soil, along with unique flora and fauna. These forests today are common on the island of Belitung where during Permian - Triassic stages of suturing there was extensive granite magmatism and that holds the distinction of being the biggest primary tin-producing islands. We documented some carnivorous plants (i.e., *Nepenthes* spp. and *Drosera* spp.), various medicinal plants, and numbers of liana/ woody liana. *Cephalopachus bancanus saltator* is one of the endemic fauna species in Belitung Island Kerangas forest. This research highlights the need to reassess the significance of the Kerangas Forest in Belitung islands, Indonesia due to the high threat of forest ecosystems in small island areas. The Belitung island as part of Sundaland craton represents a segment of the main Devonian to Middle Triassic Palaeo-Tethys ocean in the Indo-Pacific Warm Pool that supplies a sizable fraction of the water vapor in Earth's atmosphere and plays a role in propagating El Niño cycles. To address this issue, it is strongly recommended to promptly establish a permanent dynamic research plot in Belitung to investigate the diverse ecological processes within the Kerangas forest (i.e., part of ForestGEO network). The identification of plant diversity integrated with paleobiography and paleoclimate in this area are still limited. Given its vital ecological function, the Kerangas forest status as a forest ecosystem of high conservation value deserves careful assessment. Kerangas forest might be the evidence of the existence of "Savanna Corridor " during the Last Glacial Period at times of lowered sea-level when the sand dominates the bottom sediments along the submarine. Thus, more research and studies are also encouraged to reveal the evidence that comes from geomorphology, relationship between biodiversity and biogeography, record of keys species of natural vegetation and palynology.

Using historical tree plot inventory data to investigate the biogeography of Tropical America

Abstract: Tropical America, including the Caribbean, harbours the highest species diversity compared to any other region in the world. However, this remarkable diversity is facing severe threats from climate and land use change. While plot inventory networks have been successful in generating syntheses on biodiversity patterns and ecosystem functioning; cross-biome, plot-based studies in the tropics are rare, preventing the identification of general vs biome-specific responses to global change drivers. To address this knowledge gap, the SynTreeSys project is utilising world-leading expertise in tropical ecology to conduct a comprehensive assessment of tree species diversity

patterns and its conservation status across the region. To achieve this, we are constructing a harmonised database to i) identify spatial patterns of tree diversity and dominance and the underlying causes of their variation, ii) detect zones of exceptional species turnover and, iii) to assess tree species conservation status in tropical America.

One of the challenges in tropical regions is ensuring the homogeneous representativeness of biodiversity datasets. In areas with limited information or extensive land use transformation, historical data becomes a valuable source. The SynTreeSys-generated database covers a time span of almost 90 years, with approximately 10% of the plot data collected before 2000. The oldest dataset available dates back to 1934, comprising inventory plots documenting the vegetation of Moraballi Creek in Guyana, published by T. A. W. Davis and P. W. Richards, and gathered by the Amazon Tree Diversity Network (ATDN). In SynTreeSys, we emphasise the importance of "old" data, not only for the inherent value it holds but also for the rich narrative of the studies and their ability to provide historical and detailed descriptions of habitats, vegetation structure, soil, and even species interactions.

Using legacy data in long-term tree mortality monitoring and forest dieback research

T3.21 Legacy tropical forest data: current status, uses, and securing them

Hans Juergen Boehmer[1]

[1] Institute of Geobotany, Leibniz University Hannover, Nienburger Straße 17, 30167 Hannover, GERMANY

Abstract: Long-term monitoring of forest plots has been integrated into ecological research in montane forests of the Pacific island of Hawaii ("Big Island") since the 1970s. After widespread forest decline ("ohia dieback"), 26 permanent plots were established in 1976 in dieback and non-dieback forest patches to monitor the population structure of tree species. Twenty-five of these plots have been resurveyed five times during the following 27 years. Data suggested that forests affected by dieback have started to recover their tree canopy as a new cohort of young trees were growing back in these sites. However, it was not clear if these results truly represented the conditions across the entire former dieback area of ca. 50,000 hectare. We used those legacy data sets for long-term monitoring of individual trees, and to understand the landscape-level dynamics of forest dieback and regeneration in Hawaii´s rainforests. To assess the present status of the forest canopy across the eastern side of the island of Hawaii we analyzed very-high-resolution imagery collected between 2008 and 2015. The Pictometry (POL) imagery consists of three-band, true-color red-green-blue (RGB) digital photographs; the images have a spatial resolution of ~20 cm. To calibrate our assessment process we constructed POL plots around the locations for the 25 permanent plots that had been established in 1976, and then compared our new assessment of canopy dieback using POL imagery for these locations with the status from the most recent ground-based resurvey of these plots. The results were combined with habitat data to produce a spatial model depicting probability of canopy dieback within the study area.

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Assessment of two contrasting French Douglas-fir seed orchards: potential for adaptation to climate change

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

[6] Université Clermont Auvergne, INRAE, UMR PIAF, France

Abstract: Douglas fir is an important tree species in France and represents the second species for reforestation. To meet the seed demand, eight seed orchards (artificial provenances) were planted between 1978 and 1989. A research network was established in 2009 to evaluate the growth and behavior of French seed orchard progenies. Two seed orchards with different genetic compositions (clones selected from progeny tests of the northern and southern provenances of the North American native range, respectively) are differentiated mainly by their contrasting vegetative bud burst and juvenile growth. In the context of increasing recurrence of droughts, we assessed the drought tolerance of these two seed orchards.

Several experiments were conducted in France, comparing progenies from the two seed orchards. In one of them, automatic dendrometers were installed to compare daily climate impacts on the growth dynamic of the two contrasting seed orchards progenies.

Results showed that progenies from the "southern" seed orchard had significantly smaller growth compared to the "northern" seed orchard under current optimal climatic conditions. However, under drier conditions, differences between these two seed orchards were greatly reduced or showed no significant growth differences. Current results and observations from controlled experiments and automatic dendrometers showed that the progenies of the two seed orchards have different strategies to cope with droughts.

Our findings extend current knowledge on the potential adaptation of Douglas-fir genetic resources to drought. Moreover, these results could be used in further studies to understand drought tolerance mechanisms and help breeders select genetic resources for future seed orchards.

Combined metabolomic and genetic profiling reveal optimal harvest strategy model based on different production purposes in olive

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Guodong Rao[1]
[1] Research Institute of Forestry, Chinese Academy of Forestry

Abstract: Olive (*Olea europaea* L.) is internationally renowned for its high-end product, extra virgin olive oil. To further explore the genetic and breeding utilization of olive, an draft genome of olive was obtained using Oxford Nanopore thirdgeneration sequencing and Hi-C technology. Seven different assembly strategies were used to assemble the final genome of 1.30 Gb, with contig and scaffold N50 sizes of 4.67 Mb and 42.60 Mb, respectively. We assembled 1.1 Gb of sequences of the total olive genome to 23 pseudochromosomes by Hi-C, and 53,518 protein-coding genes were predicted in the current assembly. Comparative genomics analyses, including gene family expansion and contraction, whole-genome replication, phylogenetic analysis, and positive selection, were performed. Based on the obtained high-quality olive genome, a total of nine gene families with 202 genes were identified in the oleuropein biosynthesis pathway, which is twice the number of genes identified from the previous data.This new accession of the olive genome is of sufficient quality for genome-wide studies on gene function in olive and has provided a foundation for the molecular breeding of olive species.

Olive oil has been favored as high-quality edible oil because it contains balanced fatty acids (FAs) and high levels of minor components. The contents of FAs and minor components are variable in olive fruits of different color at harvest time, which render it difficult to determine the optimal harvest strategy for olive oil producing. Here, we combined metabolome, Pacbio Iso-seq, and Illumina RNA-seq transcriptome to investigate the association between metabolites and gene expression of olive fruits at harvest time. A total of 34 FAs, 12 minor components, and 181 other metabolites (including organic acids, polyols, amino acids, and sugars) were identified in this study. Moreover, we proposed optimal olive harvesting strategy models based on different production purposes. In addition, we used the combined Pacbio Iso-seq and Illumina RNA-seq gene expression data to identify genes related to the biosynthetic pathways of hydroxytyrosol and oleuropein. These data lay the foundation for future investigations of olive fruit metabolism and gene expression patterns, and provide a method to obtain olive harvesting strategies for different production purposes.

Comparative Study on Financing and Long-Term Planning of Forest Reproductive Material in Different European Countries

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Boris Rantaša[1]
Hojka Kraigher[1]
[1] Slovenian Forestry Institute

Abstract: The forest reproductive material (FRM) sector (forest nurseries and forest tree seed suppliers) plays a crucial role in the artificial regeneration and restoration of forests, particularly in the context of climate change adaptation in Europe and worldwide. The use of appropriate FRM, including a diverse range of species and genetic variations, is essential for conserving and enhancing the adaptability of forests. However, the FRM sector faces significant challenges, primarily related to financial constraints and the impacts of climate change, which affect the long-term planning of forest nurseries and seed production.

To facilitate an improved legislative and financial framework for forest nurseries in Slovenia, this qualitative study provides an overview of legislative, contractual, and funding solutions for FRM production in different European countries, with a focus on Central and Southeast Europe. The study incorporates a literature review, consultations with EUFORGEN and other experts (web inquiries, online interviews), and a qualitative analysis of the results using the grounded theory method.

The findings of this study indicate that comparing different systems for FRM provision between European countries is challenging due to the specific organizational structures in each country. Long-term contracts between FRM dealers and forest owners or state entities are uncommon and rarely implemented in practice. However, such contracts offer a sustainable model for the provision of FRM, particularly in the face of large-scale forest disturbances. Long-term predictions of FRM needs, from the public to the private sector, are infrequent except in countries with large public forest companies.

In the end, we highlight several key findings and best practices that could contribute to better organisation and financing of the FRM sector in European and other countries and regions.

Conservation and sustainable utilization of forest genetic resources for livelihood of forest communities in Western Himalayas

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Manisha Thapliyal[1]
Namitha NK[1], Sheeshram Dangwal[1]
[1] Forest Tree Seed Laboratory, Silviculture and Forest Management division, ICFRE-Forest Research Institute, Dehradun, India

Abstract: Forest genetic resources have been recognized as one of the key pillars of sustainable forest management that depend on conserving genetic diversity and ensuring its continuity among generations. India has four biodiversity hotspots, Himalayan region amongst which, is very unique that supports immense biodiversity and FGRs diversity. People inhabiting the Himalayan region have a unique and special relationship with the forests that directly support their livelihood, however they also contribute to initiatives in the conservation of forests which is based on their traditional knowledge. Himalayan forests have been under immense pressure of providing for an ever increasing population of the region which calls for conservation efforts with advanced research and technological support. A pilot research programme on conservation of Forest Genetic Resources (FGRs) with special focus on the FGRs of North-West Himalayas was implemented, under which, documentation of species populations, their characterization and germplasm storage, were done. The population of the prioritized species were explored, geo-tagged, their phenological observations and species associations recorded. After collection at optimal maturity, seeds were processed, quality-evaluated and desiccated to safe moisture levels for storage. The seed storage physiology of important Himalayan species like spruce, maples, *Carpinus*, *Buxus*, *Fraxinus*, pines, rhododendrons, walnut, hazelnut, *Hippophae*, medicinal species, etc. and few endemic species like *Pittosporum eriocarpum, Butea pellita*, etc. were standardized for chalking out a long-term *ex situ* conservation programme. Seeds of most of these species have orthodox storage physiology, which after desiccation to lowest safe moisture levels were vacuum sealed and stored in the National seed bank at -18^{0}C for conservation and periodic regeneration, in future. The germplasm of species so raised in the nurseries, will be planted back in their natural range, in collaboration with forest department and the local communities. Field germplasm banks of several species were also established for multiplication of germplasm. Knowledge generated from FGR conservation programmes will be utilized not only for conservation of the valuable genetic resources but also their sustainable utilization by the communities, in future.

EX-SITU CONSERVATION AND MANAGEMENT OF SHOREA LEPROSULA GENETIC RESOURCES VIA THE ESTABLISHMENT OF SEEDLING SEED ORCHARD

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

MOHD ZAKI ABDULLAH[1]
Nor Fadilah Wook[1], Farah Fazwa Md Ariff[1]
[1] Forestry Biotechnology Division, Forest Research Institute Malaysia, 52109 Kepong, Selangor, Malaysia

Abstract: *Shorea leprosula* is a timber tree species in the family Dipterocarpaceae. It is native to Peninsular Malaysia, Sumatra, Borneo, Java and Thailand. In 1997, a progeny trial plot of *Shorea leprosula* was established in Forest Reserve Ulu Sedili, Johor, Malaysia via a collaborative research between the Forest Research Institute Malaysia (FRIM) and Forestry Department of Peninsular Malaysia (FDPM). This pioneer study involved seed collection from 40 half-sib families in five forest reserve (FR) areas in Peninsular Malaysia whereby selection of the mother trees was made based on the tree grading characteristic. The progeny trial plot consists of 1280 trees within an area of 2.05 hectares. At the age of 20 years old, the growth performance range for its height (HT) and the diameter at breast height (DBH) ranged from 17.2 m to 25.7 m and 21.5 cm to 27.4 cm, respectively. Genetic evaluation and DNA profiling were carried out for the establishment of Seedling Seed Orchard (SSO). A total of 15 Simple Sequence Repeat (SSR) markers were utilized to assess the genetic diversity and genetic relatedness of the trees planted in the plot. Findings showed that each profile is distinctive and can be used as a denomination for registration and verification of superior trees. The mean number of alleles per locus (Aa) for the entire SSO was 13 whereas the expected heterozygosity (He) was 0.7121. Values obtained were either comparable or higher for the species and other dipterocarps. The He ranged from 0.6762 (FR Bangi) to 0.7163 (FR Tranum) and the Aa ranged from 5.60 (FR Tranum) to 11.27 (FR Gombak). Results show that SSO of *S. leprosula* established has a diverse gene pool which amplifies its potential for application in future breeding programmes and for ex-situ conservation in the central region of Peninsular Malaysia.

Keywords: selection, plus trees, progeny trial, Simple Sequence Repeat (SSR), gene pool

Ex-situ genetic conservation at the leading edge: from genetic simulations to practical implications for multifunctional genetic conservation

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Jan Peter George[1]
Mari Rusanen[1], Leena Yrjäna[1], Egbert Beuker[1], Visa Kamppari[2]
[1] Production Systems, Natural Resources Institute (Luke), Helsinki, Finland
[2] University of Helsinki, Helsinki, Finland

Abstract: Conservation of forest genetic resources has become a target in international agreements such as the United Nations Convention on Biological Diversity (CBD) and as agreed upon during the Kunming-Montreal Global Biodiversity Framework (GBF). Under Forest Europe, conservation through in situ units is implemented and monitored in a systematic manner. Yet, meaningful indicators and measures for the evaluation of conservation success or identification of conservation gaps have been rarely put into action for *ex-situ* conservation of minor tree species, mainly because *ex-situ* genetic conservation has been considered less important than *in situ* programs. However, *ex situ* genetic conservation of rare and scattered tree species at the so-called leading edge (i.e the northern population margin) will be even more crucial in the future, because northward migration of these species will not be limited by the cold climate, but rather by sufficient levels of gene flow, and dispersal capacity.

We present here an integrative framework from the Finish conservation program of forest genetic resources for nine tree species, based on simulated population and allele sampling. Delineation of populations and estimation of population sizes (mean and variance) are determined from an exhaustive archive of field observations in Finland and combined with high-resolution geoinformation, such as the Finnish forest map and land use information, to reduce potential bias in biodiversity observations. We evaluate the current *ex situ* strategy by benchmarking captured diversity against the minimum number of individuals needed to conserve 95% of allelic variance considering species-specific allele frequency patterns. We also discuss the implementation of allele copy numbers for back-up purposes in existing *ex situ* archives and the effect of different sampling and conservation strategies (clonal copies vs. seed and dynamic vs. static conservation) for optimal long-term security of genetic diversity.

We conclude that the combination of genetic simulations and publicly available biodiversity databases can be a powerful tool for guiding forest genetic conservationists while planning and establishing next-generation *ex situ* archives and seed orchards.

Exploration and Documentation of Tree diversity and Ecosystem services of forest genetic resources of CHTs Village Common Forest in Bangladesh

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Syedul Alam[1]
Asim Paul[1]
[1] Forest Botany Division, Bangladesh Forest Research Institute

Abstract: This paper presents the tree diversity resources and ecosystem services of Kapru Para Village Common Forest (VCF) Bandarban Hill District, Bangladesh, which is managed by the *Murang* community. The present investigation is carried out for collection, identification, update nomenclature and documentation of tree diversity and ecosystem services for the first time for Kapru Para, Bandarban hill district, Bangladesh. A total of 92 tree species belonging to 76 genera under 39 families has been recorded from the VCF of about 50 ha. Euphorbiaceae has the maximum number of species (10 species). Meliaceae, Mimosaceae and Moraceae have 6 species each and Lauraceae has 5 species while both Sterculiaceae and Verbenaceae have 4 species each. The families Anacardiaceae, Myrtaceae, Rubiaceae, Sapindaceae have 3 species each, while Bignoniaceae, Burseraceae, Caesalpiniaceae, Clusiaceae, Combretaceae, Dipterocarpaceae, Fabaceae, Fagaceae, Flacourtiaceae, Myrsinaceae and Tiliaceae has 2 species each and the rest 17 families contain single species. All species are found to grow in natural forest landscape in VCF. The *Holigarna longifolia, Hymenodictyon orixensis, Polyalthia suberosa, Scaphium scaphigium, Diospyros pilosula, Parkia timoriana* and *Xerospermum laevigatum* are found the rare and near threatened species in IUCN categories. The ecosystem services are wild fruits, wild vegetables, ethno-medicinal plants, and timber and fuel woods ect. collect by the ethnic people from the VCF. The VCF of Kapru Para is exist still remnant of natural primary forest of the Bandarban hill district. This VCF is conserved by community effort for conserving the tree diversity and ecosystem services response to climate change . It is a one of the model of local level forest biodiversity conservation and ecosystem services in the Bangladesh.

Genetic fingerprinting as a tool for verifying the origin of forest reproductive material

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Andrea Kodym[1]
Soňa Píšová[1], Heino Konrad[1]
[1] Austrian Research Center for Forests (BFW), Department of Forest Biodiversity and Nature Conservation, Seckendorff-Gudent-Weg 8, 1131 Vienna, Austria

Abstract: The use of the appropriate forest reproductive material (FRM) is key to adapt forests to climate change. Thus the adequate labelling of FRM during production and trade is demanded by European law. At present, paper-based master certificates are usually the only evidence for the origin of FRM. At the Austrian Research Center for Forests (BFW), fingerprinting techniques have been developed and established, allowing for the control of the origin of FRM from harvesting, seed processing, trading, to plant stock at nurseries. The basis for these techniques is provided by reference samples (cones/seeds) that must, by Austrian law, be collected from each tree from which seeds have been harvested. These single tree specimens are stored at the BFW.

Routine genotyping protocols were established for nine tree species: *Abies alba, Acer pseudoplatanus, Larix decidua, Picea abies, Pinus sylvestris, Prunus avium, Pseudotsuga menziesii, Quercus robur*, and *Q. petraea*. For each species, eight pairs of nuclear microsatellite markers were selected and lab protocols optimized on different types of material (embryos, leaves, needles, pericarps, peduncles, scales, seedlings, testa). The first test run concluded that 98.6% of the seeds from known mother trees could be matched successfully. The subsequent analyses represented real-life scenarios and consisted of single tree specimens, representing the mother trees and a mix of progeny samples. Between 65% to 87% of the samples could be matched to the single tree specimens. The results strongly depended on the quality of the material. The best results were derived from fresh or frozen leaves/needles and seeds, whereas several year old and dry material was often unsuitable for analysis. The results also depended on whether single tree specimens had actually been collected from the full set of mother trees during the harvest.

The fingerprinting system can also be used to compare the single tree specimens amongst each other and thus validate if the harvest fulfilled the mandatory minimum number of mother trees. This is another important aspect of DNA fingerprinting of FRM, as broad genetic diversity provides the basis for adaptability and lowers the risk to establish new forest.

Genetic variability in Araucaria angustifolia seedlings from populations of State Parks in São Paulo

Abstract: Araucaria angustifolia (Bert.) O. Kuntze, a native from the South and Southeast of Brazil, has had its habitat reduced due to human action. As a consequence, it's listed as an endangered species by IUCN (2018). Numerous efforts have been made to conserve this species, given it's social, economic and ecological importance for the region. Population genetics studies have produced results that are being applied to define conservation strategies. As part of a research project conducted i*n situ* conservation units in São Paulo, the objective was to genetically characterize natural populations based on phenotypic traits in order to establish seed orchards through the cultivation of seedlings. Trees from two distinct natural populations were sampled, totaling 19 parent trees. Eleven of these, along with their respective progenies, originate from Campos do Jordão State Park, while the remaining eight, with their progenies obtained in Serra do Mar State Park - Cunha Nucleus. The produced seedlings were established in a coop experiment using a randomized complete block design, with 19 treatments (progenies) and multiple plants per plot (four blocks). Seedlings were evaluated at six and 14 months of age, respectively, after sowing, for growth traits such as height (cm) and stem diameter (mm). The data obtained were analyzed using SELEGEN REML/BLUP software (2014). The average values for total height and stem diameter were 21.5 cm at six months and 36.9 cm at 14 months. As for the stem diameter, values for the two periods were 3.5 mm and 4.35 mm, respectively. The coefficient of variation ranged from 14% to 27.1% for the evaluated traits, and phenotypic correlations between the traits were positive, with an average of 0.42. Significant differences were observed for all evaluated traits, particularly regarding height among the provenances and progenies. The individual heritability estimates were high, with an average value of 0.38, except for stem diameter at 14 months (0.16). The genetic divergence obtained from the cluster analysis revealed three progenies groups with a mixture of distinct provenances. Therefore, progenies exhibit interesting genetic variability for *ex situ* conservation, aiming at future use in tree breeding for wood and seeds (Acknowledgment: FAPESP 2019/19529-8).

Identification of Germplasm Resources in Dendrocalamus by SSR Molecular Markers

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Jian Gao[1]
Ruiman Geng[1]
[1] International Centre for Bamboo and Rattan, Key Laboratory of National Forestry and Grassland Administration/Beijing for Bamboo & Rattan Science and Technology

Abstract: Dendrocalamus brandisii, Dendrocalamus asper, and Dendrocalamus hamiltonii are widely distributed in Yunnan, China and Southeast Asian countries, with similar phonotypes and rich diversity. All three
species of bamboo shoots have good edible properties. MISA (Micro Satellite Identification Tool) technology was used to analyze and identify 231789 microsatellite markers evenly distributed on 35 chromosomes of D. brandisii. 800 pairs of microsatellite primers were designed for screening polymorphic primers. A total of 41 pairs of simple sequence repeats (SSRs) primers with clear and polymorphic amplification bands were obtained, Three species of bamboo and different provenances of
D. brandisii were identified using the high-throughput and high-precision fluorescent labeling TP-M13-
SSR method. 40 SSR loci amplified 134 alleles, with an average of 3.35 alleles per locus (range 2-12).
The Nei index and Shannon's information index were 0.3913 and 0.7108, respectively. The results showed that SSR201 can distinguish three species of D. brandisii, D. hamiltonii and D. asper. SSR84 can distinguish two new varieties 'Manxie No.1'and 'Manxie No.2' from D. brandisii. When SSR201 and SSR84 are used together, different provenances of D. brandisii can be identified, Therefore, SSR201 and SSR84 were used as core primers to identify these important different species and provenances, while the remaining 39 pairs were used as extended primers. And 41 SSR markers were used to construct genetic fingerprints of 17 important provenances, and an identification technology based on SSR markers was established. The number and size of alleles discovered in this study can serve as a basis for identifying three D. species germplasm resources. Microsatellite markers provide a basis for screening and identifying high-quality Dendrocalamus germplasm resources, exploring important genes, and molecular breeding.

Implications of management by rural families on the genetic and phenotypic diversity of populations of Euterpe edulis, an Atlantic Forest palm

Abstract: Monitoring plant populations is fundamental for designing long-term conservation and sustainable use strategies. In this sense, the evaluation of genetic and phenotypic diversity can be used as a useful indicator of changes in use and management by rural communities. In our study, we analyzed the case of *Euterpe edulis*, an NUS (neglected and underutilized species), multipurpose and threatened palm of the Atlantic Forest, a biodiversity hotspot. This species has a restricted distribution in Argentina, and an important part of the populations are found in private properties. Therefore, for these populations' conservation and sustainable production to be effective, it is necessary to have in situ information. We compared different management systems applied to wild populations of this palm by rural communities. These management systems were characterized from an ethnobiological point of view in previous studies. Our analyses focused on management involving fruit and apical bud utilization compared to non-management situations. Genetic diversity was examined using isoenzyme and microsatellite markers, while phenotypic diversity was examined using fruit and seed morphometric characteristics.

Our results reveal that the evaluated populations have a high conservation potential. We hope that the diversity indicators obtained will allow us to define priority areas for the conservation of this species and that the genetic characterization of these populations will help in the design of differentiation strategies for the products obtained from this species (fruit pulp), which is highly valued by the market.

INSIGHTS INTO GENETIC STRUCTURE AND DIVERSITY OF NORWAY SPRUCE (PICEA ABIES (L.)) POPULATIONS IN LITHUANIA

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Ilona Kavaliauskiene[1]
Darius Danusevičius[2], Virgilijus Baliuckas[1, 2]
[1] Lithuanian Research Centre for Agriculture and Forestry, Institute of Forestry, Liepų St. 1, Girionys, LT-53101 Kaunas distr., Lithuania
[2] Vytautas Magnus University, Agriculture Academy, Studentų str. 11, LT-53361 Akademija, Kauno r., Lithuania

Abstract: Norway spruce produces high-quality timber and is a fast-growing, evergreen coniferous tree of high economic and ecological importance in Europe and covering 21.1% of total forest area in Lithuania. However, because of changing environmental and climatic conditions Norway spruce is facing increasing risks because of pests and diseases outbreaks. European Union Green Deal, Biodiversity strategy 2030 and EU Forest Strategy 2030 emphasize the importance of biodiversity in forest ecosystems and aims to increase resilience and adaption of EU forests to climate change. Hence, it is important to monitor the levels of genetic diversity of Norway spruce Forest Genetic Resource (FGR). Collected knowledge on effects of genetic drift, spatial genetic structure and of Norway spruce populations in Lithuania will help to manage FGR in more sustainable manner and to increase their resilience and adaptation to changing climate and environmental conditions. The aim of the PhD study is to determine the genetic structure, diversity, effective population size and spatial genetic structure (SGS) in naturally occurring Norway spruce populations (Forest Genetic Reserves) in Lithuania based on neutral DNA markers. In total 25 Norway spruce forest genetic reserves through the whole Lithuania will be sampled and genotyped based on 11 variable nuclear microsatellites. Collected phenotypic and genetic knowledge will enable us to propose updated FGR management strategies to increase their resilience to changing environment. First results of the PhD project will be presented.

Introduction of special germplasm selection of Aquilaria sinensis for easy agarwood inducing and high-quality agarwood production in southern China

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Daping Xu[1]
Xiaojin Liu[1], Zhou Hong[1], Zhiyi Cui[1], Peng Zhang[1, 2], Xiaofei Li[1]

[2] Rice Research Institute, Guangdong Academy of Agricultural Sciences

Abstract: Agarwood, namely the resinous heartwood of *Aquilaria* species, is a highly valuable raw material for medicine purposes and the perfume industry. Agarwood has become scarce and precious because it is very difficult to induce agarwood formation from plantation trees of *Aquilaria sinensis* in southern China, meanwhile, the yields as well as the quality of formed agarwood was very poor. In recent years, a group of special germplasm of *Aquilaria sinensis* has been selected from the wild population and domesticated into clones by grafting with ordinary seed seedlings of *A. sinensis*. This group of special germplasm includes about 100 individuals, and the common characteristics of these individual trees are far more easier, faster to form higher oil content and high-quality agarwood. Compared to ordinary trees of *A. sinensis* from seed seedlings, they showed higher oil content, higher content of 2-(2-phenylethyl) chromone and 2-[2-(4′-methoxybenzene) ethyl] chromone, higher hormones levels of salicylic acid, jasmonic acid and ethylene, higher activities of antioxidant enzymes, more total phenols and terpenes, higher net photosynthetic rate and photochemical efficiency of PSII, more consumption of non-structural carbohydrates. In particular, 2-(2-phenylethyl) chromone and 2-[2-(4′-methoxybenzene) ethyl] chromone, which richness in agarwood essential oil was significantly higher in contrast with the ordinary agarwood from the trees of *A. sinensis*. In this paper, morphological and genetic diversity difference, agarwood formation process and agarwood composition differences, physiological and biochemical wounding-induced agarwood formation mechanisms between ordinary trees of *A. sinensis* from seed seedlings and clonal trees from these special germplasm were studied.

Is the performance independent from soil preparation methods for planted bred and unselected material of Scots pine in northern Sweden?

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Alisa Heuchel
David Hall[1], Jörgen Hajek[1], Torgny Persson[1], Ulfstand Wennström[1]
[1] Skogforsk

Abstract: Hardy reforestation material with improved traits of economic interest is a prerequisite for the stability of tree breeding in the north. Whether selected genetic background is the only requirement for the superior field performance of reforestation material, or it acts together with site preparation methods, is a central question of the present experiment. To answer this question, we analyzed vitality classes, height, and diameter of 4200 seedlings of three seed origins (stand, orchard, and controlled crosses) across three study sites in northern Sweden. One-year-old seedlings were distributed across 3 soil scarification methods and five planting positions. Measurements were taken at 1, 3, and 5 years since planting. A subsample of seedlings was measured at the nursery and the measurements were used in correlation analysis between nursery-stage and field-stage traits. We used linear (LM) and generalized linear models (GLM) to assess the contribution of each factor on the studied traits on within- and between-site levels, and pairwise contrasts of estimated marginal means to assess the differences between the levels of factors. The selected genetic background did not contribute to mortality but did affect the height and stem volume of seedlings at the between-sites level. The soil scarification method introduced the least variation compared to all other factors and was only a significant factor in the interactions with the planting position and seed source at the within-site level. Seed weight had strong positive correlations with height and strong negative correlations with root-shoot ratio across locations. Our results suggest that the use of genetically improved reforestation material results in an increase in height without compromising survival rates.

Nurturing the Tree Seed System in Austria from an Agricultural Innovation System perspective

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Martina Perzl[1]
Georg Gratzer[1], Mario Pesendorfer[1]
[1] BOKU - University of Natural Resources and Life Sciences, Vienna

Abstract: Healthy forests are essential for Austria's society, providing protection, recreation, and climate change mitigation. Small-scale forest and farm-forest systems play a pivotal role in achieving the socio-ecological transition towards climate-resilient forests. However, climate change-induced shifts and seed shortages pose significant challenges for reforestation efforts. For example, differences in temperature and precipitation patterns, combined with disturbances drive increased seed demand while reducing seed quality, germination rates, and harvest success. This seed shortage constrains restoration projects, impacting forest owners' adaptive strategies and decision-making.

Two-thirds of Austrian forest owners are small-scale and predominantly practice rural forestry, particularly in mountain regions. Small-scale family farms continue to dominate the agricultural and forestry sectors, making them economically significant. Thus, the research recognizes the importance of examining the applicability of producing tree seeds on small to middle-scale farms (<50 ha), which serve as ideal spaces for testing new holding concepts and niche products.

Here, we use an Agricultural Innovation System (AIS) approach to examine the Tree Seed System in Austria, focusing on small to middle-scale farms. The study aims to establish a stable tree seed supply and distribution by identifying key actors, barriers, and potentials. A mixed-methods design combining qualitative interviews, participatory workshops, and a quantitative online survey will be employed.

Our findings reveal barriers such as limited seed processing knowledge, establishment of plantations, low control of seed imports, short-term incentives tied to funding, and lack of cooperation among actors. Identified potentials for improvement include the need for targeted extension services to increase seed stand harvesting activities and increasing awareness of networking opportunities among actors.

We provide policy recommendations for institutional and structural reforms that will improve the Austrian Tree Seed System by addressing its problems and leverage points. This research contributes to sustainable forest management, climate resilience, and the redefinition of the relationship between humans and nature in Austria.

Sapindus germplasm re-sequencing in China: diversity, genetic structure, evolution, and GWAS analysis

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Jiming Liu
Liming Jia[1, 2], Jarkko Salojärvi[3]
[1] State Key Laboratory of Efficient Production of Forest Resources, Beijing Forestry University
[2] National Energy R&D Center for Non-food Biamass, Beijing Forestry University, Beijing
[3] School of Biological Sciences, Nanyang Technological University

Abstract: *Sapindus* L. is an important forest tree genus with utilization in biodiesel, biomedicine, biochemical, and multifunctional economic forest species. Here we report a whole-genome resequencing experiment of 100 *Sapindus* core populations. Genetic structure analysis reveals *Sapindus* can be divided into six subgroups: *Sapindus delavayi* subgroup, *Sapindus rarak* subgroup, northern subgroup, Southeast subgroup, Guizhou subgroup, and hybrids subgroup. We found that *Sapindus delavayi* and *Sapindus rarak* were not diploid but potentially tetraploid or hexaploid, and proposed hypotheses for the differentiation of each subgroup. Selective sweep analysis identified fixed alleles of the genes CYP716A, CAMTA, and HD-ZIP to be involved in triterpenoid saponin biosynthesis and stress response. In addition, GWAS analysis revealed the KCS, FAD, and FAB homologous genes participated in kernel fatty acid biosynthesis. Our findings elucidated the genetic structure of *Sapindus* in China and provided targets and materials for genetic improvement of *Sapindus*.

SOIL-CLIMATIC CONDITION REQUIREMENTS AND GENETIC VARIATION OF ENDANGERED TREE SPECIES IN TERENGGANU

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Daljit Singh Karam Singh[1]
Roslan Rani[2], Mohd Syahrir Azrin Salleh[2], Md Zaidey Abdul Kader[2], Azni Rahman A. Wahid[3], Mohd Hakeem Mohd Ibrahim[1], Muhammad Amin Abdullah Azhar[4], Zahari Ibrahim[5], Dzarifah Zulperi[6], Keeren Sundara Rajoo[4, 7], Arifin Abdu[8], Muhammad Iqbal Hakim Johari[6]

Abstract: There is a scarce of information on the soil properties, climatic condition requirements, and genetic variation of these endangered trees species in the forest reserves of Terengganu. This information is essential for effective conservation strategies, as the lack of data puts these valuable and endangered timber species at risk. This study aims to address these gaps in knowledge by assessing the soil properties, climatic conditions and genetic variation for the preservation of endangered tree species in Terengganu's forest reserves. The study was conducted in selected forest reserves managed by the Forestry Department of Terengganu, Malaysia. Soil sampling was carried out at the research plots of identified timber species. The soil sampling included soil profiling and soil quality samples. A soil pit with a depth of 1 meter was dug at each forest reserve to study the characteristics of the current soil profile. Information collected included the soil horizon, soil colour, consistency, roots, biological activity, and the aggregates and structures of the soil. The universal pipette method was used to determine soil texture. Soil pH was determined in a 1:2.5 soil to distilled water ratio. Carbon, nitrogen, and sulfur content were analysed using CNS analyser. Exchangeable bases (K^+, Mg^{2+}, and Ca^{2+}) were extracted using 1M ammonium acetate ($NH4OA_c$) and analysed using Atomic Absorption Spectrophotometer. The results of the soil analyses will provide valuable information about the soil properties required for the growth and survival of the endangered tree species in the forest reserves. Relative humidity, wind speed, light intensity at each sampling points will be measured using the Environ-mete. Leaves and bark samples of trees species were also collected for genetic variation studies. The analyses are currently ongoing, and the results are expected to shed light on the soil quality,climatic condition and genetic variation of the endangered tree species in Terengganu's forest reserves. The results will be presented and discussed during the congress.

Using muti-knowledge to guide conservation of a widespread forest species: a case study (Dalbergia hupeana Hance)

T3.22 Managing forest genetic resources for multi-purposes for forest products, ecosystem services and response to climate change

Ping Huang[1]
Changhong Li[1], Furong Lin[1], Bin Li[1], Yongqi Zheng[1]
[1] Research Insititute of Forestry, Chinese Academy of Forestry

Abstract: The use of limited resources to maximize conservation efficiency is the fundamental goal of forest genetic resources conservation practice. Making conservation priority is the key factor to improve the conservation quality and efficiency, especially to widespread forest species. These species may be more likely to be neglected, but climate change, human activities, and other factors may have a greater negative impact on them. To understand genetic variation of populations and their response to climate change will contribute to making a sound conservation strategy. In this study, we selected a widespread hardwood *Dalbergia* species *(D. hupeana*) in subtropical area in China, and infer population historical dynamics, revealed spatial pattern of genetic diversity, and predicted potential impacts under future climate change scenarios. The result showed the genetic diversity and genetic differentiation of *D. hupeana* was moderate ($H_e = 0.615$, $F_{ST} = 0.132$ & $G_{ST} = 0.112$), and the spatial structure of natural populations was significant, and the spatial pattern of genetic diversity provided evidences for Central-Marginal hypothesis; the climate change had a negative impact on the distribution of *D. hupeana*, part of suitable habitat will disappear in different future climate scenario, and highly suitable habitat become more fragmented. According to the genetic diversity of natural population, stability of habitats in climate change, we could make different conservation priority and strategy.

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Seeding the Future: Exploring Bamboo Conservation through Seeds for Enhanced Diversity and Resilience

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Vaisakhy Prem Chand[1]
Manisha Thapliyal[1]
[1] Forest Tree Seed Laboratory, Siliviculture and Forest Management Division, Forest Research Institute, Dehredun

Abstract: Bamboo, a versatile and fast growing plant, offer numerous ecological, economic and cultural benefits. Bamboo can be propagated through various means, including rhizome division and culm cutting, the propagation through bamboo seeds create an opportunity for genetic diversity. The bamboo's flowering pattern demonstrates how infrequently seeds are available. Bamboo seeds are typically short lived and challenging to store. The development of seed storage protocols for various bamboo species helps to increase the viability, longevity, and quality of bamboo seed, supports ex-situ conservation and its availability for future uses. Our study investigated the propagation through seeds and its implications for bamboo diversity and cultivation. Through a comprehensive analysis of seed germination rates and growth patterns, we demonstrated that bamboo seeds were successfully germinated and we were able to produce healthy seedlings, providing a pathway for genetic diversity and the development of diverse germplasm. Furthermore, this research addressed the challenges and techniques associated with bamboo seed propagation, including seed collection, storage and germination protocols. The current investigation was conducted on various commercially important species of bamboos, including *Dendrocalamus sikkimensis, Bambusa polymorpha, Bambusa vulgaris*, *Dendrocalamus strictus, Bambusa bambos*. Our research shows that seeds of some bamboo species can be preserved for a long time without a significant lose of viability upon desiccation to a safe moisture level and low temperatures. The seeds of *Bambusa bambos* and *Dendrocalamus strictus* exhibited a germination rate of more than 80% and remained viable even after 24 and 21 months of storage, respectively. The seeds of *Dendrocalamus sikkimensis, Bambusa polymorpha, Bambusa vulgaris* were viable upto 7 months in storage. This study highlights the importance of harnessing the potential of diversity of bamboo seeds for the development of resilient bamboo forests, economic opportunities and ecological rehabilitation. The findings contribute to the knowledge and practices necessary for effective bamboo management and conservation on a regional scale.

Keywords: Bamboo conservation, Storage protocol, Germination, Viability, Resilience.

Agroforestry: conserving tree species diversity while reducing insect pest threats to farming

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Alice Muchugi[1]
Phoebe Mwaniki[2], Pauline Njeru[3], Sheila Cherotich[4]

[2] Egerton University , Kenya
[3] University of Nairobi, Kenya
[4] CIFOR-ICRAF, Kenya

Abstract: Natural environments host broad diversity of genetic resources all over the world. However, with increased over-harvesting of tree species coupled with loss of forests land to urban and agricultural developments the loss trees biodiversity and extinction of important and iconic tree species has became prevalent. The situation is exacerbated by the shifting local climatic conditions. The global decline and extinction of tree species have triggered plummeting of associated fauna especially insect populations, with a reported decline of more than 40 % and a third being endangered. Commercial monoculture of trees has further accelerated their decline. Even though genebanks play a major role in conservation, ex-situ conservation in seed banks lacks the ability to sustain natural fauna populations associated with the forest trees. With destruction of their natural habitat, the insects are therefore pushed out of their natural refuge into cultivated lands where they may adapt to new hosts. The result is that this is interpreted insect pest threats. It is therefore important to deliberately design refugia for the insect populations forced out of forests. Apart from public gardens and arboreta, agroforestry presents an opportunity for reforestation, conservation, multiplication and restoration of native species through woodlots, windbreakers, living boundary fences, contour strips, etc. Trees on farms have the potential to act as insects refugia and help shift insect pests from croplands too. Studies have shown that insect pests and pathogen populations are regulated by a high genetic base of tree species which also foster survival of natural enemies. Encouraging diversity of trees on farm will not only result to more benefits to famers but also broad genetic resource conservation in the locality; and this will be beneficial in offering the insects a more suitable habitat hence less destruction to the crop on farms. There is therefore a need to establish the local indigenous tree species diversity and their associated insect species populations, to develop strategies that will enhance their conservation and at the same time reduce insect-pest threat to farm productivity. We explore these approaches in this presentation

Community engagement to accelerate research and learning about the dieback of western redcedar

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Joseph Hulbert[1]
Marianne Elliott[1], Gary Chastagner[1]
[1] Washington State University

Abstract: Western redcedar is a key cultural resource for many communities in western North America, but recent increases in dieback driven by longer and hotter summer droughts, have raised concern about its availability for future generations. For some indigenous communities, the dieback is comparable to one of their dearest relatives being sick or having a language disappear. Research to understand the dieback issue, prioritize management, and find solutions are critically needed for these communities. The Western Redcedar Dieback Map (https://www.inaturalist.org/projects/western-redcedar-dieback-map/) project on iNaturalist was co-produced with state and federal agencies to expand an interagency effort to broader audiences and address the need for more information over a wide distribution in a relatively short time. Nearly 300 individuals have shared more than 2300 locations of healthy and unhealthy redcedars in an open dataset. This presentation will summarize the community engagement and the approach to leverage these data for identifying important parameters for mapping where to protect, monitor or restore western redcedar for future generations.

Forest Genetics in Sustaining Biodiversity

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

C. Dana Nelson[1]
[1] USDA Forest Service, Southern Research Station

Abstract: Forest genetics plays an important role in providing resilience to forests across the globe. This manifests in the genetic diversity of forest tree species and the biodiversity these species represent including their ecological associates. Keystone forest species may be considered for genetic improvement for conservation purposes with respect to genetic diversity as well as trait performance. Such traits may be selected to provide sustained fitness levels in changing environments such as those being currently experienced or anticipated. Options for forest genetic management and tree improvement will be considered in the context of climate change and the increasing exposure of forests to invasive pests and pathogens.

Genomics to the rescue: adaptive potential of keystone species provides crucial information for ecosystem service management under global change

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Ilga Porth[1]
Roos Goessen[1], Melanie Zacharias[1]
[1] Université Laval, Département des Sciences du Bois et de la Forêt, Canada

Abstract: To keep pace with the current speed of climate change, effective management of plant genetic resources must be developed. Keystone species such as *Populus* spp. are important targets in the study of resilience to future climate conditions because they play a crucial role in maintaining various ecosystem functions and may contain genetic material with previously untapped adaptive potential. They also exhibit some of the fastest inherent growth rates for temperate trees worldwide, with 17–30 dry Mg ha–1 yr–1 on 6–8-year rotations for certain hybrid poplars. These inherent fast growth characteristics can be exploited for short rotation management, a time and energy saving cultivation alternative for lignocellulosic feedstock supply. *Populus* spp. also have value for the rehabilitation of disturbed sites from logging or fire (i.e., land reclamation) or for the phytoremediation of soils polluted by hazardous waste. Based on our published and also ongoing research, the talk will provide a comprehensive overview of genomic regions showing signatures of adaptive potential in three important North American poplar species (*P. trichocarpa*, *P. balsamifera*, *P. tremuloides*) covering large longitudinal and latitudinal ranges across North America. The talk will also highlight species' phenotypic responses to environmental extremes to improve the selection for climate-resilient revegetation and identify appropriate management units. We are further investigating if populations within species with such large distribution ranges are genetically equipped to adapt to future climate conditions or are genomically vulnerable, and if specific populations are an option for assisted migration in Canada. The information on tree crops' genetic makeup is also useful for developing a novel wood tracking tool for which the most informative genetic markers (on species, population, and adaptive levels) will be made available to stakeholders involved in ecological restoration.

Global Tree Assessment – identification of threats to the world's trees

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Malin Rivers[1]
Emily Beech[1]
[1] Botanic Gardens Conservation International

Abstract: Trees are essential to life on earth – playing important economic, ecological, and cultural roles. However, the threats to trees are many and diverse and there is a vital need for an increased conservation focus on tree species. Without the conservation assessments of trees how can we know what are the most pressing threats to specific tree species and their habitats?

The Global Tree Assessment has filled this knowledge gap for trees through innovative and collaborative methods. We engaged with over 500 experts, partnering with more than 50 institutions, including botanic gardens, forestry departments and universities, across all continents to produce IUCN Red List assessments for the world's tree species and identify the threats to tree species survival.

Now that we have comprehensive threat information for the trees most at risk, it must catalyse action to prevent extinctions. As funds for conservation are limited, the Global Tree Assessment data is being used to prioritise the most effective conservation actions, feeding directly into conservation planning, practical projects and monitoring.

While climate change is an emerging threat to tree species globally, other significant pressures vary by biogeographic realm and habitat type. For example, temperate tree species are more likely to be at risk from pests and diseases, while tropical trees are more frequently impacted by logging and land-use change. By identifying variations in threats at various taxonomic and geographic scales, conservation interventions can be better targeted, utilizing relevant expertise within the conservation community. Hence, the results of the Global Tree Assessment will have far-reaching positive outcomes in mobilising targeted action to combat threats to tree species.

Long-term Vegetation dynamics in forest habitats across four decades of accelerating global change

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Olef Koch[1]
Simon Reinhold[2], Andreas H. Schweiger[1]
[1] University of Hohenheim, Institute of Landscape and Plant Ecology, Dpt. Plant Ecology
[2] University of Freiburg, Chair of Forestry Economics and Forest Planning

Abstract: Accelerating global change affects forest ecosystems, their composition and functioning at an unprecedented rate. While multiple drivers have a strong impact on forest ecosystems in Europe, our understanding of long-term ecosystem dynamics as a response to global change is limited, hampering an effective adaptation of conservation and management efforts. The Habitat concept is an important measure of biodiversity linking landscape, vegetation and species scales and thus a crucial target of European conservation efforts. Forest habitats are of key importance for European biodiversity. However, knowledge on trends in vegetation dynamics within and across habitat classes is scarce. We quantify vegetation dynamics within and across different EUNIS forest habitat classes throughout Germany using combined long-term time series data sets collectively covering a time period of over 40 Years. We analyse species cover and weighted Ellenberg indicator dynamics to explore trends in forest vegetation across strata, relationships between the velocity of change and within habitat class dispersion as well as between class distances over time. Our results will help to assess long-term dynamics in changing forest vegetation, aiding a better understanding of trends and directions of change in European forest habitats informing efforts to adopt conservation and management to global change.

Mobilizing midwives for the forest: volunteers, seed collection and tree planting

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Jenny Wong[1]
Jenny Knight[2]
[1] Bangor University
[2] University of Birmingham

Abstract: Different organisations in the UK, most of them third sector with the support of public funding, have taken up responsibility for activities related to seed collection and tree planting aimed biodiversity resilience and climate change objectives. These are only loosely held together by emerging policy such as the Strategy for UK Forest Genetic Resources (2019) and the National Tree Improvement Strategy (2017) which themselves sit alongside country-level action plans for increasing the area of native woodland cover.

Much of the work is undertaken by third sector organisations such as botanical gardens, the Future Trees Trust and the Woodland Trust. As is commonplace in the third sector volunteers have often been recruited in the hunt for rare species and ‘plus’ trees and to collect seed and plant trees. In addition, third sector organizations depend on voluntary donations for core funding and increasingly use crowd funding for specific projects. The effect is that civil society is mobilized as a labour force and source of income for the “scientists” who prioritize species and decide what actions are most appropriate. Nevertheless, civil society itself is not passive and there is increasing activity led by putative volunteers seeking to achieve their own objectives within their local landscapes. This can take many forms including facilitation of tree planting to capture carbon, development of community woodlands, wholesale tree seed collection or securing ‘reproductive rights’ for individual mother trees.

This paper examines the internalization of activities which help to build resilience in the next generation of native trees by citizens, communities and third sector organization in Wales. We conclude that there is much to be gained by greater negotiation on priorities and actions between traditional decision-makers and volunteers.

Monitoring nucleated seed orchards and diagnostics for failure: improving propagation efforts for American beech.

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Tara L. Bal[1]
Thomas Panella[1]
[1] College of Forest Resources and Environmental Science, Michigan Technological University

Abstract: Beech bark disease has been present in Michigan (United States) for over 20 years, killing approximately 2.5 million trees to date, and impacting the forests of two National Lakeshores managed by the National Park Service. It is estimated that roughly 1% of American beech (*Fagus grandifolia*) are naturally resistant to the disease. These resistant trees provide source material for restoring this ecologically important species. This is especially important given additional challenges to the species, with beech leaf disease increasing across the eastern range of American beech (though not confirmed in the target areas of this study). Remediation within the National Lakeshores has begun via outplanting grafted trees under existing canopies. Local provenance, confirmed resistant trees are utilized as scion material for grafting propagation. Additionally, planting trials in forests just outside of American beech's native range in Michigan were conducted in 2021 and 2022 to compare variation in site preparation, seasonality, and other planting variables.

To date, we are unaware of other studies utilizing applied nucleation techniques for American Beech remediation. No significant differences in survival or growth have been observed in the trial plantings yet, however, it is generally understood that American beech is a challenging tree to propagate and plant out, especially as a grafted tree. Mortality has been documented at numerous monitoring points, leading us to develop a diagnostic guide for identifying points of failure during American beech propagation. The guide covers trees kept in greenhouse facilities, trees in pots awaiting planting, and planted trees. Planted tree necropsies can provide a "lessons learned" manual for other beech propagation efforts. Given American beech's life history traits as a late-successional shade tolerant species, we hypothesize that understory plantings will be successful. Continued monitoring of the existing plantings allows us to best implement future outplantings to increase resistant genetics.

Plant health research in South African botanical gardens: Current status and future directions

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Felipe Balocchi[1, 2]
Michael J. Wingfield[3], John R.U. Wilson[2, 4], Trudy Paap[3]
[1] University of Pretoria, Forestry and Agricultural Biotechnology Institute (FABI), Department of Plant and Soil Sciences, South Africa

[3] University of Pretoria, FABI, Department of Biochemistry, Genetics and Microbiology, South Africa
[4] Stellenbosch University, Centre for Invasion Biology, Department of Botany and Zoology, South Africa

Abstract: International trade and climate change, among other factors, have driven an increase in plant pest and disease outbreaks worldwide. Plant pests and diseases are often moved with plant material to new areas. Many become invasive, and management is commonly difficult or even unfeasible. This continuous influx of introductions represents a serious threat to biodiversity and sustainable development. One approach to improve our knowledge and ability to timeously respond to plant pests and disease is to monitor sentinel sites and sentinel plantings. The use of plant collections such as botanical gardens and arboreta for these purposes has been facilitated by various international collaborations, such as the International Plant Sentinel Network (IPSN). South Africa has 23 botanical gardens across the country, eleven of which are managed by the South African National Biodiversity Institute (SANBI). Within the framework of the IPSN, a project to improve the surveillance and identification of plant pests in South African botanical gardens was initiated in 2016. This has resulted in new detections of numerous invasive pests such as the polyphagous shot hole borer (PSHB); and records of known pests on new hosts such as the root pathogens *Phytophthora cinnamomi* and *Armillaria mellea*. These pests have been found, in many cases, to be negatively impacting threatened species maintained in the collections and in surrounding natural areas; and, in the case of the PSHB, a nation-wide outbreak of significant concern. The project "Monitoring tree health at sentinel sites: botanical gardens and arboreta" has provided a platform to record baseline information on pests detected across the botanical gardens and has assisted in the listing of pests under South Africa's regulations on biological invasions. The project has also contributed to the development of biosecurity best practice guidelines to help botanical gardens manage pest risks in their collections, as well as to support restoration activities emerging from these.

Proactive Planning for Seed Needs in Reforestation: Challenges and Opportunities to Strengthen the Tree-Seed Supply Chain In the Western United States

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Matthew Aghai[1]
Olga Kildisheva[2]
[1] Mast Reforestation
[2] The Nature Conservancy

Abstract: Healthy forests are critically important for mitigating the effects of climate change, reducing biodiversity loss, and protecting our water resources. In regions where sustainable management of forest lands has been incentivized or required, wood products industries have relied on tree seed orchards and wild collection activities to meet their annual post-harvest regeneration needs. However, many regions with less productive forests and with complex terrain and/or poor civil infrastructure have been underrepresented by seed collection and banking efforts and have little or no genetic material for artificial regeneration activities. Additionally, decades of chronic underfunding combined with the worsening impacts of climate change and associated catastrophic disturbance events (e.g. wildfire) have increased the need for reforestation significantly. Proactive planning for seed needs is critical to shift from a reactive to a strategic approach to deal with the irregularity of mast events across a complex mosaic of species, populations, landscapes, and ownerships.

Seed collection, testing, and banking for reforestation is a century-old practice in the conifer-dominated forests of the Western United States. Few technological innovations and logistical solutions were made over the last half-century until recently when Silvaseed and Mast Reforestation began scaling wild seed collections across 11 Western States. This presentation will highlight the challenges impacting tree-seed availability and provide a historical perspective on seed collections before leveraging several years of operational data to demonstrate a technology-driven leap forward in addressing the seed pipeline. Key points derived from operational activities and from a recent publication will highlight opportunities for strengthening the tree-seed supply chain in an era of climate change.

Quantifying Genetic Variation in Threatened Ash Species: Insights from Ex situ Collections

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Melissa Lehrer[1]
Lucia Anderson[1], Jill Hamilton[1]
[1] The Pennsylvania State University, Department of Ecosystem Science and Management, University Park, PA, USA

Abstract: For many species, germplasm preserved ex situ can be critical to establishing breeding and restoration resources. While ex situ collections preserve genetic diversity, there are often gaps in our understanding of the extent of diversity preserved in these collections. Thus, particularly for rare or endangered species, evaluating extant variation preserved ex situ is needed. Seed morphological traits derived from x-ray images can be used as a proxy for assessing standing genetic variance maintained in collections, distinguishing within maternal family and between population trait differences across the ranges of diverse species. For *Fraxinus* (ash) species native to North America, understanding the distribution of genetic differences across a species' range can inform the development of resources needed to ensure long-term species preservation. The Emerald Ash Borer (EAB), one of the most destructive pests ever introduced to North America, has decimated ash populations across the US and Canada. Critically endangered black ash (*Fraxinus nigra*) is a keystone species across much of its range, supporting foundational ecosystem services in the unique wetland landscapes it dominates. Given the threat of the EAB, there is a need to extend existing germplasm collections and to quantify within and between population genetic variance preserved in collections to lay the groundwork for EAB-resistance breeding and preservation. Working alongside domestic and international collaborators, we have established an ex situ collection of black ash seed that spans the US and Canada. X-ray image analysis of seed and samara morphology in our range-wide collection will be used to assess the proportion of variance in morphological traits explained by both among-population and within-family differences. Where substantial population genetic structure within populations is observed, populations can be prioritized as regions for supplemental collection to ensure genetic differences are maintained in collections. Where significant within-family variance is observed, the evolutionary potential of individual populations can be assessed. Thus, examination of morphological trait differences from ex situ collections can provide foundational data needed to characterize population genetic differences, setting the stage for future conservation and restoration efforts.

Resilience of British woodland trees: Kew's research on genetic resistance, local adaptation, diversity and seed banking

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Abstract: The government has committed to increasing tree cover to at least 16.5% of all land in England by the end of 31st December, but its tree species are threatened by an unprecedented increase in invasive pests and pathogens, and must also adapt to climate change. Royal Botanic Gardens Kew is undertaking a range of research and conservation activities aiming to enhance the resilience of UK woodland tree populations. We and our partners are seeking to understand the genetic basis of resistance of key threats (ash dieback, acute oak decline and Dutch elm disease), using a range of genomic approaches. This allows us to better understand resilience of woodland populations and develop accelerated breeding programmes to improve the capacity of tree species to cope with these threats. We are searching for signals of local adaptation in oak and birch populations using genome-environment analyses, to inform planting of the right tree in the right place in present and future climates. We are seeking to understand the implications of natural regeneration versus tree planting for genetic diversity of tree populations. Large-scale seed banking has been undertaken under the UK National Tree Seed Project, with geo-referenced mother trees across the native range of each bankable species. For birch and alder, we have germinated and genome-sequenced representative samples of these collections, to understand their diversity and local adaptation. A large new glasshouse facility is being built next to the Millennium Seed Bank, which will facilitate our research on UK trees and the propagation of material for deployment. Kew has long collaborated with Forest Research on these projects, and this partnership has recently been further strengthened through the establishment of the Centre for Forest Protection. This research is essential to the maintenance and expansion of tree cover.

Safeguarding Biodiversity and Wild Plant Genetic Resources: The Baekdudaegan Global Seed Vault

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Jong Woo Nam[1]
Young Been Kim[1], Kyeong Mi Cho[1], Yoon Kyung Choi[1], Chi Hyun Song[1], Seo Jin Kim[1], Min Seon Kim[1], **Sanghyun Kim**[2, 3], Kee Hwa Bae[1]

Abstract: Wild plants hold immense value in human societies, as they constitute vital components of forests that harbor biodiversity. The potential consequences of any disruption to our forest ecosystems, such as the destruction of freezers due to military actions or other compromising events, would result in the loss of seeds, wild plants, and overall biodiversity. Recognizing the significance of biodiversity preservation, particularly in relation to the well-being and future of humanity, it is imperative to establish robust backup mechanisms, even extending to secondary backup measures. Addressing this challenge, the Baekdudaegan Global Seed Vault has taken on the prestigious responsibility of safeguarding the seed collections of all wild plant species on Earth. By ensuring the existence of a secure repository, the Baekdudaegan Global Seed Vault aims to guarantee the preservation of essential plant species, which play a critical role in sustaining global biodiversity. Strategically situated at an altitude of 600m or higher, the seed vault remains impervious to sea level rise resulting from the climate crisis. Furthermore, its subterranean location shields it from external physical shocks and unauthorized access, rendering it inherently inaccessible, as it should be. The seeds housed within the Baekdudaegan Global Seed Vault are meticulously packaged in black boxes and hermetically sealed, ensuring their long-term viability. Maintained at a constant temperature of -20 degrees Celsius and relative humidity of 40 percent, the storage conditions are closely monitored on a daily basis. Consequently, the seeds are perpetually conserved under uniform conditions, providing a fail-safe measure against unforeseen catastrophes that may jeopardize the original plant populations. In summary, the Baekdudaegan Global Seed Vault serves as a pivotal initiative to secure the future of biodiversity and wild plant genetic resources. By encompassing the storage of every single seed from wild plant species worldwide, the Baekdudaegan Global Seed Vault offers an invaluable opportunity for individuals possessing wild plant seeds to contribute to the preservation of our planet.

Searching for Tolerance to Laurel Wilt Disease in Avocado Germplasm from Diverse Sources

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Romina Gazis[1]
Monica Navia-Urrutia[1], Carlos A. Sendoya-Corrales[1], María de la Cruz Espíndola-Barquera[2], Alejandro Barrientos-Priego[3], Salvador Ochoa-Ascencio[4]

[3] Departamento de Fitotecnia, Universidad Autónoma de Chapingo, Texcoco, México.
[4] Departamento de Fitopatología, Universidad Michoacana de San Nicolás de Hidalgo, Morelia, Michoacán, México

Abstract: Laurel wilt (LW), a deadly vascular disease caused by *Harringtonia lauricola*, affects numerous hosts in the Lauraceae. In the USA, twelve states are already battling LW, which continues to move towards major avocado-producing areas. The destructive nature of LW makes it an imminent threat to avocado production worldwide; especially, when combined with its multiple hosts and ambrosia beetle vectors. In Florida, LW has already led to the destruction of 300,000 avocado trees. If left unchecked, it could devastate the worldwide production. To date, there are no effective and cost-efficient cultural or chemical management strategies. All tested cultivars including Hass, are susceptible to the disease, but in the field, few trees have survived or have been identified as having asymptomatic infections. Using locally sourced seedling material, our group has uncovered genotypes with varying degrees of tolerance, which suggests that the host's genetic background influences the infection outcome. This study aims to identify LW-resistant/ tolerant genotypes, establish the baseline germplasm collection for future breeding programs and create a source of propagative material for the local industry. The screening uses germplasm of the following three categories: 1) surviving avocado trees; 2) varieties of Mexican or Mexican hybrid ecotype; and 3) varieties resistant or tolerant to other biotic and abiotic stressors. Screening material is sourced from germplasm collections, local growers and collaborators from different research institutions. Thus far, our team has screened 700 seedlings corresponding to 25 accessions which are part of the largest avocado germplasm collection in Mexico, "Fundación Salvador Sánchez Colín". Although most of the seedlings developed external symptoms, the disease severity varied significantly among half-siblings within each accession; less than 5% of the seedlings developed mild symptoms (<10% wilting) or no external symptoms. Two accessions, "Arbol 274B" and "Colin V-33", contained the highest number of seedlings that developed mild symptoms or remained asymptomatic. These plants are currently being propagated for subsequent replication experiments using clonal material. Portion of the non-surviving and all surviving plants will be genotyped to identify genomic regions, which potentially confer disease resistance and/or tolerance.

The need for seeds: A call to increase global seed banking efforts.

T3.23 Mini-Symposium: Resilience of Forest Biodiversity to Climate Change and Pests: Civic Engagement and Conservation in Seed Banks, Public Gardens, and Wild, Urban, and Agroforestry Landscapes

Jill Wagner[1]
[1] Hawaii Island Seed Bank

Abstract: The 21st century is the first time in human history in which there are efforts to plant trees globally as opposed to extracting natural resources from the Earth. Seed supply is at the heart of the largest crisis factors of our time; global warming and biodiversity loss and collapse. The UN Decade on Ecosystem Restoration was proclaimed by the UN General Assemly following a call for action from over 70 countries. The UN Decade will run until 2030, which is also the deadline for the Sustainable Development Goals and timeline scientists have identified as the last chance to prevent catastrophic climate change.

Extreme climate events are already happening. Without a backup supply of seeds, nature based solutions such as reforestation and afforestation will be forced to compromise their restoration species and goals, which will impact future biodiversity.

Seed banks provide rapid response to events such as storms, floods, wildfire, which are increasing. These events destroy mother trees and lower the diversity in the field. Given that it takes on average 7-10 ten years for a tree to flower and seed, even in the best case scenarios in natural regeneration there is a risk of a permanent seed shortage in the future. Increasing fragmentation of ecosystems, pathogen and insect outbreaks also contribute to seed shortages.

In the UN Global Strategy for Plant Conservation seed banks are listed as a priority ex-situ conservation tool. It is important for land managers to collect seed now and bank it for scaling restoration, and for short term and long term storage.

Regional seed banks can provide a safety net for biodiversity and leave the next generation with the resources they will need to support healthy ecosystems.

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Clear-cut effects on in-stream metabolic rates propagate downstream

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Maria Myrstener[1]
[1] Swedish University of Agricultural Sciences

Abstract: Clear-cutting of forests with little or no regard to riparian buffers, alters the local habitat of streams by increasing temperature, incident light, suspended sediments and resource inputs. It is well documented that such habitat changes affect local stream ecosystem processes. Here, we ask whether biotic processes can also be affected downstream of clear-cuts. We tested this in nine headwater streams that run through recent clear-cuts (1-6 years) with varying buffer widths in northern Sweden to compare biofilm and whole stream metabolic rates in their upstream, clear-cut and downstream reaches. We estimated local biofilm metabolism in all nine streams using tiles and we assessed whole stream gross primary production (GPP) and ecosystem respiration (ER) from oxygen loggers in three streams. We found that biofilm GPP indeed increased, on average, by 54 % downstream of clear-cuts in July, but that the net effect on the whole ecosystem was a decrease in ecosystem productivity due to high respiration rates. In September, the situation was different as there was instead a 50% decrease in biofilm GPP downstream of clear-cuts. Wide buffer zones (>15m) could partly mitigate these longitudinal changes, except in one stream which was dominated by fine sediments. Importantly, the magnitude of downstream propagation in biofilm GPP was related to the magnitude of responses in the clear-cut, which in turn was driven by nutrient concentrations. We show that clear-cut effects on stream ecosystem processes are not only local, but can also be propagated to downstream recipient waters if management practices within the clear-cut have not been sufficient. Using maps of registered, recent (1-6 years old) forest clear-cuts and modelled forest stream networks of Sweden, we estimated that at least 3% of all forested streams in Sweden risk having metabolic rates that are affected by upstream clear-cuts. We do not know for how long (time or space) this memory effect of forest clear-cuts on fluvial ecosystem function persists but it is likely longer than 6 years and 100m in many cases.

Consequences of Alternative Forest Management in Riparian Buffer Zones: A GIS Analysis

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Elijah Ourth[1]
Alejandro Gandara[1], Anneli Ågren[1], Eliza Maher Hasselquist[1]
[1] Department of Forest Ecology and Management, Swedish University of Agricultural Sciences (SLU), Umeå, Sweden

Abstract: With increasing pressure from policymakers and the general public to conduct alternative forest management throughout the European Union (EU), Sweden needs to find ways to best prioritize the implementation of this alternative management. Riparian buffers are one possible location that may provide a win-win solution for meeting EU goals as well as benefiting water quality and biodiversity. Riparian buffers can protect the ecological functioning of a stream, typically by leaving a strip of unharvested trees in place around the stream, but in Sweden these buffers are often too narrow (5-7m) and are dominated by a single tree species. Implementation of alternative forest management that would promote a diversity of tree species in wide riparian buffers could benefit streams, as well as assist Sweden in meeting EU goals. To determine the amount of forest land contained within buffers under 5 m, 15 m, 30 m, and 60 m buffer width scenarios we conducted a GIS analysis of 11 study areas throughout Sweden. We also examined the current tree species composition in these potential buffer zones and analyzed the area around both natural channels and forest ditches. We found that there is a significant latitudinal gradient in species composition within the buffer zones from north to south, with total tree volume, deciduous tree volume, and spruce tree volume increasing from north to south, whereas the proportion of pine is highest in northern study regions. This latitudinal trend was not seen in terms of the proportion of forest land contained within the buffers that was productive forest land; however, there was a significant difference between the amount of productive forest land found around ditches versus streams. The percentage of the total study area's productive forest land that was contained within buffers, i.e., the amount of forest land that would be transitioned to alternative management, ranged between 3.5% and 34% for ditches, and 0.5% and 5.5% for natural channels. Converting riparian buffers to alternative forest management appears to offer great potential for maximizing protection of sensitive riparian zones, while minimizing economic losses.

Continuous cover forestry and biochar as a tool to reduce nutrient loading to watercourses

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Marjo Palviainen[1]
Annamari Laurén[1]
[1] University of Helsinki, Department of Forest Sciences, Finland

Abstract: Forest management practices on drained peatlands increase nitrogen (N), phosphorus (P) and dissolved organic carbon (DOC) export to downstream aquatic ecosystems. Increased nutrient and DOC loading cause eutrophication, hypoxia and changes in biogeochemical processes and food webs in watercourses. Furthermore, high DOC concentrations cause water brownification and problems in drinking water treatment processes. Continuous cover forestry (CCF) is proposed to be an environmentally more sustainable management option for peatland forests than the conventional even-aged clear-cutting. However, the environmental effects of CCF are poorly known.

We studied the concentrations of N, P and DOC in ground water and ditch water in clear-cut, partially harvested, i.e. CCF, and uncut drained peatland forests in Finland. We also studied the effects of harvesting intensity on DOC quality and the rate of DOC biodegradation to CO_2. The results suggest that CCF reduces the concentrations of DOC and nutrients in watercourses, decreases DOC biodegradability, and therefore the aquatic CO_2 emissions compared to clear-cutting in drained peatland forests.

One potential solution to decrease nutrient loading could be adsorption-based purification of runoff water using biochar. We have tested the use of wood biochar in runoff water purification in clear-cut forests. We studied adsorption and desorption rate, and adsorption capacity of Norway spruce and silver birch biochars. We found that biochar removes organic N, ammonium and nitrate from the water. The results also showed that the N adsorption capacity of biochar increases with an increase in the initial N concentration in the water. The adsorption process was fast, which suggests that biochar can clean water also with short water residence time in the biochar reactor. When biochar had first adsorbed N, significant desorption did not occur when biochar was again in contact with low concentration water. This suggests that biochar works well even in such conditions where there are seasonal fluctuations in water nutrient concentrations. Our results indicate that biochar can be a complementary water protection method in peatland forests.

Development of GIS-based Methods for a Climate Change adapted Forest Infrastructure

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

[3] unique land use GmbH, Freiburg, Germany
[4] Chair of Forest Utilization, Albert-Ludwigs-Universität of Freiburg, Germany

Abstract: Many experts predict that climate change will increase the likelihood of extreme weather events such as droughts and heavy rainfall. Vital forests retain water through interception or receptive soils. Prolonged droughts or insect infestations endanger trees causing higher surface runoff, which can lead to erosion and flooding of populated areas nearby.

To maintain a healthy ecosystem and allowing a sustainable forest management, forest infrastructure such as forest roads must be well functioning. However, forest roads are mostly gravel roads prone to erosion by water. Therefore, any runoff along or across forest roads may be critical and force erosion damage. Continuous road maintenance will take more efforts to keep operability for all functions. To respond to higher flows due to heavy rainfall or prolonged drought, forest infrastructure must be adapted. On the one hand water runoff must be directed to reduce potential damage on forest infrastructure. On the other hand, water should be retained in the forest ecosystem to maintain a healthy water balance.

The research project "*KlarWeg*" identifies the impacts of climate change on existing forest roads, generates and collects possible adaptation strategies and integrates them into a road management concept in order to improve the overall water balance in forests. One of its approaches is the development and testing of a GIS-based method for the localization of risk zones in case of heavy rainfall and for the detection of potentially useful areas for water retention.

Due to the accuracy of available GIS Data and the accessibility of OpenSource Software (*QGIS*), the modelling of potential flow paths through forest terrain is able to show accurate and field-validated results. Combining these modelled flow paths with data of forest roads, risk zones can be calculated, evaluated and ranked by size of the related watershed, to map out critical points in the forest infrastructure. These identified risk zones are highly vulnerable to high runoffs after e.g. a heavy rain fall and therefore to rain induced damages. Hydrological and hydraulic calculations show the effects and limits of the work, exemplified by three areas in Germany. The effects should be transferable to similar areas worldwide.

Ditch network maintenance exacerbates the export of sediments from historically drained forests after clear cut

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

[4] Department of Ecology and Environmental Science, Umeå University, Umeå, Sweden

Abstract: Nearly one million km of ditches have been dug in peatlands and wet mineral soils over the last 100 years in Sweden, primarily to improve forest growth. Many ditches have resulted in new areas of productive forests, while others have led to large-scale wetland degradation and poor downstream water quality. Understanding the consequences of traditional management of these ditches is important for improving our forestry practices, particularly how clearcutting and ditch network maintenance (DNM) affect suspended solids draining these management actions. Here, we present the results of four years of monitoring of total suspended solids (TSS) in a catchment-scale experiment at the Trollberget Experimental Area associated with the Krycklan Catchment in Northern Sweden. We measured pretreatment TSS on six catchments (November 2018 - August 2020), then successive treatments of clear-cut (CC) forest harvest on four of the six catchments (August 2020-September 2021), then DNM on two of the four clear-cut catchments (CC+DNM; September 2021-October2022).

We found that peaks in TSS concentrations occurred after both CC in August 2020 as well as DNM in September 2021, but when these single grab samples were combined with turbidity data taken at 15-minute intervals, we found that instead of just lasting a few hours as in the CC catchments, these peaks often lasted a few days in catchments that had both CC+DNM. These peaks were not outside the range of concentrations of TSS found during flood events in the reference catchment, for example in spring flood conditions. But on average, we found that catchments with both DNM and CC treatments had 430% higher turbidity than those with just CC. The turbidity measurements we recorded were over the World Health Organization's (WHO) drinking water quality standards 17% of the time during the reference period before treatments, while after CC and then CC+DNM, 90% of the measurements were over the standard. Clearly, forest management using CC and DNM impact water quality and at a minimum, DNM practices should be limited in the future if we want to ensure good water quality.

Effect of low-cost in-situ soil moisture conservation measures on soil erosion in montane Pinus roxburghii forests

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Digvijaysinh Rathod[1]
Dinesh Kumar[2], Parmanand Kumar[2]
[1] ICFRE-Tropical Forest Research Institute Jabalpur (M P) India
[2] ICFRE-Forest Research Institute Dehradun (U K) India

Abstract: The *Pinus roxburghii* Sarg. is a principal species of the Himalayan subtropical forests of India. It is distributed in 8690 sq km area of different Indian states. The *P. roxburghii* forest area serves as a large catchment area for two major rivers, namely, Ganga and Yamuna originated from the Himalayan mountains. Under the influence of heavy rain and moderate to steep slope terrain condition, detachment and movement of soil particles with water leads to soil erosion. Soil erosion causes loss of fertile land, and sedimentation in streams and rivers, decrease the carrying capacity of waterways. This will directly effect aquatic diversity and understorey vegetation establishment on forest land. The present study was conducted in the *P. roxburghii* forest area at Mussoorie forest division, Uttarakhand. Eight treatments (T1-Shallow ditch-I, T2-Shallow ditch–II, T3-Shallow trench, T4-Earthen bund, T5-Pine needle bund, T6-Earthen bund+ Grasses, T7-Pine needle bund+ Grasses, and T8-Control) with varying depths and lengths were applied in the field to assess the effect of low-cost in-*situ* soil moisture conservation measures (SMC) on reduction of soil losses. The recorded average annual rainfall on site was 2200 mm to 2500 mm using a tipping bucket rain gauge. Among all the treatments lowest soil sediment concentration was observed in the T5 (3436 ppm) followed by T7 (3739 ppm), T2 (3828 ppm)treatment and highest soil sediment concentration in the T8 (6817 ppm) i.e. control treatment. The T5 treatment was most effective treatment to reduce the losses of soil and it acted as a filter and stabilized soil sediments generated in runoff flow. The results indicated that utilization of dry-pine needles as SMC structure was effective to control soil erosion. Dry pine needle is readily and free-of-cost available in the extensive pine forests. The results will help in the effective management of pine needles to reduce losses of soil due to sedimentation beside reducing incidence of forest fire, improving groundwater recharge and preventing the negative effects of excess sedimentation accumulation in the natural water bodies.

Food web responses to modifying the size and configuration of riparian buffers along streams in managed forests of western Oregon, USA

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Dana Warren[1]
Ashley Coble[2], Ashley Sanders[1], Alex Foote[2]
[1] Oregon State University
[2] The National Council for Air and Stream Improvement, Inc., USA

Abstract: In managed forest landscapes, the size, configuration, and extent of riparian reserves has been and continues to be an important ecological consideration. Fixed-width buffers have value as regulatory prescriptions due to their relative simplicity in application and assessment, and they have been shown to be effective in protecting stream habitats. However, they may not be the optimal configuration to protect ecological or hydrological function in streams. Alternatives such as variable retention buffers may provide greater ecological protection by allowing for more tree retention along sensitive streamside areas, with the trade-off of increased tree removal close to streams in less-sensitive sections. Despite their potential benefits the efficacy of alternative riparian prescriptions has not been widely evaluated. Using a replicated (n=6) before-after control-impact (BACI) study design, we created six experimental blocks each of which included an uncut control unit and four riparian buffer prescriptions applied to fish-bearing streams: fixed-width buffer, buffer with thinning in outer edges (Oregon current practice), variable retention, and buffer with canopy gaps. To assess potential bottom-up effects, we collected data on benthic biofilms, macroinvertebrate abundances, and the abundance and biomass of stream vertebrates (salmonid fish, sculpin, and salamanders). Preliminary data indicate a muted response in total biofilm biomass and in total macroinvertebrate abundances. When changes were present, they did not consistently align with light responses. In the first year after harvest, adult trout population responses were mixed with some sites showing slight increases and others slight decreases. However, juvenile (age 0+) trout populations increased notably across all sites in the first year after treatment, with some sites seeing two- to three-fold increases. The reference sites did not have increases in juvenile trout or in adult trout between the pre- and post-treatment surveys, suggesting that responses were attributable to the treatments. In the sites where we completed a second year of post-treatment surveys, preliminary results indicate increases in adult trout with more moderate (but still mostly positive) responses in juvenile trout. We attribute the adult trout responses in year-2 to recruitment of the previous year's strong juvenile year-class, suggesting an overall population level response at these sites.

Forest buffers along surface water bodies on forest land in Sweden - recent findings

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Eva Ring[1]
Line Djupström[1], Emelie Fredriksson[1], Lars Högbom[1, 2], Stefan Löfgren[3], Brendan McKie[3], Johan Sonesson[1], Per Westerfelt[1]
[1] Skogforsk, Sweden
[2] Swedish University of Agricultural Sciences, Department of Forest Ecology and Management, Sweden
[3] Swedish University of Agricultural Sciences, Department of Aquatic Sciences and Assessment, Sweden

Abstract: Sweden has about 100 000 lakes (greater than 1 ha) and a vast network of rivers, streams and ditches. Productive forest land covers 58% of the land area. Thus, environmental consideration to surface water bodies is part of every-day work in Swedish forestry. Maintaining or creating 'functional' forest buffers is one important measure for protecting surface water bodies and riparian forests. In a dialogue process on environmental consideration, the concept 'functional' forest buffers beside watercourses and lakes was defined. 'Functional' forest buffers refer to streamside forests that maintain six functions in and adjacent to surface water bodies, namely soil chemical processes, shoreline stabilization and prevention of sediment transport, food supply to aquatic organisms, shading, deadwood supply and biodiversity. When necessary, measures to improve forest buffer functionality can be taken, for example by adjusting tree-species composition of the streamside forest. More knowledge on buffer delineation and consequences of different management strategies of the streamside forest could help improve the practical implementation and functionality of forest buffers. Here, findings from some recent investigations and ongoing work on forest buffers in Sweden are summarized. In a field survey in three regions across Sweden performed in 2018, characteristics of forest buffers left beside streams, lakes and ditches during clearcutting were investigated a few years after harvesting. In two small streams in south-central Sweden, long-term effects on benthic macroinvertebrates and water chemistry of selective thinning of the streamside forest at the pre-commercial thinning stage were studied. Furthermore, six new field sites have recently been established in spruce-dominated streamside forests ready for first thinning. Current knowledge indicates that the functionality as buffers of these forests would improve with an increased share of broadleaf trees. The aim is to test how different thinning regimes affect future vegetation development. Finally, the potential to digitally delineate forest buffers is evaluated by using high-resolution Lidar data that provides information on tree cover, ground surface elevation and proportion of deciduous trees. This could aid forestry planning and implementation of forest buffers.

Forest management strategies to improve ecosystem water functions in low rainfall region

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Abstract: The Eucalyptus gender occupy large areas in Brazil in a high productivity system, reaching 7.53 million hectares of planted areas. There is a concern to maintain natural areas under protection, which may vary from one region to another depending on natural conditions, but on average these areas occupy 40% of the areas managed by the sector. These protected areas, together with good management practices, are essential to maintain important water ecosystem services, which is one of the most desired services. In an experimental area in São Paulo, Brazil, hydrological data of 2 water years (WY - 2020 and 2021) from 2 experimental catchments were sampled with a frequency of 15 minutes in a pluviometer for precipitation and in a stream-gauge instrumented with a pressure sensor to measure flow. The catchment 1 (C7,5%NV) is covered with 80% of commercial plantation conducted for a short rotation cycle aiming pulp production, it was implanted in 2017 and has 7.5% of native vegetation. The catchment 2 (C51%NV) is covered with 49% of commercial eucalyptus planting conducted in a long rotation cycle to produce sawn timber, it was implanted in 2014 and has 51% of native vegetation. The WY showed differences in annual precipitation. The second WY rained less 30% in C7,5%NV and less 22% in C51%NV. However, the relative difference in water yield between the 2 WY showed a great difference. While C7,5%NV decreased about 11%, the C51%NV had an increase of 22%. For the Base Flow Index (BFI), the C7,5%NV decreased 21%, while C51%NV decreased only 1.2%. At the time of analysis, the commercial forest in C7,5%NV was between 3 and 4 years old, which is a time of higher productivity in the cycle rotation. In C51%NV, the commercial forest was between 6 and 7 years old, which is a moment when productivity is more stable. Although a complete analysis of the cycles is yet necessary, the water yield and BFI pointed to a possible way for regions trending to lower water availability, respecting the native vegetation and planted forest proportion besides the forest development time most suitable for the natural condition.

Forest Road Engineering – Climate Change Adaption Strategies in Water Management

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Christopher Pohle[1]

[4] Fischer Teamplan Ingenieurbüro GmbH, Erftstadt, Germany

Abstract: Forest roads serve a variety of functions, most of them are essential for sustainable forest management. These gravel roads are susceptible to erosion by water. Therefore, rapid drainage of forest roads after precipitation events is essential to prevent damage and maintain operability of roads. While design features such as elevated cross-sectional profiles and longitudinal gradients exceeding 2% are important for surface water drainage, it is increasingly important to retain the drained water in the forests, thereby increasing the available water resources in the forest ecosystem. Given the changing global climate and associated impacts on the water regime, forest road engineering needs to be adapted in this respect.

One of the approaches to face these challenges is to analyze international standards and best practices. Due to the dependence on regional factors in forest road engineering, specific local guidelines and manuals evolved. These documents are intended to assist practitioners considering local requirements for planning, construction and maintenance of forest roads. Reviewing these documents allows for identifying meaningful road management practices of countries with climate conditions similar to conditions projected for Germany in the near future (so called “Climate Analogues”).

The proposed presentation shows the results of this meta-analysis in session T3.24, where we will give an overview of different design parameters, such as longitudinal gradients, dimension and spacing of culverts for cross-drainage of ditches, and the design of side slopes. We will also include similarities and differences in the maintenance concepts like frequency and associated technical methods. From this set of means and measures, those will be selected that will allow the best adaptation of the design and layout of forest roads to the actual needs due to climate change.

How different riparian buffer configurations affect abiotic responses in perennial headwater streams in managed forests of western Oregon, USA.

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Ashley Coble[1]
Dana Warren[2], Ashley Sanders[2], Alex Foote[1, 2]
[1] NCASI
[2] Oregon State University

Abstract: Alternative riparian management approaches that emulate natural disturbance or enhance protection in ecologically significant locations have been proposed to improve ecological function of buffers. Riparian buffer configurations that enhance spatial heterogeneity of forest canopies may alleviate light limitation in localized sections of the stream while maintaining key shading and large wood recruitment functions. These alternative practices may create biogeochemical hotspots that can enhance in-stream primary productivity and stream food webs. We designed a large-scale, replicated field experiment (n=6) in which we applied four riparian buffer configurations in relation to an unharvested reference to manipulate spatial variability in light conditions on stream channels and then evaluate whether these treatments affected aquatic ecological function. Buffer treatments sought to establish a gradient of light conditions on the stream: 1) an unharvested reference, 2) fixed width, 3) state of Oregon current practice, 4) variable retention, 5) canopy gaps. We measured physical (large wood, substrate size, width, depth, discharge, pool area, canopy cover, light, and temperature) and chemical (nitrogen, phosphorus, dissolved organic carbon, and specific ultra-violet absorption at 254 nm; $SUVA_{254}$) responses in each of 30 streams (5 references, 25 treatments) for two years pre-harvest and two years post-harvest. Treatments enhanced light relative to reference sites, but light was not correlated with changes in canopy cover. For example, the greatest canopy cover change occurred in a variable retention treatment with minimal change in light on the stream surface. Preliminary results (n=2 per treatment) indicate large wood volume index and diameter consistently increased in fixed width buffers relative to pre-treatment and reference conditions while length consistently decreased in all treatments. Similarly, nitrate concentrations increased in fixed width and gap treatments, whereas $SUVA_{254}$ increased in variable retention and current practice treatments after harvest. Macroinvertebrates, as a biological indicator of changes in water quality, suggest variable retention treatments may have led to greatest disturbance as more chironomids, more tolerant, and less intolerant species occurred in two streams with this treatment. Post-treatment data collection is ongoing across 25 of 30 streams, and ultimately this replication will aid in understanding abiotic responses to buffer configurations across a broad geographic area.

How do ditches affect the biodiversity of Swedish forest land?

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Olivia Anderson[1]
Anneli Ågren[1], William Lidberg[1], Eliza Maher Hasselquist[1]
[1] Swedish University for Agricultural Sciences

Abstract: Nearly one million kilometres of ditches have been dug across Swedish forest land over the last 100 years to improve forest production. Not much is known about how much these ditches have changed the Swedish landscape. A key concern of land managers is understanding how ditches have affected biodiversity and where management efforts should be focused: how should they manage ditches to meet different societal goals (e.g., maintain, restore, or leave a ditch alone)? Therefore, the objective of this study is to assess how ditches, dug across Sweden's history and geography, have impacted biodiversity. We used data from 9720 plots in Sweden's National Forest Inventory (NFI) to calculate Hill-Shannon diversity, a biodiversity metric that accounts for discrepancies in sample effort and size to more accurately reflect relative abundances. Our preliminary analysis revealed little overall difference in diversity between ditched and unditched forest sites. When we considered different soil types and textures, most comparisons between unditched and ditched sites remained similar. However, peatland sites with ditches appeared to have more diversity than unditched peatland sites. Bayesian mixed modelling will enable further analysis of controls on biodiversity in relation to ditching, to ultimately inform and improve ditch management across Sweden. This study is part of a larger Swedish Research Council FORMAS project: Barriers and Opportunities to Managing (BOM) Forest Ditches for Climate.

How to minimize the concentrations of methylmercury in surface water after forest harvest

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Karin Eklöf[1]
Ulf Sikström[2], Linnea Hansson[2]
[1] Swedish University of Agricultural Sciences
[2] The Forestry Research Institute of Sweden (Skogforsk)

Abstract: Forest harvest might mobilize mercury (Hg) retained in soils and promote the transformation of inorganic Hg to its bioaccumulative form methyl-Hg (MeHg). In this presentation we will discuss possible mitigation measures in order to minimize MeHg and total Hg (THg) in surface waters, based on catchment-scale and process-based studies.

Earlier studies reveal considerable variation in effects of forest harvest on the runoff of THg and MeHg between sites. To evaluate the site specific factors influencing forest harvest response on MeHg in water, we synthesized previous studies on forest harvest effects in the northern hemisphere and harmonized them with supplementary field measurements. We also addressed one factor that may influence the effect of forest harvest: the impacts of logging residues left on site after the harvest. The availability of labile organic matter (OM) as electron donors for Hg methylators has previously been proposed as a central factor causing higher MeHg formation in harvested forest areas. The release of labile OM compounds from decomposing logging residues may thereby promote Hg methylation, in soil or in the residues themselves. Finally, the hydrological connectivity between the locations where MeHg is produced and a ditch or stream will determine the effect of the harvest. Here, we evaluated the effect of logging tracks and other soil disturbance caused by forestry machinery to determine the hydrological connectivity and mobilization of MeHg.

We found catchments with soils sensitive to compaction and rutting, i.e. those with high wetness index, low stone and boulder content and deep organic soil layers, to be at higher risk for elevated MeHg formation in soils, but not necessarily MeHg in runoff. Instead, the combination of MeHg formation in soils and hydrological connectivity to the watercourse influenced forest harvest induced increase of MeHg in runoff. Hillslopes with lower gradients and riparian buffers had lower hydrological connectivity to surface waters. Logging residues left on site after forest harvest were found to be a source of MeHg. However, the presence of logging residues can also protect the soil from disturbances by off-road traffic and thereby prevent the potential mobilization of MeHg in ruts.

Hydrological response to Pinus forest management in sub-tropical paired catchments

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Abstract: Pinus plantations represents 19,4% of planted forests in Brazil, with 1.93 million hectares for paper and corrugated cardboard packaging production according to annual report from Brazilian Tree Industry (Ibá). The WestRock Brazil company has managed a mosaic of Pinus plantations and native forests in a sub-tropical region. Besides Brazilian forestry sector is ahead in terms of sustainability, some companies go further and considers scientifically monitoring important to understand the management effects on water services. One of the most suitable methods for identifying effects of planted forests on water is the paired catchments, what involves the continuous and simultaneous monitoring of two catchments with similar edaphoclimatic conditions, one of which is submitted to forest management and the other maintains the original vegetation. As an affiliated company of Program for catchment environmental monitoring and modeling (PROMAB) from IPEF, two paired catchments have been monitored since 2009 through stream-gaging stations instrumented with pressure sensors and rain gauge registering data every 15 minutes. One of them is predominantly covered by native mixed tropical forest and the other by Pinus plantation. Both were analyzed aiming to compare hydrological indicators of water functions. The water balance has presented similar values for evapotranspiration in both catchments, which blue water varied by only 3% between them. In terms of water regulation, the Base Flow Index was similar on average, but presented differences on the first years after plantation. The Flashiness Index was already similar, but the Flow Duration Curve showed that the native catchment has lower values of maximum flows (Q10) and higher values of minimum flows (Q90). Although these general results pointed that the native catchment could be slightly more resilient, the ongoing analyses must consider the differences in the initial and final of Pinus cycle. Some differences in the first years of cycle suggest the critical moment in the forest management, but the similarity in general results can indicate that the management in Pinus catchment is fundamental to protect water and soil functions. The same similarity was observed in water quality data, what strengths the role of good practices of forest management practiced in Pinus plantation.

Incentives for improving environmental consideration in forestry - current state and need for development

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Elisabet Andersson[1]
[1] Swedish Forest Agency

Abstract: A key element in Swedish forest policy is “freedom with responsibility”. That implies that forest owners to a large extent can chose how to manage their forests, within a legislative framework setting a minimum level of requirements. The knowledge about effects of forestry practices on water quality is considered to be rather high among forest owners and managers. Ten years ago, a dialogue process with stakeholders resulted in common strategic management objectives for good environmental consideration to a variety of features in the forest landscape, e.g. to streams and lakes. However, recent results from the annual field inventory, carried out by the Swedish Forest Agency, show that there is still a large potential for more effective and functional consideration to and management of buffer zones along streams and lakes. These results are also supported by a number of scientific studies carried out during the last few years. So far, the inventories and scientific studies have reported on environmental consideration at final felling. However, other forestry related activities are also relevant in this context, e.g. thinning, construction and maintenance of forest roads and ditch network maintenance, but the a lack of data concerning environmental consideration in practice here makes it difficult to analyse impact and estimate the effects of different measures. A changing climate, challenges concerning forest health, increased demand for products from the forest, new EU regulations as well as other factors may contribute in different ways to strengthen both policy and economic incentives for improving management and protection of forests close to water.

Metabolic processes control carbon dioxide dynamics in a boreal forest ditch affected by clear-cut forestry

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Abstract: Boreal water courses are large emitters of carbon dioxide (CO_2) to the atmosphere. For forestry intensive areas of the Nordic and Baltic countries, a high share of these watercourses are man-made ditches, created to improve drainage and increase forest productivity. Previous studies have suggested that terrestrial sources of carbon sustain the CO_2 in these ditches and variability in hydrology is the main temporal control. However, few studies have explored ditch CO_2 dynamics and its associated controls in catchments being exposed to forest harvest. An altered hydrology, increased nutrient export and light availability following forest harvest are all factors that potentially can change both levels, dynamics and source controls of ditch CO_2. Here, high-frequency (30 min) CO_2 concentration dynamics together with other hydro-chemical variables were studied in a forest ditch draining a fully harvested catchment in the Trollberget Experimental Area, northern Sweden. Data were collected during the snow-free season from May to October. Ditch CO_2 concentrations displayed a clear seasonal pattern with higher CO_2 during summer than in spring and autumn. Concentrations were ranging from 1.8 to 3.5 mg C L^{-1} (median: 2.4 mg C L^{-1}, IQR = 0.5 mg C L^{-1}). Strong diel cycles in CO_2 were developed during early summer, with daily amplitudes in the CO_2 reaching up to 1.1 mg C L^{-1}. These pronounced daily cycles in CO_2 were closely related to the daily sum of shortwave radiation and water temperature. Variations in hydrology had generally a low impact on the CO_2 dynamics but did vary among seasons and between individual hydrological events. It was evident from the study that growing season CO_2 dynamics in forest ditches affected by clear-cut harvest were high and mainly controlled by light and temperature induced metabolism. These high dynamics and the associated controls need to be considered when scaling up ditch CO_2 emissions across boreal landscapes affected by forestry.

Peatland management is rocket science – holistic biogeochemical modelling as a tool for water protection

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Annamari Laurén[1]
Marjo Palviainen[1]
[1] University of Helsinki, Department of Forest Sciences, Helsinki, Finland

Abstract: World has changed and peatland management has become a rocket science. This is because management pursues to simultaneous production of multiple ecosystem services, such as wood production, water protection and mitigation of and adaptation to climate change. These ecosystem services arise from the same biogeochemical origins; therefore, they also must be solved at the same time. Peatland ecosystem is characterized by a complex network of interactions and feedbacks between processes, such as hydrology, nutrient and carbon cycling, forest and vegetation growth, transport of nutrients and water in soil and in open channels. Even though forest management changes only few of the system components, the effects reflect to all the ecosystem services, also water quality, through the feedback network. The management of the complex interactions and a pursue towards the ecosystem services fundamentally changes environmental management and poses a challenge to raise the skill level within forest and environmental sciences and among the experts already working with environmental issues. It also calls for development and application of ecosystem models taking into account the process feedbacks, applying detailed onsite data and allowing to study the effect of different peatland management, such as ditch network maintenance, clear-cutting, continuous cover-forestry, fertilization and restoration on water quality, greenhouse gas balances and forest production. In this presentation we show how interactive processes reflect to water quality in peatland management.

Structure and ecological functioning of riparian buffer zones after logging

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Ane Christensen Tange[1, 2]
Gunnar Austrheim[3], Hanne Kathrine Sjølie[2]
[1] Glommen-Mjøsen Skog SA, Elverum, Norway.

[3] University Museum Norwegian University of Science and Technology, Department of Natural History, Trondheim, Norway.

Abstract: Timber-oriented forest management has multiple impacts on non-timber ecosystem services and biodiversity. Legislation and certification schemes are implemented across countries to ensure minimum ecological standards in timber-production forests. Regulations may include sets of detailed measures to be taken during forest planning and logging operations. However, the discussion about the effects of these environmental measures to maintain biodiversity and ecosystem services is ongoing. One pivotal measure is watershed protection. Upon clearcuts, certification schemes typically demand a buffer zone to sustain the important ecotone between the water body and the forest. The width and composition of the buffer affect the ability to sustain its ecological function. Albeit the demonstrated ecological importance of the riparian buffer zon es, studies of whether its ecological functions are maintained after logging, are scarce. We aimed to fill part of this void by collecting primary field data in four areas in eastern Norway to test whether the post-logging riparian buffer zones maintained its ecological function as intended in certification schemes. All areas were subject to the Programme for the Endorsement of Forest Certification (PEFC) scheme, the world's largest forestry certification scheme. The study areas were selected in areas with recent forest management plans and aerial photos. 55 stands alongside water bodies clear-cut in 2020 - 2021 were randomly selected and field work was carried out in 2022-23. Data of buffer width, vegetation cover, multiple tree variables related to ecological structures and post-logging forest management were gathered in squared sample plots along the shoreline. We also collected data on stumps to partly reconstruct the pre-logging plots to reveal the possibilities for post-logging ecological function. Our analyses provide insight into which extent logging operations close to watersheds are in line with the scheme's intentions as well as the actual impacts of current forest management practices on the ecological function of the riparian buffer zone. This knowledge will help in the future development of forest certification schemes and forest policy and provides important information for practitioners to ensure sufficient ecological consideration in forest operations.

To ditch or not to ditch? The impact of ditching on nutrient export in a boreal catchment

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Virginia Mosquera[1]
Hjalmar Laudon[1], Eliza Maher[1]
[1] Swedish Unviersity of Agricultural Sciences

Abstract: Peatland forests provide important ecosystem services including nutrient storage, intrinsically linked to the quality of surface waters downstream. However, forest management practices such as clear cut (CC) and ditch network maintenance (DNM) may affect the release of nutrients and therefore downstream water quality. Just in Sweden, there have been nearly one million km of ditches dug in peatlands over the last 100 years to improve forest growth. Therefore, it is important to understand the consequences of these historic forest management practices so that suitable measures can be devised to protect surface waters in forested peatland catchments.

To improve the understanding of nutrient losses from catchments subjected to CC and DNM we present the results from a catchment-scale experiment at the Trollberget Experimental Area where we established six experimental catchments with control sites in the adjacent Krycklan Catchment in Northern Sweden. In the outlets of the six catchments, we measured pretreatment dissolved organic nitrogen (DON), dissolved inorganic carbon (DIN) and dissolved inorganic phosphorus (DIP), then successive treatments of CC on four of the six catchments, then DNM on two of the four CC catchments.

We found that both CC and DNM increased in organic and inorganic nutrients in surface waters. Post forest harvest, median DIP, DIN and DON concentrations were higher in all four CC catchments when compared to pre-harvest. After the DNM treatment, the catchments *without* DNM (only CC) had, on average, higher concentrations ($p<0.05$) of DIP (18.1 ±2 ppb), DIN (749.5 ±42 ppb) and DON (1314.8 ± 47 ppb) in surface water than catchments *with* DNM. Furthermore, the catchments *without* DNM had the highest percent increase for DIP, DIN and DON, at least within this two year period, having an increase of 457%, 1183 % and 88%, respectively. This suggests that forest management increases nutrient leaching, but that DNM can mitigate some of the leaching associated with CC, at least in the short term. Regardless, CC and CC+DNM sites had on average, higher export of all nutrients after management than before as a result of changes in biogeochemical and hydrological conditions with possible impact of downstream water quality.

What is a good riparian buffer?

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Lenka Kuglerová[1]
Eliza Maher Hasselquist[1]
[1] Swedish University of Agricultural Sciences, dept. of Forest Ecology and Management

Abstract: Riparian buffers have long served as an effective tool for water protection. Within forestry, safeguarding water from potential adverse effects often involves preserving a strip of untouched forest along streams or lakes. This forested fringe aims to prevent or alleviate detrimental impacts, including increased light penetration, elevated water temperature, alterations in riparian microclimate, and sediment accumulation. While it is widely acknowledged that this practice can be successful, there remains an ongoing debate regarding the key characteristics that make a riparian buffer truly effective. In many production forests, extensive management practices have significantly modified forest structure and even altered tree species composition along stream edges, suppressing natural disturbances and fundamentally transforming riparian zone dynamics. Given these circumstances, can we assume that merely preserving such forests through non-harvesting measures will sufficiently achieve our water protection goals? In this poster presentation, I will showcase recent research on riparian buffers conducted in Sweden. I will propose innovative ideas for designing buffers that not only safeguard streams and riparian zones post-forest harvest but also exhibit long-term functionality. These buffers should incorporate a diverse tree species composition, strategic canopy gaps, and intentionally created deadwood. Moreover, they should account for hydrological, topographic, and local site conditions. By doing so, these buffers can effectively fulfill crucial ecological functions, such as preventing sediment loading, conserving biodiversity, and providing high-quality resource subsidies to organisms.

What role does logging and fish stocking play in esker biodiversity?

T3.24 Minimizing forestry impacts on water quality, aquatic biodiversity and ecosystem functions

Sabrina Cloutier[1]
Guillaume Grosbois[1], Timothy Work[2], Miguel Montoro Girona[1]
[1] Université du Québec en Abitibi-Témiscamingue
[2] Université du Québec à Montréal

Abstract: Eskers are geological formation created at the end of the Ice Age that offer a wealth of sand and gravel, productive forests, high water quality and recreational resources to the Nordic countries. Esker lakes are isolated water bodies with singular characteristics: acid pH, clear water, and most of them are fishless. Such characteristics can play a decisive role regarding the species able to colonize these lakes and the predator-prey relationships. These ecosystems are submitted to a high pressure by forestry operations and fish stocking, although little is known about esker biodiversity. To increase our understanding of the biodiversity of these ecosystems, we aim to characterize the arthropod communities associated with Eastern Canadian esker lakes and assess the combined role of logging and fish stocking on their biodiversity (fish, aquatic invertebrate, and predatory insects (Odonata)). Our experimental design is composed of 18 lakes: 12 esker lakes (6 fishless and 6 stocked) and 6 lakes on the clay belt with a gradient of proximity to harvesting. Esker lakes are more acidic due to their water supply, which comes partly or totally from rainfall and/or groundwater. This is expected to influence the invertebrate species composition, given that the water body pH influences the organisms' ability to develop and reproduce. Also, we expect fishless esker lakes to be taxonomically rich in large, highly mobile, and pelagic invertebrates and teeming with large dragonflies such as *Aeshna* due to reduced predation pressure. Finally, we expect invertebrate species composition to be less affected by logging around esker lakes than clay lakes due to the maintenance of physico-chemical characteristics independent of the intensity of forest harvesting (less water runoff on sandy esker soil). This project will contribute to gain a better understanding of the invertebrate communities associated with esker lakes, and to determine the impact of anthropic disturbances (logging and fish stocking) on biodiversity to establish policies that guaranty the conservation of this singular ecosystems.

T3.25 Mitigating zoonotic and vector-borne disease risk in transformative forestry

Forests, fragmented forests, and zoonotic diseases: hazard and risk

T3.25 Mitigating zoonotic and vector-borne disease risk in transformative forestry

Abstract: According to common definitions, “hazard” is a potential source of harm, and “risk” is the probability of experiencing harm if exposed to a hazard. Biodiversity within forests (and other natural habitats) is often considered an important hazard for infectious disease, because the diversity there includes diverse pathogens. Following this common framework, risk arises from people encroaching on the forest or other biodiverse habitat. Such a framework presents ethical difficulties for conservationists, because the very biodiversity that they seek to preserve or enhance is seen as a health threat. The ethical challenge can be resolved by calling for management of human encroachment into biodiverse habitat, to ensure that the hazard ostensibly present therein is not converted into risk. But this logical approach is misguided. Recent research demonstrates that anthropogenic fragmentation, degradation, or other disturbances of forest habitat often exacerbates hazard or directly creates hazard that did not previously exist. Hazard of infectious disease is exacerbated by disturbances because reservoir hosts and vectors (and consequently pathogen populations) are favored, whereas protective organisms are often filtered out. Consequently, a given person entering a pristine forest will, in general, have lower likelihood of infection with a zoonotic pathogen than if that person enters a fragmented or degraded forest, despite the pristine forest having higher diversity. It is important to correct misunderstandings of the effect of biodiversity and biodiversity loss on hazard and risk, because the two scenarios (biodiversity constitutes a hazard v biodiversity loss increases or creates hazard) lead to different management and policy solutions. In the former (biodiversity is the hazard), disease prevention may be accomplished simply by preventing human encroachment. In the latter (anthropogenic disturbance causes hazard), the protection of forests from destruction/degradation prevents the hazard in the first place. Managing human entry or occupation becomes a secondary issue. Examples of these scenarios will be discussed.

Managing environmental, social and economic impacts of Covid-19 Pandemic by living close-to-nature: The Case of Eastern Africa

T3.25 Mitigating zoonotic and vector-borne disease risk in transformative forestry

Mercy Gichora[1]
Isaac Malugu[2], James Ndufa[3], Joram Kagombe[4]
[1] Kenya Forestry Research Institute, P. O. Box 20412-00200, Forest Productivity and Improvement Theme
[2] Environment and Forest Certification Limited,. P.O. Box 33125, Dar es Salaam, TANZANIA
[3] Kenya Forestry Research Institute, Forest Biodiversity, Environment Management and Climate Change Theme, P. O. Box 20412-00200 Nairobi, KENYA
[4] Kenya Forestry Research Institute, Socio-economics, Policy and Governance Theme

Abstract: In 2020, Kenya and Tanzania participated in a regional study of the impacts of Covid-19 pandemic on the forest sector. Desktop reviews documented the impacts and implications (including risks, threats and challenges) of the pandemic. Virtual interviews were guided by a checklist of questions by which to engage representatives of national governments, civil society, local communities and forest associations, private sector, academia and research practitioners, development partners, intergovernmental, other regional organizations and relevant international organizations operating in the region. The findings revealed that regional trade in wood products was highly disrupted by the measures taken to contain the international spread of the disease. In Tanzania and Burundi, declining demand for timber products caused factories to downsize their operations. The vulnerable, indigenous people like the Batwa in Uganda and several other local communities in the region faced economic difficulties when markets for local commodities were closed and there was food insecurity during the pandemic. In Kenya, community forests were over-exploited for economic benefit by urban dwellers who found themselves jobless during the pandemic and migrated back to rural areas. These demands placed pressure on all types of forests to supply basic needs like food, energy and income. Forests also became highly-valued as sources of medicinal plants to treat Covid-related illnesses. The threat of resource over-exploitation was higher than usual because the pandemic disrupted normal forest protection operations. Urban forests also proved especially important for people's mental well-being. They offered outdoor recreation spaces at a time when government lockdowns required urban residents to remain within restricted zones for extended periods of time. These cultural and spiritual values of forests highlighted social and health benefits of living close-to-nature. The shared experiences across Eastern Africa made a strong case for greater involvement of local communities in the region in co-managing forests in the future. Forest restoration, including continuous cover forestry, can prioritize biodiversity recovery as a major disease risk mitigation tool. The findings are useful for guiding stakeholders on how forest restoration should be performed to mitigate future disease risks.

Key words: Covid-19, Eastern Africa, impacts, living close-to-nature

RODENT ABUNDANCE, DIVERSITY AND COMMUNITY STRUCTURE IN A BUBONIC PLAGUE ENDEMIC AREA, NORTHERN TANZANIA

T3.25 Mitigating zoonotic and vector-borne disease risk in transformative forestry

Apia Massawe[1, 2]
Stella Kessy[1], Rhodes Makundi[1, 2], Christopher Sabuni[1], **Apia Massawe**[1, 2], Alfan Rija[2]
[1] African Centre of Excellence fro Innovative Rodent pest management aand Biosensor Technology Development, Sokoine University of Agriculture
[2] Institute of Pest Management, Sokoine University of Agriculture, P.; O. Box 3110, Morogoro, Tanzania

Abstract: Rodent-borne diseases, including bubonic plague, remain a significant threat to public health in tropical countries. In plague-endemic areas, little information exists on factors triggering periodic bursts. The study assessed how species richness, diversity, and community structure of rodents in Mbulu District, Tanzania, are associated with plague persistence. Rodents were captured using the removal trapping technique. A total of 610 rodents belonging to 12 species were captured, with *Mastomys natalensis* being the most abundant (10.89%). Within foci, persistent plague had significantly higher abundance, species richness, and diversity compared to non-persistent localities ($p< 0.05$). Forest habitats had significantly higher species richness compared to domestic premises ($p= 0.01$). Plague persistent localities were found to be significantly positively associated with high rodent abundance (mean= 2.34, ±1.10SE, $p= 0.03$) and species richness (mean= 0.73, ±0.16SE, $p< 0.001$). Additionally, three broad rodent community structures ($R= 0.98$, $p= 0.01\%$) were found, that varied significantly between studied habitat types ($R= 1$, $p< 0.8\%$), suggesting high population interaction at fine-scale resource abundance. The high abundance and diversity of plague-susceptible rodent reservoirs are among the possible factors contributing to plague persistence in the foci. The information may be useful to develop preparedness strategies in these areas to control plague outbreaks.**Keywords:** Bubonic plague, plague persistence, rodent abundance and diversity

The impact of restoration on disease regulation: A framework for identification and management of spillover risk

T3.25 Mitigating zoonotic and vector-borne disease risk in transformative forestry

[5] University of Helsinki

Abstract: In recent years, the link between landscape degradation, land use and the increase in the potential for zoonotic spill-over events is becoming ever clearer. Alongside mitigating the impacts of climate change, there is a growing body of thought that by restoring landscapes, ecosystem services such as disease regulation will recover. However, there is very limited empirical evidence of the way in which landscape restoration may improve disease regulation, and the mechanisms which may underpin this are unclear. In addition, restoration can be a hugely complex process, and the extent to which restored landscapes can be equated to fully functioning, non-degraded landscapes is not known, particularly when we consider the spatial and temporal scale of restoration, the mode of restoration, and whether complete floral and faunal recovery is achieved or even desirable. Here we outline a framework for monitoring diversity recovery in restored landscapes, taking into account sustained or increased human use of the space following restoration processes. This will allow a better assessment of the success of restored landscapes in protecting against disease spillover, and identifies key moments during which monitoring can be carried out to monitor potential pathogens.

The role of forest health for human health – Disease risk from zoonotic and vector-borne pathogens

T3.25 Mitigating zoonotic and vector-borne disease risk in transformative forestry

Frauke Ecke[1, 2, 3]
BEPREP Consortium[3]

[3] BEPREP, beprep-project.eu/

Abstract: Vector-borne and zoonotic diseases pose an increasing socioeconomic burden. There is mounting evidence that the structure and functioning of habitats and landscapes – including their integral biodiversity – play an important role in disease risk regulation. There are several mutually non-exclusive concepts and hypotheses that can explain this protective function of healthy environments and biodiversity. These include the dilution effect, the sanitation effect, the biodiversity and old friends hypothesis, and the microbiome rewilding hypothesis.

Forests around the globe are increasingly fragmented, resulting in smaller and more isolated forests and forest patches. This is not only consequential for biodiversity in general, but also for the prevalence and transmission of zoonotic and vector-borne pathogens. Habitat degradation induces amongst others a) a shift from species communities with specialist non-reservoirs to communities dominated by generalist reservoir species, and b) an increase in habitat edges that are favourable for vectors and reservoirs. How can the vicious cascade of habitat degradation, community changes and disease risk then be interrupted? Are nature-based solutions and rewilding the answer? Do we have enough scientific evidence to recommend or condemn certain forestry practices from a human disease risk perspective? Does climate change amplify disease risk induced via habitat degradation? What are the gaps in knowledge and how can they be overcome?

The presentation will provide an overview of current knowledge, challenges, potential pitfalls but also a roadmap for the development of a forest management strategy that increases human health via forest health. Forest types from various biomes will be addressed in the talk with experiences gained from the on-going Horizon Europe project BEPREP (beprep-project.eu/).

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Adaptability of two European black poplar (Populus nigra L.) genetic conservation units in contrasted environments

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Abstract: Describing the properties of genetic conservation units (GCUs), and more generally forest genetic resources, currently relies largely on static descriptors such as genetic diversity. However, there is an urgent need to complement these with dynamic indices that can underpin forecasts of both the adaptability of forest genetic resources, as well as their resilience to future environmental threats, such as climate crisis. Here we thoroughly characterized two environmentally contrasting European black poplar GCUs (2 x 500 adult trees and 2 × 250 juveniles) using high-throughput technologies to gather the following data: (i) genomic variation (12,211 SNPs used to estimate fecundity and kinship), (ii) hard traits (i.e. adaptive traits challenging to measure) derived from Near Infrared spectroscopy (NIRS), and (iii) unmanned aerial vehicle (UAV)-derived fertility and environmental data. Using these data we used quantitative genetic models to estimate the heritability of these adaptive traits and to explore the relationship between these traits and fitness (defined as fecundity and fertility) across a range of parentage-based selection gradients. Our work highlights the challenges in obtaining the key data and in optimising ways of integrating these various datasets to predict accurately the ability of forest tree populations to adapt. Here we address these challenges by focusing on: (i) Comparing the estimations of fitness using genomic markers versus UAV data, (ii) Exploring the possibility to calibrate NIRS models for several adaptive traits, (iii) Comparing methods to properly estimate heritability by combining phenotypic and environmental variables together with relatedness variation. By exploring different approaches our ultimate objective is to optimise our ability to predict the potential of our forest tree populations to adapt to future.

Assessing drought resilience of selected European forest plots using a hydraulic process-based modelling approach

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Abstract: Forests play a crucial role in promoting global biological evolution and community succession and maintaining a delicate ecological balance at the global scale. The persistence and functionality of forests are highly dependent on their resilience, defined as their ability to withstand and recover from environmental disturbances. The average increase in atmospheric drought or higher vapor pressure deficit and soil drought in recent years has led to a decline in forest productivity and increased tree mortality in many areas of the world. This trend is likely to continue due to ongoing climate change. Trait-based plant hydraulic models have great potential for studying the responses of individual trees, tree cohorts, or forest stands to drought. They simulate the movement of water through the plant from roots to leaves, predict water flow and storage in different plant compartments, and can predict the risk of hydraulic failure, which is a major cause of mortality under climate change. Using the recently developed hydraulic model SurEau-Ecos and different data sources, we will assess the resilience of selected European forest plots to drought using different metrics simulated by the models, including growth and the occurrence of cavitation in the conductive tissue of trees. We will select several forest plots on which the required input parameters for hydraulic models have been measured. The forest plots belong to a set of EUFORGEN (European Forest Genetic Resources Programme) genome conservation units of European beech (*Fagus sylvatica*), Scots pine (*Pinus sylvestris*), or maritime pine (*Pinus pinaster*). We will consider the variability of tree vulnerability within a species (i.e. tree traits), and also the variability between plots in terms of hazard (i.e. climate variability) and exposure (stand density, soil properties). We anticipate that accounting for trait variability will profoundly change estimates of the risk of hydraulic failure under climate change.

Can silviculture foster genetic adaptation to climate change in naturally regenerating forests? A demo-genetic modelling approach

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Abstract: Management strategies to reduce forest vulnerability to climate change currently concentrate on two main principles: a silvicultural control of forest structure to reduce stress and disturbance impacts, or a control of the genetic composition by plantation to improve its capacity to respond to hazard. Considering jointly functional and genetic aspects opens new perspectives.

For naturally regenerated forests, i.e. most of the forest area around the world, we still have limited knowledge on how fast can existing forests evolve towards adaptation by natural selection and how far can silviculture interfere with natural adaptation. To address these questions, we developed an eco-evolutionary approach using a demo-genetic individual-based model that integrates forest dynamics processes, genetic diversity of tree growth and sensitivity traits, stochastic disturbance regimes and silviculture interventions.

Our results reveal that natural selection under stress can lead to a rapid positive response in terms of stand growth and survival, visible after just one generation. The higher the selection intensity, the higher the adaptive response. Reducing tree density is a strategy to reduce drought stress, which is one option to mitigate the short-term impacts of climate change. However, reducing drought stress also reduces the intensity of natural selection; and frequent, early and intensive thinnings may hamper genetic adaptation. Considering realistic levels of within-stand genetic variation of growth sensitivity to drought, we find that strategies that promote natural selection can be more effective than stress reduction strategies to enhance the forest's response to stress over long-term. As a compromise between short- and long-term benefits, we propose an evolution-oriented thinning strategy that consists in maintaining high density during the juvenile stage to maintain some level of stress exposure and facilitate natural selection, followed by classical stress reduction through thinning operations in later stages.

We conducted this simulation research for a temperate conifer species in even-aged forests, but similar approaches can be extended to other forest types.

Combining provenance trials with whole-genome analyses to identify climate resilient forest reproductive material for European white oaks

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Abstract: Oak trees can live for over 1000 years. Fixed in place, the climate change-mediated environmental shift that individual oak trees experience is likely to be substantial and potentially harmful. European white oaks grow from the Mediterranean coast to Southern Scandinavia, a huge environmental gradient that has fostered local adaptations that could be beneficial under future climate scenarios like drought and extreme temperature. Assisted seed translocations from forest genetic resources from drier and warmer sites, could ensure oak forest health by matching trees with their predicted future climates. However, an understanding of the geographical patterns and genomic architecture of environmental adaptation is needed as a guide. Particularly because it is unclear if the genomic basis of environmental adaptation is highly localized or even population specific in oak trees, or if it similar at a range-wide scale.

To characterize local adaptation in white oaks (*Quercus robur*, *Q. pubescens*, *Q. petraea)*, we have established three common gardens of oak seedlings (Switzerland, Turkey, Austria). Provenances were selected from both distributional and local environmental extremes (i.e. chronic soil drought vs. wet soil), and seedlings measured at traits related to phenology, productivity, and water use efficiency. Each seedling was whole-genome sequenced at low coverage to describe genomic relatedness and perform genome-wide association analyses with the assessed traits.

Quantitative genetic analyses of trait data from across the gardens shows limited differences between provenances from local environmental extremes relative to distribution extremes. This suggests environmental adaptation is predominantly visible at a large geographical scale for the three species. The genomic architecture of these adaptations is now being explored through genome-wide association studies of fitness-related traits to identify if the same genes drive the trait differences observed. This large, interdisciplinary study combines common garden experiments with genomic data to identify climate-resilient forest genetic material for the future.

Drought adaptation of Italian silver fir provenances in a climate change perspective

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Abstract: The resilience of Mediterranean forest ecosystems to climate change is closely linked to adaptation to drought and increasing temperatures. Intraspecific genetic diversity (i.e. tree provenances) can directly affect such adaptive responses. It is therefore essential to define guidelines for promoting conservation and sustainable management of resilient forest genetic resources.

In this study, we analyse growth dynamics of silver fir (*Abies alba*) in relation to drought, comparing morphological and physiological performances of natural populations and plantations, both currently unmanaged. Growth responses to drought has been studied deeply in three silver fir Italian provenances (western Alps, northern Apennines (local) and southern Apennines), in plantations located in the Tuscan-Emilian Apennine National Park (Italy). Drought severity was defined through the SPEI Index. Dendrochronological analyses included climate-growth relationships, drought 'resilience indices' (RRR) based on tree ring width, and water use efficiency (iWUE) estimated through carbon isotope analyses ($\delta^{13}C$) on wood samples. Finally, we used FORMIND, an individual-tree process-based model, to simulate forest dynamics under three climate scenarios (R.C.P. 2.6, 4.5 and 8.5) and compare three different climate global models (HadGEM2, NorESM1 and MPI). We used field data to parametrize the allometric and growth equations used by FORMIND to describe provenance-specific behaviour.

Our results show that plantations had a faster growth than natural populations, also showing higher resilience and recovery during severe and/or extreme drought episodes. Provenances slightly differed in mean growth rates, with higher basal area increment by the southern Apennine provenance. The southern Apennine provenance also showed significant higher recovery and resilience during moderate and extreme dry years. Modelling results confirmed these trends, even if the differences among climate scenarios and global models were rarely significant. Carbon isotope analyses highlighted physiological responses of silver fir to drought, showing a strong signal during dry years and depending on provenance.

The workflow proposed in this work couples morphological with eco-physiological analyses, allowing a comprehensive overview of tree response to drought. Our results provide new and useful

insights on the adaptive responses of silver fir under drought conditions, highlighting the potential of forest reproductive material from rear-edge populations to support future adaptation to climate change.

Ecological niche modelling for forest genetic resources mapping: key challenges and interdisciplinary solutions

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Maneesh S. Bhandari[1]
Rajeev Shankhwar[1], Deepak Pant[1], Shailesh Pandey[1], Rajendra K. Meena[1], Harish S. Ginwal[1]
[1] ICFRE-Forest Research Institute, Dehradun, Uttarakhand, India

Abstract: Forest genetic resources (FGRs) are important for adaptive traits, functional genomics approaches, and climate-resilient forecasting. RS&GIS-based techniques, such as DOMAIN, BIOCLIM, GLM, GAM, GARP, MaxEnt-based ENM, etc., are applied to generate eco-geographic maps of FGRs. Under all these approaches, MaxEnt uses present-only data, bio-climatic variables, satellite GIS-layers to develop species' current occurrence, habitat suitability maps, niche future scenarios, molecular marker-based diversity patterns, population genetics spatial data representation, etc.

The MaxEnt model uses large amounts of datasets at a given time, often leading to issues related to handling intricate data, the risk of generalization, and difficulties in terms of interpretation, besides demands for large storage capacity and efficient computer processing systems. Two important considerations are the huge geospatial dataset (which requires ground validation) and the use of open-access satellite imagery (LANDSAT, SENTINEL, etc.) in modelling exercises. High resolution needs more time as compared to low resolution, but the former would be easier to generate LULC and forest types maps, biodiversity maps, etc. The power of MaxEnt prediction accuracy is statistically governed by the input data. While working on 50 FGRs of the state of Uttarakhand (India), MaxEnt was applied to 37 wide-distribution species based on a minimum of 10 geo-coordinates available for species presence data. Accordingly, Class-I (>80 geo-coordinates), Class-II (35-80 geo-coordinates), and Class-III (10-<35 geo-coordinates) included 11, 12, and 14 species, respectively. The area of estimated range in the case of 37 prioritized FGR species ranged from as low as 15.54 km^2 (*Tsuga dumosa*) to 832.4 km^2 (*Quercus semecarpifolia*), representing 0.03% to 1.56% of the geographical area, and 0.06% to 3.43% of the forest cover of the state. Species *viz*., *Bombax ceiba*, *Rhododendron arboreum*, *Taxus wallichiana*, *Myrica esculenta*, *Ougeinia oojeinensis*, *Betula utilis*, *Oroxylum indicum*, and *Terminalia chebula* had a relatively higher extent of distribution range, amounting to 716.9 km^2, 617.48 km^2, 545.86 km^2, 477.26 km^2, 384.73 km^2, 305.16 km^2, 286.51 km^2, and 262.89 km^2, respectively. We concluded that the MaxEnt logistic output is solely based on the prevalence assumption given environmental suitability rather than an actual extensive and intensive field-level assessment and estimation.

The genetic consequences of population marginality: a case study in maritime pine

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Abstract: Geographical marginal populations are located at the edge of the species' range and fragmented into sparse isolates, often in non-optimal environments. Because of their location, marginal populations may harbour highly specific alleles for local adaptation, thus potentially constituting valuable genetic resources for biological conservation. However, we lack evidence of the extent to which marginal populations are affected by particular genetic processes related to their typically small size, such as genetic drift or the purge/accumulation of genetic load. In this study, we used *Pinus pinaster* Ait., a widely distributed and economically important conifer characterized by a fragmented range, as a model species to better understand the genetic processes at play in marginal populations, as well as to test some of the main predictions of the Central-Peripheral Hypothesis (CPH). Based on 81 populations (1,431 individuals) and 10,185 Single Nucleotide Polymophisms, we estimated population genetic indicators potentially related to ecological resilience (genetic diversity, genetic differentiation and inbreeding) and population vulnerability to climate and adaptability (genetic load and genetic offset), and correlated them with eight geographical marginality indices computed following Picard et al. (2022). Our study showed some significant correlations between marginality indices and genetic indicators. Indeed, we observed a trend towards decreasing genetic diversity and increasing genetic differentiation with geographic population marginality, which is consistent with the range-wide patterns of genetic diversity and differentiation described for this species, and which supports the CPH. However, we did not find a significant relationship between inbreeding, genetic load or genetic offset and population marginality. Overall, our results suggest that marginal populations keep similar levels of genetic variation and adaptive capability as central populations, and thus may still be a valuable source of pre-adapted alleles to atypical environmental conditions in *Pinus pinaster*.

The role of intra-specific genetic diversity in forest productivity, mortality and resilience

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

Astor Toraño Caicoya[1]
Hans Pretzsch[1], Enno Uhl[1], José María Climent[2], Miren Del Río[2]
[1] Technical University of Munich
[2] CSIC-INIA

Abstract: The research on species mixtures has shown how species diversity has an overall positive effect on productivity, as well as on the resistance and resilience of forest stands, especially when the complementary between species is high. In this work, we investigate whether these benefits occur also in genotypes mixtures. To this aim, we transfer the methodologies commonly used when analyzing species mixtures to study the impacts of mixing provenances on forest growth. We present models for the study of genetic diversity effect on growth, analyzed in a broad set of provenance plots, for *Pinus sylvestris, Pinus pinaster*, *Picea abies* and *Abies alba*, in Spain and Germany. With the help of a moving window design, that selects the immediate vicinity of every tree, we calculated relevant tree and stand characteristics, together with the diversity of provenances and mean genetic distance inside of each moving circle. With this data we have fitted generalized linear models with growth and stand characteristics, accounting for the site as a random effect.

A higher number of provenances has shown a positive and significant effect in the structural diversity (coefficient of variation of diameter at breast height - dbh). Our results have also shown a positive impact in the height growth, but not on diameter growth, potentially indicating a higher competition for light, at least noticeable in the young development phase of *Pinus sylvestris.* Although this may change with age, silviculture guidelines and management recommendations could be drawn up for young stands. Moreover, we will analyze logistic models on mortality in young and old stands. Yearly growth based on cored data from all sites will be used for detecting dry years, and to calculate resilience accordingly. With linear modelling we will study the effect of genetic diversity on the stand structure to resilience of each site. Finally, general management recommendations to improve stand resilience and sustainable use will be developed.

When dendroecology meets genomics: Adaptive genetic variation to drought in white spruce indicates a potential for increasing forest resilience

T3.26 Multi-disciplinary approaches to the modelling of FGR resilience: there's more than genetics to Forest Genetic Resources

[2] Natural Resources Canada, Canadian Forest Service, Laurentian Forestry Centre, Québec, QC, Canada

Abstract: Rapidly warming climate and increasing instability is affecting water availability for conifer species at mid-latitudes, thus urging the need for assessing their adaptive capacity to better predict forest vulnerability and resilience under drier climates. In this study, we first used a dendroecological approach to determine the level of climate sensitivity of white spruce (*Picea glauca*) trees grown in a long-term provenance-progeny trial. We detected a clear signal of local genetic adaptation to drought, with provenances originating from drier locations showing a higher resilience than those from wetter locations. The study of carbon and oxygen isotopes in wood rings revealed different water use strategies even within white spruce populations, in response to extreme drought conditions. We also dissected the genomic features underlying drought adaptation in white spruce, combining gene-environment associations (GEAs), genotype-phenotype associations (GPAs) and transcriptomics. We identified a set of 285 genes significantly associated with climatic factors or key phenotypic traits, of which 110 genes were differentially expressed under drought stress in controlled greenhouse conditions. Our multidisciplinary approach has provided new insights into the nature and relative importance of the physiological mechanisms underlying drought resistance in conifers. These findings represents an important step towards characterizing the genomic basis of drought resistance in these species.

T3.27 New forests with greater resilience: the importance of forest genetic resources in forest landscape restoration

Gene flow and seed production in fragmented landscapes

T3.27 New forests with greater resilience: the importance of forest genetic resources in forest landscape restoration

[2] Austrian Research Centre for Forests

Abstract: The primary objective of forest restoration and conservation is to facilitate the adaptation of forests to climate change, enhance the biodiversity of forest ecosystems, and address the consequences of climate change-driven large-scale disturbances. In recent years we have seen an increase in initiatives, such as the EU Green Deal, which plans to plant 3 billion additional trees in Europe. However, newly established forests require high tree species diversity and genetic diversity to meet ecosystem services and carbon storage. Therefore, these initiatives require large amounts of quality seeds and seedlings of various species, albeit many of the species are currently occurring in fragmented populations with unknown genetic composition. Seed procurement is regulated internationally by the OECD, the EU, and within individual countries' legislature – all to various extents, often entailing recommendations on the size and density of seed stands and harvested trees. Most EU recommendations were developed in the 1990s and put into regulation in 2002 without considering climate change.

Moreover, since then, scientific knowledge of gene flow and genetic diversity has increased exponentially, mainly due to the availability of better genetic markers and analysis tools. Challenges to seed production have continued to grow. As a result, the quality of seeds used for afforestation and restoration is declining. Tree population fragmentation and its impact on seed production is an aspect that can be addressed through specific conservation and restoration strategies to mitigate its adverse effects on seed production. However, despite extensive research on fragmentation genetics and seed quality, it is surprising that the link between these two subjects has hardly been explored. Our research aims to consolidate existing knowledge on the relationship between fragmentation, genetic diversity, gene flow, and seed quality in the context of declining seed production and the need for forest ecosystem restoration. Moreover, our work aims to identify gaps in communicating the latest scientific knowledge to policymakers and seed source regulations.

Genomic information as decision support for use of stone pine in Mediterranean agroforestry landscapes

T3.27 New forests with greater resilience: the importance of forest genetic resources in forest landscape restoration

Abstract: The emblematic umbrella-shaped Mediterranean stone pine *Pinus pinea* L. has been widely used for coastal land reclamation and restoration of degraded oak coppices and scrublands, and its forests render an emblematic nonwood forest product: Mediterranean pine nuts, the highly priced edible seed kernels of the species. In the last fifty years, stone pine has increased its area in more than 70%; since 19th century, its expansion by plantations has been threefold.

Under the drier and warmer conditions predicted for the near future in Southern Europe, the use of this resilient multipurpose tree might become even more relevant as tool for diversifying complex forest and agricultural landscapes. Its role as nut tree in agroforestry is relevant for the forest-farmland and forest-urban transition zone, where it can both help to restore open tree cover on marginal farmland, as well as structure abandoned zones of encroaching woodlands by creating open gaps or bands without understorey, essentially also as support for wildfire control.

In the last decades, outstanding cone producing plus trees have been selected in Spain and Portugal. Grafting allowed replication in common garden trials, aiming at the selection of best clones for orchard plantations. Aiming to assess accurately forest genetic resources (FGR) and their use in stone pine conservation, improvement and deployment, a recent genomic tool for the species (5,671 SNP markers) has allowed the verification of identity preserved of more than a hundred clones, some already registered as base materials for producing graft scions, others still under evaluation. Clonal identification and hence feasibility of identity checks for traceability and certification is more accurate with SNPs than the previous tool based on microsatellite markers. The SNPs have also allowed screening genetic differences among Iberian populations, defining gene pools in relation with breeding and FGR conservation programs. Combined with quantitative genetics from field trials, these results set the base for a knowledge-based deployment of the species.

Keywords: *Pinus pinea*, pine nuts, clonal identification, breeding, SNP array

Management and conservation of valuable forest genetic resources of Quercus petraea: an example from a national park in Austria

T3.27 New forests with greater resilience: the importance of forest genetic resources in forest landscape restoration

[4] University of Natural Resources and Life Sciences (BOKU), Institute of Soil Research, Peter-Jordan-Straße 82, 1190 Vienna, Austria

Abstract: The increasing demand for climate-adapted seeds and planting material poses a challenge due to the limited availability, particularly for tree species such as oaks. National parks, known for their large-standing diversity and a wide range of habitats, can serve as valuable sources for identifying "elite phenotypes" suitable for both the conservation strategies and initiation of tree breeding valuable for tree management.

We aimed to identify and secure valuable forest genetic resources of the National Park Thayatal in Austria by selecting drought-tolerant "elite" phenotypes and autochthonous genotypes of high neutral genetic diversity. For this purpose, we selected 404 mature trees of *Quercus petraea* (Matt.) Liebl. from eight populations growing on medium to arid sites in eight populations. Genetic markers were applied to estimate autochthony, genetic structure, and genetic diversity indices. Further, we assessed their age and characterised them for possible drought tolerance using wood core analysis and water use efficiency (WUE) analysis. In the summer of 2023, potentially drought-tolerant tree progeny will undergo high-throughput plant phenotyping (HTTP) and transcriptomics to assess their reaction to drought.

The trees ranged in age from 40 to 240 years. The DNA analyses indicate a high genetic diversity in the studied mature trees, exhibiting a plastid haplotype 17a, autochthonous for this area. Nevertheless, the genetic structure estimated by ten nuSSRs revealed a pronounced structure in the dataset. A total of 85 elite potentially drought-tolerant trees were found based on their response (resistance, recovery ability, hardiness, and relative resistance) to three historical drought events (1992-1994, 1947, 1917). Based on the isotopic analysis of δ13C of latewood in wet (1987) and dry (1994) years, it was found that the estimated WUE did not display any significant differences among the groupings of trees (drought tolerant, or not drought tolerant) for the four responses.

We discuss the studied oaks towards their conservation and sustainable use for establishing seed stands and orchards to enhance seed production, genetic monitoring initiatives, and the integration of other omics approaches such as phenomics and transcriptomics for deep analyses of drought tolerance of selected phenotypes.

Sustaining gains made towards achieving the Bonn Challenge target for Ghana

T3.27 New forests with greater resilience: the importance of forest genetic resources in forest landscape restoration

Shalom Addo-Danso[1]
Lucy Amissah[2]
[1] Forests and Climate Change Division, CSIR-Forestry Research Institute of Ghana, Ghana
[2] Biodiversity Conservation and Ecosystem Services Division, CSIR-Forestry Research Institute of Ghana

Abstract: Following the launch of the Bonn Challenge in 2011, many countries made pledges to bring several millions of degraded lands under restoration. Ghana is making much effort to achieve its commitment of bringing 2 million degraded lands under restoration in 2030. Many forest landscape restoration initiatives/ projects are ongoing across the country, but given the complexity of implementing such projects, there is the need to determine the success factors and identify the key challenges and barriers in order not to derail progress towards the 2030 target. Data and information was collected using a mixed method approach including desk study and case studies through stakeholder consultations with local communities and other relevant stakeholders. The findings showed that most restoration projects have contributed to increasing tree cover in degraded areas, enhancing water protection and carbon sequestration, and improving women's access and ownership to land and tree tenure, supporting smallholder communities to diversify their income sources and contributing to behavioral changes towards resource extraction. Some factors that have contributed to these project benefits include the existence of relevant policies and strong institutional frameworks supporting restoration actions. Despite these successes, major technical and governance challenges remain. Key among them includes the unavailability of high quality seeds and seedlings in sufficient quantities that would their survival and establishment in the field. Access to high quality germplasm should be prioritized at the planning stage of restoration projects. Ensuring that the diversity and quality of germplasm is sustained will require capacity building and training for local communities and private who engage in the supply of seedlings and there is for relevant government agencies to map trees that are potential seed sources in reserved and conservation areas and protect them from illegal logging and mining.

The choice of post-fire restoration strategies affects functional trait diversity of early successional communities and future forest resilience

T3.27 New forests with greater resilience: the importance of forest genetic resources in forest landscape restoration

Katrin Fröhlich[1]
Johanna Gaber[1], Somidh Saha[1]
[1] Karlsruhe Institute of Technology, ITAS, 76133 Karlsruhe, Germany

Abstract: Under the ongoing climate change, forest disturbances are increasing in Germany. Restoration and reforestation actions in those areas are further challenged by extreme weather conditions such as recurrent drought and heat waves.Regaining resilient and productive forest stands after disturbance is a key goal. Resilient forest stands can be characterized by specific functional traits of the plant community such as drought tolerance or resprouting capacity. Such traits can be brought in by planting of specific (non-native) target tree species. However, artificial plantings require active restorations as extensive soil preparation. Active restoration strategies expose the disturbed soils further to extreme conditions for a longer time. Contrary to active restoration of functional trait diversity; passive restoration promotes natural adaptation of the regenerating forest ecosystem over a long time span. To date, knowledge on the combination of restoration strategies and it´s impact on early and later stage functional trait diversity is scarce. In order to increase the knowledge base on restoration and functional trait diversity we investigated early stage succession three years after a forest fire in Brandenburg, Germany. We studied early successional plant communities after fire, that underwent passive, purely active (full clearing), and combined restoration actions. Using plant trait data of encountered herbaceous and tree species from TRY database we identified differences in functional trait diversities along the gradient from active to passive restoration. Areas under passive and a mix of active and passive restoration showed a community of short-lived herbaceous species which can be potentially used for topsoil regeneration and the protection for recently introduced target tree species. In unburnt areas and areas of full active restoration, we found a highly competitive vegetation layer, indicating a highly dynamic and unstable environment. Based on the field investigations and secondary data analyses we conclude that a mix of restoration measures can be useful in creating favourable environments for target tree establishment while shaping the functional trait community towards a more resilient forest .

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

A review of connectivity studies in European forests: target species, scales and methods.

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

[3] University of Vienna

Abstract: Habitat connectivity plays a crucial role in mitigating the negative impacts of habitat isolation and promoting species migration. It is widely acknowledged as vital for preserving biodiversity at various levels, from genes to communities. Consequently, connectivity has gained significant attention in conservation plans and policies. However, due to the diverse range of approaches and concepts surrounding connectivity, its assessment and evaluation can sometimes be inconsistent and uneven. Measuring ecological connectivity is not yet a standardised process, and the systemization of measurements and comparability of connectivity results remains challenging. Our review focused on studies conducted in the past 20 years that analysed forest connectivity in Europe. We classified the measuring methods into 15 categories and examined their relationship with the study's main goals, study area scale, and selected focal taxa. Among the 142 articles reviewed, more than 1,000 different focal species were studied, with birds and mammals being the most commonly researched groups, and amphibians the least. Notably, 90% of the epiphyte studies included temporal connectivity, suggesting a potential vulnerability of this subgroup to habitat temporal continuity. The majority of studies were carried out at a regional scale and in mixed landscapes (forest plus two or more other landscape classes), and most of them had the intention of a connectivity assessment without further conservation goals stated. Less than a quarter of the studies compared different measuring methods. A trend towards methods assessing functional versus structural connectivity has emerged over the years, however, there are still relationships between the selected methods and other factors (such as focal taxa and scale) that require further examination. Based on our findings, we propose future directions to explore these relationships and develop standardized methods for assessing forest connectivity. By addressing these gaps, we can enhance our understanding of connectivity patterns and effectively incorporate connectivity considerations into conservation strategies.

Assessing the Socio-Ecological Effectiveness of Forest Management Institutions in Bangladesh- A Case Study from a North Eastern Forest Ecosystem

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Mohammad Belal Uddin[1]

[1] Department of Forestry and Environmental Science, Shahjalal University of Science and Technology, Sylhet-3114

Abstract: There are many studies done on biodiversity in tropical forest ecosystems. However, researches on the management institutions regarding the biodiversity conservation are rare. The present study focuses on this issue. Since, Bangladesh is burdened with highly populated country which affects forest ecosystems. This is why, researches on forest management issue is essential in this forest ecosystem. North-eastern forest ecosystems are not in exception. Therefore, it was conducted in north-eastern forest ecosystems in Bangladesh. Traditional (reserve forest) and co-managed (reserve forest with co-management) forest areas had been selected for the field study. GIS technologies are used for the plot selection in the field. Systematic sampling technique and circular plots had been used to collect the data required for this study. Biodiversity parameters: species richness, abundance, basal area, canopy cover, regeneration, disturbances had been collected to analyze the ecological effectiveness of the management techniques. The data were analyzed using R-statistical program to compare the ecological effectiveness of different management institutions in the study area. Ecological parameters were found higher in co-managed areas than the traditionally managed areas. However, social parameters show mixed and ambiguous results. This study opens the avenue for the further assessment on the role of management institutions for biodiversity conservation as well as for the management of forest areas of Bangladesh.

Keywords: management institutions, co-management, traditional management, biodiversity, livelihoods.

Assisted dispersal as a tool to promote the recovery of biodiversity in newly afforested agricultural soils.

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Davide Barsotti[1]
Mathias Just Justesen[1], David Bille Byriel[1], Sebastian Kepfer Rojas[1], Inger Kappel Schmidt[1]
[1] Department of Geosciences and Natural Resource Management, University of Copenhagen, Copenhagen 1017, Denmark

Abstract: With climate and land use changes adding pressure to the dwindling populations of forest specialists in Northern Europe, the establishment of new populations in forest plantations can be a successful strategy to ensure their preservation on the long term.

New forests are often planted on agricultural soils, however, isolated in a matrix of unsuitable anthropic landscape, with little access to source populations. Furthermore, the planted areas bear a legacy of their former land use, which could constrain the development of late-successional communities.

Our study explores the efficacy of assisted dispersal as a tool to restore plant and soil microbiome in recently afforested agricultural land: in 2015, $2m^2$ soil turfs were transplanted from an old forest to young tree plantations in Denmark. A full factorial setup was used, with 10- and 20-years old forests of beech and oak, in sand and clayey soils. Further, assisted dispersal of *Anemonoides nemorosa* (L)Holub rhizomes and of a 0,3 mm sieved soil layer were carried out in separate $1m^2$ quadrats. Soil was sampled at the time of establishment, and vegetation was surveyed annually. The establishment success of anemones and the other transplanted species was monitored, along with changes in the flora in nearby areas unaffected by the transplant.

In 2022, new soil samples were taken and soil E-DNA was extracted in the transplants and the donor site. The plant communities and the microbiome will be analysed, in order to unravel the belowground outcomes of the transplant, and how these interlace with the patterns seen in the ground vegetation. The experimental setup will also allow a comparison of different conditions at the moment of transplant: differences in development due to tree age, species, and soil texture will be addressed.

This study will shed light on the efficacy of assisted dispersal as a tool to promote biodiversity in afforested agricultural soils, adding a new perspective on the persistence of the microbiome almost 10 years after inoculation, establishment of forest communities across different taxa, and under different environments conditions.

Biodiversity and forest management abandonment in boreal and temperate forests: a meta-analysis reveals time since abandonment and climate interact

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Abstract: Growing evidence suggests that forest management practices are threatening the long-term conservation of a number of animal, fungi, and plant species worldwide. Although unmanaged forests are considered important for biodiversity, forest management continues to affect these vital habitats. We systematically reviewed the scientific literature to gain insight into the effects of forest management abandonment on biodiversity. We calculated log response ratio effect sizes to perform a meta-analysis on species richness between still managed (MAN) and no longer managed (NLM) forests, throughout the world's boreal and temperate forest ecosystems. Our statistical approach included improvements relative to a rigorous treatment of pseudo-replication, an objective choice of taxonomic resolution, and new forms of residual heterogeneity. Plant species richness was significantly lower in NLM than in MAN stands, while fungi richness was higher in NLM sites. We, in addition, tested the effect of time since abandonment of management (TSA), and climatic variables, on the biodiversity difference between NLM and MAN forests. These results underline the slow but real and context-dependent recovery capacity of certain taxa after management abandonment. Our findings support the call for more coordinated and contextualized policies aiming to set aside forest zones in production forest systems for worldwide conservation purposes.

Bryophyte-Seedling Associations in Nothofagus Sub-Antarctic Forests: Insights into Ecological Relations and Regeneration Dynamics

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Abstract: Bryophytes, including mosses, liverworts, and hornworts, play a crucial role in the dynamics of native forests by contributing to fundamental ecological processes such as tree regeneration. This study aimed to investigate the association between bryophytes and *Nothofagus* seedlings in sub-Antarctic forests and determine if the substrates on which bryophytes grow influence this association. The research was conducted in contrasting landscapes (coastal and mountain) of Tierra del Fuego, Argentina, to better understand the ecological relations in the natural regeneration processes. The hypothesis proposed that bryophytes serve as a substrate for seed germination and initial growth in pure and mixed forests of *N. pumilio* and *N. betuloides*, leading to widespread associations between tree seedlings and bryophytes in all landscapes. The study involved establishing 60 transects in each forest and landscape location, evaluating bryophyte cover using the point intercept method, and assessing substrate types such as bare soil, decaying wood, and litter cover. The relative interaction index (RII) was adapted to analyze the competition or facilitation between bryophytes and tree seedlings by comparing their respective cover percentages. Twenty-seven bryophyte species (15 mosses and 12 liverworts) were identified, with nine mosses and eight liverworts associated with tree seedlings. The results revealed that *N. pumilio* seedlings were less abundant in bryophytes than other substrates, indicating an inhibitory effect on their germination and growth. In contrast, *N. betuloides* seedlings, in both pure and mixed forests, exhibited higher abundance on bryophyte substrates, particularly in mosses in the mountain landscape. These findings suggest that bryophytes play a facilitating role in the germination and initial growth phases of *N. betuloides* seedlings. The conservation of bryophyte communities is crucial for the natural regeneration of *N. betuloides*, as it promotes the continuity of this forest type in both pure and mixed structures.

Co-management Approach: An Innovative Governance to Promote Sustainable Management of the Sundarbans Mangrove Forests of Bangladesh

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Md. Wasiul Islam[1, 2]
[1] Forestry and Wood Technology Discipline, Khulna University, Khulna 9208, Bangladesh
[2] Deputy Chief of Party, USAID Ecotourism Activity, Bangladesh

Abstract: The Sundarbans is the largest single tract of mangrove forest in the world which is located in the southwest corner of Bangladesh. This is a unique ecosystem which is a great breeding and nursing ground for a great biodiversity. It supports the livelihood of about 3.5 million coastal dwellers and also protect the coastal belt area and inland area from various natural calamities. Historically, the management of the Sundarbans was controlled by the Bangladesh Forest Department following top-down approach without the involvement of local communities. Such fence and fining-based blue-print approach was not effective to protect the forest which caused Sundarbans to be deforested severely in the recent past. Therefore, local multi-stakeholder-based bottom-up co-management approach was introduced in the Sundarbans in 2006 to facilitate its biodiversity conservation. Various co-management organizations (CMOs) were introduced under the co-management approach where the local community people could actively involve in various activities related to the management and welfare of the Sundarbans including the decision-making process. The objective of the study was to assess the performance of CMOs to facilitate sustainable management of the Sundarbans. The qualitative study followed face-to-face interview to collect data from a total of 40 respondents using snowball sampling technique. The study showed that the co-management approach improved governance of the Sundarbans through the active participation of local community people and their interactions with the officials via the platform of CMOs. It facilitated accountability and transparency to some extent through following some formal and informal rules and regulations. It also improved the power structure of the management by fostering local empowerment process particularly the women. Moreover, people were able to learn from their interactions with and within the CMOs as well as interventions improved environmental awareness and promoted social learning. The respondents considered good governance as the most important factor for achieving the goal of sustainable management and biodiversity conservation of the Sundarbans. However, the governance was also facing various challenges resulted barriers to the sustainable management of the Sundarbans. Respondents recommended greater patronization form the government with effective participatory monitoring and evaluation system to improve sustainable management of the Sundarbans.

Deadwood as key element for bryophyte diversity in interaction with macroclimatic variables in managed and unmanaged temperate lowland forests

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Abstract: Setting aside strict forest reserves is one of the conservation measures promoted to preserve a proportion of the biodiversity threatened by forestry. However, there is a lack of knowledge concerning the respective roles of management abandonment, forest stand structural attributes and climatic or topographic variables in determining biodiversity in temperate forests. To address this issue, we conducted the first national-scale study in France to compare the biodiversity of managed versus unmanaged forests. Focusing here on bryophytes – all species and forest specialists –, we analyzed the data from 132 plots in ten lowland forests throughout France comprising both managed and unmanaged stands. Our aim was to disentangle the relationships between bryophyte richness and (i) management abandonment per se, (ii) associated forest structure variables such as deadwood volume and (iii) macroclimatic variables known as important for bryophytes (temperature, precipitations, relative humidity, solar radiation and vapor pressure deficit). For each studied combination of variables (single, additive or interactive models), we compared hierarchical Bayesian models of several types: linear with fixed slope, linear with random slope – one slope per forest –, quadratic, sigmoid or threshold models. The main drivers of bryophyte richness were deadwood variables, in managed as well as in unmanaged stands. We observed a sigmoid relationship of the total deadwood volume for the overall richness and threshold effect of the large and very large deadwood volume for the forest specialist richness. Combination of deadwood and macroclimatic variables were the best predictors of bryophyte richness, following non-linear relationships: higher solar radiation reinforced the positive effects of large deadwood on forest-specialist bryophyte richness; higher mean annual temperature counteracted the positive effects of total deadwood amounts on total bryophyte species richness. We conclude that high amounts of deadwood in managed as well as unmanaged forests are key elements for bryophyte richness and that ongoing climate changes may modulate their effectiveness as conservation structures.

Effect of different silvicultural treatments on the understory of temperate oak forests: the Pilis Forestry Systems Experiment

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

[5] Eötvös Loránd University, Institute of Biology, Doctoral School of Biology, Hungary

Abstract: Forest management has a major impact on the understorey vegetation. We compared understorey variables across different experimental silvicultural treatments in a temperate oak-hornbeam forest in Central Hungary. Five treatment types were used in six replicates representing rotation and selection silvicultural systems: control (C), clear-cutting (CC), gap-cutting (G), preparation (partial) cutting (P), and retention tree group (R). The response of several community variables of the understorey was investigated to the treatments in the first 6 years after their implementation.

We found a large temporal and spatial variability over the study period. In all cases, the interventions led to an initial increase in species richness, often followed by a decline later, as the regeneration layer started to close. At the end of the study, R had the highest average species richness, comprising a heterogeneous group of perennial forb species. The interventions all resulted in a rapid increase in total herb layer cover, mainly in favour of graminoid and perennial species. The extent of the cover increase depended primarily on the intensity of the intervention, reflecting the amount of additional light received (CC > G > P > R > C). Turnover values, i.e. the rate of compositional change, also decreased in the same order. The effect of game exclosure was especially pronounced in CC and G, where game browsing slowed downed the regeneration outside the fences. The most significant changes in almost all variables were in the CC. It had the highest number of indicator species, many of them annual, ruderal, and invasive. G preserved the forest character of the vegetation dominated by light-flexible species. R and P preserved successfully the forest characteristics of the understorey.

Increasing the share of continuous cover forestry methods is crucial to preserve the forest herb layer at the landscape scale. Rotation forestry with large cutting areas is not recommended or should be kept at low landscape rates, as these areas are highly exposed to disturbance-related and invasive species. Leaving retention tree groups can be crucial to the survival of numerous forest species.

Forest degradation assessment in the Andean-Amazon region based on species composition approach

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Kazuki Miyamoto[1]
Sonia Palacios Ramos[2], Edgar Alexs Arana Olivos[3], Juan Carlos Ocana Canales[2], Sara Lucia Terreros Camac[2], Carlo Eduardo Reyes Grande[2], Tamotsu Sato[1], Naohiro Imamura[1], Wei Yang[4], Yasumasa Hirata[1]

[4] Center for Environmental Remote Sensing, Chiba University, Japan

Abstract: The montane forest ecosystems in the Andean-Amazon region are being degraded by anthropogenic disturbances such as logging and fire. Forest degradation not only reduces carbon stocks, but also promotes the decline of other ecosystem functions through changes in forest structure and biodiversity. However, changes in biodiversity are more difficult to be captured in broad-scale assessments compared to changes in biomass and carbon stocks. This study aimed to understand forest degradation status in montane forests in the Andean-Amazon region and to provide information that will contribute to planning of forest conservation, sustainable forest management, and restoration in the forest-agricultural landscape. We investigated the variation in forest structure and tree community composition with the different extent of anthropogenic disturbance by ground-based surveys, then evaluated forest degradation status at a regional scale by remote-sensing approaches including satellite imagery and UAV photography. Our study areas were Huanipaca district in Apurimac and Yanatile district in Cusco, Peru. Huanipaca is located in an Andean mountainous region, while Yanatile is in a high Amazon region. We set up circular plots with 20 m radius, and conducted field surveys including tree size measurement and species identification. For the regional scale assessment, we developed statistical models that relate dissimilarity in species composition among sites and band data from satellite imagery (Landsat 8 and Sentinel-2). The model including normalized burn ratio (NBR) as an explanatory variable reasonably accounted for forest degradation status based on dissimilarity in species composition among sites. By using this model, we obtained maps of forest degradation status in the regions. The maps produced were able to detect less degraded forest areas that we observed by the ground-based survey. Such areas can be extracted as priority sites for conservation. Our results suggest that species composition can be a key indicator for evaluating forest degradation status. In this presentation, we also introduce the application of the 3-dimensional forest structure data obtained by UAV-SfM to extract structural features to represent forest degradation status for the model accuracy improvement.

Forest Management Practice Influences Bird Diversity in the Mid-Hills of Nepal

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Bijaya Neupane[1, 2]

[5] Center for Integrative Conservation, Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Menglun 666303, China

Abstract: Forest management practice plays a critical role in conserving biodiversity. However, there are few studies on how forest management practice affects bird communities. Here, we compare the effectiveness of the Panchase Protection Forest (PPF; protected forest with government administration) and the Tibrekot Community Forest (TCF; community forest with community forest users' group administration) in hosting bird diversity in the mid-hills of Nepal. We examined 96 point count stations during summer and winter in 2019 and recorded 160 species of birds with three globally threatened vultures (red-headed vulture *Sarcogyps calvus*, slender-billed vulture *Gyps tenuirostris*, and white-rumped vulture *Gyps bengalensis*). Forest management practice, season, and elevation all influenced the richness and abundance of birds. The diversity, richness, and abundance of birds and the most common feeding guilds (insectivore, omnivore, and carnivore) were higher in TCF than in PPF; however, globally threatened species were only recorded in PPF. We also recorded a higher bird species turnover (beta diversity) in TCF than in PPF. Our study indicates that community-managed forests can also provide quality habitats like those of protected forests managed by the government and provide refuge to various bird species and guilds. However, we recommend more comparative studies in other tropical and sub-tropical areas to understand how different forest management practices influence bird diversity.

Global long-term impacts of forest management on biodiversity

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Hanneke van 't Veen[1]
Rob Alkemade[1]
[1] Netherlands Environmental Assessment Agency (PBL), Nature and rural areas (NLG), The Netherlands

Abstract: Forest managed for wood production could play an important role in biodiversity conservation outside protected areas; yet current global annual extraction of 3.9 billion m^3 roundwood and woodfuel results in a rapid decline and degradation of forests and its biodiversity. Previous studies show that sustainable forest management mitigates harmful impacts on biodiversity on the short term. Yet, little is known about long-term recovery times, nor about the ecosystem properties that explain management impacts on biodiversity, such as vegetation structure and composition. Through an expansion of three meta-analysis-based global databases (i.e., PREDICTS, GLOBIO and an unpublished database) with data on forest management (178 studies, 399,304 observations), time since management impact (113 studies, 209,129 observations) and vegetation structure and composition (3-38 studies, 47,098-162,138 observations), we aim to better understand ecological principles underlying impacts of forest management on animal biodiversity expressed as mean species abundance (MSA). In line with previous studies, we show that reduced-impact logging and selective logging have the least impact on biodiversity (MSA: 0.7, variance weighted average), and perennial tree crop plantations the highest (0.4). We find indications that management-specific vegetation structures partially produce this order, where high tree density and foliage cover negatively affect MSA, while the opposite is true for tree species richness, understory height and basal area. Each management type changes forest vegetation in their specific way, producing management-specific biodiversity impacts over time. Effects of selective cutting on MSA remain stable over 50 years, displaying no sign of recovery. MSA in clear cutting systems is relatively high in the years following cutting, after which it declines and stabilizes between 30 to 70 years. We find similar patterns for perennial tree crop and plantation systems; yet, we for these systems observe a slight MSA recovery between 50 and 80-100 years after establishment. Interestingly, agroforestry systems display a gradual MSA increase between 0 and 30 years following establishment before stabilizing. Overall, our results highlight the need to consider long-term effects of forest management systems on biodiversity to prevent under- or overestimations of their impacts.

Impact of active coppice management on microclimate and understorey vegetation in a Mediterranean oak forest

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Ilaria Santi[1]
Elisa Carrari[1], Pieter De Frenne[2], Mercedes Valerio Galán[1, 3], Cristina Gasperini[1, 4], Marco Cabrucci[1], Federico Selvi[1, 4]

[4] National Forest Biodiversity Centre

Abstract: Understorey diversity contributes to forest functionality and services. Thermophilization processes caused by global warming have been detected especially in regions with warm macroclimates, such as the Mediterranean one. Coppice-with-standards is still one of the most common types of management in this region, aimed at the production of renewable energy (firewood). The modification of forest structure caused by coppicing could limit the capacity of forest canopy to offer microclimatic refuges for the herb communities. Hence, it is crucial to assess the sustainability of this traditional management under the current climatic stressors. We contributed to this topic by analyzing shifts in temperature, understorey diversity (taxonomic, phylogenetic, functional), and productivity in an ancient forest of central Italy with *Quercus cerris* and *Q. petraea*. Here coppice-with-standards and high forest are next to each other under homogeneous site conditions for long time. To this purpose, in 2021 we installed air and soil temperature dataloggers in three high forest and three coppice-with-standards sites. Following a nested sampling design, forest structural variables, light availability, and soil pH were determined before surveying understory vegetation in four 5 x 5 m randomly selected quadrats in each of the six sites. Understory aboveground productivity was determined in two 0.5 x 0.5 m subplots per quadrat. Functional traits associated with the acquisition and conservation of resources (vegetative traits) and reproductive efficiency were collected from the TRY database. Regarding microclimate, the mean offset values between forest and open areas in daily maximum temperatures were significantly larger in the high forest than in coppice stands during all seasons. Our results supported that coppicing promotes understorey species richness, although this is due to the presence of mostly generalist species. Interestingly, coppicing led to clustering in phylogenetic structure and differed significantly from high forest in functional diversity for some traits, highlighting the presence of ongoing acclimation processes. In light of these results, we emphasize the need to take into account different facets of plant diversity, to reach a more holistic understanding of the effects of coppicing on deciduous oak woodlands of the Mediterranean region, on plant diversity, and temperature buffering capacity of the forest.

Impact of Community Based Forest Management on floristic composition and structure of dry Miombo woodlands

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Abstract: Forest decentralization has promoted sustainable woody biomass harvesting in several Tanzanian forest reserves. However, the impacts of this management approach on species composition and structure changes remain largely unknown, yet people's preference for certain species, especially for fuelwood, is well documented. This study assessed the effect of community-based forest governance on the availability of preferred fuelwood species and changes in the overall status of the 6000 ha Gangalamtumba village-land forest reserve over the past ten years. A comparative analysis of forest attributes was carried out by re-measuring 33 permanent (but non-conspicuous) 0.126 ha nested sample plots. Through 81 household interviews, we link the floristic findings to preferred and extracted fuelwood quantities. Insignificant changes were observed in the overall basal area and species composition and structure of highly preferred fuelwood species, including *Brachystegia spiciformis,* Combretum sp*., Brachystegia boehmii, Dichrostachys cinerea, Senegalia nigrescens* and *Codyla densiflora.* Nevertheless*,* significant changes were observed in the abundance of tree species and in certain diameter classes. However, this observation appeared the result of natural processes rather than harvesting activities . Therefore, the study suggests that decentralization has served to conserve the growing stock down to the species level, especially where the most preferred and used species are also the most dominant species within the ecosystem. As the demand for wood is likely to grow we recommend a further expansion and institutional development of decentralized forest governance in Tanzania.

Impacts of Livestock Practices on Forest Degradation and Resilience in Northern Patagonia

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Alejandro Huertas Herrera[1]
Fernanda Rivas Guíñez[1, 2], **Mónica Toro Manríquez**[1]
[1] Grupo Ecología Forestal, Centro de Investigación en Ecosistemas de la Patagonia (CIEP). Camino Baguales s/n Km 4, Coyhaique, Chile.
[2] Facultad de Agronomía e Ingeniería Forestal, Pontificia Universidad Católica de Chile. Avenida Vicuña Mackenna (4860) Santiago, Chile.

Abstract: Livestock grazing has been recognized as a significant driver of ecological change in *Nothofagus* forests and their understory plant communities. The impacts of grazing can result in alterations in vegetation composition and structure, leading to potential shifts in ecosystem dynamics and resilience. Understanding the factors influencing these state changes and irreversible modifications is essential for assessing ecosystem resilience and facilitating effective ecosystem recovery strategies. In this study, conducted in the northern Patagonia region of Chile, the objective was to explore the factors influencing state changes and irreversible modifications within *Nothofagus* forests subjected to livestock grazing. Comprehensive field assessments were carried out to achieve this, including forest structure inventories, understory censuses, microsite characteristics evaluation, and herbivore presence assessment. The collected data were then subjected to thorough analyses using uni- and multivariate statistical methods. These analyses aimed to examine the impact of grazing on forest dynamics, assess potential stocking rates, and elucidate the interactions between livestock and herbaceous plants. The findings of this study revealed that livestock interactions with herbaceous plants, both directly through grazing and indirectly through trampling and nutrient cycling, can have significant consequences for the structure and composition of the vegetation. Canopy openings caused by grazing can affect light availability and create microhabitats favouring certain plant species. Some plant species may experience increased cover and biomass, while others may suffer from reduced competitiveness or displacement. Intensive pastoral pressure can also lead to shifts in plant community composition, altering the abundance and distribution of different species and potentially facilitating the invasion of undesirable plant species. These changes in vegetation characteristics have broader implications for trophic interactions, nutrient cycling, and overall ecosystem functioning. This study provides valuable insights into the impacts of livestock grazing on *Nothofagus* forests. It highlights the need for proactive management approaches integrating ecological knowledge and adaptive strategies to achieve sustainable land use practices and promote biodiversity conservation in these ecologically significant areas.

Landscape scale mixtures of intensively and unmanaged forests increase biodiversity - Empirical effects of the Triad zoning

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Rémi Duflot[1, 2]

Abstract: For three decades, the concept of Triad zoning has been proposed to balance the social, ecological, and economic demands at the landscape scale by providing intensively, extensively, and un- managed forests. However, the assumed effect on biodiversity was rarely tested against empirical data.

We used the Europe-wide multi-taxon database compiled by the Bottoms-Up Platform to quantify, for the first time, the effects of Triad components' forest landscape composition on regional (multi) biodiversity. We defined Triad components according to the silvicultural system applied; INT: clearcutting with and without tree species change and coppice, EXT: shelterwood and selection cutting, UNM: natural development. To ensure comparable environmental conditions and avoid regional bias, we searched the database, comprising 88 sites across Europe, for sites of the more or less eutrophic, (sub-) montane beech forest natural vegetation type, keeping only sites with at least two Triad components and three taxa represented, arriving at a well-balanced dataset of 222 plots from 9 sites from Czechia, France, Germany and Italy.

To analyse the effect of Triad components on biodiversity, the composition of forest landscapes was varied in steps of 10% using 1,000 resamplings of up to 20 plots per step (66 unique landscape compositions), quantifying regional (gamma) diversity.

Biodiversity of five taxa responded significantly but differently to forest landscape composition (R^2 from 0.243 to 0.748). Regional diversity of bryophytes, lichens and deadwood fungi was highest for pure UNM landscapes, while birds and deadwood beetles profited from adding INT to UNM. Vascular plants regional diversity was promoted by INT with minor contribution of UNM. Multi-biodiversity culminated in landscapes composed of 70% UNM and 30% INT (95.1%), dropping drastically towards pure EXT and INT (73.3 %) landscapes, suggesting complementarity between unmanaged and intensively managed forests, at least for some taxa.

The relative contribution of INT, EXT and UNM to multi-biodiversity may change according to the

forest natural vegetation type, and further investigations are needed with this respect. Our results emphasize the value of multi-taxa biodiversity monitoring and call for widespread use of standardized sampling methods.

Large scale restoration using semi circular bunds and retention ditches ("Fanya juu" and "Fanya Chini") in East African rangelands

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Jesse Owino[1]
Jackline Kemboi[1]
[1] Justdiggit Foundation

Abstract: The need for large-scale restoration initiatives in Sub-Saharan Africa is urgent. Land degradation, deforestation, and climate change pose significant challenges to ecosystems, biodiversity, and livelihoods. Restoration efforts are crucial to reverse these trends, enhance resilience, and promote sustainable development in the region. Large-scale restoration efforts in East African rangelands have increasingly employed innovative techniques such as semi-circular bunds and retention ditches, commonly known as "Fanya juu" and "Fanya chini" respectively. These techniques, championed by organizations like Justdiggit, aim to restore degraded landscapes, improve water infiltration, and enhance vegetation cover. The success of these methods lies in their ability to harness the natural processes of water flow and soil erosion to rejuvenate the ecosystem. The implementation of semi-circular bunds and retention ditches offers several benefits. Firstly, it helps combat soil erosion by reducing the velocity of water runoff, preventing gully formation, and retaining sediment on-site. This leads to improved soil structure and reduced sedimentation in downstream water bodies, positively impacting water quality. Secondly, the increased water infiltration and retention result in enhanced soil moisture levels, supporting vegetation growth. This allows the restoration of grasslands, shrubs, and trees, which in turn promotes biodiversity conservation and provides fodder for livestock. Large-scale restoration using "Fanya juu" and "Fanya chini" techniques is not only ecologically beneficial but also contributes to the socio-economic well-being of local communities. Restoration of vegetation cover improves forage availability, allowing pastoralists to sustain healthier livestock populations. The restored landscapes also provide opportunities for diversification, such as agroforestry and beekeeping, creating additional income streams. Moreover, by involving local communities in the restoration process, these projects foster community engagement, ownership, and empowerment, resulting in long-term sustainability. In conclusion, large-scale restoration efforts utilizing semi-circular bunds and retention ditches in East African rangelands present a promising approach to combat land degradation, improve water management, and restore ecosystems. These techniques harness natural processes to restore vegetation cover, enhance biodiversity, and provide socio-economic benefits to local communities. By combining ecological restoration with community engagement, these projects hold great potential for achieving sustainable landscapes and resilient livelihoods in East Africa.

Long-term response of saproxylic beetles to ecological restoration

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Joakim Hjältén[1]
Anders Dahlberg[2], Anne-Maarit Hekkala[1], Therese Löfroth[1]
[1] Swedish University of Agricultural Sciences, Department of Wildlife, Fish, and Environmental Studies, SE-90183 Umeå, Sweden
[2] Swedish University of Agricultural Sciences, Department of Forest Mycology and Plant Pathology, SE-750 07 Uppsala, Sweden

Abstract: The aim of this study is to assess the effect of time since restoration on substrate availability, assemblage composition and species richness of beetles. We used a unique large-scale long–term field experiment conducted in northern Sweden. Dead wood inventories and window trapping of beetles was conducted in 18 stands, six of each treatment (burned, gap-cutting, including dead wood creation, and control) during tree year: 2010 (baseline), 2012 (one year after treatment) and 2019 (eight years after treatment). The total volume of dead wood was approximately 10 m^3/ha prior to restoration but in 2019 it increased to 50 and 20 m^3/ha in burned and gap-cut stand, respectively. Beetle assemblage composition differed between burned stands and controls all years, except 2010, the pre-treatment year. However, the initial dominance of fire dependent and fire favoured beetles in burned stands 2012 decreased over time and by 2019 few individuals from these group could be found. Instead, other species, secondary favoured by fire, dominated the catch in burned sites. Assemblages in gap-cut stand differed significantly from control stands in 2012 but not in 2019. Thus, we found partial support for our prediction that assemblages would become more similar to controls with time. However, the species response to restoration differed between feeding guilds, e.g., fungivores exhibited a different response than predators and potential explanation for this will be discussed. In summary, prescribed burning had a strong and long-lasting effect of substrate availability/diversity and on beetle assemblage composition. But there was a fast turnover of species following burning and in 2019 species that apparently are secondary fire favoured, a group for which we have limited knowledge, dominated the catch. This implies that prescribed burning will have long lasting effects on saproxylic communities but short lasting effects on early successional fire specialists. Gap-cutting had much subtle effects on both dead wood availability and beetle assemblages than burning. Most of the species present prior to gap cutting, was also present post restoration but complemented by some more light demanding species, suggesting that this restoration method is less detrimental to species associated with old forests and forest continuity.

Microclimatic changes induced by experimental gap openings in a sessile oak–hornbeam forest: the Pilis Gap Experiment

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Abstract: Forest management integrating nature conservation aspects into timber production focuses increasingly on small-scale interventions. However, the ecological consequences of gap cuttings remain ambiguous in oak-dominated forests. In the Pilis Gap Experiment, we analyze how combinations of different gap shapes (circular and elongated), and gap sizes (150 m^2 and 300 m^2) affect the microclimate and biota of a mature sessile oak-hornbeam forest in Hungary.

We first report the changes in direct and diffuse light, soil moisture, daily air and soil temperatures, and relative air humidity in the experimental cuttings in the vegetation season directly following their implementation. Diffuse light had a central maximum and a concentric pattern. Direct light was distributed along a north-south gradient, with maxima in northern gap parts. Soil moisture was determined by gap shape: it increased significantly in the centre of circular gaps, with multiple local maxima in the southern-central parts of large circular gaps. Its pattern was negatively related to direct light, and larger spatial variability was present in circular than in elongated gaps. The daily mean air temperatures at 1.3 m increased in all, especially in large gaps. Soil and ground-level temperatures remained largely unchanged, reflecting light and soil moisture conditions affecting evaporative cooling. Relative humidity remained unaltered. Even though the opening of experimental gaps changed microclimatic conditions immediately, effect sizes remained moderate. Gap size and gap shape were both important determinants of microclimate responses: gap size markedly affected irradiation increase, gap shape determined soil moisture surplus, while soil and air temperatures, and air humidity depended on both components of the gap design.

We conclude that 150-300 m^2 sized management-created gaps can essentially maintain forest microclimate while theoretically providing enough light for oak regeneration; and that the manipulation of gap shape and gap size within this range are effective tools of adaptive management.

Motivating better husbandry of Forested Ecosystems

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Jerome Vanclay[1]

[1] Southern Cross University

Abstract: Many countries require landholders to observe a "duty of care" for conservation of their land, often requiring adherence to explicit guidelines, sometimes supported by up-front grants with long-tailed obligations, all of which are problematic. These approaches may be coupled with other arrangements that hamper land management at the landscape scale, needed to support biodiversity. In contrast, many European countries have a long tradition of hunting game species, and revenues from hunting rights provide a powerful incentive to manage forests for wildlife and biodiversity values. This review highlights some of the unintended consequences of the "duty of care" approach, and canvasses alternatives and incentives that may foster more effective and innovative management of both private and public forested lands. An effective alternative is to make annual payments for attaining selected conservation outcomes. Efficient ways to implement such payments will be reviewed and discussed.

Natural forest transformation: an analysis of changes over the last century in the Świętokrzyski National Park in Poland

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Michał Orzechowski[1]
Wojciech Kędziora[1]
[1] Warsaw University of Life Sciences, Institute of Forest Sciences, POLAND

Abstract: The forests of the Świętokrzyski National Park in southern Poland are an example of changes in the species composition of forest stands occurring mainly spontaneously. The main forest-forming species in this area was the European silver fir (*Abies alba*) with an admixture of the European beech (*Fagus sylvatica*). Both species appear to be beneficiaries of the climatic changes occurring in this part of Europe: an increase in mean temperature with a slight decrease in precipitation in upland and mountainous areas. This study aimed to analyse the changes occurring in the species composition of the Świętokrzyski National Park's forest stands from 1925 to 2014. In this area and in the assumed time horizon, data from long-term studies of permanent sample plots characterising changes in most of the park area were not available. We used 299 random sample points distributed evenly over the study area and descriptions of the stands where the points were located during the inventory period. Inventory data from the years used were: 1925, 1954, 1971, 1997, and 2014. Data from the forest management plans were compiled into a database and processed to determine the biodiversity and role of species in each stand layer. The share of each species in all forest layers and their regeneration was used to determine their forest-forming role. The forest-forming role of the two species studied was linked to the forest habitat type, moisture variant, forest type, and forest condition. Spatial analyses were based on a digital elevation model, from which derived layers were calculated and their values were related to forest-forming role. The widespread and persistent dominance of fir in the forest ecosystems of the study area was confirmed. In the case of beech, a correlation between forest-forming strength and altitude was observed. Up to a level of 480 m above sea level, this strength increases and then decreases at higher elevations. Changes in the occurrence of other tree species important in the lower layers of the stands were analysed. This may be significant for further transformation of the forests of the study area.

Species colonization-extinction dynamics in understory vegetation communities in response to forest and climate conditions

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Laura Chevaux[1]
[1] SLU Swedish Species Information Centre, Swedish University of Agricultural Sciences, Uppsala, Sweden

Abstract: Modifications of forest ecosystems due to climate change, conjointly with forest harvesting, are shaping boreal forest biodiversity. Long-term composition of understory vegetation communities results from the dynamics of each species. Climate conditions as well as the structure and composition of the overstory vegetation, modified by forest management, influence the species dynamics. Moreover, the ability of an understory vegetation species to colonize and occupy a plot also depends on its functional traits that influence growth, reproduction, and survival. Functional traits in understory vegetation community thus reflect species responses to the environment. In order to understand large-scale and long-term changes in understory vegetation communities, we take into account the dynamics of individual species, i.e. their colonization and extinction. In this sense, our first objective is (i) to increase understanding of effects of stand structure and climate conditions on the dynamics of understory vegetation. We then (ii) investigate the effects of different forest management actions on understory vegetation. We used hierarchical modelling of species communities to analyze changes in the rates of colonization and extinction of each understory plant species depending on stand structure and climate conditions. For this purpose, we used vegetation-monitoring data from permanent plots in the Swedish National Forest Inventory from 1993 to 2021. We use presence-absence surveys conducted every 5 years of 268 plant species. Finally, to study the interactions between species in understory plant communities, we investigated the effects of species presence and cover of 71 species on colonization-extinction rates. We hypothesize that stand structure will directly affect understory vegetation, especially through changes in available light. Younger, less dense stands would have more light-favored species and, on the contrary, older, denser stands would have more shade-favored species. We therefore expect changes in colonization and extinction according to the species and its associated functional traits, and thus modifications of understory vegetation communities. Furthermore, we expect that forest management actions will lead to larger short-term direct and indirect effects on understory vegetation communities, while climate change will lead to longer-term changes.

Transformation of non-native Sitka spruce stands to Continuous Cover Forestry (CCF): enhancing biodiversity value of managed forests in Ireland.

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Laura Harris[1]
Prof Áine Ní Dhubháin[2], Dr Ian Short[3], Dr John Devaney[1]
[1] Maynooth University, Co. Kildare, Ireland. Funded by DAFM.
[2] University College Dublin, Belfield, Dublin 4, Ireland.
[3] Teagasc, Ashtown, Dublin 15, Ireland.

Abstract: The majority of Irish forests are even-aged plantations of non-native conifers, managed under the clearfelling silviculture system. However, current national forest policy promotes the transition to Continuous Cover Forestry (CCF), which has been shown to have multiple environmental benefits in comparison to clearfell-replant silviculture. Transformation to CCF typically relies on promoting natural regeneration to restock felled trees. In cases where natural regeneration is unsuccessful or management aims to introduce broadleaf trees to conifer plantations, underplanting represents a viable method to introduce the greater tree species richness in forests. The aim of this study is to assess the relationship between canopy openness in stands of Sitka spruce and the survival, growth, and health of underplanted broadleaf trees. In addition, the occurrence of natural regeneration and changes in vegetation communities following transformation to CCF are also being monitored.

Sitka spruce plantations that have had selective CCF thinning interventions are being used for this study. Broadleaves (*Quercus petraea* and *Fagus sylvatica*) were planted with in gaps of varying canopy openness (2%- 42%). Mortality, height and photosynthetic efficiency of underplanted seedlings are being monitored to directly assess the impact of light intensity on tree survival and productivity. Determining canopy openness that maximises tree health, natural regeneration, and understorey vegetation diversity will offer valuable insights into how CCF can enhance the biodiversity value and resilience in managed forests in the face of climate change.

Vegetation changes due to prevalent mammalian herbivores foraging in native forests in Chiliean Austral Macrozone

T3.28 Opportunities to promote biodiversity recovery and protection through innovative forest management approaches

Alejandro Huertas Herrera[1]
Mónica Toro Manríquez[1], Fernanda Rivas Guíñez[1]
[1] Grupo Ecología Forestal, Centro de Investigación en Ecosistemas de la Patagonia (CIEP). Camino Baguales s/n Km 4, Coyhaique, Chile.

Abstract: The native forests in the Chilean Austral Macrozone are a valuable natural resource, providing significant economic benefits for the local communities. However, these forests are facing numerous challenges due to the pressures exerted by mammalian herbivores, including domestic livestock and wild native or exotic herbivores. The primary objective was to assess how prevalent domestic and wild mammalian herbivores impact understory vegetation by engaging in differential foraging across native forest gradients in the Chilean Austral Macrozone. To achieve this objective, gathering information on biotic and abiotic factors that contribute to forest degradation or change within the Macrozone was essential. Several specific objectives were identified: (i) Determine understory vegetation biomass, distinguishing between palatable and non-palatable, and native and exotic species. (ii) Identify potential factors, both biotic and abiotic, that influence the composition of vascular plant communities by analyzing the herbivore pressures exerted by prevalent species across the studied forest gradients. (iii) Evaluate the nutrient content, such as dry matter, of dominant vascular plant species, and identify indicator species that can be used to assess forage nutritional quality for prevalent herbivores within the studied forests. Data was collected from stands located in ranches and national reserves in the Aysén and Magallanes regions. Various forest use scenarios were considered, such as livestock grazing during summer and winter, and different densities of mixed herbivore species or herbivore exclusion. The study examined factors such as stand variability characteristics (microsites), edaphic conditions, and the level of anthropization within the landscape and climate patterns. The existing herbivore pressure on the native forests necessitates adopting more sustainable strategies to prevent irreversible degradation in the long run. Overgrazing has already caused changes in vegetation cover and distribution of native plant species, inadvertently resulting in undesired new ecosystems that lead to economic losses for local ranchers. The findings from this study will contribute to the development of conservation strategies by providing insights into effective, sustainable development practices in the Chilean Austral Macrozone.

T3.29 Reforestation Under Drought Conditions

Alternatives to Herbicides for Reforestation Under Drought Conditions in the Pacific Northwest U.S.

T3.29 Reforestation Under Drought Conditions

Yury M. Llancari Valenzuela[1]
Carlos A. Gonzalez-Benecke[1], Emily C. Von Blon[1], Florian Deisenhofer[2], Maxwell G. Wightman[2]
[1] Oregon State University
[2] Washington State Department of Natural Resources

Abstract: Sustainable forest management of Douglas-fir represents an essential component of the environmental, economic, and social well-being of the state of Washington and the U.S. However, forests in the Pacific Northwest are challenged by annual summer droughts, with evidence of decreased survival of Douglas-fir seedlings after intense summer seasons. This scenario could become more severe in the context of climate change as soil water is often the main limiting resource for the early growth of planted Douglas-fir. Forest vegetation management (VM) has become an important component of reforestation programs, improving seedling survival and growth by reducing competitor abundance and increasing soil water availability. There are several strategies for VM, including chemical, mechanical, and manual alternatives; however, there is little information on the comparative effects of these methods and their relationship with the environment. Alternative methods to controlling vegetation are limited and many may not be feasible to employ across the total acres harvested annually across the region. Recently, members of the public have raised concerns over the use of herbicides in forestry, especially the use of glyphosate. Thus, this research evaluates the effectiveness of different herbicide and non-herbicide VM strategies. Eight VM treatments were evaluated at five sites in Washington State. These treatments included no-action control, pre and post planting herbicide applications with and without glyphosate, mechanical harvest residue management, and manual hand weeding during the first growing season or the first two growing seasons. We analyzed seedling survival, growth and physiology (including stomatal conductance and predawn and midday water potential), soil moisture availability, as well as early-seral vegetation abundance and diversity during two growing seasons after planting (the project will continue for three more years). This research aims to provide a better understanding of the effect of multiple VM alternatives on seedling growth conditions. Our goal is to inform public opinion and reforestation managers about the effectiveness of chemical and non-chemical VM alternatives for reforestation under water-limited conditions.

Can a biodegradable paper donut help to reforest pine Mediterranean species under harsh environments?

T3.29 Reforestation Under Drought Conditions

Marta PARDOS[1]
Guillermo Madrigal[1], Matías García[1], Juan Manuel Calvo[2], María Bragado[3], Francisco Javier Ezquerra[4], Francisco Javier Gordo[5], Rafael Calama[1]

[4] Servicio de Gestión Forestal, Junta de Castilla y León. Spain.
[5] Servicio Territorial de Medio Ambiente de Valladolid. Junta de Castilla y León, Spain.

Abstract: Creating more resilient and productive landscapes is a key goal of most reforestation projects. However, the attainment of these targets is not straightforward under harsh environments, as outplanted seedlings need to survive to complete successful establishment. This study assesses how the outplanting success of two pine species in the Mediterranean continental region can be improved by using a biodegradable paper donut. The so called Cocoon is a circle made from recycled cartons with a hole in its center that serves as water reservoir for the seedling during their fist summer after planting. For this purpose, in April 2019, we set up two experimental plots in each of two sites (Segovia and Valladolid) that show different environmetal conditons. Five hundred (500) one-year old *Pinus pinaster* and 500 *Pinus pinea seedlings* were planted in each site to test the efficiency of the Cocoons in the short- (after first summer) and in the long-term (after 4 years). Treatments were species (*Pinus pinaster* and *Pinus pinea*) and presence/abscence of Cocoons (control vs cocoon). During the first summer, the highest mortality rates were recorded in July and August for both sites and treatments. In October 2019, after the first summer, mean survival rates in Valladolid site were 62.8% in P. pinea and 67.8% in *P. pinaster*, with slightly higher survival rates in seedlings grown with the Cocoon. The positive effect of the Cocoon was higher in Segovia site, where survival rates were as high as 85,6% in *P. pinaster* and 92,8% in *P.pinea* in sedlings grown with Cocoon, decreasing to 28,4% and 55,6%, respectively, in control plants. The positive effect of Cocoon is corroborated, mainly in Segovia site, where the climate and edaphic conditions are not optimal for reforestation purposes. However, four years after outplanting (summer 2023), the effect of the Cocoon is expected to be reduced, as once the seedlings are installed and have been able to develop an adequate root system they will not be so dependent on addtitional water input.

Drip irrigation in the context of forest regeneration in areas with dieback from drought and other causes

T3.29 Reforestation Under Drought Conditions

Ellen Schaeffel[1]
Jürgen Bauhus[1], Ulrich Kohnle[2]
[1] University of Freiburg, Chair of Silviculture, Germany
[2] Forstliche Versuchs- und Forschungsanstalt Baden-Württemberg, Germany

Abstract: The Upper Rhine region is one of the most heat-stressed and driest regions in Germany. Therefore, the inter- and transdisciplinary project '*WaldlabOR'* focuses on this area as a model region to study forest transformations. In the context of the sub-project '*Adaptation strategies for the conservation of forest ecosystem services in climate change hot-spots'*, an experiment is conducted on the influence of irrigation to regenerate forests in areas with dieback from drought and other causes. The experiment takes place at three sites in the Upper Rhine region and focuses on four tree species to identify long-term adapted tree species for extremely dry and hot sites: *Tilia cordata, Quercus rubra, Quercus petraea* and *Acer platanoides.* The irrigation technology is being developed in close cooperation with NETAFIM, one of the world's leading irrigation companies. The technology will be based on drip irrigation in tree clusters. Using a fully factorial design in the experiment, we compare non-irrigated and irrigated tree clusters. The effectiveness and efficiency of the irrigation technology will be quantified through different variables such as mortality, growth, root quality and soil moisture. Here, we present the experimental design along the chosen technology, climatic projections for the area and calculations of water requirements. The project aims to have model character for regions with similar problems now or arising in the future. Concrete solutions and action approaches for forest management will be developed in an innovative inter- and transdisciplinary approach.

Effects of stem decapitation, water-deficit stress, and pot size on the growth, morpho-anatomy, and physiology of Pterocarpus indicus seedlings

T3.29 Reforestation Under Drought Conditions

Jonathan O. Hernandez[1]
Marilyn S. Combalicer[1], Arthur Glenn A. Umali[1], Lerma S.J. Maldia[1]
[1] Department of Forest Biological Sciences, College of Forestry and Natural Resources, University of the Philippines Los Baños, College 4031, Laguna, Philippines

Abstract: Predicting how transplanted seedlings survive in planting sites necessitates an understanding of how multiple stresses interact and affect seedling growth, morpho-anatomy, and physiology. Here, we analyzed the interacting effects of stem decapitation, water-deficit stress, and pot size on the growth, morpho-anatomical, and physiological traits of *Pterocarpus indicus*seedlings. Significant changes in root collar diameter (RCD), biomass allocation, number of leaflets (NL), mean leaf area, guard cell size, stomatal aperture size, phloem cap fiber (PCF) thickness, xylem vessel density (XVD), relative leaf water content (RWC), stomatal conductance (g_{sw}), transpiration rate (E), fluorescence quantum yield, transpiration (E), photosynthesis (P_N), and electron transport rate (ETR) of decapitated and undecapitated *P. indicus* seedlings in different pot sizes (Small, Medium, Large) and watering regimes (every 2, 7, and 14 days) were analyzed. The decapitation × water-deficit stress × and pot size interaction did not affect growth and morpho-anatomical variables, but they did on most physiological aspects of the seedlings. Decapitated seedlings watered every 14 days and planted in either medium or large pots have lower g_{sw}, P_N, E, and RWC. However, significant effects of pot size × watering interaction on RCD and stem, fine root, and coarse root biomass allocations were also detected in decapitated seedlings. While the RCD of large-potted and water-stressed (every 14 days) seedlings decreased, allocations to stem and fine and coarse roots significantly increased. Moreover, we found significant effects of decapitation × watering reactions on the NL, PCF, ETR, and XVD. The NL and PCF significantly decreased, while the ETR and XVD significantly increased in decapitated and water-stressed seedlings. Overall, the decapitation-watering interaction can cause significant stress to *P. indicus* seedlings; however, it can be alleviated by utilizing medium and/or big pots during initial growth in the nursery. This could be a viable nursery practice for boosting seedling survival in actual planting areas. Real-scale field experiments are recommended to elucidate the responses of the seedlings to interacting multiple stresses.

Enhancing Reforestation Success through Hydrogels in Mountainous Forests: Investigating Drought Stress Mitigation and Ecological Implications

T3.29 Reforestation Under Drought Conditions

Marie Lambropoulos[1]
Boris Rewald[1, 2], Hans Sandén[1], Hanna Teuchert[1]
[1] BOKU Vienna
[2] Vienna Scientific Instruments

Abstract: Alpine forests are already experiencing the impacts of climate change, and these effects are expected to intensify in the future with more frequent and severe disturbances. To enhance forest ecosystem resilience and adapt to human-induced climate change, optimizing forest management practices is crucial. Artificial regeneration, particularly on marginal sites with challenging growth conditions, requires a detailed understanding of native and non-native forest reproductive materials and planting methods to ensure successful tree establishment.

One significant challenge for reforestation is the increasing occurrence of longer and more frequent spring and summer droughts, which pose a threat to seedling survival. This study focuses on evaluating the effectiveness of hydrogels as a solution to mitigate drought stress and promote sustainable reforestation. By enhancing soil water storage capacity, hydrogels have the potential to improve soil moisture retention and seedling survival after disturbances or during forest conversion. The study considers various factors such as tree species, geology, exposure, accompanying vegetation, reforestation method, and planting period, while also conducting a cost-and-benefit analysis.

The research employs both and large-scale in-situ experiments in alpine forest landscapes and ex-situ experiments to investigate the interaction between hydrogels and tree seedlings. In an ex-situ rhizobox experiment, soil and ecophysiological methods, including stable isotopes, are utilized to examine the extent to which spruce and oak seedlings use water stored in hydrogels during drought stress periods. The different treatments affect above- and below-ground growth, plant nutrition (including ectomycorrhizae), and the hydraulic system of the plants.

The findings of this study provide scientific insights and practical knowledge to enable forestry professionals to effectively address the challenges of climate change and enhance the resilience of tree seedlings in reforestation efforts, particularly in the context of increasingly frequent drought events.

Exploring Assisted Tree Regeneration to Support Sustainable Forest and Woodland Management in Oshikoto and Kavango Regions, Namibia

T3.29 Reforestation Under Drought Conditions

Abstract: Forests, woodlands, and trees play a key role in African economies, including a dry country such as Namibia, supporting the livelihoods of many people in rural and urban areas. They provide a range of goods and services, including timber, food, medicines, construction and fencing material, habitats, and energy. Moreover, woodlands play a significant role in ecosystem functioning especially in biodiversity, water, and nutrient cycling. However, Namibia's dry forests and woodlands are facing many threats such as climate change, deforestation for agriculture, natural disturbances such as uncontrolled fires and droughts, and poverty-driven unsustainable harvesting. Additionally, the natural regeneration of indigenous trees is often hampered by the browsing of seedlings, seed predation, and competition. To address these issues, this study aims to investigate methods to support assisted tree regeneration and seedling establishment in nurseries as a strategy for sustainable forest and woodland management. The research will be conducted in two vegetation types: the mountain savanna and karstveld at Ongava Research Centre, and the forest-savanna and woodland at Mashare Agricultural Development Institute. The study will assess seed germination and vegetative regeneration through stem cuttings and assess bio-inoculants' impact on seedling growth. The study will gather comprehensive data on the germination success, vegetative regeneration success, and impact of bio-inoculants on seedling growth across different soil mediums, and seeding depths. The findings will contribute to developing tree nursery protocols, promoting sustainable forest management, and reducing pressure on heavily used tree species while assisting reforestation and afforestation efforts. The results will be shared with stakeholders and local communities to encourage active regeneration. Ultimately, this research seeks to advance knowledge in assisted tree regeneration and its potential contributions to sustainable forest and woodland management.

Keywords: Assisted tree regeneration, Sustainable Forest management, climate change, vegetative propagation, bio-inoculant, nursery protocol

Important effects of soil water legacy on tree growth of plantations under contrasting climatic seasonality of the semiarid regions

Abstract: Wood growth, as one of the major components in vegetation carbon storage, is commonly described as a linear function of carbon assimilation in existing vegetation models. However, recent evidence suggests that wood growth is highly responsive to climate, particularly to soil water availability. Insufficient soil water poses a significant challenge for afforestation in semiarid regions, limiting the survival and carbon sequestration potential of plantations. Therefore, comprehending the relationship between soil water availability and tree growth is essential for evaluating the effectiveness of afforestation efforts under climate change. Using high temporal-resolution dendrometer measurements, we investigated the relationship between tree stem growth and the seasonal dynamics of soil water in plantations located in two semiarid regions characterized by different climate seasonality. Our results suggested that the daily growth rate of trees in semiarid areas is primarily influenced by the availability of soil water and the atmospheric vapor pressure deficit, resulting in discontinuous growth patterns throughout the growing season. In cold-dry regions (northern China), *Larix principis* utilizes the residual spring snowmelt in the soil to complete its growth before the peak rainfall period. In warm-dry regions (southern Israel), *Pinus halepensis* sustains its growth by tapping into the water stored in the soil after the peak rainfall period. Despite variations in climate patterns and dominant tree species, our results indicate a consistent conclusion that trees in semiarid areas can effectively harness the legacy of soil water to maximize their annual growth. This finding highlights the adaptive strategies of tree plantations in semiarid regions, efficiently utilizing the local soil water resources to maintain carbon sequestration.

Increasing green cover and carbon accumulation through afforestation of salt affected areas in drylands of India

T3.29 Reforestation Under Drought Conditions

Ranjana Arya[1]

[1] Retd. Scientist, Arid Forest Research I(institute, Jodhpur, India

Abstract: As part of its intended nationally determined contribution (INDC) to the Paris climate agreement 2015, India has committed to create an additional carbon sink of 2.5 to 3 billion tonnes of CO_2 equivalent through additional forest and tree cover by 2030. One of the strategies worked out towards this is to afforest about 2.98 million ha of salty wastelands in Rajasthan, Gujarat, Haryana and Punjab states of India.

Trials were conducted on barren lithic, calcid, coarse sandy to loamy sand salt affected soil in Jodhpur (Rajasthan) and silty black highly saline soil in little Rann of kachchh (Gujarat). The approach was to grow salt tolerant species & use soil amendments. The indigenous multipurpose halophytic tree *Salvadora persica* maintained 66.7 to 85.2 % survival even after ten years. Gypsum + 9g N treatment gave 85.2 % survival and 12.0 & 5.67 kg tree^{-1} of fresh & dry biomass in arid sandy soils in Rajasthan while on black soil in Gujarat, wheat husk (WH)+FYM+urea treatment gave 90% survival and 7.17 & 3.71 kg tree^{-1} Green & dry biomass. *A. bivenosa* was more suitable with WH+FYM treatment on black soil.

Acacia ampliceps (Australian tree) recorded 76 % survival on gypsum treated deep alkali soils (60 to 75 cm depth) and yielded twofold biomass (12.0 & 5.35 tree^{-1} to 5.43 & 2.14 kg tree^{-1} fresh & dry biomass for gypsum treated and 8.1 & 5.35 kg tree^{-1} to 3.9 & 1.56 kg tree^{-1} fresh & dry biomass for untreated trees on deeper and shallow soils) at five years of age. Natural regeneration of *S. persica* was also observed on sandy soil in Rajasthan, especially under *Prosopis juliflora.* Overall, significant improvement in site conditions improved and growth of indigenous vegetation was observed.

Intensive silviculture enhances carbon sequestration and natural forest regrowth in restoration plantations in Brazil

T3.29 Reforestation Under Drought Conditions

[3] Centre de Coopération Internationale en Recherche Agronomique lour le Développement (CIRAD), France
[4] Bracell, Brazil
[5] São Paulo State University (UNESP), Brazil

Abstract: Brazil has committed with the Bonn Challenge to restore 12 million hectares of degraded lands by 2030. This pledge is particularly important because Amazon and Atlantic Forest biomes have lost 22% and 74% of their original cover, respectively. Therefore, the country has a huge task for the following years.

A significant part of these hectares to be restored are degraded pastures in tropical regions, covered by aggressive non-native C4 grasses, making these landscapes very difficult to restore by natural forest regrowth. Under these conditions, the strategy is to plant native tree species using the best silvicultural practices to ensure survival and high productivity. Unfortunately, this is not a viable option for landowners who try to restore forest ecosystems. With the undesirable competition with grasses, the resource-use rate (light, water, and nutrients) for the trees is low, leading to high mortality and marginal growth. The objective of this study is to assess the effect of intensive silviculture, similar to commercial plantations of *Eucalyptus*, applied to mixed-species plantations for restoration purposes.

To assess the effects of silvicultural practices to increase survival, growth, and carbon sequestration in forest restoration plantations, we integrated data up to 20 years from 3 experimental sites in different locations testing variations in planting spacing, soil preparation, competing vegetation control and fertilization.

Intensive silvicultural practices on early stages of these restored areas, until canopy closure, were critical for the success of the planting project, with intensive competing vegetation control acting as the main important factor for increasing survival and growth. Carbon sequestration in aboveground biomass under intensive silviculture can reach up to 4 $Mg.ha^{-1}.year^{-1}$, compared to ~1 $Mg.ha^{-1}.year^{-1}$ under low silviculture. Under intensive silviculture, canopy closure occurred at 3.5 to 4 years after planting, leading to competing vegetation control (mainly non-native C4 grasses) by shading which enabled natural regeneration of tree species. The canopy closure under low silviculture takes 10 years or more and the grasses limit natural forest regrowth. This network of trials will be monitored for the following years to evaluate the long-term effects of intensive silviculture in restoration plantations in Brazil.

Leaf morpho-physiological traits of Populus sibirica and Ulmus pumila in different irrigation regimes and fertilizer types

T3.29 Reforestation Under Drought Conditions

Byambadorj Ser-Oddamba[1]
Nyam-Osor Batkhuu[1]
[1] Laboratory of Forest Genetics and Ecophysiology, National University of Mongolia, Ulaanbaatar, Mongolia

Abstract: Climate change can intensify soil dryness and nutrient deficiency, and this calls for an environmentally sustainable forest and groundwater resource restoration. Massive afforestation, however, may deplete groundwater supply due to increased evapotranspiration, resulting in a more severe water scarcity. Thus, we investigated the effects of different watering regimes and fertilizer types on the morpho-physiological traits of *Populus sibirica* (Horth ex Tausch) and *Ulmus pumila* (L.). The leaf area (LA), specific leaf area (SLA), chlorophyll concentration, stomatal conductance (g_s), chlorophyll fluorescence, and predawn and midday leaf water potential were measured across treatments. During the first growing season, the LA of *P. sibirica* was higher in the 4-8 L h^{-1} without fertilizer, but it was lower in the 4 L h^{-1} + COMP during the second growing season. The 2 L h^{-1} without fertilizer and 2 L h^{-1} + NPK had larger LA compared with CON for the first and second growing seasons, respectively, for *U. pumila. P. sibirica* seedlings at 4 L h^{-1} without fertilizer had the highest SLA for 2021 and at 2 L h^{-1} + NPK for 2022, whereas CONT and 4 L h^{-1} had the highest SLA than the other treatments for 2021 and 2022 growing seasons, respectively, for *U. pumila.* The chlorophyll concentration of *P. sibirica* seedlings in the first year was generally higher in CONT, while the 2 L h^{-1} without any fertilizer yielded a significantly higher chlorophyll concentration of *U. pumila.* CONT and 2 L h^{-1}+NPK-treated *P. sibirica* seedlings had a significantly greater g_s during the first year and second year, respectively. The CONT with NPK/COMP generally had a higher g_s compared with the other treatments in both experimental periods for *U. pumila.* The predawn and midday leaf water potentials of *P. sibirica* and *U. pumila* were generally the lowest in CONT, followed by 2 L h^{-1}+NPK/COMP during the first growing season, but a different pattern was observed during the second growing season. Overall, the morpho-physiological traits of the two species were affected by watering and fertilizer treatments, and the magnitude of the effects varied depending on growing season, amount of irrigation, and fertilizer type.

Local and traditional knowledge restoration techniques of savannah landscapes for climate change adaptation, Burkina Faso.

T3.29 Reforestation Under Drought Conditions

Nouhou Zoungrana[1]
[1] Université Félix Houphouet Boigny

Abstract: Land degradation is occurring in almost all terrestrial biomes and agro-ecologies, in both low- and high-income countries. Thus, the populations have developed traditional techniques (Zaî system, stone cordons, half-moons, etc.) to better manage water for agriculture in the face of its degraded lands. We refer to the literature review on local techniques and traditional methods of water and soil conservation, using cultural mapping which integrate Geographic Information Systems and social data. This article aims to map its different techniques, assess the impacts, the involvement of gender with social aspects and policies. The studies were carried out at the beginning of the rainy season in Zitenga. We therefore retain local and traditional water and soil conservation techniques that contribute to local and national economies, sequester significant amounts of carbon, strengthen food and clean water supplies and safeguard biodiversity. Local and traditional water and soil conservation techniques is strongly connected to sustainable development and contributes directly to UN Sustainable Development Goals 1, 2, 6, 13, 14 and 15, through: creating jobs and sustainable value chains; enhancing food security and dietary diversity; increasing water availability; supplying wood energy for cooking; mitigating the effects of climate change and enhancing the resilience of ecological and social systems. It can also contribute to Goal 16 by increasing the availability of natural resources. A policy brief is in perspective for taking into account indigenous and local knowledge in water and soil conservation policies.

Morphophysiological Responses of High and Low Elevation Douglas-fir Seedlings to Drought-Preconditioning in Idaho, United States of America

T3.29 Reforestation Under Drought Conditions

Vovener de Verlands Edmond[1]
Andrew Nelson[1], Mark Coleman[1], Armando McDonald[1], Jeremy Pinto[2]
[1] University of Idaho
[2] USDA Forest Service

Abstract: Climate projections anticipate that changes in precipitation will vary regionally, with some regions likely seeing higher moisture and others experiencing a decrease in precipitation. These alterations present challenges for reforestation in regions such as Northern Idaho, where droughts have become more frequent and intense, as exemplified by the 2021 drought, highlighting the need for drought-hardy seedlings. With climate change expected to exacerbate drought and extreme cold events, producing tree seedlings resistant to these conditions becomes crucial. Nonetheless, there is a dearth of applied research that guides nursery practices for producing drought-hardy seedlings for reforestation sites. Knowing the elements that affect the drought hardiness of Douglas-fir seedlings can produce more robust seedlings that endure harsh climatic conditions. This study aimed to enhance the production of drought-hardy seedlings for reforestation in drought-prone regions. We conducted an experiment in a greenhouse, using container seedlings derived from seeds collected at high (6100 ft) and low (2050 ft) elevations in the northern Idaho Rocky Mountains. We investigated the effects of drought durations (two and three months) and intensities (Control, Moderate and extreme) on Douglas-fir seedlings physiology, morphology, root growth potential, and cold hardiness.

We found a significant effect (p 0.0001) of drought intensities and durations on predawn and midday water potential, resulting in a decrease in water potential in both provenances. High-elevation seedlings exhibited a root collar diameter that was 0.181 mm smaller and a height that was 2.29 cm shorter than low-elevation seedlings. Moreover, the high elevation provenance demonstrated increased root growth potential, with a 1.11 cm increase in root length. The control treatment exhibited higher root growth, while the extreme drought displayed reduced growth. The Injury index was affected by freezing temperatures and the treatments but not by seedling provenance. In comparison to other treatments, seedlings subjected to extreme and moderate droughts exhibited enhanced cold hardiness.

This study emphasizes the drought resistance of seedlings and the beneficial effect of drought preconditioning on their cold hardiness, which are essential to their survival and growth in natural forest ecosystems. These findings have practical implications for forest seedling nursery practices and reforestation efforts in drought-prone regions.

Population demographic characteristics Saxaul (Haloxylon ammodendron C.A.Mey.) Bunge forests in Mongolia

T3.29 Reforestation Under Drought Conditions

Enkhchimeg Tsedensodnom[1, 2]
Ser-Oddamba Byambadorj[2], Batkhuu Nyam-Osor[2]
[1] Institute of Geography and Geoecology, Mongolian Academy of Sciences, Ulaanbaatar, Mongolia
[2] Laboratory of Forest Genetics and Ecophysiology, National University of Mongolia, Ulaanbaatar, Mongolia

Abstract: Desertification affects all parts of the ecosystem of arid regions and becomes the main reason for soil erosion, shortage of biological diversity, loss of productivity, loss of soil nutrition, and water shortage. The Saxaul forest (*Haloxylon ammodendron* (C.A.Mey.) Bunge ex Fenzl) covers 1650 km from west to east and 360 km from north to south in the southern part of Mongolia. In order to determine age group and survival, we involved 21 populations in 16 soums of 6 provinces (Khovd, Gobi-Altai, Uvurkhangai, Bayankhongor, Umnugobi, and Dornogobi) in Mongolia. We established a sample field of 30x30 m size and measured the height, diameter, and crown of all the tree trunks. The total number of the trees on the sample field is 2141 trees, the average height of the trees is 72.27±1.33 cm (max 480 cm; min 3.5 cm), the diameter is 3.6 cm (max 40.0 cm; min 0.1 cm), and crown diameter 86.85±1.55 cm (max 464.5 cm; min 3.0 cm), respectively. Tree height in the Saxaul forest population occupies 33.27% in the 40 cm class, 36.54% in the up to 80 cm, and 15.28% in the up to 120 cm class; the number of trees decreases and the percentage of the population reduces as the height class increases. As for the diameter class of the trees, it occupies 30.8% in up to 1cm class, 39.65% in up to 3cm, and 13.96% in up to 6 cm class. We calculated the survival by the tree ages: the percentage of loss is high for the cultivated and small trees but the loss reduces for the young trees and the survival has been stabilized. Therefore, it shows the necessity to plan the work of protecting the Saxaul forests.

Screening for drought tolerance of two high-value conifers in British Columbia, Canada

[4] Forest Improvement and Research Management Branch, Ministry of Forests, Victoria BC, Canada

Abstract: Western redcedar (Thuja plicata) and Douglas-fir (Pseudotsuga menziesii) are important commercial tree species used extensively in reforestation programs in western North-America where they provide a wide range of economic, social and ecological benefits. In addition, western redcedar is of particular importance to Indigenous cultures. Both species have benefitted from dedicated tree breeding programs established several decades ago. Ongoing concerns about climate change and the increased impact of more frequent and more intense drought events have led to renewed interest to identify seed sources that will be successful for reforestation under dry conditions. Two large scale studies, one for each species, were established to screen a large number of full-sib families for drought tolerance. Multidisciplinary research teams evaluated the performance of these families under drought conditions from a wide range of research angles: i) growth and survival; ii) biomass allocation and morphological characteristics; iii) physiological response and gene-expression; iv) nutrient translocation and soil characteristics. Authors present and discuss the main takeaways and lessons learned over the course of these studies, with particular emphasis on reforestation-drought interactions. Results will contribute to identifying seed sources with superior performance under drought conditions.

The application of nitric oxide-releasing chitosan nanoparticles as a nature-based solution to improve drought tolerance of neotropical tree seedlings

T3.29 Reforestation Under Drought Conditions

Giovanna Camargo Do Carmo[1]

[2] Center for Natural and Human Sciences, Federal University of ABC, Santo André, Brazil

Abstract: Approved in the 2019-2020 BiodivClim call from BiodivERsA, the RESTORE (natuRe-basEd SoluTions for imprOving REforestation) project aims at developing innovative biotechnological strategies to induce drought tolerance in tree seedlings used for reforestation purposes. Among the developed biotechnological tools, we are testing the inoculation with associative microorganisms isolated from forest sites and the application of nanoparticles synthesized from natural polymers as eco-friendly carrier systems for plant growth regulators. In this talk, we will focus mainly on nitric oxide (NO)-releasing nanoparticles, that have been shown to enhance the protective effects of this signaling molecule in plants submitted to abiotic stresses. We will show the results of a study that evaluated the effects of NO-releasing nanoparticles on drought-stressed *Cecropia pachystachya* Trécul seedlings, a pioneer neotropical tree largely used in reforestation efforts. S-nitrosoglutathione (GSNO) was encapsulated into chitosan nanoparticles, which protected this natural NO donor from premature degradation and extended its half-life. When applied to the substrate, nanoencapsulated GSNO delayed the appearance of wilting symptoms in seedlings exposed to moderate and severe drought conditions, yielding higher leaf water potential and relative water content compared to the other treatments (control, free GSNO and nanoparticles without NO). Gas exchange analyses showed that GSNO-loaded chitosan nanoparticles increased the stomatal conductance of drought-stressed plants, which allowed the maintenance of high CO_2 assimilation rates. This effect was mainly restricted to early morning, when the high air relative humidity prevents excessive loss of water. Moreover, nanoencapsulated GSNO had a positive effect on biomass accumulation in plants submitted to moderate drought. Overall, these results suggest that GSNO-loaded chitosan nanoparticles enhance the tolerance of *C. pachystachya* seedlings to moderate and severe water deficit. Experiments in the field and with other tree species are in progress to ratify if this nanoformulation could be applied as a strategy to produce tree seedlings more tolerant to drought stress, thus increasing the success of reforestation programs in a scenario of climate change.

Supported by BiodivClim ERA-Net COFUND programme with Fundação Araucária, FAPESP, CAPES, CNPq, ANR, and German Federal Ministry of Education and Research.

The influence of retention forestry on reforestation success following dieback of Norway spruce stands

T3.29 Reforestation Under Drought Conditions

Mareike Mohr[1]
Jürgen Bauhus[1]
[1] Chair of Silviculture, University of Freiburg

Abstract: The extremely dry and hot period between 2018 and 2020 caused massive bark beetle infestations and extensive dieback of Norway spruce stands in many European regions. Frequently, the lack of advance regeneration with tree species suitable for future climatic conditions necessitates artificial regeneration. Yet, owing to the increasingly extreme climatic conditions following complete salvaging of dead stands, the success rate of planting has often been very poor. Here, we aimed at investigating whether the retention of dead trees and other structural elements could mitigate microclimatic conditions for tree seedlings and thus improve their survival and growth.

For this purpose, we established a landscape-scale replicated experiment in the southern Black Forest to compare four treatments differing in retention levels/salvaging intensity: (1) complete removal of all dead trees, (2) retention of high stumps (2 m height) and slash piles, (3) partial harvest of two thirds of dead trees, and (4) no harvest. In all treatments we planted saplings of sessile oak, Norway maple and Douglas fir. To study the influence of different retention levels, we measure solar radiation, wind speed, temperature, precipitation, soil moisture and soil temperature as well as plant growth and mortality, photosynthetic rates, chlorophyll fluorescence, water potential, nutrient content and carbon allocation within the seedlings that were planted between autumn 2021 and spring 2022.

Following the hot and dry summer 2022, 17 % of the seedlings had died until the end of August. Mortality was higher for individuals planted next to stumps and high stumps compared to standing dead trees. Microclimatic conditions were most extreme for saplings planted on the southern side of dead trees and stumps with temperatures of up to 30° C even in October and fluctuations of up to 20° C within one day. At the northern side of trees and stumps and in circles of crown material, it was 10° C cooler on average. Data on growth performance of seedlings will be complemented with physiological analyses and measurements will be continued in 2023. Results of this project will contribute to the development of efficient and appropriate regeneration approaches following dieback of forest stands.

Tree diversity reduces uncertainty in sapling survival under drought

T3.29 Reforestation Under Drought Conditions

Haben Blondeel[1]
Lander Baeten[1]
[1] Ghent University

Abstract: Current forest research recognizes the importance of tree diversity to foster resilience to climate extremes, such as drought. So far little attention has been given as to how tree diversity can generally reduce uncertainty in survival of young planted trees. We conducted a global analysis on sapling survival from 34 tree diversity experiments (363 167 trees, 168 species, 3744 plots, 7 biomes) to answer two questions: 1) Does drought and tree diversity alter the mean and variation in plot-level tree survival, with less uncertainty in survival as diversity increases? and 2) Do trait syndromes associated with drought resistance associate with higher species survival under non-drought conditions? First, we found a general reduction in variability of plot-level survival because mortality risk differs among species and is spread across them in more diverse stands (a "stock option effect"). This reduction in survival uncertainty was enhanced as drought severity increased, meaning that more diverse stands were less variable in survival compared to monocultures of the same species with increasing drought severity. Second, we found that xylem resistance to cavitation (P50) was a predictor of higher species survival independently of the drought conditions encountered by the species in this study. In addition, lower P50 (stronger drought resistance) was coordinated with traits of the leaf economic spectrum that are indicative of a conservative resource use, which may have contributed to higher survival. These results highlight: 1) The effectiveness of tree diversity as insurance for sapling survival under drought, and 2) stronger drought resistance confers to higher species survival in drought and non-drought conditions. From a management perspective, we advocate the mixing of tree species to reduce uncertainty in survival of planted trees and the addition of drought resistant species with conservative growth strategy in mixtures to increase survival of young planted forests.

What is the impact of repeated droughts on young trees and how do we inform future drought-resilient planting?

T3.29 Reforestation Under Drought Conditions

Georgios Xenakis[1]
Anna Cumming[1], Mike Perks[1]
[1] Forest Research, Northern Research Station, Roslin EH2 9SY, UK

Abstract: Precipitation patterns are shifting, changing our climate towards more frequent and intense climatological drought events. As a result, newly established forests will be exposed to higher and repeated water deficits, increasing their vulnerability. Although the impact of a single drought event on growth is well understood, it is still unknown what exposure to repeated droughts has on the recovery post-event and when recovery is inhibited on such a scale that becomes catastrophic, leading to mortality. In this study, we present the first results of a potted drought manipulation experiment, in which we expose six species (three commercial conifers and three broadleaves) in two drought severities (30% and 60% reduction in water input) and three duration (two, three and four weeks). We assess several leaf-level and soil traits to quantify the impact and recovery on photosynthesis and water uptake. We ask if there is full recovery to post-drought conditions or if there is acclimation to drought. Finally, using our knowledge, we present a new classification method of drought tolerance that will provide evidence-based guidance to underpin future planting with drought-resilient species.

T3.30 Research advances towards sustainability for the high-value Meliaceae

Boron fertilization on the growth of Khaya grandifoliola C. DC. seedlings in sandy and clay texture soils

T3.30 Research advances towards sustainability for the high-value Meliaceae

[1] Federal University of São João del-Rei (UFSJ), Department of Agricultural Sciences, Brazil
[2] Federal University of São João del-Rei (UFSJ), Department of Forestry, Brazil

Abstract: Planted forests have been widely used as an alternative to guarantee the preservation of native forests around the world. African mahogany (*Khaya grandifoliola* C. DC.) is a tree of African origin belonging to the botanical family Meliaceae. It has noble wood of great economic potential for internal and external trade and can be used in the furniture industry, shipbuilding, civil construction, panels, and laminates, among other uses. In Brazil, commercial plantations of the species have expanded, and studies are essential to obtain greater productivity and better adaptation of the species in the country. The objective of this work was to analyze the effect of the application of boron (B) sources and doses in clayey and sandy soils on the growth of *K. grandifoliola* seedlings. Two types of soil (clayey and sandy), two sources of boron with different solubilities, and four different doses were evaluated. The boron sources selected were: a) application of low solubility boron fertilizer (borogran®, 10% B); and b) application of high solubility boron fertilizer (granubor®, 15% B). The doses of each boron source tested were: a) 2.5 kg ha^{-1} of B; b) 5.0 kg ha-1 of B; c) 7.5 kg ha^{-1} of B; and d) 10.0 kg ha^{-1} of B. In the control treatment, there is no external source of B. The experiment was carried out in a 2 x 2 x 4 factorial, with four replications in a randomized block design, with the control as treatment additional. Every 30 days, during a period of 150 days, the height, diameter, and height/diameter ratio of the seedlings were measured. Regression equations for seedlings behavior in different treatments were estimated and data from the last evaluation were compared using Tukey's test at a 5% significance level. The results obtained allow to infer that the application of a high solubility boron source (borogran®) at a dose of 5kg.ha^{-1} in clayey soil enabled greater growth of *K. grandifoliola* seedlings. For sandy soils, the dose of 7.5 kg ha^{-1} of boron from the source (borogran®) is recommended.

Construction of core collection and phenotypic evaluation of Toona sinensis

T3.30 Research advances towards sustainability for the high-value Meliaceae

Abstract: *Toona sinensis*, commonly called Chinese toon, is regarded as a valuable mahogany belonging to the genus of *Toona* in the Meliaceae. The young leaves of *T. sinensis* are edible woody vegetables that are deeply loved by the masses. In addition, the old leaves are important raw materials for silage feed and medicinal ingredients, with great economic value.The wood grain of *T. sinensis* is interlocked and the structure is fine, with a hard and slightly heavy texture that is easy to process. The longitudinal section is smooth and slightly glossy, with a uniform and consistent color. It is suitable for use as a material for beams, columns, doors, windows and other uses.

T. sinensis is widely distributed in eastern and southeastern Asia. An efficient mechanism for preserving and utilizing of germplasm resources is crucial for speeding up the process of genetic improvement of *T. sinensis*. We have collected a total of 1040 germplasm resources of *T. sinensis* from China, Britain and New Zealand. Using a total of 27,040 markers, we have analyzed the genetic diversity, genetic structure and core collection of these resources. Additionally, a comprehensive evaluation method for phenotypes of *T. sinensis* was established by principal component analysis (PCA) and the technique for order preference by similarity to ideal solution (TOPSIS). Our analysis included three main results: Firstly, the breeding population, consisting of a total of 1040 individuals, contains a diverse genetic pool and can be divided into two genetic clusters. Secondly, the best core collection was obtained from the alternative population, consisting of a total of 208 individuals and comprising 20% of the breeding population. It was screened out based on Core Hunter 3 software with the average entry-to-nearest-entry (E-NE) algorithm. Finally, a comprehensive evaluation method was established based on eight selected agronomic traits of the core collection. This method allowed us to screen out the best individual plants of the core collection, including N0237, N0972 and N0409. Overall, our research findings will enable better preservation and utilization of *T. sinensis* germplasm resources and result in faster improvement of *T. sinensis* varieties.

Early growth characteristics of native trees under mono and mixed plantation conditions: High potentials for Meliaceae and Combretaceae species

T3.30 Research advances towards sustainability for the high-value Meliaceae

Adejoke Akinyele[1]
Samuel Olajuyigbe[1], Ayodeji Omole[1]
[1] University of Ibadan, Nigeria

Abstract: In Africa, tropical forests have become highly degraded and are losing their productive and protective functions. There is an urgent need for an increase in tree plantation establishment to boost product supply and reduce pressure on natural forests. Pure and mixed indigenous plantations of high-value timber species from Meliaceae, Combretaceae, and other native species are being promoted as preferred sources of hardwood timber supply, carbon sequestration, and biodiversity conservation. However, limited information is available on the early growth characteristics, structural and management requirements of such plantations. This research is investigating the potential of plantation development of pure and mixed stands of species in the Meliaceae (*Khaya* spps), Combretaceae (*Terminalia*) and Malvaceae (Mansonia, Triplochiton) families. Pure and mixed species plots (50m by 50m) were established for *Mansonia altissima*, *Khaya ivorensis*, *Khaya superba*, *Khaya grandifoliola, Terminalia superba* and *Triplochiton scleroxylon* species, using 2m by 2m and 3m by 3m espacements. The survival rate, early growth characteristics, challenges, and prospects of plantation development were monitored. After 18 months, 68% survival was observed among species, while mean height and stem collar girth were 79.0±0.82cm and 5.6±0.08cm, respectively. High mortality occurred among the seedlings of *Mansonia altissima* and *Triplochiton scleroxylon*, particularly during the dry season. Factors such as increasing cost of site maintenance, pest attack, extended dry spells, insect attack, competition from weed and understorey vegetation; limited stand development, while silvicultural treatments such as spot and line weeding, site cleaning as well as mulching, promoted seedling establishment. High growth performance and early formation of canopy were observed for *Khaya senegalensis*, *Khaya ivorensis*, *Khaya grandifoliola and Terminalia superba*, under monoculture and mixed plantation conditions. The choice of species is critical to the successful establishment of native tree plantations. However, intensive monitoring and effective silvicultural management are essential for the successful establishment of indigenous tree plantations for productive and protective forestry.

Effects of fertilization on growth and physiological characteristics of Toona ciliata var. pubescens

T3.30 Research advances towards sustainability for the high-value Meliaceae

Junbin PAN[1]
Yuanshen LIU[2], **Lu ZHANG**[1], Qiangqiang CHENG[1], Jian WANG[2], Ting JIA[1], Yunyan WU[1], Chunlan GUO[1]
[1] (1.Jiangxi Provincial Key Laboratory of Silviculture, 2011 Collaboration Innovation Center of Jiangxi Typical Trees Cultivation and Utilization, Jiangxi Agricultural University, Nanchang 330045, China;
[2] 2. Anfu County Mingyueshan Forestry Centre, Anfu 343200, Jiangxi, China

Abstract: In order to explore the response of the precious tree species *Toona ciliate* var. *pubescens* to different amounts of fertilizers.In this paper, the young forest of *T. ciliate* var. *pubescens* was taken as the research object.A random block d young forest of *T. ciliate* var. *pubescens* , and three fertilization levels (high, medium and low) were set, including nitrogen fertilizer (N), phosphorus fertilizer (P), compound fertilizer (CF) and slow release fertilizer (SRF).The results show that: (1) fertilization could promote the height and DBH growth, and the effect of nitrogen fertilizer and compound fertilizer wasmore obvious.The average tree height, average DBH and average volume of 4-year old with nitrogen fertilizer increased by 15.0%, 21.9% and 67.5% compared with CK, respectively, and the annual average growth of DBH under low nitrogen (N1) treatment was the highest (2.99 cm).Compared with CK, the average tree height, average DBH and average volume of compound fertilizer were increased by 16.7%, 19.2% and 54.3%, respectively.High slow-release fertilizer (SRF3) and low phosphorus (P1) had the largest annual increases in tree height and DBH (1.96m and 2.33cm) in the 4th year, respectively.(2) Fertilization significantly increased chlorophyll content and non-structural carbohydrate content in leaves of *T. ciliate* var. *pubescens*, nitrogen fertilizer significantly promoted the synthesis of soluble sugar and phosphate fertilizer significantly promoted the synthesis of starch.(3)Low nitrogen (N1) and phosphate fertilizer promote the content of N and P, respectively, and P fertilizer, compound fertilizer and nitrogen fertilizer significantly increased K content in leaves.The principal component analysis showed that the effect of fertilizer to promote growth was nitrogen fertilizer > compound fertilizer > phosphorus fertilizer > slow-release fertilizer > control . Among them, low nitrogen (N1), i.e. 100 $g \cdot plant^{-1} \cdot year^{-1}$, had the highest comprehensive evaluation value.Comprehensive fertilization cost and benefit, nitrogen fertilizer or compound fertilizer can effectively promote the growth and development of *T. ciliate* var. *pubescens* young forest . It is recommended to apply 100 g nitrogen fertilizer per plant per year in young forest stage.The results can provide a reference for the forest nutrient management in the early stage of afforestation.

Electrical Resistance Tomograph (ERT): An innovative technique in estimation of heartwood content in standing trees of Swietenia macrophylla King

T3.30 Research advances towards sustainability for the high-value Meliaceae

Prajwal Mahalgod Bhadrappa[1]
Baragur Neelappa Divakara[1], **Prashanth M**[1]
[1] Institute of Wood Science and Technology, 18th Cross, Malleshwaram, Bengaluru – 560 003 (Karnataka), India.

Abstract: *Swietenia macrophylla* King, also known as big-leaf mahogany, is a large deciduous tropical tree species native to Central and South America. *S. macrophylla* frequently reaching heights of over 20-30 m and diameter at breast height (DBH) of more than 1-1.5 m with an umbrella-shaped crown. *S. macrophylla* have been reported to grow in large plantations and also widely used for avenue planting in South India. Tree is gaining importance as a promising tree species for industrial plantations as well as for reforestation and afforestation. The ability to predict the growth and yield potential of *S. macrophylla* plantations is of considerable importance for planning plantation programmes. However, relatively very little reliable periodic stand measurement data are available. Added to this, information on heartwood development and estimation is totally lacking. Keeping this in view, tree tronic tomograms like Electrical Resistance Tomograph (ERT) was applied as a non-destructive method for advanced aiding for tree inspection to understand heartwood development and estimate in standing trees to predict the yield. In this study, we tested the validity of electrical resistance tomograph (ERT) to estimate heartwood diameter in big leaf mahogany by collecting core samples from fifty trees. The study revealed that the resistivity pattern in mahogany trees consisting of high resistivity in the inner part of the stem with lower resistivities on the outside. On an average resistance pattern of mahogany trees varies from 200 ohms to 943 ohms. The demarcation of SW-HW boundary was based on the distinct colour differentiation from blue (low resistance) to red (high resistance). A comparison between ERT and actual heartwood diameter shows a slope of the linear regression close to unity (0.90) with a narrow spread of values ($R^2 = 0.90$). Finally, by this study Electrical Resistance Tomography proved to be a significant predictor of heartwood diameter in standing trees of mahogany trees.

Keywords: Mahogany, Electrical Resistivity Tomography, Heartwood, Resistance pattern, Core sample

In situ genetic conservation: Mahogany and Spanish cedar in the Yucatan Peninsula as a possible test case

T3.30 Research advances towards sustainability for the high-value Meliaceae

Sheila Ward[1]
María Angelica Navarro Martínez[2]
[1] Mahogany for the Future, Inc., Puerto Rico, USA
[2] Colegio de la Frontera Sur, México

Abstract: As deforestation continues, more tree species become endangered, along with their genetic variation. Approaches to genetic resource conservation include *ex situ* plantings (away from the sites of origin) and in situ forest stands. We explore the viability of *in situ* conservation, using big-leaf mahogany (*Swietenia macrophylla*) and Spanish cedar (*Cedrela odorata*) in the Yucatan, Mexico, as a test case.

Various *ex situ* plantings have been made of germplasm for both Spanish cedar and big-leaf mahogany in the Yucatan peninsula, but these plantings are susceptible to maintenance problems, fire, hurricanes, disease, and local development. Other options must be considered. Most forest land in the Yucatan peninsula (and in all of Mexico) is held by communities (ejidos). *In situ* conservation of designated seed trees in community forest reserves might be a more practical solution. Stands can be replicated in different ejidos, reducing overall vulnerability to loss.

Several factors in Mexico may facilitate *in situ* conservation. 1) Mexican forest law and regulations create a legal framework for both *in situ* and *ex situ* conservation. 2) At least some of these forest ejidos have reserves set aside within their property. Forest inventories in ejidos also provide information on the presence of these species in different locations. 3) There may be sufficient interest in ejido communities to maintain their forests. We will explore how these factors may enhance the viability of *in situ* conservation for these species in the Yucatan, and present a draft plan for consideration. We also consider how this case may apply to species under threat in other places.

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Consequences of diversity in the white oak syngameon for functional variation, adaptation and symbiont biodiversity

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Abstract: Organisms exist as part of dynamic, flexible, and evolving ecosystems, with multiple interacting levels of biodiversity. Genetic and functional variation in one species influences and is influenced by variation in sympatric species, often at different trophic levels. This complexity is magnified by introgression, which moves adaptive alleles among phylogenetic lineages, shaping community assembly and species interactions. This talk presents a project investigating a suite of closely coordinated studies on two continents, jointly funded by US and Chinese research teams with complementary skills in phylogenomics, ecophysiology, fungal and insect taxonomy and ecology, to investigate the genomic, functional, and phylogenetic diversity of oak trees and the ectomycorrhizae, endophytic (leaf) fungi, and gall wasps that associate with them. The project objectives are:

Objective 1. Reconstruct the genomic mosaic of differentiation and introgression in the white oak syngameon across the range of focal oak species and co-occurring white oak species and characterize geographic patterns of (i) leaf functional and phenotypic variation in oaks and (ii) the functional and phylogenetic diversity of mycorrhizal fungi, leaf endophytic fungi, and gall wasps associated with focal oak species.

Objective 2. Evaluate the effects of genetic diversity and differentiation among populations within focal host species, across a climatic gradient, on (i) oaks' relative fitness and functional traits, and (ii) phylogenetic and functional diversity of their fungal and insect communities.

Objective 3. Assess the effects of forest community phylogenetic diversity on the phylogenetic and functional diversity of oak fungal and insect communities.

In this presentation, we will present preliminary findings from the eastern North American white oak syngameon centered around *Quercus macrocarpa* (bur oak) based on genome-wide SNP data. We

present estimates of introgression between *Q. macrocarpa* and several widespread sympatric white oaks, including *Q. alba*, *Q. bicolor*, *Q. muehlenbergii*, and *Q. stellata*. In addition, we will present preliminary findings on the relationship between leaf endophytic fungal communities and oak genetic and phylogenetic diversity.

EXPLORING CYTONUCLEAR INTERACTIONS AND THEIR PHENOTYPIC OUTCOMES IN A POPLAR HYBRID ZONE

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

[4] University of Vermont, Burlington, VT, USA,

Abstract: The interaction between nuclear and cytoplasmic genomes, which includes chloroplast and mitochondrial genomes, is crucial for maintaining essential functions in plant species. The maintenance of these functions largely depends on the coevolution of cytoplasmic genes with co-functioning nuclear genes, including mitochondrial-nuclear (mt-N) and chloroplast-nuclear genes (cp-N). Thus, cytonuclear interactions, or the interplay between mt-N/cp-N genes with cytoplasmic genes, have likely coevolved at the species level. However, when interspecific hybridization occurs, it can affect the co-evolved cytonuclear interactions and have consequences for phenotypic trait variation, which is important for adaptation. *Populus* trees are an excellent model for studying cytonuclear interactions because they have weak reproductive barriers and extensive hybridization in nature. In this study, we utilized whole genome resequencing data of 576 *Populus* trees from a hybrid zone between *Populus trichocarpa* and *P. balsamifera*, spanning seven latitudinal transects. We used genotypes sourced from across the hybrid zone transplanted to three replicated common garden environments to investigate the contribution of cytonuclear interactions to phenotypic variability in novel environments. We estimated admixture proportions from nuclear data and assigned chloroplast identity using phylogenetic analyses. Initially, we examined the impact of climate on changes in ancestry for nuclear genes, cp-N genes, and chloroplast genes across the hybrid zone. Preliminary analysis of clinal variation showed similar patterns across the gene groups, but different centers and widths of clines, suggesting that fine-scale selection might influence cytonuclear interactions in the hybrid zone. Through our common garden experiments, we evaluated the role of cytonuclear interactions in phenotypic traits relevant to adaptation. Our findings indicate that chlorophyll content is influenced by varying cytonuclear interactions. These results highlight the importance of thoroughly evaluating the role of cytonuclear interactions in hybridizing species to understand how these interactions can affect phenotypic outcomes, which are crucial for predicting fitness in novel environments.

Ficus Hybridization and Enhancing Adaptive Capacity of Tropical Forests

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Gang Wang[1]

[1] CAS Key Laboratory of Tropical Forest Ecology, Xishuangbanna Tropical Botanical Garden, Chinese Academy of Sciences, Mengla, Yunnan, China.

Abstract: Tropical rainforests are the most ecologically diverse and complex terrestrial ecosystems, and their preservation and adaptation to rapid environmental change in the Anthropocene is crucial for the health and development of both natural ecosystems and human societies. *Ficus* plants is one of the largest genera of woody plants, with over 800 species distributed throughout the tropics. *Ficus* plants maintain highly specialized pollination relationships with their specific fig wasp pollinators through their unique enclosed inflorescences (figs) and species-specific figs volatiles. This supports thousands of pollinating and non-pollinating fig wasps, arthropods, and over a thousand species of vertebrate frugivorous animals, making the *Ficus* plants become a keystone group in many tropical rainforests. Understanding the mechanisms behind the formation, maintenance, and future adaptation of the extremely high species diversity and complex ecological relationships of the *Ficus* plants is importance for the stability and adaptation of tropical rainforest ecosystems in the Anthropocene.

Here, I will introduce the latest research progress on the fig-fig wasp co-diversification via plant-pollinator coevolution and plant hybridization. By revealing the patterns and mechanisms of introgressive hybridization of *Ficus* plants, as well as their impact on the speciation and key trait evolution of both fig trees and fig wasps, I propose a concept of "species community with a shared future", in which sympatric species responding to the environment changing as a whole system via the ecological networks and genetic exchange networks among them, and this may supply an overall package protection strategy to enhance the adaptive capacity in community level.

Genetic consequences of hybridization between oak species

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Baosheng Wang[1]
Biao-Feng Zhou[1], Yi-Ye Liang[1], Paul S. Manos[2]
[1] Key Laboratory of Plant Resources Conservation and Sustainable Utilization, South China Botanical Garden, Chinese Academy of Sciences, Guangzhou 510650, China
[2] Department of Biology, Duke University, Durham, NC 27708, USA

Abstract: Hybridization is common between modern oak species and presumably occurred among their ancestral lineages. To investigate the deep history and genetic consequence of hybridization in oak species, we used phylogenomic analyses of nuclear and plastid genomes to detect signatures of hybridization across the Fagaceae. We showed that introgression resulted from historical hybridization events between ancestral species representing three oak sections, *Ponticae*, *Quercus* and *Virentes*. Identity-by-descent (IBD) analyses based on whole-genome SNP data clearly detected a large number of shared haplotypes between these sections. These shared haplotypes apparently originated during hybridization, and most of them are significantly longer than expected under neutrality. These results suggested that shared haplotypes were maintained by natural selection, providing convincing evidence for the persistence of adaptive introgression. Current hybridization also may provide an additional genetic pathway for species to repeatedly adapt to similar environments via molecular parallelism. To test this hypothesis, we studied a pair of sympatrically distributed East Asian oak species, *Q. variabilis* and *Q. acutissima*. Population genomic analyses revealed an east-west divergence within *Q. variabilis*, and detected a ~270kb region showing a strong signal of selection. This region contains 20 genes, including 10 members of ethylene-responsive factor (ERF) family, which are involved in the response to abiotic stress. To investigate the origin of advantageous variation in this region within *Q. variabilis*, we first performed forward simulations to reject models of selection acting on *de novo* mutations or standing variation. Next, a battery of tests including phylogenetic analysis, efficient local ancestry inference, and gene flow analysis revealed multiple lines of evidence supporting beneficial alleles in this region originated through introgression from *Q. acutissima* into *Q. variabilis*. Finally, we found that the same ~270 kb region was under selection in *Q. acutissima*, suggesting that adaptive introgression has contributed to molecular parallelism in repeated climate adaptation in oaks. These studies underscore the importance of hybridization in the evolution of oak species across time scales.

Genomic evidence for extensive introgression among oaks and assessment of mal-adaptation

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Louise Gathercole[1, 2, 3]
Nathan Brown[3], Sandra Denman[3], Richard Nichols[2], Richard Buggs[1, 2]
[1] Royal Botanic Gardens Kew, Plant Health and Adaptation, UK
[2] Queen Mary University London, Department of Biological and Behavioural Science, UK
[3] Forest Research, UK

Abstract: The two native species of oak in Britain, (Quercus robur L and Q. petraea (Matt) Liebl.) are resilient keystone species, supporting over 2000 macro species, and are a major feature of the British landscape, economic history and culture. Many observations suggest Q. petraea is found mostly in the north and west and Q. robur in the south and east, with slightly different environmental preferences, although the species are often sympatric and can hybridise. Hybrids are hard to identify based on morphology.

Here, we report whole genome re-sequenced data from 418 oak trees sampled at 60 sites across England, Wales and Scotland. These sites were previously part of a long-term forest condition survey. We used genomic methods to allocate trees to species, and identify hybrids and introgression. We found large numbers of hybrids and extensive of introgression of Q. robur alleles into Q. petraea genomes. None of our sampled individuals from Scotland were pure Q. robur. Within each species we found little genomic population structure.

To seek evidence for genetic adaptation to local environments, we used latent factor mixed methods models to identify associations between allele frequencies and nineteenth century climate parameters. We used genetic offset methods to assess potential future mal-adaptation within a changing climate.

The resilience of UK oaks may be partly due to dynamic exchange of alleles between two species with slightly different niches. Adaptation to future climates may involve co-planting of the two species and changes to a “local is best” seed sourcing policy

Interspecific hybridization of tropical rainforest trees in Southeast Asia

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Koichi Kamiya[1]
[1] Graduate School of Agriculture, Ehime University

Abstract: Interspecific hybridization is occasionally common in tropical rainforest family, Dipterocarpaceae. Previous studies have shown that there is a species possibly derived through hybridization, suggesting the importance of hybridization in species divergence. We studied the possibility of hybridization between closely related species in *Shorea*, the largest genus in Dipterocarpaceae and found that interspecific hybridization is not uncommon in a small isolated tropical rainforest in Singapore. In the forest, *Shorea curtisii* is the most abundant species, while ecologically divergent species such as *S. leprosula* and *S. parvifolia* also occur at lower densities. Field observations and DNA analysis revealed that hybridization between *S. curtisii* and *S. leprosula* is relatively common, while the hybridization between other species is less so. Phenological observation in 2009 indicated that the flowering times of *S. curtisii* and *S. leprosula* were nearly identical, and that the hybrid trees were fertile, implying that the strength of pre-zygotic isolation is weak between these species. To test whether the hybrids are maladaptive, we monitored growth of seedlings in nature and found that survivorship and growth of the hybrid seedlings are equivalent or even higher than the "pure" species. This implies that post-zygotic isolation is not complete and successive introgression may enhance the consolidation of distinct gene pools of two species. We also found the hybrid individuals from other coastal hill dipterocarp forests, or hill dipterocarp forests with human disturbance where two species coexist, indicating the hybrids may be considerably widespread. Other than *Shorea*, hybrids are also present between ecologically distinct species of *Dyera* (Apocynaceae). The hybrids of Swamp Jelutung (*D. polyphylla*) with Hill Jelutung (*D. costulata*) are occur at the damaged peatlands. Together these results suggest that hybridization and introgression are likely to occur in Southeast Asian tropical rainforest species, mediated by damage from natural and human disturbances.

Introgressive hybridization is a major source of diversification and helps maintain adaptive capacity

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Charles Cannon[1]
[1] Center for Tree Science, The Morton Arboretum

Abstract: The Anthropocene is driving rapid environmental change in many different ways, both local and global. The rate of change is substantially greater than most living organisms on Earth have experienced for many millions of years. The emerging environments of the future will also be novel combinations of abiotic and biotic conditions, suggesting that overall fitness of currently existing diversity will decline during the Anthropocene. How will organisms, particularly those with great longevity, generate functional diversity in order to adapt in the future? The creation of novel and adaptive functional traits through endogenous mutation seems unlikely to be sufficient, given its slow pace. Introgressive hybridization has played an important role in the diversification of many lineages, plant and animal and seems to be particularly associated with deep major bifurcations and innovations in the Tree of Life. This introgression process may be the best source of functional diversity available, particularly for trees and other long-lived organisms. Here, I explore the role that introgressive hybridization plays in a syngameon, given different scenarios of environmental change, in the maintenance of functional diversity. Statistical modeling suggests that the syngameon is particularly stable as advantageous traits can diffuse through the network rapidly corresponding to its fitness. The interconnectedness of the species creates a wide range of phenotypes more quickly than pairwise or isolated species. I would argue that an important step in anticipating the upcoming biodiversity bottleneck would be to enhance introgressive hybridization among interfertile species. Diversify first and allow natural selection to choose the winners from a much broader and deeper candidate pool of phenotypes. I discuss potential experiments that could be installed to examine the underlying nature of introgressive hybridization and generate novel phenotypes for trialing.

Phenotypic and genomic studies of two California sympatric oak species show compelling evidence of adaptive hybridization and introgression

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Scott O'Donnell[1]
Sorel Fitz-Gibbon[1], **Victoria L. Sork**[1, 2]
[1] University of California, Los Angeles, Department of Ecology and Evolutionary Biology, USA
[2] University of California, Los Angeles, Institute of the Environment and Sustainability, USA

Abstract: Oaks are notoriously promiscuous, but why. Introgression has rarely jeopardized the species identities across this diverse genus despite their frequent hybridization with other oaks and pervasive, yet not indiscriminate, ancient interspecific gene exchange. These observations beg the question whether hybridization is just the outcome of weak reproductive isolating mechanisms among species that allow limited exchange of neutral genetic variation. Alternatively, does it allow the introduction of beneficial genetic variants that enhance the fitness of hybrids and subsequent backcrossed generations? In this talk, we will examine hybridization and introgression between two distantly related oak species found sympatrically in southern California USA across a range of environments—the California endemic shrub oak, *Quercus berberidifolia*, and the non-endemic tree oak, *Quercus engelmannii*. This study system is ideal because strong interspecific phenotypic differences make putative hybrids easy to identify and a long divergence time of 35-40 million years makes it less problematic to detect interspecific DNA sequences. To test the adaptive introgression hypothesis, we will describe evidence from four studies. First, as proof of ongoing hybridization, we will describe phenotypic and genetic analyses of putatively “pure” and “hybrid” individuals to identify their species’ assignment and degree of admixture. Second, we will analyze transcriptomes to show that drought-associated functional genes are enriched in hybrid individuals. Third, we will use single nucleotide polymorphisms (SNPs) from reduced library sequences to test whether historical gene flow is asymmetrically favoring gene flow from the endemic into non-endemic oak, as one might predict if the endemic oak is more adapted to California Mediterranean-type climate than the non-endemic species. Finally, we will provide direct evidence in support of the adaptive introgression hypothesis using whole genome sequence data for 33 *Q. berberidifolia* and 31 *Q. engelmannii* individuals. Within the genomes of *Q. engelmannii* individuals, we find 24 unique introgressed regions containing 32 well-annotated functional genes, including several genes associated with biotic stress and pathogen resistance. We conclude that *Q. engelmannii*, the non-endemic oak, has benefitted historically from selective introgression from the endemic shrub oak and that the presence of on-going hybridization may be key to its ability to adapt to future climate conditions.

Predicting fitness under future climates across Populus trees from a natural hybrid zone

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

Alayna Mead[1]

[3] Virginia Tech University
[4] University of Vermont

Abstract: If tree populations are unable to adapt to changing climates, migrate to suitable climates, or survive changes through phenotypic plasticity, they will become extirpated without human intervention. Populations may be able to adapt to new climates relatively rapidly when standing genetic variation that increases fitness under new environments is already present. One mechanism that can introduce new genetic variation is interspecific hybridization. Forest trees often form natural hybrid zones and experience adaptive introgression, in which beneficial genetic variants are introduced from one species to another. In fact, hybrid individuals may have higher fitness in novel environments compared to their parental species, which are adapted to a particular environmental niche. These natural hybrid zones can be used to understand the fitness effects of hybridization and to inform management of tree populations under climate change. We have established 15 common gardens with *Populus* genotypes collected from multiple latitudinal transects spanning the natural hybrid zone of *Populus trichocarpa* and *P. balsamifera*. Replicated genotypes were planted into each common garden site, enabling us to model the relationship between climate and phenotype and identify the climate under which each genotype accumulated the greatest growth, a proxy for fitness in forest trees. We test which genotypes have the highest overall growth and which grow well across a wide range of environments. Populations may experience a trade-off between the maximum rate of growth and the ability to grow well across a wide range of environments, i.e. between generalist and specialist strategies. We predict that "specialist" genotypes that are strongly locally adapted and able to outcompete foreign genotypes in a home environment will have lower fitness in non-home environments when compared to "generalist" genotypes, which are well-adapted to a wider range of environments. Furthermore, we predict that *Populus* hybrids will exhibit a more "generalist" strategy than parental genotypes due to their novel genomic architecture, and thus will be pre-adapted to the novel environments expected under climate change. Our results can be used to determine the best strategies for planting *Populus* into restored or managed stands while taking into account future climate and the uncertainties in its prediction.

Sequential hybridization facilitated ecological transitions in the Southwestern pinyon pine syngameon

Abstract: The evolutionary importance and prevalence of multispecies interbreeding networks, or syngameons, have been increasingly reported in natural systems. However, the formation, structure, and maintenance of syngameons have received little attention. Through gene flow, syngameons can increase genetic diversity, facilitate the colonization of new environments, and contribute to hybrid speciation. In this study, we evaluated the history, patterns, and consequences of hybridization in a pinyon pine syngameon using morphological and genomic data to assess genetic structure, demographic history, and geographic and climatic data to determine niche differentiation. We demonstrated that *Pinus edulis*, a dominant species in the Southwestern US and a barometer of climate change, is a core participant in the syngameon, involved in the formation of two drought-adapted hybrid lineages including the parapatric and taxonomically controversial *fallax*-type and the allopatric *P. californiarum*. This is the first study documenting sequential hybridization events in natural systems, in which a novel independent lineage resulting from gene flow (*P. californiarum*) hybridized with one of its parents to create a second novel lineage (*fallax*-type). Overall, we found that species remain morphologically and genetically distinct at range cores, maintaining species boundaries while undergoing extensive gene flow in areas of sympatry at range peripheries. The recognition of *P. californiarum* as a species has conservation implications as it has a narrow and scattered distribution divided by the US-Mexican border. Our study shows that sequential hybridization may have caused relatively rapid speciation and facilitated the colonization of different niches, resulting in the rapid formation of two new lineages. Participation in the syngameon may allow adaptive traits to be introgressed across species barriers and provide the changes needed to survive future climate scenarios.

Unraveling the effects of introgression on local adaptation in red spruce (Picea rubens Sarg.): Genetic rescue and shaping of adaptive traits

T3.31 The impact of introgressive hybridization on adaptive capacity of forest trees in the Anthropocene

[4] Bent Creek Experimental Forest, USDA Forest Service, Asheville, NC 28806, USA

Abstract: Introgression, the transfer of genetic material between species through hybridization, can significantly influence the patterns of local adaptation in forest trees. Introgression can act as a type of "genetic rescue" for ecologically important species by introducing adaptive genetic variance for selection to act upon. Red spruce (*Picea rubens* Sarg.), a climate-sensitive coniferous tree with a distribution along the eastern coast of North America, is known to hybridize with its sister species, black spruce (*Picea mariana*). Red spruce suffers from very low genetic diversity and N_e; thus we aimed to unravel the possible contribution of introgression on local adaptation in red spruce by utilizing large-scale genomic data and phenotypic traits.

Traditionally, testing for local adaptation has relied on reciprocal transplant experiments involving a pair of "home" and "away" populations planted in both sources' environments. However, this approach becomes complicated when investigating more than two populations and fails to consider the complexities arising from demographic history and population structure. To overcome these limitations, we employ a novel version of the Q_{ST}-F_{ST} test called Q_{PC} analysis, wherein genomic data is used to infer population structure and genomic relatedness to estimate additive genetic variance in phenotypic traits. We used Q_{PC} to test for local adaptation in trait means and their plasticities, using measurements of growth, phenology, and physiology on >5,000 trees in three common gardens established along a latitudinal gradient across the species range.

The results indicate that while some traits such as phenology show local adaptation along a latitudinal climate gradient, most of the selection on adaptive growth, phenology, and physiological traits was driven by introgression between red and black spruce. The influx of genetic variance from black spruce introgression resulted in admixed genotypes with early flushing buds, increased water use efficiency (WUE), height growth and biomass production. These results suggest that for genetically depauperate species like red spruce, past introgression served as a major source of genetic variation that selection acted upon to shape locally adaptive traits. These admixed genotypes hold the potential for improving the chances of successful establishment and long-term survival of red spruce in current and new ecological niches.

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

A long term study reveals that restoration guided by an umbrella species, the white –backed woodpecker, does not reach target levels.

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Albin Larsson Ekström[1]
Joakim Hjältén[1], Therese Löfroth[1]
[1] Swedish University of Agricultural Sciences, Department of Wildlife, Fish and Environmental Sciences

Abstract:

1. Maintaining structural and functional elements of ecosystems are essential in order to preserve biodiversity and ecosystem function. As a means of streamlining conservation work, the umbrella species concept was developed. In Sweden, the putative umbrella species the white-backed woodpecker has guided conservation and restoration of deciduous forests for two decades.
2. Here, we evaluate the decadal effects of restoration aimed at the white-backed woodpecker on biological diversity patterns of saproxylic beetles. We compare stands that were restored ten to twenty years ago to non-restored stands and historical white-backed woodpecker habitats acting as restoration target stands.
3. Deciduous deadwood volumes were greater in restored stands than non-restored stands but less than restoration target stands. Deadwood in restored stands was also concentrated to later decay stages whereas target stand deadwood was more evenly spread across decay stages.
4. We found that restored stands show similar levels of species richness and abundance of most groups of saproxylic beetles to that of non-restored stands while not reaching the same levels as the restoration target stands. Species assemblages were different in restored stands compared to non-restored stands but also compared to restoration target stands. Indicator species in restored stands were mainly generalist species whereas indicator species in target stands where deciduous specialists.
5. *Synthesis and applications:* We conclude that now, after one to two decades, initial restoration effects found in a previous study are mostly gone, and restoration has not managed to mimic diversity patterns found in restoration target habitats. We stress that continuous restoration is needed by either revisiting the same stands or restoring adjacent stands in the surrounding landscape every ten to twenty years. Our results stress the importance of identifying a target level when assessing restoration outcome.

Age is not paramount for ground cover vegetation in ageing hemiboreal Scots pine and Norway spruce stands

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Ilze Matisone[1]
Diāna Jansone[1], Ieva Jaunslaviete[1], Roberts Matisons[1], Agnese Anta Liepiņa[1], Āris Jansons[1]
[1] Latvian State Forest Research Institute (LSFRI) Silava, Rigas str. 111, Salaspils, Latvia, LV2169

Abstract: Intensifying forest management and reduction of rotation period necessitates intensive conservation strategies, such as the triad concept, under which connectivity of biodiversity hot-spots and reserves is facilitated by specific extensive management. Mostly, biological value of a stand has been associated to stand age, although stand properties, which are often intercorrelated with age, might be of the primary importance. Hence, disentangling of the effects of age and structure on biological diversity of a stand is a precondition for the specific management of the ecological network and connectivity of intensively managed forest landscape. The relationships between ground cover vegetation (vascular, woody, bryophyte), which is a principal component and often used as indicator of biodiversity, and stand properties were assessed in pre-harvesting/harvesting age and two-times older old-growth coniferous stand in the eastern Baltic region (Latvia). Stands corresponding to mesotrophic site conditions, dominated by Scots pine and Norway spruce were surveyed. Both stand groups showed generally similar ground cover flora, with 18–23 species per stand. Though ground cover vegetation showed higher variability in the old growth stands, which favoured species with lower occurrence. The principal gradients of ground cover vegetation were related to light, site fertility and structural components such as standing stock and canopy composition (degree of deciduous, particularly *Betula* spp.). Considering the explicit contrasts, stand age did not affect ground cover vegetation, implying principal effects of stand structure, which are manageable properties. The relationship between ground cover vegetation and stand structure implies that currently applied rotation period of ca. 70–110 appears efficient for ground cover vegetation to reach a stable stage. Accordingly, conservative management strategy regarding rotation period while facilitating compositional and structural diversity of stands appears efficient for areas crucial for connectivity under the intensive triad conservation concept, aiding sustainability and multifunctionality of forests.

Can tree-related microhabitats solve the trade-offs between beetle biodiversity conservation and timber production in managed forests?

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Abstract: The Mediterranean forests are known as among the richest biodiverse forest ecosystems due to their environmental heterogeneity. Human pressure and climate change are the main threats to these ecosystems compromising their functions. For this reason, ensuring the multifunctionality of forests is the greatest challenge for forest managers. Although the establishment of protected areas helps to halt the loss of biodiversity, the release of certain structures, such as tree-related microhabitats (TreMs), habitat trees, and deadwood, in regularly managed forests could help to preserve many species of vertebrates and invertebrates, such as birds, amphibian or insects, and despite human action. Knowing and analysing the relationships between these structures and different taxa is essential to balance seemingly conflicting ecosystem services and to integrate biodiversity conservation and timber production, also in managed forests. This study aims to analyse the existing relationships between beetles, especially saproxylic beetles, and TreMs in a managed forest, to understand how and how much these structures impact beetle communities. The study was conducted in a regularly managed pure beech forest in the Apennine mountains of central Italy. The influence of environmental factors, forest structure, and biodiversity-related parameters on the abundance and richness of beetles and saproxylic beetles was assessed. Results, showed the key role of TreMs as predictors of beetle abundance and richness, demonstrating for the first time the one-to-one association between individual TreMs types and saproxylic specimens. The study emphasises the importance of TreMs as proxies for the maintenance and enhancement of beetle biodiversity. Furthermore, the relationships observed can guide silvicultural interventions, allowing foresters to better choose the habitat trees to release, to promote biodiversity without renouncing timber production.

Characteristics of tree microhabitats in commercially managed forests in Lithuania

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Gediminas Brazaitis[1]
Žydrūnas Preikša[1], Gailenė Brazaitytė[1]
[1] Vytautas Magnus University Agriculture Academy, Lithuania

Abstract: Tree related microhabitats (TrM) are recognized as important substrates and structures for biodiversity in forests. The aim of study was to evaluate microhabitats in intensively managed forests, provide protection recommendations and long term biodiversity monitoring. In total we surveyed 132 study plots (500m^2) and evaluated 3.4 thou. trees in 11 regions of Lithuania. We aimed to analyse TrM in pedunculate oak, Scotch pine, Norway spruce, Birches, black alder, Eurasian aspen, Norway maple and linden stands.

On average we observed 6.27 TrM in one study plot. Higher density observed in black alder (15.7 TrM/plot) and oak, aspen, linden stands (5.9-7.7 TrM/plot). Birch stands had less (4.9 TrM/plot), however coniferous stands (1.7-2.4 TrM/plot) the least density. Most of the trees with TrM contained one (18.8%), two and more microhabitats had 4.4% of trees. The diameter of tree had significant effect of TrM appearance (χ^2=284; p<0.00001). When the diameter of tree was 30cm, probability of TrM occurrence was 0.2. However, the probabilities reach 0.5 and 0.8 with the increase of diameter up to 55cm and 85cm. On average, the diameter of the trees with one TrM was 35cm, two – 50cm, three – 58cm, four – 75cm, five – 85cm, six – 88 cm.

We found TrM on 23.3% mature for felling trees. Highest proportion were evaluated on pedunculate oak (51.1%), dominated crown deadwood (31.2TrM/100tree) and epiphytes (15.04TrM/100 tree); Norway maples (43.2%) - epiphytes (30.53 TrM/100 tree) and cavities (CV-10.31 TrM/100 tree); and black alder (43.4%) - root buttress cavities (31.76 TrM/100 tree). Less TrM were on Eurasian aspen (26.8%), mostly often observed epiphytes (19.08 TrM/100 tree); birch (21.2%) - stem deformations (10.1 TrM/100 tree); and linden (15.4%) - epiphytes (7.02 TrM/100 tree). However, Norway spruce and Scotch pine related with least proportion of TrM (respectively – 8.0 and 8.6%), dominated stem deformations (3.33 TrM/100 tree), injuries and wounds (2.85 TrM/100 tree); as well as bark (1.77 TrM/100 tree) and injuries and wounds (3.28 TrM/100 tree) respectively.

Trees with two and more TrM should be protected during felling's. Mostly valuable trunk cavities, old bark loss, coarse bark, large dead branches, epiphytes should be prioritized. Diversity of TrM should be sustained during management.

Does retention forestry help conserve biodiversity in the boreal forest?

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Abstract: Retention harvesting has become a prominent practice under the paradigm of ecosystem-based, or disturbance-based, forest management. A central aim is to conserve biodiversity, or to facilitate recovery of biodiversity towards that of unmanaged forests. The EMEND (Ecosystem Management Emulating Natural Disturbance) project, located in north-western Alberta, Canada, includes five levels of dispersed green-tree retention (clearcut, 10%, 20%, 50%, 75% retention) plus unharvested reference stands replicated in four different boreal mixedwood forest types (deciduous (broadleaf)-dominated (DDOM), deciduous-dominated with conifer understory (DDOMU), mixed deciduous-coniferous (MIX), conifer-dominated (CDOM)). There were three replicate, 10 ha, compartments per forest type per treatment. The experiment was established in 1998 and abundance and composition of various biotic groups has been monitored regularly in permanent sample plots ever since. We used generalized additive mixed models (GAMMs) to characterized the temporal pattern of community similarity (Chao-Jaccard Index) between post-harvest stands and unharvested reference stands for up to 17 years post-harvest, for: songbirds, bryophytes, carabid beetles, spiders (Linyphiidae, Lycosidae, and other spiders, separately), Staphylinid beetles, and vascular understory plants. We compared this to the average similarity among reference compartments sampled in a given year and defined “recovery” as the time period at which the lower confidence interval of that similarity intersected with the recovery curve (GAMM smoother). We found that recovery trajectories varied among biotic groups and forest types. Still, many biotic groups had recovered within 12 – 17 years post-harvest, even in clearcuts; that is, their compositional similarity to unharvested reference forest was equivalent to that between unharvested reference compartments. There were notable exceptions: bryophytes, carabid beetles and Linyphiidae and other spiders, and understory vascular plants showed poorer resistance or resilience following harvesting than did other biotic groups. Further, recovery tended to be poorer / slower in forests with a conifer component (CDOM, MX, DDOMU) than for the deciduous-dominated forest type. There was some evidence that higher levels of retention harvesting better conserved biodiversity or facilitated faster post-harvest recovery than did clear-cutting, but a longer time period is needed for further clarity on any such effects.

ECONOMIC VALUATION OF PRIORITY AREAS FOR THE CONSERVATION OF PLANT DIVERSITY IN A CLOUD FOREST IN CENTRAL MEXICO

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Alin Torres-Díaz[1]
Manuel González-Guillén[1], Héctor De los Santos-Posadas[1], Patricia Hernández-de la Rosa[1], Aurelio León-Merino[1]
[1] COLEGIO DE POSTGRADUADOS

Abstract: Biodiversity is a natural resource that can be evaluated under a monetary metric to establish a framework for environmental management. The cloud forest shelters a high species richness and is one of the most threatened systems. The objective of this study was to estimate the use and non-use values of the flora diversity in priority areas for conservation in a cloud forest and map its value. To estimate the use value, we obtained information about useful plants and their market prices or wasted time in their recollection. The choice experiment method was used to calculate the non-used values of species richness, biomass, and accessibility. To project spatially these values, we classified the area covered by cloud forest and qualified its conservation condition. We proposed an Index of Importance for Biological Conservation (InICoB), based on quantitative indicators of the composition and structure of the vegetation such as life forms, the presence of endemic, climax, native, and protected species, diversity, structural complexity, and complementarity that can be applied to any plant community and are easy to interpret. The use value was higher in areas with preserved cloud forest because it contains a greater number of species, more used resources, and a greater density of large trees, which contribute significantly to the economic value. The non-use value of species diversity was the highest, and people showed a greater concern for the conservation of biodiversity. However, the value of plant diversity also depends on its accessibility. Closer sites with soft slopes, although having medium biological quality, have a high total value. We projected these values on a spatial scale, and the classification carried out with the InICoB adequately evaluated the different environmental units. Knowing spatially the total economic value of ecosystems is a valuable tool in land use planning and decision-making.

Effect of retention forestry on biodiversity conservation in planted forests in Hokkaido, Japan

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Nobuhiro Akashi[1]
Akira Unno[1], Yuichi Yamaura[2], Satoshi Yamanaka[2], Kenichi Ozaki[2]
[1] Hokkaido Research Organization, Japan
[2] Forestry and Forest Products Research Institute, Japan

Abstract: Natural forests in Hokkaido, northern Japan, are dominated by mixed stands of evergreen coniferous and deciduous broad-leaved trees. The forest floor is typically covered with dwarf bamboo, *Sasa* spp., which prevents natural tree regeneration, in turn, resulting in the degradation of natural forests by selective cutting. Since the 2000s, most timber has been harvested from planted forests with even-aged coniferous stands. Therefore, retention forestry is considered an effective approach to conserving biodiversity in Hokkaido. This study conducted a retention forestry experiment in planted forests with native conifer species, *Abies sachalinensis*, to determine the effectiveness of conserving biodiversity. We established aggregated retention (60 × 60 m was retained), dispersed retention (10, 50, and 100 broad-leaved trees/ha were retained), clear-cut, and unharvested sites during the 2014–2016 period and monitored understory plants, birds, and ground beetles. Planted forests provided habitats for numerous understory plants before logging compared to the adjacent broad-leaved forests, where the forest floor was dominated by *Sasa* spp. The forest floor was disturbed by logging, site preparation, and weeding to grow the planted seedlings. Disturbed sites were invaded by ruderal plants, whereas undisturbed areas in aggregated retention sites provided refuge for forest understory plants. Forest species of ground beetles were least abundant in clear-cut sites, but their abundance increased with the level of dispersed tree retention; aggregated retention sites also functioned as refuges for ground beetles. A low level of dispersed retention mitigated the negative impacts of logging on forest bird abundance, whereas aggregated retention did not have similar effects. Overall, effective retention methods that depend on the target organisms and a combination of aggregated and dispersed retention are desirable.

Enhancing Biodiversity Conservation through Multi-Taxon Approaches: Insights from Longitudinal Studies

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Jörgen Sjögren[1]
[1] Department of Wildlife, Fish, and Environmental Studies, Swedish University of Agricultural Sciences

Abstract: Biodiversity loss, mass extinction, and ecosystem collapse are central concerns in contemporary literature on biodiversity conservation. While numerous studies focus on the impacts of land-use and land-use changes on individual organism groups, there is a growing need to extend conclusions to broader biodiversity and ecosystem levels. Over the past few decades, our research team has conducted several studies revealing distinct responses among organism groups to environmental changes. Our findings emphasize the potential risks associated with solely examining a single organism group, as it may overlook substantial inter-taxon variations and lead to contrasting conclusions regarding the effects of environmental changes on biodiversity aspects.

For instance, our investigations demonstrate that commercial thinning operations favor many lichen species while negatively impacting numerous bird species when understory spruce is removed. Additionally, we have observed that moss species richness on stumps is higher when the stumps are lower, whereas lichen species richness exhibits an inverse relationship. Had we solely focused on one organism group in each study, our conclusions would have varied significantly depending on the selected group.

While single-taxonomic group studies undeniably contribute valuable insights to conservation biology, the urgency to acquire knowledge as a foundation for biodiversity protection necessitates a broader approach. Therefore, we propose that researchers incorporate multiple organism groups in their studies to capture a more comprehensive representation of biological diversity. By adopting this multi-taxon perspective, we can enhance our understanding of complex ecological interactions and make informed recommendations to safeguard biodiversity in a time-constrained context.

Forest disturbance, biodiversity and ecosystem functioning

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

David Wardle[1]
[1] Department of Ecology and Environmental Science, Umeå University, Umeå, Sweden

Abstract: Disturbance is a fundamental driver of forest dynamics, aboveground and belowground ecosystem processes, and plant, animal and microbial biodiversity. In this presentation I will focus on fire, because it is arguably the most important forest disturbance globally, because forest management has a major impact on fire return intervals and severity, and because fire regimes in much of the world are being altered by human-induced climate change. First, I will discuss the mechanistic basis by which fire affects ecosystem functioning both above and below ground over contrasting time scales ranging from years to millenia. Second, I will draw on work we have been carrying out on a group of lake islands in northern Sweden over the past 30 years that collectively represent a 5000 year post-fire chronosequence, to better understand how fire history and time since fire impacts on aboveground and belowground biodiversity and ecosystem processes that drive carbon sequestration. Finally I will compare this chronosequence with other long term forested chronosequences around the world to make the case that disturbances are an essential component of forests and are needed to rejuvenate forest ecosystems and maintain their long term functioning. Key conclusions from this presentation will emphasize the role of disturbance regimes in regulating processes that drive carbon sequestration and biodiversity in forested ecosystems in the long term, and the relevance of this to forest conservation and management.

From nature reserve to mosaic management: retention forestry as land sharing to conserve birds in plantation landscape

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Yuichi Yamaura[1]
Akira Unno[2]
[1] Shikoku Research Center, Forestry and Forest Products Research Institute
[2] Forestry Research Institute, Hokkaido Research Organization

Abstract: Meeting wood demands with increasing human population and consumption is a pressing conservation issue, and is often framed as a choice between land sparing and land sharing. Although most empirical studies comparing the efficacy of land sparing and sharing supported land sparing, land sharing may be more efficient if its performance is tested by rigorous experimental design and habitat structures providing crucial resources for various species—keystone structures—are clearly involved. Landscape planning how to integrate land sparing and sharing is also an important but open question.

We launched a manipulative experiment to retain naturally regenerated broad-leaved trees when harvesting conifer plantations in central Hokkaido, northern Japan. We surveyed birds in harvested treatments, unharvested plantation controls and natural forest references one-year before the harvest and for three consecutive post-harvest years. Results showed that retaining some broad-leaved trees increased total abundance of forest birds over the harvest rotation cycle (i.e., before and after harvesting). Retaining a small amount of broad-leaved trees (20-30 broad-leaved trees per ha) may be a cost-effective on-site conservation approach for the management of conifer plantations.

We conducted a simulation experiment to inform retention forestry applied to tree plantations in the landscape. Landscape comprised natural habitat, unimproved matrix and improved matrix, which are equivalent to natural forests, intensively managed plantations, and extensively managed plantations (plantations with retained trees), respectively. We examined matrix effects on regional populations across a gradient of habitat loss and fragmentation by integrating demographic processes and movement modeling based on circuit theory. Results showed that matrix improvement aimed at increasing movement survival will likely bring large conservation benefits. Buffering and connecting habitat remnants with improved matrix could provide benefits as long as movement survival is increased. Simultaneous implementation of habitat management and matrix improvement would yield synergistic conservation benefits.

We propose that retaining native regenerating trees in plantations can be a useful option, and can be incorporated into management systems using certification schemes and best management practices. The approach of retention forestry as land sharing can be integrated with land sparing to efficiently reconcile wood production and biodiversity conservation in the landscape.

Habitats complexity and biodiversity indicators in beech forests with different management systems in the Italian Apennines

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Davide Travaglini[1]
Francesco Parisi[2, 3], Cristina Vettori[1, 4], Cesare Garosi[1], Gugliemo Londi[5], Donatella Paffetti[1]

[5] Dream Italia, Arezzo, Italy

Abstract: Forest management is a primary driver of habitats complexity and may impact or enhance forest biodiversity based on the applied management practices. In this study we compared biodiversity indicators in high beech (*Fagus sylvatica* L.) forests in the Tuscan Apennines (central Italy) managed with different sylvicultural systems.
The work was carried out in five study areas: three even-aged stands of about 10, 60, and 100 years old managed with the uniform shelterwood system, one uneven-aged stand managed with the single tree selection systems, and one unmanaged stand (old-growth forest). In each area, field works were carried out in a plot of 2500 m^2 (50 x 50 m). In each plot, we collected data to derive biodiversity indicators related to stand structure, deadwood, tree-related microhabitats, beetles and birds. For each area, we analyzed the stand structural attributes, deadwood characteristics and microhabitats occurrence, evaluating their role on the abundance, distribution and diversification of saproxylic and non saproxylic beetles and bird fauna.
Our results show that silvicultural practices have led to a simplification of the forest complexity in managed sites compared to the old-growth site, both in terms of structural heterogeneity, amount of deadwood, relative diversity of microhabitats and abundance of beetles and birds. However, in the managed stands, despite being affected by anthropic disturbance, species included in the Italian Red List were 36% of whole beetle communities. Furthermore, two species were in the Habitats Directive: *Morimus asper* (Cerambycidae) and *Lucanus cervus* (Lucanidae). In the old-growth stand, the discovery of the black woodpecker (*Dryocopus martius*) and crested tit (*Lophophanes cristatus*) was of particular ecological value.
Our findings provide a better knowledge of the influence of forest management on biodiversity, providing a contribution to develop management practices useful to combine forest production and biodiversity conservation in montane beech forests.
The study was carried out within the LIFE SySTEMiC project - LIFE18ENV/IT/000124.

How "close-to-nature" are forest disturbance regimes in managed forests in Germany?

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Kirsten Krüger[1]
Cornelius Senf[1], Rupert Seidl[1, 2]
[1] Technische Universität München
[2] Berchtesgaden National Park

Abstract: Close-to-nature forestry is considered our best option to address the societal demands towards forests while simultaneously safeguarding forest biodiversity and ecosystem functioning. However, close-to-nature forestry in Central Europe has largely focused on stand-level processes while ignoring landscape-scale phenomena such as disturbances. What hinders a current modulation of management after natural disturbance regimes is a lack of quantitative information on disturbances under unmanaged conditions.

At the same time, forest disturbances will amplify in the future under climate change. A central premise of management is that disturbances can be reduced through risk management, yet whether and to what degree unmanaged forests differ in their natural disturbance impacts from managed forests remains unclear.

To tackle this knowledge gap, we investigate disturbance regimes for managed and corresponding unmanaged forests across Germany. We integrate a Landsat derived forest disturbance map, tracking the disturbances of the last decades, with climate and environmental data and compare them between managed and unmanaged forests across different ecoregions.

In order to account for diversity in forest types, management practices and climates, we structurally match Germany-wide unmanaged forest sites (management ceased at least 35 years ago), with multiple comparable managed forest sites. The matching includes site condition (including climate), elevation and forest type to isolate the effect of management.

We ask two questions: (i) are the canopy openings in managed forests within the recent range of natural variability derived from unmanaged forests, and (ii) are natural disturbance impacts higher in managed or unmanaged forests?

The findings bear significant implications for biodiversity conservation, as they explore whether forest management impacts the frequency and size of canopy openings, thereby influencing forest biodiversity in a crucial manner. Furthermore, assessing disturbance impacts in relationship to different management addresses the question of potential co-benefits between climate-adapted forest management and biodiversity conservation.

Influence of green retention trees to growth of pine plantation and environmental factors in hemiboreal forests, Lithuania

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Darius Jurevičius[1]
Vitas Marozas[1]
[1] Vytautas Magnus University Agriculture Academy, Lithuania

Abstract: Green retention trees in pine forests are important for maintaining biodiversity. Retention trees provide shade, shelter, and food for wildlife, and can create a diverse habitat for birds, mammals, and other species. Green retention trees create a microclimate which can also affect the growth of planted seedlings. The aim of this research was to determine the effect of green retention trees on pine plantation growth and environmental factors: soil pH, temperature, humidity, and light conditions. The study was carried out in the south-eastern part of Lithuania in the plantations of pine trees, growing in the clear-cutting areas next to green retention trees. In pine stands in dry, poor sites, where clear cutting was carried out and green retention trees were retained, 50 transects were set up. Parameters of green retention trees were measured; pine plantation growth and growth conditions were assessed. The number of pine saplings was recorded; sapling height and the length of apical shoot were measured. Soil pH, moisture, and temperature were measured with portable "PNT 3000" and "WET" devices, while the light index - with "Hemi View Canopy System". The findings of the research revealed that green retention trees affected the density, height, and length of the apical shoot of nearby growing pine plantations. The impact on soil temperature, moisture, pH, and light was also found.

Influences of stand tending on forest microclimate and woodlice populations in temperate forest ecosystems

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Sanne Verdonck[1, 2]
Yannick De Win[1], Koenraad Van Meerbeek[1], Arno Thomaes[2], Bart Muys[1]
[1] Department of Earth and Environmental Sciences, KU Leuven, Belgium
[2] Forest Ecology and Management, Research Institute for Nature and Forest, Belgium

Abstract: Climate change impacts the health of forests through hotter droughts, resulting in increased tree mortality and decreasing growth trends. To preserve forest ecosystems, climate-smart forest management has been proposed as a drought alleviation strategy, with stand tending, more specifically thinning intensity, as a potential tool. However, the possible negative effects of thinning on forest microclimate and forest-related biodiversity are often overlooked. Thinning reduces canopy cover, a key driver of the microclimate and climate buffering capacity of a forest. With climate change, the microclimate becomes increasingly important for the survival of forest-related biodiversity. Forest-related species are highly dependent on local microclimate conditions, which are preserved by a closed canopy. Woodlice, for example, require relatively high levels of humidity and often serve as microclimate indicators. Therefore, this study aims to investigate the relationships between thinning intensity, forest microclimate and woodlice populations in pedunculate oak (*Quercus robur* L.) and beech (*Fagus sylvatica* L.) dominated forests in the Brabantse Wouden, Belgium. In this study, we hypothesize that increasing thinning intensity reduces the forest's temperature and humidity buffering capacity due to more open stand conditions, leading to shifts in woodlice communities towards drought-tolerant species. To address these research questions, TMS4-loggers monitored the forest microclimate (temperature and soil moisture) while woodlice populations were caught using pitfall traps during the summer of 2022, characterized by intense droughts. Preliminary results show that when macroclimate temperatures rise, so do microclimate temperatures, but at a slower rate, meaning that higher macroclimate temperatures result in a stronger temperature buffering capacity. Contrary to the scientific consensus, forest stand characteristics and thinning intensity did not seem to significantly affect the temperature buffering capacity. Maximum surface temperatures were found to influence the weighted drought tolerance of woodlice communities with higher temperatures favoring more drought-tolerant species. These findings shed light on the complex relationship between forest management practices and forest microclimate, providing insights to support informed climate-smart forest management strategies. It emphasizes that forest managers, when deciding on the intensity of their stand interventions, should not only consider tree growth but also other ecosystem functions, such as the role of microclimate in maintaining forest biodiversity.

Repeated clear-cutting of boreal forests - a tipping point for forest biodiversity?

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Lisa Fagerli Lunde[1]

Abstract: Boreal forests are important carbon sinks and host a diverse array of species that provide important ecosystem functions. Boreal forests have a long history of intensive forestry, in which even-aged management with clear-cutting has been the dominating harvesting practice for the past 50-80 years. A a second cycle of clear-cutting is emerging, and there is an urgent need to review the effects of repeated clear-cutting events on biodiversity. Clear-cutting has led to reduced numbers of old and large trees, reduced volumes of dead wood of varied decay stages and diameters, and altered physical and chemical compositions of soils. The old-growth boreal forest has been fragmented and considerably reduced. We reviewed short- and long-term (≥50 yrs) effects of clear-cutting on boreal forest biodiversity in four key substrates: living trees, dead wood, ground vegetation and soil. We assessed landscape-level changes (habitat fragmentation and edge effects) on this biodiversity. There is evidence for long-term community changes after clear-cutting for several taxa: epiphytic lichens; saproxylic fungi, bryophytes and insects; epigeic bryophytes; soil snails, bacteria, and ectomycorrhizal fungi. Still, for the majority of taxa, long-term effects of clear-cutting are not well understood. On the landscape level, reduced connectivity to old-growth forests has negative effects on several species of fungi, lichens, bryophytes and insects, notably among red-listed species. Repeated cycles of clear-cutting might pose even stronger pressures on the boreal forest biodiversity due to continued fragmentation of old-growth forests and accumulation of extinction debts. Boreal forest ecosystems have undergone drastic changes over the past century and we fear the breadth of today's forestry practices could push the biodiversity across a tipping point.

Safe operating boundaries for boreal forest harvesting

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Abstract: All human societies and economies are bounded by the limitations of the planet Earth. This scientific fact implies that ecological boundaries set by the biosphere are fixed and not negotiable. Forest ecosystems have a specific capacity to provide ecosystem services and sustain biodiversity, determined by their current state, future environmental conditions (e.g. climate), and future management. Not overshooting this capacity, i.e., keeping the use of forest resources within their ecological boundaries, requires that forest management is conducted in ways and harvesting is kept at levels that allow maintenance of natural capital. A major challenge is to maintain a constant high flow of wood biomass for bioeconomy purposes within ecological boundaries. To this end, management that emulates natural disturbances, such as continuous cover forestry, are potentially useful. In this study, we aimed at defining a safe operating boundary for boreal forest use. We applied forest growth simulation and optimization tools to select management regimes that effectively halt the decline in biodiversity, and eventually allows forest ecosystems to achieve a favourable conservation status at a targeted time. This analysis is carried out in heath forest types using large forest dataset representing central and south boreal regions in Finland. We used the criteria defined in the assessment of threatened habitat types in Finland and defined favourable conservation status being a state where forest habitat types will be removed from the red-list. The results show that if the society wants to keep forest use within the safe boundaries, harvesting levels should be considerably below the maximum economically sustainable roundwood removals. The safe harvesting level and optimal management regimes vary among forest habitat types. However, in addition to forest protection, continuous cover forestry turned out an effective management regime in production forests in mitigating negative forestry effects on biodiversity. These results challenge the society to find sustainable socio-ecological ways of using forest resources.

Species diversity and spatial heterogeneity jointly drive the aboveground biomass in temperate and tropical forests

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Jie Yao[1]

[1] Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Key Laboratory of Forest Ecology and Environment of National Forestry and Grassland Administration

Abstract: The important roles of biodiversity in maintaining ecosystem functioning and stability have been confirmed by a large number of studies. However, most previous biodiversity and ecosystem functioning (BEF) studies have generally been limited to very small spatial grains. Thus, knowledge regarding the biodiversity-ecosystem functioning relationships across spatial scales is lacking. Moreover, the multiscale nature of biodiversity, and specifically β diversity (i.e., spatial heterogeneity in species composition) was still largely missing in BEF studies. Here, using the vegetation and functional trait data collected from four 6-ha forest dynamics plots (FDPs) in temperate and tropical forests in China, we examine the scale-dependent relationships between tree diversity and the aboveground biomass (AGB), as well as the roles of species spatial heterogeneity in determining the AGB. In tropical forest, effect of species richness on AGB decreased with spatial grains, while functional dominance played a dominant role at larger spatial grains. In temperate forest, on the contrary, positive relationship between species richness and AGB occurred at all spatial grains, while roles of functional dominance decreased with spatial grains. β diversity was positively correlated with AGB, but weaker than α diversity in determining AGB. AGB was positively correlated with turnover but negatively correlated with nestedness component. Overall, complementarity and selection effects play dominant role in determining AGB in temperate and tropical forest, respectively. The roles of these underlying mechanisms are more pronounced with increasing spatial scales. β diversity, a hitherto underexplored facet of biodiversity, is likely to increase ecosystem functions by species spatial turnover, and should not be neglected in BEF explorations in the context of multifunctionality across large areas of spaces. Our findings have practical implications for forest management, and demonstrate that biotic heterogeneity plays an important positive role in ecosystem functioning.

Keywords: aboveground biomass (AGB); α- and β diversity; biodiversity-ecosystem functioning (BEF); functional diversity; spatial scales; species diversity

The importance of tree-related structures and tree continuity for biodiversity in boreal forests – how to prioritize forest for set-asides

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Joachim Strengbom[1]
Cedric Åkermark[1], Tyr Nilsson[2], Gustaf Granath[2]
[1] Swedish University of Agricultural Sceinces
[2] Uppsala University

Abstract: Although it is well known that both habitat availability and continuity are important factors in maintaining biodiversity, their relative importance in applied contexts is still unclear. The unclear situation is problematic as it has bearing on which conservation strategy that is optimal when it comes to preservation of forest biodiversity. Is it best to prioritize forest with long tree-continuity as set-asides over forest with shorter tree continuity, irrespectively of their structural richness? The unresolved issue is also highly relevant for the question if continuous-cover forestry is better at preserving biodiversity than stand-replacing clearcut-forestry. To clarify how the diversity of beetles, wood-inhabiting fungi and lichens depend on structural diversity and tree continuity we examined species diversity of these groups in relation to tree-continuity and forest structural diversity (richness and amounts of dead wood and old-growth trees) in north-west Sweden. This region still harbour a large area of forest that never been exposed to clearcut-forestry. Despite their long tree continuity, many of these forest have been exposed to selective logging, and their conservation value is of is debated. In our presentation we will show results demonstration how and why the response to tree continuity and structural diversity differ among species gropes. The results will be discussed in relation to1) how to prioritize among forests that should be exempted from forestry, 2) refine the methods currently used to assess the value of forests, and 3) refine criteria for identifying the most effective trees to leave as retention trees during forest harvesting. Our study contributes to increased sustainability by supporting decisions on which forests should be excluded from forestry and which can be managed, as well as improve guidelines for the retention forestry that is currently practiced, and the one that needs to be developed as alternative forestry practices, such as continuous cover forestry become more common in boreal forests.

The management of European forests impacts the resilience of understorey vegetation

Abstract: Ecological resilience is fundamental to maintain forest functions despite global changes. Although understorey hosts most forest plant diversity and is key in forest nutrient cycles and regeneration, its resilience is relatively unexplored.

We analyzed management influence on European forests' understorey resilience, as proxied by functional diversity (FD) and redundancy (FR) calculated on specific leaf area, plant height and seed mass. FD quantifies the complementarity of species responses, FR sustains functions despite species diversity erosion. We used understorey vascular plant species abundances in 2,096 sampling units across Europe, each associated with one silvicultural regime or with unmanaged forests, here used as a reference. We used generalized linear and additive mixed models to respectively assess the effect of different silvicultural regimes on FD and FR, and to explore their reciprocal relationship across silvicultural regimes.

Results indicated that intensive silvicultural regimes influenced understorey resilience by decreasing FD and increasing FR, thus buffering species erosion while jeopardizing the resilience to environmental changes. Low intensity management maintains resilience levels comparable to unmanaged forests, which displayed the best combination of FD and FR. European forests' ecological resilience would benefit from trait-based approaches, pointing to the application of multiple management approaches covering different pathways to ecological resilience.

The scientific support for integrating measures for biodiversity in production forestry

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Lena Gustafsson[1]

[1] Department of Ecology, SLU (Swedish University of Agricultural Sciences). Uppsala. Sweden

Abstract: Integrating nature conservation measures into production forestry is common today in many boreal and temperate countries with a main aim of maintaining and promoting biodiversity. Different forms are practiced from saving parts of the forest, often including border zones, retaining individual trees of presumed habitat value, to maintaining and creating dead wood. Although this integrated approach has been applied in certain forest types and contexts for centuries, large-scale application has expanded greatly in recent decades. A milestone was a scientific framework presented by Jerry Franklin, Univ. of Washington, USA in the late 1980s, based on disturbance ecology. A diverse terminology for the approach has developed since then, including terms such as retention forestry, green-tree retention, and variable retention. A large amount of research has been conducted to evaluate the effectiveness of the various components and several meta-analyses and overviews have been presented. Using boreal Europe as an example, I will summarize the type of research being carried out and evaluate the strength of the evidence base.

The sound of silviculture - Experimental soundscape ecology in temperate forests

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

Abstract: A wide range of forests worldwide are subject to silvicultural interventions. Depending on economic or silvicultural objectives, these interventions are carried out with varying intensity and spatial arrangement. They may also include biodiversity-oriented practices such as deadwood retention. As many species produce sounds or vocalize for communication, the analysis of forest soundscapes is increasingly used for cost-effective biodiversity monitoring. However, a lack of experimental studies has hindered our understanding of vocalizing species communities. Here, we investigate the effects of different well-established silvicultural practices on the soundscape of a temperate production forest in a forest manipulation experiment in central Europe. We performed simultaneous sound recordings in 59 forest plots in the summer before and after silvicultural interventions by recording in intervals of one minute every tenth minute a 24h day. Interventions included logging at different intensities and the creation of standing deadwood, both in two different spatial arrangements (aggregated vs. distributed). The aggregated arrangement resulted in small-scale canopy gaps, while the distributed arrangement maintained closed canopies. From each recording, we calculated four common acoustic indices that well represent different aspects of the soundscape and its biodiversity with indices focusing on sound coverage along the frequency range (Soundscape Saturation), the sound diversity over time (Acoustic Complexity, Entropy of Variance Spectrum) or the pure activity (Events per Second). We used linear models to analyze the impact of logging intensity, spatial arrangement and standing deadwood on the acoustic indices and found differences in the forest soundscapes according to silvicultural interventions, especially when analyzing different intervals of the day separately. Our results suggest that different taxa play a key role in the generation of sounds throughout the day, thus shaping the soundscape response to silvicultural interventions, which highlights the importance of experimental soundscape studies and the focus beyond the dawn chorus. Together with emerging machine learning technologies and algorithms for species identification from sound recordings, experimental soundscape ecology may be another step towards a more precise biodiversity monitoring.

Woody species diversity, composition and vegetation structure in protected and unprotected areas of Chyulu Hills ecosystem in Kenya

T3.32 The scientific basis for how to safeguard biodiversity in production forestry

[3] Department of Wildlife Management, University of Eldoret, P.O. Box 1125-30100, Eldoret, Kenya

Abstract: Chyulu Hills ecosystem is characterized by varying land use (management) schemes based on land tenure system from fully protected Chyulu Hills National Park (CHNP) and Tsavo West National park (TWNP); to Kibwezi Forest Reserve (KFR) which permit selective logging; to open areas represented by four community group ranches, Kuku A, Kuku B, Rombo and Imbirikani, where human settlements flourish with uncontrolled grazing, charcoal burning and farming. Few studies have looked at conservation success in protected areas, relative to non-protected areas in Kenya. The aim of this study was to determine whether government protection on forest reserves and national parks has effects on species diversity, composition and vegetation structure as compared to open areas where few restrictions on resource use exist. We hypothesized that heavily protected areas were the best conserved in terms of woody plants species diversity and stand structural characteristics. A total of 70 permanent circular plots were sampled in each of the land use scheme; CHNP, TWNP, KFR, Kuku A, Kuku B, Rombo and Imbirikani using stratified random approach with each plot measuring 17.84 meters in radius which was equivalent to 0.1 ha. All woody plants, both life and dead with a DBH $\geq$ 5 cm were identified, counted and assessed for DBH, height and crown diameter. Data was analysed and means of different variants were determined and compared with ANOVA across different areas. The results revealed that CHNP had the highest individuals' frequency followed by KFR and TWNP, while, Kuku A and Rombo had the least individuals. On floristic composition, genus *Commiphora* followed by *Acacia* were dominant in Kuku A, Rombo and Kuku B ranches; while *Diospyros* was the most common in Imbrikani, KFR and CHNP. In terms of diversity, TWNP had the highest followed by Kuku B and A while Imbirikani had the least diversity. This study concludes that protection does not influence the plants diversity of an area but affects the floral composition and vegetation structure.

Key Words: species diversity, composition, vegetation structure, protected, unprotected, Chyulu

T3.33 Top five business and policy innovation challenges to accelerate landscape restoration as a nature-based solution

Assessing multifunctionality and climate smartness of restored landscapes

T3.33 Top five business and policy innovation challenges to accelerate landscape restoration as a nature-based solution

[2] International Centre of Insect Physiology and Ecology

Abstract: Integrated implementation of various land management options is the key for successful land restoration programs. Integrated sustainable land management practices could improve land restoration success and enhance multiple ecosystem services generated by the landscape. Implementation of land and water management options at landscape level can cause tradeoffs due to conflicting land uses and varying needs of land users. It is thus essential to assess the climate-smartness of those landscapes in order to sustain the benefits associated with the management practices. We used various in-situ data, empirical and the Integrated Valuation of Ecosystem Services and Trade-offs models to assess the multifunctionality of landscapes and evaluate the associated benefits enjoyed in selected landscapes of Ethiopia. We employed a climate smartness landscape index to determine the climate-smartness of those landscapes by integrating multifunctional services provided by the landscapes due to the various interventions. We obtained a positive change in multiple ecosystem services due to land restoration efforts in four watersheds in Ethiopia. The result is substantiated by both modelling results and in-situ observation data. Even though the land management activities conducted in the study watersheds broughted a positive impacts, the optimal scenario shows that there are still opportunities to further enhance the magnitude and multifunctionalities of ecosystem services that would be obtained in the optimal land management scenario. All watersheds analyzed in this study showed climate smartness at the landscape level, with some level of difference among them. Gudoberet and Aba Gerima watersheds showed more climate smartness than the Anjeni and Debre Mewi. The study shows that investigating the multiple functions of more than five ecosystem services can be designated as multifunctional landscapes.

Can gender-conscious business models in large scale restoration address gender gaps and provide fair incentives to women?

T3.33 Top five business and policy innovation challenges to accelerate landscape restoration as a nature-based solution

Kalpana Giri[1]
Rene Zamora[1], Maria Ines Miranda[2], Jean Marie Ntakirutimana[1], Viktoria Elisa Zipper[1]
[1] World Resources Institute
[2] Fair Connections

Abstract: The urgency to deliver restoration solutions demands aggregation and scale. While large-scale restoration offers promising solutions, the pace and scale with which restoration actions are implemented can also deepen inequalities, by structurally bypassing actors such as women who have lesser and limited rights and influence to land and land governance. Compared to men, women in land and land governance tend to have weaker rights, fewer resources, less say in decision-making, fewer positions of authority, less access to justice, and so on. The failure to adequately recognize and account gender gaps and gender inequalities in restoration is likely to create more harm to women, entrench gender gaps to land, finance, and restoration governance, and undermines gender equality. To address gender gaps and inequities in restoration, attention to both financial/non-financial incentives and social norms is needed. Using gender conscious operational practices of restoration businesses in Latin America and Africa, we describe diverse practices that are used to engage and benefit women. Our findings shed insights on the intersection of gender norms, relations of labor, and financial incentives at local and global level, and how these intersections shape the framing, entry-points, and range of benefits that can emerge from restoration. We also discuss the opportunities of using gender conscious models in addressing key land degradation challenges with multiple effects across Initiative 20x20 in Latin America and AFR100 in Africa. We argue that large-scale restoration needs to move beyond the simplistic framing of tree-planting and transaction models of inputs/outputs. We offer some recommendations for equitable transition through restoration.

Capacity building to accelerate landscape restoration

T3.33 Top five business and policy innovation challenges to accelerate landscape restoration as a nature-based solution

Carolina Gallo Granizo[1]
Andrea Romero Montoya[1], Yelena Finegold[1]
[1] Food and Agriculture Organization of the United Nations

Abstract: To support and scale up efforts to prevent, halt and reverse the degradation of ecosystems worldwide, the UN General Assembly proclaimed 2021 – 2030 to be the United Nations Decade on Ecosystem Restoration (UN Decade). One of the main pathways to achieve the mission of the Decade is the development of capacities to empower professionals and institutions involved in the field of restoration to design, implement, monitor and sustain effective restoration initiatives. To that end, UN Decade partners have pursued several efforts including: i) the development of a Capacity, Knowledge and Learning Action Plan for the Decade, as a joint effort of the members of the UN Decade Taskforce on Best Practices, established under the leadership of FAO to enhance knowledge dissemination and capacity development throughout the UN Decade. The plan identifies the gaps where knowledge products or capacity-development initiatives are needed across various stakeholder groups, based on the results from a global capacity needs assessment, a stocktaking of capacity-development initiatives and knowledge products, and several targeted consultations. Based on these efforts, the action plan specifies the terms of reference for eight key capacity- and knowledge-development initiatives, tailored to different stakeholder groups, and aimed to achieve three main objectives: develop individual and organizational capacity across sectors and scales; foster networks, partnerships and collective action mechanisms; and strengthen the enabling environment for ecosystem restoration; and ii) the development of several tools to help stakeholders plan and monitor restoration actions. As part of the UN Decade Monitoring Task Force, platform to report on restoration efforts has been developed. This Framework for Ecosystem Restoration Monitoring (FERM) provides a space for stakeholders to register their restoration projects and best practices and to visualize the geospatial data. Also, the Assessment, Understanding and Reporting Of Restoration Actions (AURORA) is an important tool that directly contributes to the Decade, assissing in the planning and setting up of monitoring systems according to restoration objectives.

FInance and policy challenges of implementing Assisted Natural Regeneration

Abstract: Assisted Natural Regeneration (ANR) of forests has tremendous potential to provide cost-effective socio-economic and environmental benefits for ecosystems and landscapes. But implementation and upscaling of ANR confront many challenges at local, national and global scales. Three regional workshops (Africa, Asia-Pacific, Latin America-Caribbean) led by key stakeholders in the ANR Alliance identified major finance and policy challenges. Legal restrictions on harvesting naturally regenerating trees limit economic benefits and favor tree planting or commercial forestry over management of fallow vegetation or existing secondary forests, even on private land. In many cases, farmers must obtain approval from public forest agencies to harvest trees, requiring high transaction costs. In other cases, naturally growing trees belong to the government and cannot be used by farmers for economic gain. Few countries offer economic incentives, subsidies, technical support, or extension services for implementation of ANR. Investors are generally unaware that assisted natural regeneration can be a highly effective reforestation approach or perceive higher risks than investing in tree planting for carbon storage. Biodiversity benefits of ANR are taking a back seat to carbon storage in the rush toward carbon finance.

These obstacles emerge from a history of economic and land-use policies that favor either commercial forestry or strict conservation of natural forests, relegating natural regeneration to uncertain status and vague definitions. They also stem from outdated agrarian reforms that require clearing land to demonstrate use and obtain land-use rights. Forest regeneration is associated with indigenous and traditional communities' shifting agricultural systems, which are strongly penalized in many countries. Young natural regrowth areas are often viewed as "idle" lands that are not valued or protected. Regenerating forests lack an enabling policy context and are often excluded from reforestation and forest restoration programs. Practice of ANR is further disincentivized by conflicting policies across agriculture, forestry, and conservation sectors.

Pathways that enable ANR implementation include cross-sector collaboration and policy alignment, communicating knowledge on the benefits and feasibility of ANR in specific restoration contexts,

providing technical support for farmers and land managers, and designing economic incentives that value naturally regenerating forest ecosystems and their sustainable management.

My Farm Trees, implementing a blockchain enabled digital platform for farmer led restoration

T3.33 Top five business and policy innovation challenges to accelerate landscape restoration as a nature-based solution

Chris Kettle[1]
[1] Alliance of Bioversity International and CIAT, CGIAR

Abstract: My Farm Trees is a revolutionary digital platform to catalyze change in the way restoration is implemented with smallholder farms. It aims to improve the tracking of seed material, empower rural entrepreneurship and enhance value chains around nature-based solutions. We will present lessons learnt from the pilot phase of this GEF funded, IUCN Implemented and Alliance of Bioversity and CIAT CGIAR project executed in Cameroon and Kenya. We present the platform, farmers perspectives, barriers to adoption and scaling solutions that will help to catalyze restoration action that delivers local needs, and global impact.

Promoting the inclusion of youth in landscape governance and restoration: experience of the Latin American Model Forest Network

T3.33 Top five business and policy innovation challenges to accelerate landscape restoration as a nature-based solution

Natalia Ruiz-Guevara[1]
Leonardo Duran Gárate[1, 2], Max Yamauchi[1], Leslie Morrison[1], Cristina Vidal[1], **Juan Pablo Rodríguez Garavito**[1]
[1] Red Latinoamericana de Bosques Modelo
[2] Universidad Mayor de Chile

Abstract: The Latin American Model Forest Network (RLABM) links 35 territories in 15 countries of Latin America and the Caribbean. Model Forests (MF) are multi-stakeholder territorial governance platforms in forest landscapes. In mid-2020, the RLABM identified the need to promote the inclusion of youth.

Through an online survey applied to MF representatives in 11 countries (17 adults and 45 youth) and interviews with 06 youth leaders, we obtained information on topics of interest related to landscape restoration and management, as well as forms of organization, patterns of representation and local leadership, and willingness to networking. Subsequently, the first virtual meeting of RLABM youth was organized, which included 04 sessions for the exchange of experiences led by young people and reflections on three key themes: innovation, sustainability and organization for change. Seventy young people from 13 countries participated, in gender parity.

The results showed that the empowerment of the youth of the MFs and the promotion of their initiatives is a priority. For capacity building, the thematic priorities cover different dimensions of ecological and productive landscape restoration, such as productive diversification, ecosystem and biodiversity restoration and conservation, local enterprise management, technological innovation, knowledge management, organization and leadership. Other priorities are to strengthen and provide institutional support to their organizations, guarantee their participation in decision-making, articulate them in networks, promote decent employment opportunities and access to seed financing for local enterprises.

Based on these results, since 2021 RLABM has focused its efforts on empowering young people for their inclusion in governance and landscape restoration processes. The main strategy has been to generate instances for the exchange and development of training activities whose curricula are based on the identified priorities. Both strategies have involved 232 young people from 18 countries.

For RLABM, young people are the driving force for change and sustainability, and for this reason, in the medium term, it is expected to give continuity to the training processes for youth leadership in the region, and to strengthen instances of dialogue and collective construction to address the challenges of landscape restoration in Latin America.

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Breeding Melia volkensii for Improved Commercial Forestry in Drylands of Kenya: Plus Tree Selection, Seed Orchards and Progeny Trials Establishment

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Jason Kariuki[1]
Hisaya Miyashita[2], Valentor Okul[1], James Ndufa[1]
[1] Kenya Forestry Research Institute (KEFRI), P. O Box 20412, Nairobi, Kenya
[2] Forest Tree Breeding Centre, Japan

Abstract: *Melia volkensii* is a fast growing drought tolerant and termite resistant tree occurring naturally in drylands of Kenya. The species produces high quality mahogany-grade timber that is harvested in 10-12 years. Overharvesting of trees of good form over time has resulted in reduction in quality of remnant populations. A Melia breeding strategy was initiated in 2010 with the aim of improving adaptability, productivity and timber quality. Main activities included: selection of Candidate Plus trees (CPTs), collection of scions and grafting, and establishment of clonal seed orchards. One hundred CPTs were selected between 2010 and 2012 in an 800-km range extending from northern to the Kenyan coast. Two 11-Ha first generation clonal seed orchards were established in 2012. In 2015, seed was collected from the orchards and seedlings raised to establish 8 progeny trials in various sites. Objectives of the progeny trials were to: Test the genetic worth of the CPTs; rank the parent trees based on performance of their progenies; and estimate heritability of traits assessed. Height, diameter at breast height (DBH), tree form and fecundity were assessed bi-annually from planting and annually from 5 years. Five-year family mean height range at different sites was 5.7 to 9.6 m (Marimanti), 4.2 to 9.9 m (Tiva), 4.1 m to 9.1 m (Kibwezi), and 5.4 m to 9.2 m at Kasigau. Mean family DBH was 11.7cm (Marimanti), 12.9cm (Tiva), 11.9 cm (Kibwezi), and 10.9 cm (Kasigau). Ranking showed the best families were CPTs 43, 26, 53 and 49. Family heritability was moderate, 0.48 for height and 0.32 for DBH, suggesting a potential for transmitting desirable characteristics to operational commercial plantations. Progeny of 76 out of 100 CPTs showed a positive General Combining Ability (GCA) for both height and DBH. Gains of 16% in volume were obtained by rogueing first generation orchard using Progeny trial results. Using forward selection, four hundred 2nd generation trees have been selected from the progeny trials. Establishment of second generation clonal seed orchards has been done for provision of further improved seed for commercial forestry in the drylands.

CLONAL TEAK BASED AGROFORESTY SYSTEM FOR CARBON SEQUESTRATION AND FOOD SECURITY

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Widiyatno Widiyatno[1]
[1] Laboratory of Silviculture and Agroforestry, Faculty of Forestry, Universitas Gadjah Mada, INDONESIA

Abstract: Teak (*Tectona grandis* L.f) is one of dominated species in the lowland plantation monsoon forest in Java Island Indonesia covering more than 1,2 million ha. Increasing teak forest productivity could be established through clonal forestry as a result of tree breeding producing selected clones with mean annual diameter increment > 2 cm/years. The total carbon sequestration of clonal teak at 8 year and 20 years is 116 C tons/ha (1,100 individuals/ha), and 205 C ton/ha (416 individuals/ha), respectively. Clonal teak plantation in Java is mainly planted as agroforestry system combining with food crops, i.e., upland paddy and corn. In the early clonal teak plantation, upland paddy corn under clonal teak plantation produces 5 tons/ha and 6.5 tons/ha, respectively. It suggested that clonal teak plantation-based agroforestry system could increase the carbon stored in the forest plantation and food security as climate change mitigation for reducing emission and sustainable forest ecosystem.

Comprehensive insights in lignified-callus and wound-induced adventitious rooting in ancient Platycladus orientalis

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Ermei Chang[1]
Jianfeng Liu[1], Yao Dong[1], Zirui Jia[1], Zeping Jiang[1]
[1] Chinese Academy of Forestry

Abstract: Stem cuttings of endangered ancient *Platycladus orientalis* are high fidelity genetic resource for cryopreservation and propagation. However, low tendency of adventitious roots (AR) formation adversely affects regeneration. In this study, we explored causes of decline in AR formation in *P. orientalis* cuttings (5-, 100-, and 700-year-old) at different stages (S1-S3) and possible solutions. Proteomic analysis revealed upregulation of flavonoid and phenylpropanoid associated proteins including chalcone synthase (CHS), chalcone isomerase (CHI) and flavonone-3-hydroxylase (F3H), and down regulation of auxin transport associated proteins such as BIG and auxin responsive (AIR12) at S3 stage in cuttings of 700-year-old *P. orientalis* donors. Biochemical analysis confirmed over-accumulation of flavonoids, phenolics and lignin resulted in callus-lignification and halt in AR formation in cuttings of 100- and 700-year-old donors. Notably, wounding of lignified-callus significantly increased AR formation in cuttings of 100-year-old donors. Meristematic cells regulatory proteins including enolase (ENO) and elongation factor 1α (EF1α) involved in carbohydrate metabolism, and vitamin B6 biosynthesis proteins including pyridoxine synthase (PDX1) and aldehyde oxidase (PDXK) promote AR formation in lignified-callus on wounding of cuttings of 100-year-old donors. Our results revealed that lignification of callus inhibited, while wounding induced AR formation in cuttings of ancient *P. orientalis*. This study is expected to provide a theoretical basis for improving the rooting rate and shorten the rooting time of ancient *P. orientalis* and other difficult-to-root species cuttings.

Cooperative Pinus Improvement Program in Brazil for wood and resin production: Current results

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Ananda Virginia De Aguiar[1]

[6] Consultant

Abstract: *Pinus* is the second forest genus most commercially planted in Brazil. The principal economic products generated from these plantations are wood and resin. Its wood is widely used in furniture, cellulose, and paper production, civil construction industries, among other applications. The resin is applied in solvents, paints, varnish and adhesives industries, pharmaceuticals and cleaning products. Brazil is among the largest producers of sawn wood and resin in the world. In view of its economic importance, a cooperative project for genetic improvement of pine trees (PCMP), in Brazil, was created in a joint effort between Embrapa Florestas, Associação Catarinense de Empresas Florestais (ACR) and Associação Paranaense de Empresas de Base Florestal (APRE). Ten companies participate in the project with the aim of developing pine seeds and clones that exhibit high productivity and quality in both wood and resin. Selection strategies adopted include mass selection, intrapopulation recurrent selection and recurrent reciprocal selection. As a means of reducing the period of generation cycles and maximizing genetic gains over time, we resort to cloning, top-grafting, somatic embryogenesis and genomic wide selection. The preliminary findings of the PCMP include: generation of a germplasm bank of selected trees based on strict criteria regarding the shape of the stem and crown, resin production and characteristics of wood quality and resin, designated to compose breeding populations and improved seed orchards; establishment of clonal seed orchards of *P. taeda*, *P. elliottii*, *P. patula* and *P. elliottii* x *P. caribaea* hybrids; installation of a network of test of progeny and stands of *P. taeda*, *P. patula* and hybrids, with materials selected from commercial stands and also in first generation of progeny tests; obtaining strobili at early age (three years old) for some selected genotypes; advance in development of somatic embryogenesis protocols for *P. taeda*, hybrids and *P. elliottii*; interspecific hybrid seeds of *Pinus* spp. production;ongoing controlled pollination activities among tested materials; technicians and students training in the processes of grafting, controlled pollination and evaluation of parent trees. The collaboration between research institutions, universities, and affiliated companies has been the primary strength of this program.

Delineation of seed transfer zone for Pinus densiflora and its application to climate change

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Yeongkon Woo[1, 2]
Kyungmi Lee[1], **Kyu-Suk Kang**[2]
[1] National Institute of Forest Science, Department of Forest Bioresources, Republic of Korea
[2] Seoul National University, Department of Agriculture, Forestry and Bioresources, Republic of Korea

Abstract: The seed transfer zone is an area where plants can be transferred with minimal risk of maladaptation. Establishing appropriate seed transfer zone plays an important role in promoting forest health and productivity. Rapid climate change may affect seed transfer zone and lead to maladaptation of forest tree species, so it is essential to consider climate change when establishing seed transfer zone. In this study, in order to estimate the seed transfer zone of Korean red pine (*Pinus densiflora*), transfer functions were generated based on the growth characteristics of 36 provenances in 10 test sites and six bioclimatic variables selected by correlation analysis. Based on the transfer function, critical seed transfer distance for each climatic factor was calculated and plotted on the map, and the seed transfer zone was determined by overlaying the maps for all climatic factors. Using this method of establishing the seed transfer zone, we examined how seed transfer zone would change under different climate change scenarios. The results show that the seed distribution zones of Korean red pine vary considerably depending on the climate change scenarios.

[4] Researcher of Embrapa Forestry, Estrada da Ribeira km 111, Colombo – PR.

Abstract: The species of the *Pinus* genus were introduced into commercial plantations in the South and Southeast regions of Brazil, driven by fund incentives from 1960 onwards. With the advancement of research and the creation of forest tree breeding programs, trees were selected to establish seed orchards for wood and resin production. The proposal aims to characterize the resin production in an untested clonal seed orchard of *Pinus elliottii* var. densa, with the purpose of identifying the clones with lower productivity to establish technical criteria for proper orchard management. Additionally, it aims to enable seed collection to validate overall productivity. The untested clonal orchard was established in 1986 in the Assis State Forest, São Paulo, Brazil. The grafted propagules are from resin-selected trees, with an intensity of 1:100,000. The spacing between clones is 6 x 6 meters, comprising 600 trees. The traditional method, consisting of 18-centimeter-wide panels with 23 streaks, was used for resin tapping. The resin production evaluation was conducted through three harvests between October 2020 and September 2021. Descriptive statistics were analyzed using the Selegen-REML/BLUP program. The average resin production for the three harvests was 2.04 kg, 2.27 kg, and 2.94 kg, with an overall average of 7.25 kg. The average resin per streak was 0.31 kg. Approximately 50 trees had a total resin production in the range of 10 kg, indicating a good average production for this species. The variation coefficients were of 39%, 36%, and 32% for the three collects of resin tapping, respectively. The correlation between resin collects and resin total production ranks was 0.80 for the first and second collections, and 0.75 for the third collection. Furthermore, the correlation between total resin tapping and the amount of resin per streak was 0.92. The most productive trees maintained their productive performances throughout the year. The obtained results will be considered for the management of the clonal seed orchard, to realize controlled pollinations, and seed and propagules collections to establish progeny and clonal tests.

Effect of different pretreatment techniques on the germination of Vitex keniensis

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Millicent Jepchumba[1]
Bernard Kamondo[1], Eugene Ojuku[1], James Kimondo[1]
[1] KENYA FORESTRY RESEARCH INSTITUTE (KEFRI), PO BOX 20412 – 00200 NAIROBI

Abstract: *Vitex keniensis* (Meru oak) is an economically important species in Kenya due to its durable wood and desirable grain. The species is also a documented source of edible indigenous fruits with the potential for juice and jam production. However, the increase in the overuse of forestland has resulted in the major loss of its natural habitat. Additionally, the seeds have continually yielded poor germination, making their propagation difficult. These events have resulted in the species being rare and endangered, despite its potential for diverse use in the production of wood and non-wood forest products. The current study aimed at determining the requirements for breaking seed dormancy. Fresh matured seeds were obtained from a seed stand and pretreated by nicking the seeds, and a combination of nicking and soaking them in cold water and potassium nitrate for varying amounts of time. The study also involved pretreatments on dried seeds. The results showed that the pretreatments varied statistically ($P>.001$) for germination capacity for the dry seeds. The viability of fresh seed was 52%, which improved to 62% when soaked in water for 48 hours. The dry seed had a viability of 42% whereas nicking with a combination of soaking in cold water for 48 hours improved the germination of the dry seeds to 60%. This, therefore, indicates the importance of pretreating the species before sowing to obtain optimum germination.

Effects of pre-treatment and substrate on germination and growth of Neocarya macrophylla Sabine

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Antoine Sambou[1]
[1] Assane Seck University of Ziguinchor

Abstract: Neocarya macrophylla Sabine is a species that plays an important role in providing ecosystem services. Despite its importance, the diversity and density of N. macrophylla stands have declined sharply as a result of natural and anthropogenic factors. A better understanding of N. macrophylla seedling production techniques is needed for effective reforestation. The aim of this study was to evaluate the effects of pre-treatment and substrates on germination and growth of N. macrophylla. To do this, a completely randomised design with three replications and twelve elementary plots of nine sheaths was set up. Three factors were studied: provenance (Enampore and M'lomp), pre-treatment (crushing and non-crushing) and substrate (cow and SONACOS manures and control). Seed characteristics, germination, growth parameters (height, diameter, number of leaves and lateral roots and length of main root) and dry biomass were measured or counted. The results showed that seed size and weight varied significantly ($pv<0.0005$) according to provenance. Seeds from Enampore were longer (3.41±0.04 cm), wider (2.89±0.03 cm) and heavier (16.15±0.32 g) than those from M'lomp. Pre-treatment significantly influenced ($pv<0.05$) germination rate and duration. Crushed seeds had the best germination rate (43.27±5.19%) and germinated much faster (26.23±1.61 days) than non-crushed seeds. The substrate had a significant influence on growth parameters and biomass. SONACOS manure favoured growth in height (8.92±0.17 cm), diameter (0.072±0.01 cm), number of leaves (10.05±0.18) and biomass (1.80±0.20 g). Leaves (2.03±0.16 g) and roots (2.10±0.16 g) produced more biomass than stems (0.69±0.05 g). Roots (64.88±2.15%) and stems (66.47±2.01%) recorded more moisture. SONACOS and cow manures gave the best performance for Neocarya macrophylla seedlings.

Effects of sowing conditions in the germination of Eucalyptus seed

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Bernard Kamondo[1]
Eugene Olung'ati[1], Millicent Jepchumba[1], Simon Kahwai[1], Lydia Ikhibali[1], Allan Wafula[1], Dennis Lemaiyien[1], Ruth Tsuwi[1], Irene Gakere[1]
[1] Kenya Forestry Research Institute

Abstract: A number of eucalypts are some of the most demanded commercial forestry species for forest products due to their favorable growth habit, quick maturity, and coppicing ability. *Eucalyptus grandis* and *Eucalyptus saligna* are the most popular species in Kenya. Production of seed of the two species in the country is faced with the challenge of separating seed from chaff and currently seed is availed to users as semi-processed with seed mixed with chaff. The germination potential of the two species is based, and reported on the number of seedlings on a weight basis rather than on germination percentage. The number of resultant seedlings varies greatly when seed is sown in different media and environments with most seedlings realized when seed is sown in the laboratory. This study set to develop techniques to enhance the number of seedlings produced when seed is sown with sand as germination media in the glasshouse. Semi-processed seeds of *Eucalyptus grandis* and *Eucalyptus saligna* were sown using three regimes. In the glasshouse, seed (0.1 g) was sown in 4 replicates at two depths (top-sowing, and 5-mm deep furrow) and subjected to two watering techniques; through the use of misting sprayer and watering can. In the lab, the same quantity of seed and replicates was sown on 1% agar. Top sowing and misting technique realized on average 4,800 and 3,800 seedlings of *E. saligna* and *E. grandis*, while furrow and water can technique realized an average of 2,500 and 2100 seedlings for *E. saligna* and *E. grandis* respectively. Comparatively, germination in the lab with agar resulted in an average of, 7,500 for *E.saligna* and 5,100 for *E.grandis*. The number of seedlings in the treatments varied statistically ($p<.001$). Tree nurseries raising eucalyptus seedlings in glasshouses using sand as a germination media would enhance the number of seedlings raised from a given weight of seed for the two eucalyptus species by adopting top-sowing and misting as a watering technique.

Establishment of Seed Orchard in Cambodia

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Kimsrim SEAB[1]
[1] Vice Chief of Provincial Department of Agriculture, Forestry and Fisheries, Siem Reap

Abstract: Since 2016, the Institute of Forest and Wildlife and Research and Development of the Forestry Administration, Ministry of Agriculture, Forestry and Fisheries, Cambodia with collaboration of the Asian Forest Cooperation Organization are conducting research on seed orchard establishment for three native species namely 1. *Dalbergia conchinchinensis,* 2. *Pterocarpus macrocarpus,* and 3. *Dipterocarpus intricatus.* It is a ten-year project from 2016 to 2025 and aiming for implementing a long term tree breeding plan and strengthening the tree breeding capabilities of the young forestry administration officials. Thus, the implementing team has established a 24 hectars of progeny test plantation and 6 hectars of clonal and seedling seed orchard of the target species for selection of the good seed from well-performanted plus trees. The seeds and scions were collected from a one hundred native plus tree each species in the forests located in 11 provinces in Cambodia. The seedlings from seeds were planted in the progeny test plantation randomly, while the seedlings producing from scions using grafting technique were planted in the clonal seed orchard chronollogically. Pararelly, one of the major activities is to produce a mask production of seedling of the tree species from a tissue culture. laboratorian has trialed varios media for growing the seedling from tissue. It is also a part of capacity building of the young forester who are joining in the project. Moreover, the project provided supports to the university students in conducting research for undergaduated research thesis and supported field study visits for exploring varios forest restoration techniques, landscape restoration as well as the ground activities of the project. Furthermore, there are training local and international program provided for strenthening the capacity of the project staff and young forestry officials. All in all, it is a first research project ever in Cambodia to has a seed orhcard establishment. Resulting for considering as a model for further researching in the near future.

Fertility Variation and Gene Diversity in Forest Populations

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Kyu-Suk Kang[1]
Nebi Bilir[2], Koeun Jeon[1], Yeji Kim[1]
[1] Seoul National University
[2] Isparta University of Applied Sciences

Abstract: Fertility variation, defined as a difference of the ability to give progeny (i.e. reproductive success) among individuals, was reviewed by related available theoretical and practical literature to contribute, and to improve future studies on the subject. Fertility variation is a useful tool for different purposes such as gene conservation, seed production programs, managing forest genetic resources (i.e., seed sources), and evolutional and physiological study. Many papers and proceeding were published in theoretically or practically, or both on fertility variation to be improved it in last two decades. We reviewed the literature combined our own unpublished knowledge to examine fertility variation and its linkage parameters. Fertility variation and their related parameters (i.e., gene diversity, status number, effective number of parents, parental-balance curves) estimated based on reproductive characters is easy, cheap and light surveys used for different purposes in plant science for many years. It is getting importance and using widely because of these advantages, improved from paper to paper. While many research papers were published on fertility variation and linkage parameters recently, a review paper has not been published. So, a review on fertility variation and gene diversity in forest populations is presented int the session as a guide for future studies.

Flowering abundance is related to phenology of Norway spruce clones in clonal seed orchards

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Darius Danusevicius[1]
Darius Raudonius[1]
[1] Faculty of Forest Science and Ecology, Agricultural Academy, Vytautas Magnus university

Abstract: We studied the abundance of male/female flowering together with development stage of male, female and vegetative buds in a 10-year-old Norway spruce clonal seed orchard in central Lithuania. The clones originate from forward selection in field tests from ca. 20-year-old ortets. We studied 50 clones with ca. 10 ramets each during spring 2022 and 2023. The results showed that clones from north-eastern Lithuania started active growth and developed the male and female much earlier than the clones from other parts of Lithuania. There was significant non-overlapping of flowering between clones from different parts of Lithuania. Interestingly, the north-eastern clones had markedly less generative flowers than the remaining clones, some of them none. In spring 2022, no radiation frosts occurred in May. Our results indicate that phenology of the clones plays an important role during the process of bud differentiation in July of the previous year. In this way phenology may be associated with cone yield of Norway spruce clones in seed orchards.

Forecasting seed production in perennial plants: identifying challenges and charting a path forward

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Valentin Journé
Andrew Hacket-Pain[1], Iris Oberklammer[2], Mario B. Persendorfer[2], Michał Bogdziewicz[3]
[1] Department of Geography and Planning, School of Environmental Sciences, University of Liverpool
[2] Institute of Forest Ecology, Department of Forest and Soil Sciences, University of Natural Resources and Life Sciences
[3] Forest Biology Center, Faculty of Biology, Adam Mickiewicz University

Abstract: Interannual variability of seed production, known as masting, has far-reaching ecological impacts including effects on forest regeneration and the population dynamics of seed consumers. Because the relative timing of management and conservation efforts in ecosystems dominated by masting species often determines their success, there is a need to study masting mechanisms and develop forecasting tools for seed production. Here, we aim to establish seed production forecasting as a new branch of the discipline. We evaluate the predictive capabilities of three models (foreMast, ΔT, and a sequential model) designed to predict seed production in trees using a pan-European dataset of *Fagus sylvatica* seed production. The models are moderately successful in recreating seed production dynamics. The availability of high-quality data on prior seed production improved the sequential model's predictive power, suggesting that effective seed production monitoring methods are crucial for creating forecasting tools. In terms of extreme events, the models are better at predicting crop failures than bumper crops, likely because the factors preventing seed production are better understood than the processes leading to large reproductive events. Understanding the drivers of seed production is crucial for ensuring the availability of reproductive material in the future. We summarize the current challenges and provide a roadmap to help advance the discipline and encourage the further development of mast forecasting.

FOREST TREE BREEDING IN MALAYSIA

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Mohd Zaki Abdullah[1]
Nor Fadilah Wook[1], Farah Fazwa Md Ariff[1]
[1] Forestry Biotechnology Division, Forest Research Institute Malaysia, 52109 Kepong, Selangor, Malaysia

Abstract: Forest plantation in Malaysia has encountered various challenges and the main problems being lack of superior planting materials and poor soil quality. The application of biotechnology in tree breeding such as the use of tissue culture, temporary immersion system as well as molecular breeding have greatly improved both the availability and quality of planting materials for establishment of forest plantations. This paper aims to provide information on forest tree breeding efforts in Malaysia with particular examples of R&D conducted by Forest Research Institute Malaysia (FRIM) since the 1950s. As the sole research institution responsible for conducting R&D in breeding of forest tree species, FRIM has vast experiences in conducting breeding trials which include selection of improved plant materials, establishment of clonal trial plots and monitoring of growth. In addition, breeding of plantation species that are resistance towards diseases have also been carried out.

Genetic improvement of Gmelina arborea for increased tree productivity in Kenya

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Oliviah Nyaundi[1]
Stephen Omondi[2], Asenath Adienge[2], Stanley Nadir[1]
[1] Kenya Forestry Research Institute, Coast Eco- Region Research Programme- Gede
[2] Kenya Forestry Research Institute, Central Highlands Eco-Region Research Programme- Muguga

Abstract: In Kenya, *G. arborea* is one of the major exotic timber tree species in which is also used for wood carving due to its good workability qualities. Despite its numerous and wide range of products and ecosystem services, the high potentiality and maximum utility of Gmelina tree has not been met. Most trees in Kenya are slightly crooked with heavy and low branching characteristics while some have been attacked by pests and diseases lowering timber quality and quantity on sawing while limiting the productivity on other wood products hence the need for this study. This study is being conducted to genetically improve the tree species focusing on biomass production, fast growth rate, tree form and, freedom from pests and diseases. The improvement strategy has encompassed; testing of the phenotypically selected CPTs through progeny trials and establishment of seed orchards for improved seed production. Both the single tree and comparison tree methods were used for selection of *G. arborea* CPTs. In comparison tree method, candidate trees were first selected and screened for desirable traits in relation to the five surrounding trees referred to as comparison trees. Where the candidate tree exceeded the mean of the neighboring comparison trees, it was selected as a candidate plus tree. Preliminary findings have yielded selection of One hundred and twenty-six (126) CPTs from Kwale, Kilifi, Lake Victoria Basin, Kitui, Makueni and Elgeyo Marakwet counties covering 28 Gmelina population stands. Six F1 clonal seed orchards and two progeny trials have established in Arabuko Sokoke Forest, Kerio Valley, Siaya and Homabay. CAMCORE provenance/progeny trials have been set up in Gede and Migori to evaluate for survival and height performance of individuals within the families. Annual assessments are ongoing and data analysis so far has indicated significant variations between and within the families in the two traits at 48 months. The interim assessment of different individuals indicated large genetic improvement possibilities of *G. arborea* in Kenya.

Key words: *G. arborea*; improvement; breeding; productivity; Kenya

Genetic parameters of Pinus caribaea var. bahamensis in an open-pollinated orchard in the municipality of Assisi, São Paulo

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Abstract: Tropical species such as P. caribaea var. bahamensis have relevance for the productivity of the country in tropical regions due to its adaptability to climatic conditions. This work proposed the characterization of the heritability and genetic gain of a test of provenance and open pollination progeny of P. caribaea var. bahamensis with the purpose of selecting the most productive progenies in wood production for future breeding programs. The test was implemented in March 1988 in the Assis State Forest (22º35'S and 50º22'W), in a randomized complete block design, with 72 progenies, one plant per plot, and 28 repetitions with 6 x 6 m spacing. The Selegen - REML/BLUP program was used for statistical analysis. Among the silvicultural characters analyzed for average heritability we highlight the wood volume and the diameter breast height (DBH), presenting indexes of 0.75 and 0.64, respectively. The genetic gain for wood varied from 0.79% to 28.48% and genetic diversity ranged from 0.01% to 1%. The number of individuals ranged from 14 to 986 plants, in four selection methods with 6 intensities. Heritability values for volume and DBH showed a strong indication of genetic gain. The selection proposal that showed the best genetic gain is the individual selection (28.48%) with the selection intensity of 2% and the number of selected individuals is 22 plants. The proposal that showed the best genetic diversity was the selection within progeny (ranging from 0.98 to 1.00), with a number of individuals ranging in selection from 72 to 986 plants. The selection methods mentioned are satisfactory because they demonstrate possible genetic gains and help in the choice of material for genetic improvement programs for wood production.

Genetic Qualities, Cold Hardiness, and Performance Evaluation of Locally Collected Lodgepole Pine Seeds from Stands of Seed Orchard Material in Sweden

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Johan Kroon[1, 2]
Ulfstand Wennström[3], Mari Suontama[3]
[1] The Forestry Research Institute of Sweden, Skogforsk, Svalöv, Sweden
[2] Department of Forestry and Wood Technology, Linnaeus University, Växjö, Sweden
[3] The Forestry Research Institute of Sweden, Skogforsk, Sävar, Sweden

Abstract: Lodgepole pine (*Pinus contorta*; LP) has become the dominant non-native tree species in Swedish forests. Forest regeneration with LP offers an efficient method for boosting forest production in northern Sweden.

The utilization of seed collections from practical plantations offers a low-intensity approach to capitalize on the improved traits resulting from initial plus-tree selection. To address an acute seed shortage, extensive stand seed collections have been conducted in Swedish LP plantations (F1 generation, seed orchard offspring's) that have been in operation for approximately 30-35 years. This study aimed to assess the genetic qualities, for particularly cold hardiness and growth traits, of such stand collected seeds in comparison to known Swedish and Canadian seed sources. The analysis included plant material from commercially collected stands, the seed orchards, and the original seed sources in Canada, in comparison with Scots pine (*Pinus sylvestris*; SP) seed sources. The freezing test results revealed that the stand-level collected seeds in Sweden exhibited comparable cold hardiness to the plantation-sourced seeds. Latitude of the collection site emerged as the most influential factor impacting cold hardiness. Furthermore, the study investigated potential differences in field test results between stand collected seeds and seed orchard derived progenies, as well as the influence of different seed sources on estimated variation and heritability. The findings contribute valuable information on genetic gain, genotype-environment interaction, transfer effects, and grouping in the breeding evaluation system. This research provides crucial insights into the quantification of disparities in growth, survival, and resistance between improved and unimproved material. The comparison between LP and SP, as well as the results obtained, hold significance for estimating genetic gain.

LP is advantageous for breeding strategies due to its early flowering, capability for rooting cuttings, and suitability for clone testing and rapid generation turnover. In the late 1970s, Sweden initiated a seed orchard program to ensure self-sufficiency in genetically superior LP material. The program involved plus tree selection in Canada, genetic testing of open-pollinated families in Swedish field trials, and establishment of seedling seed orchards for genetic enhancement.

Genetic Selection Using Linear Deployment for the 2nd Generation Seed Orchards of Quercus acuta and Q. glauca

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Ye-Ji Kim[1]
Koeun Jeon[1], Kyu-Suk Kang[1]
[1] Department of Agriculture, Forestry and Bioresources, Seoul National University, 08826 Seoul, Korea

Abstract: The impact of climate change is causing a gradual northward shift in the distribution of warm-temperate tree species. To address this phenomenon, the Korea Forest Service is actively improving growth characteristics of *Quercus acuta* and *Q. glauca*, focusing on their high carbon absorption and adaptability to climate-induced stress. Seedling groups were propagated in 2022 at Jinju and Naju nurseries in South Korea, intended for establishing new seed orchards on Jeju Island. This study conducted genetic selection using linear deployment on the seedling groups of both species. Breeding values were calculated for mother trees in the base populations, considering biomass and seed production. The mean of initial breeding value was 2 and the standard deviation was 0.76 for *Q. acuta* base population and the mean was 2 and the standard deviation was 0.81 for *Q. glauca*. Three scenarios were simulated: 1) selecting all mother trees except for the lowest breeding value, reducing selection intensity by 10%; 2) selecting 34 and 50 mother trees in *Q. acuta* and *Q. glauca*, reducing selection intensity by 10%; and 3) selecting 34 and 50 mother trees in *Q. acuta* and *Q. glauca*, adjusting selection intensity based on seed orchard size and tree spacing. As the results, under the first scenario, when 50% of the seedlings were selected from the total, the selection difference was 0.343, the status number was 101.1, and the number of seedlings was 753 for *Q. acuta*. For *Q. glauca*, under the second scenario, when 50% of 50 mother trees' seedlings were selected, the selection difference was 1.067, the status number was 120.7 and the number of seedlings was 1070, which the selection difference was compared to 1.7 times for the first scenario as the same number of seedlings. Finally, if we create a 2-ha seed orchard for each species, *Q. acuta* has a selection difference of 0.315 and the status number of 104.0, while *Q. glauca* has 1.084 and 118.7, respectively. This study would provide valuable information for establishing genetically improved populations and contribute to enhancing carbon sequestration in forestry.

Genetic testing in a Larix kaempferi plantation using pedigree reconstruction and spatial analysis

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Kyungmi Lee[1]
In-Sik Kim[1], **Kyu-Suk Kang**[2]
[1] National Institute of Forest Science
[2] Seoul National University

Abstract: Genetic testing and selection for diameter growth in a Larix kaempferi plantation were conducted through the integration of pedigree reconstruction and spatial analysis. This study aimed to identify genetically superior larch individuals in a plantation as an alternative to progeny trial. Genetic variation assessment was precedently conducted to validate the suitability as breeding material. Genetic testing followed with a model incorporating pedigree information and spatial autoregression for accurate analysis. As results, the expected heterozygosity for mother trees and offspring was 0.672 and 0.681 respectively showing the retention of considerable genetic variation in the offspring. 188 offspring were assigned to 92 candidate mothers and one to six progenies were belonged to each family. Genetic testing employing the model considering phenotypic spatial autoregression structure improved model fitness compared to the result using model without spatial factor. The estimated genetic variance for diameter at breast height (DBH) was 9.086 in the former model, highly increased from 4.9E-5 in the latter model. Predicted breeding values for DBH ranged from -5.937 cm to 5.655 cm and the estimated heritability was 0.344. The genetic testing combining pedigree reconstruction and spatial analysis is expected to be an effective alternative to traditional progeny trials. It can facilitate the identification and selection of superior individuals for tree improvement purposes. The approach utilizing genetics and spatial information also would be useful to enhance the efficiency and accuracy of breeding program.

Genetic Variation of Cone and Seed Characteristics in the Second-Generation Clonal Seed Orchard of Pinus densiflora

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Koeun Jeon[1]
Ye-Ji Kim[1], Kyu-Suk Kang[1]
[1] Department of Agriculture, Forestry and Bioresources, Seoul National University, Seoul 08826, Republic of Korea

Abstract: This study aims to investigate genetic variation in phenotypic characteristics of seed cones and identify superior clones for seed production in a second-generation clonal seed orchard of *Pinus densiflora*. The seed orchard was established in 2014 in Chuncheon, Republic of Korea, and comprised grafted seedlings re-selected through a progeny test. A total of 42 clones and 1,300 ramets were sampled, and cones were collected from them during the years 2020, 2021, and 2022. Various cone characteristics, including weight, length, width, dry weight, seed potential, aborted ovules, filled seeds, and empty seeds were examined. Analysis of variance (ANOVA) was performed to assess genetic variation and estimate heritability, as well as to conduct correlation analysis among clonal cone characteristics. As a result, there were significant differences among clones in relation to all cone characteristics. The heritability of filled seed production was estimated as 0.667, 0.927 and 0.757 for the years 2020, 2021 and 2022, respectively. Statistically significant variations were observed among clones in all cone features, except for the year 2020 due to a high rate of cone insect damage. Furthermore, correlations among cone and seed characteristics were identified, particularly between filled seed rate and mature seed rate, length, weight and dry weight ($p<0.0001$) in 2020, 2021 and 2022. This study provides genetic insights into the impact of clonal variation on seed production and emphasizes its significance in seed orchard management, along with genetic thinning and selective seed harvest based on phenotype, besides the selection of superior clones for establishing a third-generation seed orchard.

High stand density improves seed production in seed orchards of the masting species Picea abies

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Curt Almqvist[1]
[1] Skogforsk (The Forestry Research Institute of Sweden)

Abstract: Masting or mast seeding is the phenomena of synchronous and highly variable seed production between years by populations of conifers and other perennial plants. Examples of economic important tree species besides *Picea abies* is *Quercus robur*, *Fagus sylvatica*, *Picea glauca*, *Pinus nigra* and *Castanea sativa*. The physiological mechanisms and how they are linked to internal resource status and to external weather factors are still under scientific exploration and debate. Masting behaviour can be difficult to manage in the production of improved seed in seed orchards. Short term results may lead to incorrect conclusions. Here, results from a long-term thinning experiment in a *Picea abies* seed orchard will be presented.

How useful are the acorn resources? Quantifying the plant-available carbon in acorns using achlorophyllous oaks

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Anna Monrad Jensen[1]
Helle Jakobe Martens[2], Karolina Pehrson[1]
[1] Department of Forestry and Wood Technology, Linnaeus University, Lückligs plats 1, 351 95 Växjö, Sweden
[2] Department of Geosciences and Natural Resource Management Faculty of Science, Rolighedsvej 23, 1958 Frederiksberg C, Denmark

Abstract: Seed size is an important phenotypic trait commonly associated with the overall fitness of young seedlings. However, determining the actual plant-available resources provided by the seed is difficult. We utilize a one-of-a-kind natural mutation that has created a population of achlorophyllous oaks (*Quercus robur* (L.)), plants without chlorophyll, to quantify the plant-available carbon in the acorns. The achlorophyllous oak population was discovered in spring 2022 in an 80-year-old Q. robur forest in southern Sweden. Growth and survival were measured in the achlorophyllous oak population, as well as a normal green (chlorophyllous) oak population. The two populations were followed from germination until all achlorophyllous seedlings had died. Interestingly, the achlorophyllous oaks survived almost a year on the acorn resource. By comparison, 76% of the normal green oaks survived the first year. The photosynthetic capacity was similar across the growth season for both the achlorophyllous and chlorophyllous oaks. For the achlorophyllous oaks, we were unable at any time to detect any carbon uptake, whereas the chlorophyllous oaks had a maximum photosynthetic capacity (A_{max}) averaging around 3-7 mmol m^{-2} s^{-1}. Leaf area-based day-time respiration was similar for both achlorophyllous and chlorophyllous seedlings. However, the leaves of achlorophyllous oaks were significantly thinner. The number of leaves, leaf area, and seedling height were similar between the white and green oaks, indicating similar seedling carbon investment independent of chlorophyll content and photosynthetic capacity. Our findings suggest that the acorn provides the young seedling with sufficient resources for growth and maintenance respiration in the first year, independent of photosynthesis. We are also modeling the total amount of carbon used by the seedlings, and thus the total amount of plant-available carbon in the acorns.

Identification and selection of individuals as seed sources for the restoration of the tropical dry forest in the Upper Magdalena River Basin

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Laura Camilla Flórez[1]
Norma Constanza Liz Rojas[1], Jennifer Lorena López Hoyos[2], Diana Carolina Vásquez Castro[1], Juan Carlos Villalba Malaver[3]

[2] University of Valle
[3] Université de Bordeaux, INRAE - BIOGECO

Abstract: The tropical dry forests (TDFs) of Colombia have experienced a significant reduction in their original area due to human activity. Ecological restoration processes for TDFs have been developed with different strategies for the recovery of this ecosystem, one of which is the use of seed sources. Currently, there is a loss of tree individuals of native species, which leads to a reduction in seed sources and a decrease in the obtainment, quality, and availability of plant material that plays an important role in conserving genetic diversity and species adaptability in restoration projects. To address these challenges, a study will be carried out in the Huila Department, specifically in the environmental compensation zone of the El Quimbo Hydroelectric Plant, from July to December 2023. The objective of the study is to identify and select individuals with optimal phenotypic characteristics to classify them as seed sources, thus meeting the demand for forest seeds required to continue these restoration processes. The methodology to be used is based on previous studies conducted in this area, which provide information about existing seed sources in the project. Additionally, an increase in tree individuals with favorable characteristics for native seed production will be carried out. Physical, physiological, and sanitary analyses of the seeds will be conducted according to International Standards for native seeds in Ecological Restoration, adapted to the protocols of the ISTA (International Seed Testing Association). It is estimated that this research will result in native tree species adapted to environmental variables, pests, and diseases, contributing to the growth of forest genetic diversity and the availability of propagation material. Furthermore, it aims to contribute to Colombia's National Restoration Plan by providing relevant information for the recovery of Tropical Dry Forests.

Identifying and using a minicore PSR gene cluster to assess phosphate nutrition in plants and soils

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Guo Meina[1]
Niu Shihui[1], Han Fangxu[1], Ruan Wenyuan[2]
[1] College of Biological Sciences and Technology, Beijing Forestry University, Beijing 100083, PR China
[2] Key Laboratory of Plant Nutrition and Fertilizer, Ministry of Agriculture, Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences, Beijing 100081, China

Abstract: Adequate phosphate (Pi) nutrition is essential for plant growth and development. However, it remains a challenge to effectively assess whether the corresponding Pi status in plants and/or soils is appropriate for a given plant. Here, we show that Pi status in plants and soils can be assessed by a minicore phosphate starvation response (PSR) gene cluster (MCPG). The MCPG cluster is isolated from the common PSR genes in Chinese pine, Arabidopsis, maize, rice, soybean, and wheat by RNA-sequencing analysis. Moreover, we find that the MCPG cluster is conserved across species and is controlled by the Pi-central regulators of PHRs-SPXs. Furthermore, we find that the expression levels of the MCPG cluster are negatively correlated with Pi status in plants and soils. Based on this correlation, we developed a PCR method for the successful and standardized assessment of Pi status in plants and soils worldwide. Taken together, this study highlights the importance of MCPG cluster in response to Pi status and provides an effective molecular diagnostic method for estimating Pi status in plants and soils, which will be useful in guiding future precise applications of Pi fertilizers.

Influence of cone physical characteristics and extraction exposure period on seed yield of Pinus patula

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Alice Adongo Onyango[1, 2]

[1] Department of Natural Resources Management, Egerton University, Kenya
[2] Kenya Forestry Research Institute, Kenya

Abstract: *Pinus patula* is one of the serotinous coniferous species whose cone opening for seed release is influenced by temperature. This study examines the correlation between extraction exposure periods and cone physical characteristics on *P. patula* seed yield. Systematic random sampling was employed for tree identification in an even-aged clonal seed orchard, and the laboratory phase was laid down as a factorial experiment with two factors: cone physical characteristics and extraction exposure period at three levels. Seed counts were taken for cones categorized as; heavy, light, narrow, and wide at three extraction exposure periods 6 hours, 12 hours, and 24 hours in a constant oven temperature of 65°C. The experiment had 12 (L1, H1, N1, W1, L2, H2, N2, W2, L3, H3, N3, W3) treatments with 60 cones per treatment. The time spent counting and returning cones during the inter-stage observation ranged from 10 to 15 minutes. Data collected were tabulated and means analyzed using ANOVA with results generated as per the objectives. The number of seeds released within the hours of exposure was captured as the seed extraction rate. The first six hours yielded the optimum number of seeds per cone with the mean highest number of seeds from wide cones. The lowest mean number of seeds released observed was 28, from light cones, while the highest mean number of seeds was observed to be 56 from wide cones. Cone sorting based on size before extraction is recommended for optimized seed yield. The stages of seed extraction employed here can be used in mechanized seed extraction cabinets equipped with timers at controlled temperatures.

Influence of Cupressus lusitanica Mill. Cones and seed characterization on germination in Kenya

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

[1] Rift Valley Ecoregion Research Program Kenya Forestry Research Institute (KEFRI) P.O. Box 382-20203 Londiani, Kenya
[2] Department of Natural Resources Management Faculty of Environment and Resources Development Egerton University P.O. Box 356, Egerton, Kenya
[3] Central Highlands Eco-region Research Program Kenya Forestry Research Institute (KEFRI) P.O. Box 20412-00200 Nairobi, Kenya

Abstract: *Cupressus lusitanica* is a key plantation species with many uses leading to demand for seed. This species produces seeds within cones, which are collected for seed extraction. There are variations in seed collection and handling which compromise quality. Few studies focus on cone morphometry and seed characterization, thereby causing a gap in quality improvement through packaging and subsequent germination. Fifty cones were collected from each of the thirty identified trees within a clonal seed orchard. Cone characterization, seed extraction and germination were performed in the laboratory. This was a factorial experiment with three factors: cone diameter, seed diameter and seed density and their influences on germination. The present study separated the cones by diameter (20mm sieve) and weight. Seed were sieved (2mm sieve) weighed, floated and germinated. The results showed that seed size and density heavily impacted on germination and thereby showing that sorting through sieving and floatation would provide a low cost technique for seed quality improvement. The technique in the present study improved germination from 25% to 50%, and also reduced the number of seeds per kilogram from 290,000 to 105,000.

Macropropagation of Khaya senegalensis (A. Juss): A Vulnerable tree species

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Adejoke Akinyele[1]
Adedolapo Abiola[1]
[1] Department of Forest Production and Products, University of Ibadan, Ibadan, Nigeria

Abstract: *Khaya senegalensis* (Juss). is one of the valuable timber tree species of West Africa which is vulnerable to extinction because of its high demand. The use of growth hormones for mass propagation of tropical tree species has become very important due to scarcity of viable plant materials. This study investigated the effects of organic hormone (coconut water and *Aloe vera*) and inorganic hormone (Naphthalene Acetic Acid (NAA) and Indole Acetic Acid (IAA) at different concentrations) on single stem cuttings of *Khaya senegalensis* (Juss) to ensure availability of quality seedlings for plantation establishment. Leaves of treated cuttings were reduced to half of their sizes to reduce the rate of evapotranspiration. These were set in sterilized riversand and replicated twice with 5 cuttings per replicate, and arranged in a completely randomized design (CRD) under a mist propagator. Untreated cuttings were also included to serve as the control. After 60 days, cuttings were assessed for number of roots, longest root, total length of root, percentage callusing, percentage sprouting and percentage rooting. The use of organic hormones had no significant effect on the number of roots of *Khaya senegalensis* at $\alpha_{0.05.}$ Organic hormones had a significant effect on root length but coconut water was not significantly different from the control and *Aloe vera*. Effects of inorganic hormones were significantly different from each other with NAA producing the highest number of roots (4.27cm), followed by control (3.5cm) while IAA produced the least (2.33cm). The control recorded 100% callus formation, rooting, sprouting and survival while inorganic hormones had <90% in the variables. Based on the findings of this study, it was concluded that cuttings of *Khaya senegalensis* seedlings could root and sprout with or without hormones. If it is necessary to use hormones, organic hormone, *Aloe vera* gel or coconut water at 100% concentration is recommended.

Mixed mating patterns and pollen introgression in Melia volkensii clonal seed orchard; implication for genetic improvement and germplasm production

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Stephen Omondi
Japhet Rotich[1], Steve Runo[1], So Hanaoka[2], James K. Ndufa[3]
[1] Kenyatta University P.O. Box 43844-00100 Nairobi, Kenya
[2] Shizuoka University 1623-1, Nishifujidaira, Tenryu-ku, Hamamatsu city, Shizuoka, 431-3352, Japan
[3] Kenya Forestry Research Institute P.O Box 20412 Nairobi

Abstract: *Melia volkensii* is a monoecious, insect-pollinated tree species endemic to semi-arid region of east Africa valued for high quality termite resistant timber, however, limited knowledge of its mating patterns is hampering advancement of its genetic improvement in Kenya. We evaluated mating systems, gene flow patterns and level of pollen introgression within *M. volkensii* clonal seed orchard using 12 microsatellite markers. Four hundred and eighty open pollinated progenies from ten clones and 200 potential pollen donors were studied. One hundred individuals representing the total number of clones within the orchard and 128 individuals from the orchard background population were used as the potential source of pollen. We conducted pedigree reconstruction to assign each seed's male parents, followed by determining the extent of pollen contamination, selfing rate, and, parental gametic contribution. High values of multi-locus (t_m = 0.933; 0.016) and single locus (*ts* = 0.919; 0.013) estimates of outcrossing rate indicates presence of mixed mating pattern with predominant outcrossing breeding system. The difference between tm–ts (0.014; 0.027) was low indicating absence of bi-parental inbreeding. Likewise, estimated correlation of paternity (*rp* = 0.029) was low indicating that many of the progenies did not share the same paternal genitors. The fixation index for maternal genotypes (*Fm*) within progenies was non-significantly low showing lack of inbreeding. The estimation of the probable number of pollinators (1/*rp*) indicated that about 69 pollen donors contributed in the fertilization of the progenies. The paternity analysis implicitly assigned 389 out of 471 progenies (82.6%) were assigned to 69 (69%) of the seed orchard clones. The unassigned 82 progenies (17%) did not match any of the 100 seed orchard clones and were considered to be derived from donors outside the orchard. Our findings indicate existence of adequate gene flow within the orchard probably due to predominant out crossing breeding nature and reproductive synchrony among genotypes. The seed orchard design and flowering synchrony with the background population could have contributed to the pollen introgression in the orchard. Review of the current isolation distance between the orchard and the background population should be considered to ensure integrity of the seed source.

Morphometrics of Pinus patula crown and its effect on cone characteristics and seed yield in Kenya

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Peter Murithi Angaine[1]
Alice Adongo Onyango[1, 2], Jesse Owino[1]
[1] Rift Valley Ecoregion Research Program Kenya Forestry Research Institute (KEFRI) P.O. Box 382-20203 Londiani, Kenya
[2] Department of Natural Resources Management Faculty of Environment and Resources Development Egerton University P.O. Box 356, Egerton, Kenya

Abstract: *Pinus patula* like other conifers have cones as an important unit for seed production. Cone production is however not uniform and often varies among compartments and sectors within the crown. This study sought to evaluate within-crown cone production patterns, cone characteristics and seed yield in a *Pinus patula* clonal seed orchard in Londiani, Kenya. Crown height was divided into 3 equal portions and a further subdivision done for each of the portions into 2 sections. From each crown section 10 mature cones were collected to total 60 cones per tree as a sample size. The cones were put in a preheated oven at temperature 65°C for 24 hours to open for seed extraction. This study observed cones collected from the top portion of the crown yielded the highest amount of seed (33.3±4.91 seeds) ($p<0.05$) while the bottom part had the lowest (14.4±2.76) ($p<0.05$). The study recommends collection of *Pinus patula* seeds from the upper part of the crown in unmanaged stands and further recommends that management through pollarding be done regularly to minimize within-crown differences.

Optimizing Genetic Gain and Diversity in Seed Orchards

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Milan Lstiburek[1]
Kyu-Suk Kang[2]
[1] Faculty of Forestry and Wood Sciences, Czech University of Life Sciences Prague, Czech Republic
[2] Department of Forest Sciences, College of Agriculture and Life Sciences, Seoul National University, Republic of Korea

Abstract: In this presentation, we introduce a cutting-edge methodology designed to optimize both genetic gain and diversity in seed orchard crops. Our tool relies on the Mathematical Programming Language (AMPL) capabilities. This innovative system offers several marked improvements over some heuristics currently employed in various tree breeding programs. A significant advantage is the assurance of globally optimal solutions and the elimination of continuous software maintenance. The AMPL system distinguishes itself by separating model and data inputs. This results in a simplified process that enables quick modifications to the model statement, capitalizing on its straightforward algebraic format. Our practical guide details how to seamlessly incorporate genomic data, reproductive biology data, pollen contamination statistics, and other pertinent information into the optimization process. We argue that the ideal solution obtained from our tool should act as a benchmark. This allows tree breeders to compare other potential strategies or assess the efficiency of current seed orchards, all within the context of the comprehensive data available. Our methodology extends its utility to specific applications, such as genetic thinning, supplemental mass pollination, or selective seed harvesting. By employing our algorithm, tree breeders can make these processes more efficient and optimized. We hope this methodology will empower tree breeders to take full advantage of the potential of their programs.

Parental contribution dynamics and seedling cold-hardiness in the Scots pine seed orchard Västerhus

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Abstract: Seed orchards are the most crucial source of genetically improved tree seeds for forestry. Ample yearly flowering of orchard rametes, regular and abundant seed crops, and uniform parental contribution from all orchard genotypes are prerequisites for stable crop production and the economic efficiency of breeding. In reality, variation in flowering is multifaceted, comprising yearly, individual, and age-related variation. Consequently, parental contribution to the crop deviates from the assumptions due to these irregularities and is further complicated by such factors as phenological asynchrony and clone representation. Finally, the inflow of alien pollen into the orchard results in the progeny with unknown genetic background and unpredictable traits. In the present study, we aim to understand the connection between the cone and pollen production within the orchard and the contribution to the crop from the orchard genotypes, calculate background pollen contamination (BPC) rate, and estimate the extent to which affects cold-hardiness of seedlings is affected by the external gene flow. The needle material for DNA extractions was sampled from seedlings (n=927) in the Scots pine orchard Västerhus that was organized following the linear deployment concept of multiplying ramet numbers according to their breeding values. We constructed sequencing libraries from three seed crops using a genotyping-by-sequencing (GBS) strategy and multiple single-nucleotide polymorphisms (SNP) markers to reconstruct parentage. We coupled this data with the pollen and cone records gathered in the orchard to assess the dynamics of clone contribution to the gamete pool in the orchard. Results from freeze tests performed on orchard seedlings were analyzed in order to link the BPC rate and the degree of cold damage among seedlings. The results elucidate the extent of yearly variation in the parental contribution to the crop from the orchard genotypes as well as the link between the unknown genetic background of the crop and the degree of freeze damage and may serve as a reference for orchard management.

Pedigree reconstruction in a black pine half-sib progeny test to assess paternal success and improve breeding efficiency

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Paraskevi Alizoti[1]
Barbara Fussi[2], Irene Stogioudi[1], Nikoleta Diadiasi[1], Monika Konnert[2]
[1] Aristotle University of Thessaloniki, School of Forestry and Natural Environment, Thessaloniki, Greece
[2] AWG - Bayerisches Amt fuer Waldgenetik, Teisendorf, Bayern

Abstract: Wind/Open pollinated (OP) progeny testing is predominant in tree breeding, and particularly in the first breeding cycle, aiming mainly in efficient backward selection or forward selection. The OP families are usually considered and being treated, as half-sib (HS) families, as mother trees are known and the number of pollen donors is considered to be large. However, the half-sibs are only real half-sibs if none of them resulted from selfing and if all of them were sired by different males. But this is seldom the case in OP families, and for this reason the estimates of genetic parameters are biased, leading also to the not accurate ranking of parental trees based on their breeding values. In the current work we performed paternity analysis in an OP progeny test by using microsatellite markers. The progenies originated from a black pine seed orchard established by following the honeycomb experimental design in order to minimize kinship in the produced seed/seedlings. The seed orchard consists of 60 clones originating from the geographic region of Central Macedonia in Greece, while each clone was represented in the orchard by 20 ramets. The results showed that clones differed in their paternal success and some of them scored overall a very high paternal contribution. True half-sibs (HS), full-sibs (FS) and selfs were identified per maternal genotype, but their number varied depending upon the maternal genotype. The results are discussed in terms of breeding efficiency and accurate ranking of parents based on their breeding values for growth traits, as well as in relation to male strobili production of clones and morphological traits of their pollen grains.

Physiological and molecular mechanisms of nitric oxide during seed germination

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Ling Yang[1]
Yue Zhang[1], Ruirui Wang[1], Xiaodong Wang[1], Caihong Zhao[1]
[1] State Key Laboratory of Tree Genetics and Breeding, Northeast Forestry University,China

Abstract: Trees reproduce by producing seeds, and the seed dormancy-germination pro-cess, which initiates the tree life cycle, is crucial for the establishment of seedlings and their ability to survive adverse external environments. Seed germination is of great significance for nursery stock yield. Nitrogen is an essential nutrient for tree growth and development. Reactive ni-trogen species (RNS) have important regulatory functions in tree physiological activ-ities. Recently, nitric oxide (NO) has been shown to not only serve as an important nitrogen source during seed development but also to participate in a variety of stress responses in trees to high salt, drought, and high temperature. In addition, NO can affect the process of seed germination by integrating multiple signaling pathways. However, due to the instability of NO gas activity, the network mechanism for its fine regulation of seed germination remains unclear. Therefore, this abstract aims to summarize the complex anabolic processes of NO in plants, to analyze the interaction mechanisms between NO-triggered signaling pathways and different plant hormones abscisic acid (ABA) and gibberellic acid (GA), ethylene (ET) and reactive oxygen species (ROS) signaling molecules, and to discuss the physiological responses and molecular mechanisms of seeds during the involvement of NO in abiotic stress, so as to provide a reference for solving the problems of seed dormancy release and improving tree stress tolerance.

Physiological process determination and transcriptome analysis during seed germination of moso bamboo

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Juan Li[1]
Chunju Cai[1], Yucong Bai[1], Yali Xie[1], Jian Gao[1]
[1] International Center for Bamboo and Rattan

Abstract: This research explore physiological process of seed germination, the mechanisms in the main pathways during seed germination and the mechanism of gibberellic acid treatment on seed germination, that could be used as the foundation for bamboo seed production, expansion breeding, and research.

In this study, ultrastructural observations and transcriptome data analysis of the germination seeds with and without GA_3 treatment were performed. In addition, the germination-related indicators (germination rate, germination potential, vigor index, respiration rate), total starch content, crude oil content, and enzymes related to respiratory activities of non-treatment seed were measured.

The results indicated that: (1) the optimum seed water content of moso bamboo using different storage times was 12.4%, after moderate drying of fresh seeds, seed water decreased, germination rate increased, respiration rate decreased, and seed vigor increased. However, with the extension of storage time, seed water content decreased, and the seed germination rate, germination potential, and vigor index decreased, seed water content of moso bamboo largely influences vitality index and respiratory; (2) the degradation of carbohydrates including lipid and starch metabolism play an important role in providing energy during seed germination of moso bamboo. Total starch and crude oil decreased and the starch metabolism and the lipid body degradation pathway genes were consistently upregulated during moso bamboo seed germination. AP2 and bHLH proteins were the most common upregulated transcription factors related to seed germination and may play significant roles in seed germination. (3) The low gibberellic acid concentration treatment on germination seed accelerated the decomposition of starch and fat and promoted the vacuole formation of cells, but the high gibberellic acid concentration damaged organelles and increased the endocytosis of cells. After gibberellic acid treatment, GID1 and DELLA-related genes homologous to rice genes is not expressed, but the expression of PIF4, PIF5, GA_3 *ox*2, GA_2*ox*s, etc., were up-regulated.

Regulation of the vegetative to reproductive growth transition in conifers

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production
Shihui Niu[1]
Meina Guo[1], Fangxu Han[1]
[1] College of Biological Sciences and Technology, Beijing Forestry University, Beijing 100083, PR China

Abstract: Conifers are the backbone of forest ecosystems in the Northern Hemisphere and the most widely planted tree species. Coniferous trees usually have a long vegetative growth period, and it takes years or even decades for some trees to enter the reproductive growth phase. There is considerable interest in how perennial trees reckon their growth times and developmental ages and enter the reproductive growth phase at a specific age. This is also a crucial issue for the breeding of trees with long juvenile period. Relative to the thorough understanding of the vegetative phase transition in angiosperms, a little is known about this process in perennial conifers. Based on the high-quality reference genome and annotation of *Pinus tabuliformis* (Chinese pine), we identified *PtDAL1* as an age timer, a MADS domain transcription factor (TF) gene that shows an age-related expression profile. Two regions, a 10.5 kb and a 6 kb segment, at the five-prime end of the first ultra-long intron in the *PtDAL1* showed a gradual reduction of CHG methylation as the age increased, which was highly correlated with its expression profile, suggesting that DNA methylation serves as an important epigenetic signature of developmental age in conifers. In addition, the PtDAL1 directly regulates the *PtDAL10* transcription by binding to its promoter region, resulting in a ternary MADS domain TF complex with PtDAL10 and PtMADS11, two potential candidate regulators of the vegetative to reproductive transition in Chinese pine. We provide insight into the molecular components associated with the PtDAL1, which integrates the vegetative to reproductive phase transition into age-mediated progressive development of the whole plant in conifers. These molecular components associated with the age-dependent cone-setting pathway may be used as a potential genetic tool to shorten the breeding cycle of conifers with a very long vegetative stage.

Reproductive systems for accelerated delivery of genetic gains in important quantitative traits in Acacia crassicarpa.

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Gustavo Martins[1, 2]
Gary Hodge[2], Juan Acosta[2]
[1] April Asia
[2] North Carolina State University

Abstract: *Acacia crassicarpa* A.Cunn. ex Benth. is an important tree species in Asia. Its vigorous growth, disease resistance, and good bole form are valuable features for tropical forestry. Still, there are constraints to maximizing the delivery of genetic gains. Although feasible, controlled pollination is impractical for advancing populations requiring a huge effort to produce a few crosses per year. Vegetative propagation is possible only with juvenile ortets. Finally, there is limited knowledge about its wood properties. This study applied genomics to unveil reproductive systems, reconstruct full-sib families for trial testing, and evaluate the potential of genomic selection to accelerate genetic gains delivery. Additionally, important wood properties were characterized, and within-tree patterns of variation were investigated for efficient phenotyping.

One reproduction season of a seed orchard was characterized by genotyping 84,315 seedlings with forty-two SNP markers. 67.8% of the seed collected was derived from male parents within the orchard. The average number of male parents per family was 50, with the dominant male proportion at 23%. Cumulative combined male-female reproductive success indicated 50% of parents producing 80% of the seed.

Forty trees were selected for destructive sampling at 50 months and assessed for wood density, kraft pulp yield, α-cellulose, carbohydrate composition, lignin content, and S/G ratio. The mean basic density was 481 Kg/m^3, and pulp yield 53.8%. Ground-level sampling could reliably predict the whole-tree property for basic density, pulp yield, and glucose content.

Genetic control of quantitative traits was studied with multi-environmental trials. Growth traits, basic density, and straightness were predominantly additive, with heritability ranging between 0.09 to 0.45. Genetic correlation across sites was high for all traits. Straightness was independent, survival correlated with MAI, and growth traits correlated among themselves. Surprisingly, basic density was correlated with growth. Genomic models with 10 thousand trees outperformed pedigree-based models. Accurate individual selection resulted in valuable gains for all units of selection. The gain from within-family genomic selection was 18%, doubling the gain achieved compared to deployment based on family means.

This comprehensive study provides real answers to the conservation and breeding efforts of *A. crassicarpa,* allowing the maximization of the delivery of genetic gains.

Resin Tapping from Pinus elliottii var. elliottii clones in the state of São Paulo, Brazil

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Abstract: The resin tapping has great economic importance in the forestry industry for the Southern and Southeastern regions of Brazil. *Pinus elliotti var. elliotti* is the most widely planted conifer for resin tapping. This is due to its high productivity and adaptability to different soil and climatic conditions. The aim of this work was to characterize the resin production of an untested clonal seed orchard of *P. elliotti* var. *elliotti* to identify the most productive clones and manage the orchard based on technical criteria. The clonal seed orchard was established in 1984 with grafts from selected resin-tapping trees at an intensity of 1:100,000 in the municipality of Assis in São Paulo State. The orchard has a spacing of 6 x 6 meters and consists of 980 trees. In 2022, resin tapping clones was extracted based on traditional methods with a panel size of 19 cm and 29 streaks. Resin was collected and weighed during the months of March, July, and December of the same year. Statistical analysis was performed using the Selegen-REML/BLUP program. Since the species is not adapted to the planting local soil and climatic conditions, the graft survival rate was 52%. The average total amount of resin was 4.6 kg for the 29 streaks, with an average per collection of 1.55 kg. The maximum and minimum values for each collection ranged from 0.05 kg to 5.77 kg between months. The phenotypic correlation between the average amount of resin per harvest and the total amount was 0.92. The correlation between the total amount and the individual harvests was also high, indicating that the most productive trees maintain their performance throughout the year. In addition to seed, propagule and pollen collection from the grafts that produced above-average resin were harvested to establish clonal and progenies tests. Furthermore, the pollen was used to performance and control pollination. The clone’s productivity was validated based on the genetic tests.

Screening of Salix clones for morpho-physiological and biomass attributes under varying planting density and salt stress

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Sapna Thakur[1]
Manjot Kaur[1], Manpreet Kaur[1], Baljit Singh[1], Sumita Chandel[2], Jai Pal Sharma[3]

Abstract: Global climate change has emphasized on utilizing perennial trees as a renewable source of energy. Genus *Salix* of family salicaceae is a well-known commercially raised short-rotation tree species that has immense utility in sports industry, phytoremediation and biomass production. In India there are about 31 indigenous and 4 exotic species of willow. Identifying high biomass producing clones could promote the use of short rotation high density *Salix* plantations thereby supporting crop diversification, restoration of degraded wastelands, meeting demand of wood based industries as well as enhancing the farmer's income. Keeping in view the economic potential of the species, selected forty two clones of *Salix* were procured from Department of Tree Improvement and Genetic Resources, College of Forestry, UHF, Solan, Himachal Pradesh and screened under nursery conditions in tropical environment, out of which twenty eight clones were evaluated under field conditions. The best performing four clones were established under different planting densities (1 x 1 m, 1 x 2 m and 2 x 2 m) using factorial randomized block design in February 2020 and were evaluated for growth and physiological traits for three consecutive years. Significant effect of different spacings and clones were observed for various growth and physiological parameters except stem straightness. Overall, the spacing of 2 x 2 m has been found to be most suitable for maximizing growth in terms of volume index, irrespective of clones in willow based short rotation forestry. The phytochemical profiling of bark and leaves of the best performing hybrid clones using GC-MS analysis has revealed the presence of various pharmaceutically important phytochemical compounds. Furthermore, the remediation potential of selected *Salix* clones has been evaluated in pot experiment under varied levels of salinity and the promising clone(s) are under field evaluation on problematic soils.

Abstract: Climate change has serious impacts on Austrian forests: not only are the climatic optima and distribution areas of tree species shifting, but extreme climatic events are increasing, leading to destabilization of forests. Reforestation of disturbed areas thus will become one of the key challenges for forestry in Central Europe in the coming decades.
To enable "assisted gene flow", artificial regeneration will become even more important in the future. However, forest nurseries often cannot meet this high demand due to lack of suitable seeds. This is especially the case for oaks and silver firs, whose seeds cannot be stored in the long term, but which are at the same time particularly important for the establishment of climate-resilient forests. Furthermore, in recent years in Austria, decreasing germination percentages and/or harvest failure have been increasingly observed in these species, for which seed demand has steadily increased in recent years. Therefore, it is essential to better understand the physiology of seed production in oak and fir to develop improved management tools to enhance seed production at least in seed orchards. The goal of the project FORSEE is to develop practical concepts for intensifying orchard management to ensure a long-term supply of high-quality forest reproductive material.
Results from manipulation experiments in fir seed orchards will be used to develop treatment procedures regarding fertilization and irrigation as needed for continuous yields. The potential and effects of phytohormone treatments on uniform seed yields in oak plantations will be evaluated. In addition, we present the results for a series of fir and oak seed treatment experiments with the goal to optimize harvest and storage logistics for fir and oak.

Strobili, conelet and cone productions in clonal seed orchards of Anatolian black pine*

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Abstract: Seed orchard is one of the most important seed source to produce improved seed crop for forestry practices for different purposes. Numbers of female and male strobilus, and conelet and one year old cone productions were compared together with estimations of variations among clones within orchard in three clonal seed orchard populations of Anatolian black pine [*Pinus nigra* Arnold. subsp. *pallasiana* (Lamb.) Holmboe] to contribute management practices of seed orchards. The seed orchards consist of 30, 30 and 34 clones selected phenotypically in natural stands 1994 (SO_1), 1991 (SO_2) and 1985 (SO_3), respectively. The reproductive data were collected on five grafts, chosen at random, from each clone.

The orchards produced >80% male strobili than female strobili. Conversion of female strobili to conelet and cone productions was about 50% and 15%. Clones within orchard showed difference for cone productions in all the orchards, while other characteristics changed according to orchards. Many biotic and abiotic factors could impact on the differences. The coefficient of variation ranged from for number of female strobili (36.8% and 29.3%) and cone production (71.9% and 74.1%) in SO_1 and SO_3, respectively. However, the coefficient of variation was between number of conelet (32.4%) and number of male strobili (41.9%) in SO_2.

Positive and significant ($p<0.05$) relations both phenotypic and genetic among the characteristics were estimated generally.

Studies on Dof Transcription Factors from Moso Bamboo (Phyllostrachys edulis) Responding Abiotic Stress and Influencing Flowering Initiation

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

Zhanchao Cheng[1]
Jun Liu[1], Jian Gao[1]
[1] Key Laboratory of National Forestry and Grassland Administration/Beijing for Bamboo & Rattan Science and Technology, International Center for Bamboo and Rattan, Beijing, China

Abstract: Moso bamboo (*Phyllostrachys edulis*) is the most widely distributed and extensive use among the bamboo species, it is one of the dual-use bamboo species that combines economic, ecological, and social benefits. However, moso bamboo collectively die after flowering, causing serious economic losses and ecological damage. Previous studies found that *PheDofs* might be involved in the flowering and abiotic stress response of moso bamboo and has many biological functions, but the mechanism was unclear. Six *PheDofs* genes (*PheDof1*, *PheDof2*, *PheDof4-1*, *PheDof12-1*, *PheDof12-2*, *PheDof26*) were isolated from moso bamboo by molecular biology method, having a conserved single zinc finger domain. *PheDofs* took part in ABA and GA3 stress responses. GUS staining showed that *PheDof4-1* was expressed in the roots and hypocotyls of transgenic *Arabidopsis*, and *PheDof12-1* was detected in the roots, hypocotyls, leaf vascular bundles, stamens, and petals of transgenic plants. Under drought stress, over-expressing *PheDof12-1* transgenic *Arabidopsis* seeds had earlier germination time, faster growth rate and had longer roots than wild type, which increased the drought tolerance of transgenic *Arabidopsis*. Under the condition of 150 mM NaCl, salt stress tolerance of transgenic *Arabidopsis* was enhanced after overexpression of *PheDof26* and RNAi interference. However, antisense expression of *PheDof26* reduced salt stress tolerance in transgenic *Arabidopsis*. Under drought and salt stresses, overexpression of *PheDof4-1* resulted in low germination rate, slow growth and seedling yellowing of transgenic *Arabidopsis*, stress-related genes *CBF2*, *CBF3*, *COR15A*, *KIN1*, *RD22*, *DREB2A*, *ERD10*, and *ZAT12* genes were down-regulated, reducing resistance of transgenic *Arabidopsis*. In contrast, antisense expression of *PheDof4-1* leaded to up-regulation of stress-related genes and increased tolerance to drought stress in transgenic *Arabidopsis*. By yeast two-hybrid library, the resistance-related protein PheeIF5A was initially screened to interact with PheDof4-1. The results of this study provided scientific basis for the research on resistance breeding and molecular regulation mechanism of moso bamboo flowering.

Utilizing an early cone-setting trait to implement a Rapid Cycle Breeding program for Norway spruce.

T3.34 Tree improvement delivery system: breeding, selection, and seed and seedling production

[4] Swedish University of Agricultural Sciences (SLU), Department of Forest Genetics and Plant Physiology, Umeå, Sweden
[5] Umeå University, Department of Plant Physiology, Umeå, Sweden

Abstract: One of the largest challenges facing tree breeding programs is a long juvenile period. In Norway spruce (*Picea abies*), reproductive maturity is not reached until a tree is 20-25 years old. This makes it difficult to produce improved trees that are adaptable, disease/pest resistant, and productive in a rapidly changing climate. Therefore, the most valuable way to make genetic gains that can address these issues would be to reduce generation time.

We recently discovered a natural mutation within a miRNA156/529 binding site of a SQUAMOSA BINDING PROTEIN-LIKE transcription factor (*PaSPL1*). Trees with this mutation display an early cone-setting trait and produce cones and cone-like structures in 3-5 years. Using this trait, we aim to develop a Rapid Cycle Breeding (RCB) program to breed Norway spruce more rapidly and efficiently. Our strategy builds on three pillars that each contribute to a shortened breeding cycle. The first is to use Genomic Selection (GS) to identify genotypes with high breeding values with respect to yield, pest and disease resistance, and climate resilience. The second is to use recent advances in automated micropropagation of somatic embryogenic lines to create clonally propagated breeding lines. The third pillar is to temporarily introduce the early cone-setting trait in selected breeding lines to allow for a rapid transition into the next generation and a renewed round of GS. Our early work towards this started by transforming *PaSPL1* with different mutations in the miRNA156/529 binding site into *Arabidopsis* and *Populus* in order to better understand regulation of *PaSPL1*. We then transformed mutated *PaSPL1* genotypes into Norway spruce cell lines. Once trees are regenerated, we will evaluate early cone-setting and choose which mutated *PaSPL1* genotypes produce the most useful early cone-setting phenotype. Additionally, early cone-setting genotypes will be generated using CRISPR, and non-transgenic protocol using PEG-mediated transfection of protoplasts are also planned.

After the methods are evaluated and efficient protocols have been created, we will mass-propagate elite cell-lines of Norway spruce via somatic embryogenesis. These cell-lines will be transformed with the mutant *PaSPL1* and used in the RCB program. Offspring with mutant copies of *PaSPL1* will be segregated away.

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Actors' perceptions of profitability along a bushmeat commodity chain in West Africa (Southern Benin)

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Fifanou Vodouhe[1]
[1] Laboratory of Economic and Social Dynamics Analysis (LARDES), Faculty of Agronomy, University of Parakou, Benin

Abstract: Bushmeat trade is increasingly viewed as main factors of faunal extinction in Africa. This study aims at providing details on hunters' economic drivers, traders and consumers' behaviour and factors determining trading actors' perception about bushmeat trade sustainability. Data were collected from 120 bushmeat trade actors in southern Benin through direct interviews. Economic and financial indicators were estimated and compared using descriptive statistics. Factors affecting the actors' perception of wild animal hunting, trading or supply sustainability were assessed using binary logit. About 15 wild species were traded along the bushmeat commodity chain in southern Benin. Hunters gross product is higher during the dry season ($t= 10.3; p<0.0001$). The bushmeat trade during intensive hunting period allows traders to earn more commercial margin compared to weak hunting period ($t=12.8; p<0,0001$). Hunting reasons, number of hunters per household, availability of large fauna and bushmeat products selling prices increase actor's perception to continue long-term hunting activities while trading issues and regulatory measures on the wild animal trade decrease actors' perception of bushmeat trade sustainability. Consumers' monthly income and the opportunity to purchase on credit, influence positively their perception of wild animal consumption. Commercial hunting and bushmeat trade offer significant compensation to actors involved in the wild animal commodity chain in southern Benin.

An analysis of the wild meat trade in the Colombian Amazon.

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Luis Fernando Jaramillo Hurtado[1]
Mariela Osorno Muñoz[1]
[1] Instituto Amazónico de Investigaciones Científicas - SINCHI

Abstract: The uncontrolled and increasing commercialization of wild meat has repercussions for the conservation of wildlife and the health of forest ecosystems, as well as the food security of local communities and the cultural connections that indigenous people have with wildlife. In the department of Vaupés in the Colombian Amazon, more than 80% of the population is indigenous belonging to 27 ethnic groups. A great proportion of this population has migrated from the interior of the department to the largest population center and provincial capital Mitú, in search of education, employment, medical services and, in recent years, attracted by state benefits. "San Victorino" is Mitú's main port, where the local populations trade fish, fruits, tubercles, insects, fariña, casabe, and wild meat obtained from the rivers, farms and forests of the region. We present results of a long-term monitoring of the commercialization of wild meat, conducted from September 2017 to date in Mitú. Through this monitoring we were able to identify the species of wild animals involved, the amount traded, and place of harvest. In total, 838 commercialization events were recorded, equivalent to 4,646.92 kg, from 9 taxa, among which the paca (*Cuniculus paca*) was the most traded species, with a volume of 2,503.8 kg, followed by the tapir (*Tapirus terrestris*) with a volume of 1,159.9 kg. Trade of wild meat came from 72 communities that marketed it with different intensity and proportion to satisfy the demand in the urban area. This commercialization situation identified in Mitú is a reflection of the Amazonian context, where commercial hunting to supply urban demand is the main driver for unsustainable overexploitation of wildlife. We discuss strategies to influence a constructive norm-building dialogue between the indigenous and environmental authorities that benefit the conservation of commercialized fauna species in the municipality of Mitú, as well as the greater Colombian Amazon region

Community wildlife management in a RAMSAR wetland in northeastern Colombian Amazon

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Mariela Osorno-Muñoz[1]
Edgar Oleriana[2], Christian Daniel Martinez-Rodriguez[1], Natalia Atuesta-Dimian[1]
[1] Instituto Amazónico de Investigaciones Científicas SINCHI
[2] Mesa Ramsar EFI

Abstract: Community wildlife management in a RAMSAR wetland in northeastern Colombian Amazon.

The reduction of wild species populations due to unsustainable harvesting levels is an acute risk for tropical forest integrity and future livelihood strategies for local communities. We present ongoing collaborative research from the Colombian Amazon department of Guaínia, were we are working with a group of 30 indigenous researchers from different ethnic groups (Curripaco, Puinave, Piapoco, Cubeo, Sikuani and Tucano) in the city of Inírida and in an internationally recognized Ramsar wetland area (complex of wetlands of the Estrella fluvial Inírida) which covers some 250,000 ha. Since 2019, and with the support GEF Heart of the Amazon Project, we evaluate the variety of species and quantities used for food and meat trade. Furthermore, we collect data on the availability of wild populations, to study the extent to which cultural use practices are sustainable and contribute to wildlife preservation. We use daily consumption and sale registration methods and estimate population abundances through linear transects, camera traps and counts by time or distance to compare abundances through catch per unit effort (CPUE). We find that seventy species are consumed, most commonly reptiles (turtles and alligators), and mammals like medium size rodents, peccaries and armadillos. A significant proportion of the volumes traded in Inírida come from areas adjacent to a Ramsar wetland. While the availability of populations is still under evaluation, indigenous researchers, local communities and their authorities are discussing management measures to ensure the viability of the resource in order to guarantee food security, cultural preservation, and maintain legal and sustainable economic alternatives

Do large herbivores enhance soil organic carbon storage and persistence in a temperate lowland forest?

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Joanne O'Keeffe[1]
Jeppe A. Kristensen[2], Dries P.J Kuijper[3], Marcin Churski[3], Lars Vesterdal[1], Carsten W. Müller[1]

[2] School of Geography and the Environment, University of Oxford, Oxford, UK
[3] Mammal Research Institute, Polish Academy of Sciences, Białowieża , Poland

Abstract: Defaunation results in the production of ‘empty forests’, i.e., forests lacking large and medium sized mammal populations. The presence of animals is an integral component to ecosystem functioning of many forests but one important function is often overlooked; soil organic carbon (SOC) storage and persistence. The roles animals play in these processes have been highlighted in recent years making the continued defaunation of forests worldwide a potential source of GHG emission from soils as well as a major adversary of biodiversity. The majority of research into ‘empty forests’ has been carried out in tropical regions and little has been focused belowground, thus, in this study we aim to determine the effects of defaunation on how much and where carbon is stored in soils under an old-growth unmanaged temperate lowland forest in eastern Europe.

Soils were sampled at 15 sites in Białowieża National Park in June 2023 in deciduous and mixed deciduous areas. The sites consisted of an exclosure (7.5m x 7.5m), erected in 2000 to keep out all large fauna, and a nearby unfenced control plot of the same size. Five forest floor and 40cm soil core samples were taken in each exclosure and control. The soil cores were split at 0-5cm, 5-10cm, 10-25cm, and 25-40cm increments. All soil samples (600) were analysed for carbon content, nitrogen content, pH, EC, and bulk density. Forest floor samples (30) were analysed for carbon and nitrogen content. Soil samples were pooled per plot at the four depth increments (150 samples) and subjected to physical soil organic matter (SOM) fractionation yielding a differentiation of particulate OM (POM) and mineral-associated OM (MAOM). Carbon and nitrogen contents were analysed for each of these SOM fractions. We will demonstrate whether large herbivores have a clear effect on the storage of SOM in POM or MAOM, and thus the persistence of SOM.

The results from this study are shedding light on the cascading effects large herbivores have on belowground processes in intact forests. They will also help guide decision making and policies for restoration and rewilding efforts with goals of rehabilitating the GHG mitigation potential of forest ecosystems.

Effects of herbivore exclusion on soil greenhouse gas fluxes and biogeochemistry in the Białowieża forest

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Frederik Philipsen[1]
Joanne O'Keeffe[1], Marcin Churski[2], Dries Kuijper[2], Klaus Larsen[1], Jesper Christiansen[1]
[1] Department of Geosciences and Natural Resource Management, University of Copenhagen, Copenhagen, Denmark
[2] Mammal Research Institute, Polish Academy of Sciences, Waszkiewicza 1, 17-230 Białowieża, Poland

Abstract: Large animals are important for maintaining forest ecosystem functions that sustain biodiversity and carbon storage. Animals mediate fluxes of carbon (C) and nitrogen (N) through effects on plant community structure (e.g. seed-dispersal and changing abiotic conditions) and chemical quality of organic matter entering soils. Forest soils constitute significant C and N pools that are important controls of atmospheric greenhouse gas (GHG) concentrations, but the isolated significance of animals in forest soil biogeochemical cycling is lacking. A better understanding of the faunal dimension of soil biogeochemical cycling and associated GHG fluxes will increase our mechanistic understanding of forests as possible nature-based solutions to climate change mitigation and inform contemporary efforts to (re-)introduce large mammals in so-called trophic rewilding projects.

In this study we show how soil C and N dynamics are influenced by multi-decadal exclusion of large herbivores (European bison, deer species) in the strictly protected zone of Białowieża Primeval Forest in Eastern Poland. By using 30 fenced exclosure plots established in 2000, we investigate changes in soil physicochemical properties and associated soil GHG-fluxes inside and outside of these exclosures. We expect to observe hot spots of soil GHG-flux in soils recently disturbed by large herbivores as a result of lowered soil diffusivity through trampling as well as deposition of labile organic matter through excrement. Furthermore, we expect that sustained long-term animal disturbances increase soil C and N pools as well as their persistence, congruent with expectations of increased aboveground C and N storage.

How is the distribution and diet of a reintroduced population of Crax blumenbachii Spix 1825?

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Maria Paula Miranda Xavier Rufino[1]
Carlos Moreira Miquelino Eleto Torres[1], Lucas Abreu Kerkoff[1], Kesleyane Pereira Camilo[1], Paulo Henrique Villanova[1], Fabiano Rodrigues de Melo[1]
[1] Departamento de Engeharia Florestal, Universidade Federal de Viçosa, Brazil

Abstract: *Crax blumenbachii* is an endemic and endangered cracid from the Atlantic Forest. Reintroduction projects for this species have been taking since the 90's and one of the biggest challenges is the low knowledge about their ecology. Thus, monitor reintroduced populations is an important ally in this process to ensure their conservation. The objective was to evaluate the diet and distribution of a reintroduced population of *Crax blumenbachii* in an Atlantic Forest fragment. The work was conducted at Fazenda Macedônia, in Minas Gerais, Brazil. The 631 ha property was divided into four regions: North, Center, Headquarters and South, and *C. blumenbachii* feces were collected from trails, roads, and built-up areas. Eighteen monthly campaigns were made between 2021 and 2023. The feces were georeferenced, and the seeds were separated, photographed, morphotyped and stored for species identification. 398 feces were collected, and 64.6% were found in the Headquarters, indicating a greater presence of birds. The release of this birds is made out in the Central (18.3%), near to the Headquarters, suggesting the dispersion of birds is relatively close to the point of release. The North (15.8%) and South (1.3%) had fewer records, reinforcing this strong relationship, since the South is farther from release point and Headquarters. 196 feces had seeds in their content and the proportion with seeds was higher in the Central (72.6%), indicating that although the largest number of birds in the Headquarters, they may be feeding on other sources there, such as insects and leaves. 97 species were recorded, and the Headquarters was the one with the highest number (58), probably due the landscaping of this region, which has many fruit trees, some of them from exotic species. Thus, we can state that the reintroduced individuals still have a strong relationship with the release site and the Headquarters, an area that suffers the greatest anthropic intervention, which increases the availability of resources for the reintroduced birds. However, measures, such as avoiding human contact and preventing access to water and food available to captive birds, must be adopted to reduce this dependency and ensure the dispersal of birds throughout the fragment.

Investigating the Relevance of 'Corridors' for Asian Elephant Conservation and Human Elephant Conflict Mitigation

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

[4] University of Ruhuna, Sri Lanka

Abstract: The Asian elephant is one of the few remaining mega-herbivores on the planet, with a habitat that includes grasslands, tropical and deciduous forests, scrublands and cultivated lands in some cases. Due to habitat loss and fragmentation, the species is now classified as Endangered, with a reduction in population size and range. To mitigate the negative impacts of isolation, wildlife corridors have been proposed as an important strategy in conservation, therefore could be important for elephant conservation also. In Asia, elephant corridors have been widely adopted as an elephant conservation and human-elephant conflict management tool.

Sri Lanka holds an important position with regard to Asian elephant conservation and is the range country with the highest density of elephants and the third highest density of humans. The Human Elephant Conflict (HEC) in Sri Lanka is escalating, while the degradation of elephant habitats continues, necessitating active management for conservation and conflict mitigation. A number of elephant corridors at a landscape level have been proposed by the Department of Wildlife Conservation in Sri Lanka mainly for HEC mitigation but have still not been implemented. Other, smaller-scale corridors have been identified on radio tracking data, mainly from an elephant conservation point of view. Therefore, the likely effectiveness of the identified elephant corridors and their role in elephant conservation and mitigating HEC in Sri Lanka needs to be analyzed.

This study is to determine the conformation of identified elephant corridors to the definitions and specifications of wildlife corridors and assess their effectiveness in HEC mitigation and elephant conservation. This will be done using a combination of GIS and field data analysis. The analysis will include the physical characteristics of the corridors and linked areas, the legal status of the corridors, the presence of elephants and the attitudes and perceptions of residents within and around the corridors. Understanding the efficacy of elephant corridors and their relationship with HEC mitigation and elephant conservation will enable the development of effective conservation strategies and sustainable land-use planning in areas where HEC is prevalent, as well as help prioritize management actions and fund allocation.

Mediterranean riparian forests under new biotic interactions: stand structural changes and management implications

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Abstract: Riparian forests are one of most threatened ecosystems in Europe; the exposure to land-use changes and global warming, coupled with new biotic interactions, will contribute to increase biodiversity loss and induce unpredictable structural shifts in the mid-long term. In particular, Mediterranean riparian ecosystems are recently being recolonised by the Eurasian beaver (*Castor fiber* L.). This species is considered an "ecosystem engineer" because it modifies riverscapes by using woody vegetation for feeding and sheltering purposes (e.g., creation of lodges and river dams). In many riverine areas, the impacts of this large rodent on the tree layer can also shape woodlands that are already managed for hydraulic safety issues. We selected a cluster of three rivers to study compositional and structural changes of Mediterranean riparian woodlands under different pressure of beaver gnawing activity. We collected qualitative and quantitative data both at plot and stand level. Our results provide new insights on the topic by integrating information from studies in the Continental and Boreal sites. The main gnawed trees belong to *Salicaceae*, however trees can also be selected depending on the stand structure. Diameter mean of gnawed trees is significantly lower than not gnawed ones. Most of the selected trees fall into low diameter classes (< 15 cm), even if stand tree size distribution affected the diameter preferences. Over 90% of the gnawed trees are entirely harvested, with stumps as remnant elements. Main changes on stand structure are observed in the first ten meters from the river bank; beaver gnawing activity is significantly influenced by the interaction among tree distance from the river and diameter size classes. Structural and biodiversity indices help deepening multi-scale effects (at plot/stand level) of beaver activity. Our approach can be replicated in other Mediterranean sites to predict mid-term riparian forests vegetation changes due to beaver population expansion. Moreover, the collection of standardized data will facilitate dissemination by the scientific community aiming at informing stakeholders on the benefits and possible disservices linked to beavers in riparian forests.

Re-storying forests as animated through foundational fauna

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Andrea Petitt[1]
Harry Fischer[2]
[1] South Asia Institute of Advance Studies, Kathmandu
[2] Swedish University of Agricultural Sciences, Uppsala

Abstract: Once upon a forest the humans came to save

Some species over others, told all how to behave

Restoring a vision based on ideas of the Wild

Sometimes disturbing fauna, not yet reconciled

We can tell a different story, restore something else

Listening to stories deep down in the cells

Re-storying the forest from a different point of view

Including new perspectives that tells us something new

Forest and fauna, two corridors of thought

Emphasis aligning to what we have been taught

Shifting our focus to how they interact

Can break our assumptions but leave our goal intact

As Land is far more than the dirt on which we stand

Including the relationships readily at hand

So is Forest more than what the eye first sees

Have we failed to see the Forest focusing on trees?

It is time that we let trees share the centre-stage

Because a humans and plants entangle and engage

With insects, herbivores, predators and dryads

In what we think of as multispecies triads

Choose a group of humans, an animal and plant

And relations emerge that before seemed rather scant

Re-storying the forest and animate the woods

See the social life beyond services and goods

If cognition is a verb rather than something that 'is had'

Human exceptionalism was nothing but a fad

Cognition of plants might be slow but has been found

Created in interactions with the environment around

Using creative language can help us think anew

Theorize a Forest that we didn't know we knew

Rhyming up our reasons shows us rhizomes of thought

How they're tied to feelings in way that might be fraught

Postscript:

Policy discussions argue that restoring degraded forests can support improved well-being. Yet restoration planning often falls short of this objective. This is, in large part, due to our inability to "tell a better story" that includes relations beyond species dyads. We outline an emerging research agenda for how creative, artistic, and storytelling methods can forge new directions to build richer, place-placed expressions of forest restoration agendas in support a broader vision of multi-species thriving.

Traditional Ecological Knowledge (TEK) for sustaining tropical forest wildlife and local livelihoods.

T3.35 Wildlife use and defaunation in the world's forest - what do we know about its impacts and responses?

Carlos Hernandez-Velez[1]
Torsten Krause[1]
[1] Lund Center for Sustainability Studies (LUCSUS). Lund University. Sweden.

Abstract: Healthy forests are crucial for biodiversity and people. The sustainable use of forest wildlife by local and indigenous communities plays an important role in local social-ecological relationships. Science has only recently started to engage with local indigenous systems of knowledge referred as Traditional Ecological Knowledges (TEK). However, there are several methodological challenges for researchers who seek to integrate different types of knowledge, including TEK, to inform and understand the sustainability of wildlife use in tropical forests areas.

We draw on Participatory Action Research (PAR) and participatory methods with two indigenous communities in the Colombian Amazon region. We present findings on the social-ecological relation of local indigenous hunters in the two study sites and reflect on the role of traditional ecological knowledge in the regulation of wildlife use in tropical forests. Together with local researchers we developed a process of knowledge co-production and created diverse local cartographies containing traditional ecological knowledge on species distribution and social-ecological information. We complemented this data using camera traps, semi structured interviews with wildlife hunters and traditional leaders, drawing on ethnographic methods including participant observations and daily field interactions.We show how the immense knowledge that indigenous communities have of their territory and how the local TEK can contribute to a more sustainable use of wild fauna. We also describe how some drivers in the local context influence and change TEK.

The insights into knowledge coproduction we present, describe how dialogues of knowledge co-production methodologies can inform other initiatives involving TEK and wildlife use in the Amazon region. We present our study in a global context with the interest to connect to other different scenarios where these results can be applied and are looking forward to receive feedback that could enhance our ongoing research process.

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

Bridging actors and institutions in forest resource use and management in the global south: Theorizing on the framework conditions

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

Jude Kimengsi[1, 2]
Lukas Giessen[1]
[1] Chair of Tropical and International Forestry, Faculty of Environmental Sciences, Technische Universität Dresden
[2] Department of Geography, The University of Bamenda

Abstract: The separate treatise of actors on the one hand and institutions in global forest use and management literature represents a yet-to-be-resolved scientific impasse. Consequently, questions related to how actors steer the process of institutional formation and change on the one hand, and how institutions and institutional change plays out on actors on the other hand, remain partially understood in forest management literature. While studies agree on the need to jointly analyze actors and institutions, a comprehensive theoretical proposition which speaks to both actors and institutions is lacking. Yet, theoretical constructs which show actors-institutional interactions and the conditions under which they collectively shape natural resource (forest) management choices demonstrate potentials as an extension of the knowledge frontier in the field of natural resource management. The foregoing lacunae perhaps, explains why policy recommendations are yet to address the natural resource management conundrum in diverse parts of the Global South. A holistic appreciation of forest management processes therefore requires fostering the "marriage" between actors and institutions; that is, determining how institutions set inclusion/exclusion criteria for actors to constrain and/or enhance forest use and management practices, and how actors on the other hand, employ their power elements to enforce, modify, make less effective or redesign institutions in forest management. This paper provides reflections on the tentative conditions/assumptions underlying an actor-cum-institutions theoretical framework in the context of forest use and management in the global south.

Distal flows and distant benefits – the case of tree plantations in North Borneo since 1982

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

Grace Wong[1, 2]
Helena Varkkey[3], Sarah Ali[3], Gordon John[4], Maria Brockhaus[5]

[3] Universiti Malaya, Malaysia
[4] PACOS Trust, Sabah, Malaysia
[5] University of Helsinki, Finland

Abstract: Forest and agricultural spaces in Southeast Asia have been subject to contestation throughout history. Various actors, ranging from local communities and indigenous groups to state actors and multinational corporations, have participated in shaping forest landscapes and determining allocation of resources. The increasing involvement of international actors has introduced new dimensions to these dynamics, influencing the direction and magnitude of change.

One central question is then who are benefitting from former and current dynamics? What and who is enabling such transformations? We argue that any assessment of social and environmental outcomes in forest-agricultural frontiers will require a historic and critical global political economy perspective, as these outcomes are often shaped by distal flows of ideas, commodities and finance, and actors' underlying worldviews and aspirations for development and gain.

Malaysia, and the north Borneo state of Sabah in particular, are not exempt from these changes. Here, tree plantations were seen as a silver bullet to poverty reduction, sustainable development and to meeting global and domestic demands for timber and biomass. Our case study of Peninsular Bengkoka, built on a literature review and interview material, is a region that is still one of the poorest in socio-economic and environmental terms in Malaysia, despite the presence and promises of domestic and international actors and activities. Distal flows are deeply linked to these dynamics.

Shifting cultivation farming practiced by the locals in the Bengkoka Peninsula was deemed "primitive" by the Sabah government, a common colonial trope, and a resettlement and afforestation programme to plant 60,000 ha of *Acacia Mangium* was introduced to the locals in 1982 to encourage "start of a new life". Initial financing came from a World Bank loan, and expertise were provided by the World Bank, Australian and Japanese forestry and development consultants. As of today, plantation management, harvesting and processing is linked to complex and constantly changing public-private corporate structures with diverse flows of financing, including Australian, American and Finnish equity funds with global investors, accompanied by varied sustainability discourses. Yet, such investments have led to territorial exclusion of local land users, as precarity prevails in Peninsular Bengkoka.

Endogenous and exogenous actors in Forest Landscape Restoration: Insight from the Western Highlands of Cameroon

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

Raphael Owusu[1]
Shambhu Charmakar[1]
[1] Forest Institutions and International Development (FIID) research group, Chair of Tropical and International Forestry, Faculty of Environmental Sciences, Technische Universität Dresden, Germany

Abstract: With the heightened global political and scientific interest in restoring degraded forest landscapes, governance issues on Forest Landscape Restoration (FLR) have recently received extensive scientific attention. However, studies on FLR-related exogenous and endogenous actors' interests and the extent to which they shape institutional arrangements are currently unclear, especially in the context of Cameroon. This paper attempts to fill this lacuna by analysing FLR-related actors' interests and how they influence FLR-linked institutional arrangements in rural Cameroon. We used a households survey complemented with expert interviews, key informant interviews, and focus group discussions to obtain data for the study. The analysis of the study's data revealed that endogenous actors show more interest in the cultural, social, and economic benefits of FLR but less interest in the ecological and politically related benefits of FLR than their counterparts. Also, most actors use more dominant information to shape other actors, while incentive measures are less employed. Additionally, dominant information and incentives exerted by actors resulted in full or partial compliance with associated institutional arrangements, while coercive and disincentive measures are linked with non-compliance with the respective institutional arrangements. Therefore, relevant FLR exogenous and endogenous actors should use a combination of dominant information and incentives to motivate compliance with FLR-related institutional arrangements.

Health-shocks and the dynamics of Forest management institutions: a comparative analysis of the Ebola virus and COVID-19 pandemic in Uganda

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

George Acquaah[1]
Jude N. Kimengsi[1], Alice Nakiyemba[2]
[1] 1Forest Institutions and International Development (FIID) Research Group, Chair of Tropical and International Forestry, Faculty of Environmental Sciences, Technische Universität Dresden;
[2] Faculty of Natural Resources and Environmental Sciences, Busitema University, Uganda;

Abstract: The dynamics linked to forest management institutions in sub-Saharan Africa continue to gain scientific and policy traction as indicated by renewed interests triggered by health-related shocks. It is therefore imperative to analyze the institutional change in forest communities within the context of health-related shocks. This paper draws from communities around the Busitema Forest Reserve of Uganda to explore the perceptions of forest users on the triggers of the Ebola virus and the COVID-19 pandemic and discuss forest management institutional responsesrds these health shocks. The paper is informed by field evidence; household surveys (n=135), focus group discussions (n=4) and expert interviews (n=8). The findings reveal that adherence to formal and informal institutions remains high. Furthermore, health-related shocks precipitate institutional change in a bricolage-like process, this manifests through the transposition of existing institutions to new functions, changes in rule application, the introduction of new institutions, and the modification of old ones. However, this study indicates that the scale of disease outbreak determines institutional change; compared to the COVID-19 pandemic, the Ebola virus did not induce substantial forest management institutional changes around the Busitema Forest Reserve. We argue for an actor-driven analytical approach to further enhance our understanding of the dynamics around forest management communities in the context of health-related shocks.

Nongovernmental organizations as interest groups and their roles in policy processes: Insights from Indonesian forest and environmental governance

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

[4] Chair of International and Tropical Forestry, Technische Universität Dresden, Dresden, Germany
[5] Leadership & Policy Innovation Program, The Graduate School, Universitas Gadjah Mada, Yogyakarta, Indonesia

Abstract: The traditional conceptions and claims of nongovernmental organizations (NGOs) have profiled NGOs as civil society representatives and as benevolent philanthropic actors of development in the Global South. However, recent phenomena indicate NGOs often acting in opposition to their benevolent claims. This study attempts to move away from the normative concepts of NGOs and develop an analytical framework fitted with the current empirics in environmental governance. Using theories of organized interest groups in a democratic political system, we analyze the extent of NGOs fulfilling their roles as organized interest groups (OIGs), where they should take roles representing the interests of particular groups within societies and exerting political influence on governments on the basis of these common interests. We use empirics from Indonesian forest and environment-related governance, and our framework is called "Representation–Influence Framework,"which assists in establishing more systematic coherent typologies of OIGs. Analyzed from the perspective that NGOs claim to serve as representatives of specific groups within societies, we establish three overarching categories of OIGs, that is, 1) en route to fulfilling the claim, 2) breaking the claim, and 3) opposing the claim. We further detail our framework into a subset of nine OIG typologies. In this way, we provide pathways to begin deconstructing the common simplifications and misunderstandings about NGOs. For empirics, we identified 38 OIGs in the cases of social forestry and timber legality policies and populated them according to the typologies. We found that most of them are en route to fulfilling the claim of representing the groups' interests, although their political influence on the government is, in most cases, limited.

Power manifestations in forest ecosystem services use and management institutions: Empirical insights from community forests of Nepal

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

Shambhu Charmakar[1]
Lukas Giessen[1]
[1] Chair of Tropical and International Forestry, Faculty of Environmental Sciences, Technische Universität Dresden, Germany

Abstract: Community Forest (CF) has gained momentum worldwide in the last four decades. Studies show that power and institutions are inextricably interwoven. However, the actors' power manifestations in reshaping community forest management institutions persist in fragmented or tacit forms. This paper attempts to fill the gap by responding to the questions: who are the actors and their resources of interest, and how do these actors manifest power to (re)shape forest management institutions in community forests of Nepal, one of the pioneer countries for community-based forest management in the global south. We drew data from the eight CF that were chosen, which represent four different geographic regions of Nepal, by interviewing actors and conducting focus group discussions. The facts acquired from the interviews were supplemented by a review of provincial and federal policies and regulations, the forest management plan and annual report, and meeting minutes connected to the chosen CF.

The preliminary findings show that: i) there were differences in power dynamics among geographic regions concerning interest in specific forest ecosystem services (FES) and forest management outcomes. ii) despite many similarities, the actors differed in their ability to use power resources, such as coercion, (dis)incentives and dominant information to reshape FES management institutions; iii) The powerful actors, such as the government and the CF executive committee manifest all power resources, whereas non-state actors (donors, and civil society organizations) mostly use dominant information and incentives, and market actors manifest incentives; and iv) local actors, with better socio-political positions or networks, economic wellbeing, ethnicity and gender, could navigate and adapt diverse formal and informal institutions and power resources. This paper thus clearly demonstrates how external and elite local actors shape or reshape FES management institutions and outcomes. This paper further suggests the future direction of research and practices to clearly understand the consequences linked to the dynamics of actors' power and promote sustainable FES management in the CF.

Keywords: Community forestry, forest ecosystem services, institutions, power resources, power manifestation

Who should benefit from global forest governance incentives at domestic level? Insights from the Democratic Republic of Congo

T4.1 Actors and the dynamics of forest management institutions: concepts and cases in the Global South

Alexandra Rasoamanana[1]
Max Krott[1], Symphorien Ongolo[1, 2], Eliezer Majambu[3, 4], Moses BIN ALIMASI IMANI MUSSA[5]

[4] Department of Political Science, Official University of Mbujimayi, Democratic Republic of Congo (DRC)
[5] Agronomy Science Institute of Maniema, Democratic Republic of Congo (DRC)

Abstract: State bureaucracies have a dominant position with respect to the ownership of forestland and related resources in the tropics. This situation is one of the major legacies of the colonial period in African countries like the Democratic Republic of Congo, DRC. In those countries, forest-dependent communities struggle to retain the upper hand over the local management of forest resources. These communities have been resisting the marginalization of their rights in autocratic regimes, especially in the context of an increasing assimilation and limited sight of tropical forests as carbon storage and climate change mitigation zones. DRC has about 60% of the Congo basin forest areas (approximatively 100 million ha of rainforests), has been active internationally in claiming compensation in global forest governance arenas to leave its trees stand for climate change mitigation purposes. The debate on the exploitation for development ambitions versus conservation for biodiversity and climate change mitigation has become a fundamental societal battle and sensitive political issue among key actors involved in the governance of forestland resources in DRC. One of the major conflicting political issues in this debate is associated to what should be the most equitable benefit sharing system for the financial rewards expected from global forest governance incentives to keep rainforests standing and forest carbon stored in DRC? Using institutional choice and recognition framework, this paper aims at addressing this question with a specific focus on the challenges in transforming into practice the rhetoric of reducing deforestation through an incentive-based mechanism (REDD+) in the context of institutional weaknesses and social inequality. Our findings show that the REDD+ project has failed to meet the expectations of both the state bureaucracy and the forest dwellers. Both actors deployed cunning and resistance strategies that led to the poor performance of the projects in resisting the top-down approach of REDD+ implementers.

T4.2 Carbon and nutrient cycling in urban forests

Bootstrapping to estimate the variability and uncertainty of equivalent carbon dioxide quantifications

T4.2 Carbon and nutrient cycling in urban forests

Geronimo Quinonez-Barraza[1]
[1] National Institute of Forestry, Agricultural and Livestock Research (Mexico)

Abstract: The carbon forest projects in managed forests are an important opportunity to remove the greenhouse gases of atmosphere through improve forest management. This study utilized the Bootstrapping technique to create multiple resamples by randomly sampling forest inventory plots with replacement. The focus was on quantifying equivalent carbon dioxide. A total of 16,281 sample plots in a forest community covering 28,210.0540 hectares were used for analysis. Different sample sizes were selected, ranging from 100 to 1000 plots in increments of 100, and each sample size was resampled one thousand times. Confidence intervals at 90%, 95%, and 99% levels were computed for population mean and total estimates of equivalent carbon dioxide. By applying Bootstrapping, the distribution of population mean, total estimates, and sampling errors were obtained to assess variability and uncertainty. The statistical distributions followed a normal distribution pattern for various sample sizes. When considering a sample size of 1000 plots, the sampling error for population mean and total were 2.35%, 3.60%, and 4.30% at 90%, 95%, and 99% confidence levels, respectively. The estimated population mean for equivalent carbon dioxide was approximately 218.4087, 218.5257, and 218.3596 tons of CO2e per hectare at 90%, 95%, and 99% confidence levels, respectively. The baseline estimate for equivalent carbon dioxide was 6,161,322.3727 tons CO2e, 6,164,620.4740 tons CO2e, and 6,159,935.8490 tons CO2e at 90%, 95%, and 99% confidence levels, respectively. The results indicated that sample sizes of 400, 600, and 800 plots ensured a sampling error of less than 5% at 90%, 95%, and 99% confidence levels. Therefore, resampling through Bootstrapping proved to be a powerful tool for statistical inference, providing a data-driven approach to estimating uncertainty in the population distribution and determining appropriate sample sizes for carbon inventory in carbon forest projects.

Development of quantitative models to estimate carbon storage and uptake by urban landscape trees in Korea

T4.2 Carbon and nutrient cycling in urban forests

Hye-Mi Park[1]
Hyun-Kil Jo[1], Seong-Gyeong Choi[1]
[1] Dept of Ecological Landscape Architecture Design, Kangwon National University, Chuncheon 24341, South Korea

Abstract: The increasing concentration of CO_2, which negatively affects environmental, social, and economic systems, is a serious challenge globally. Urban landscape trees play a key role as carbon sinks to mitigate climate change. However, there are only few information on the calculation of carbon reduction by urban landscape trees in Korea. The objective of this study was to develop quantitative models to estimate carbon reduction by urban landscape trees using a direct harvesting method. To this end, this study selected 13 tree species, which are commonly planted as urban landscape trees in Korea: *Abies holophylla*, *Acer palmatum*, *Camellia japonica*, *Ginkgo biloba*, *Ilex rotunda*, *Lagerstroemia indica*, *Machilus thunbergii*, *Pinus densiflora*, *P. koraiensis*, *Prunus yedoensis*, *Quercus myrsinaefolia*, *Taxus cuspidata*, and *Zelkova serrata*. A total of 131 trees (10–11 trees for each species) were sampled at a regular interval. These sample trees were dug in the field, and the fresh weights of each part of the trees, such as stem, root, branch, and leaf, were measured. To convert fresh weight of the sample trees to dry weight (hereafter referred to as biomass), the collected specimens of each part were dried in an oven at 85 °C. The ratio of dry weight to fresh weight was calculated to estimate the dry weight for the part and tree total. The biomass was converted to carbon storage by multiplying its value by 50%. The annual carbon uptake was computed by analyzing the radial growth rates of stem diameter at breast height (DBH). Thereafter, quantitative models were derived to easily estimate carbon storage and uptake per tree using the DBH as an independent variable. All the quantitative models exhibited good fitness with high r^2 values. Carbon storage and uptake of the study species and their differences between DBH sizes increased as DBH get larger. This study provided scientific information for urban landscape trees to overcome limitations of the previous studies, which substituted coefficients from forest trees. This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (NRF-2022R1I1A1A01071990).

Effects of species and growing situation for carbon storage in urban trees

T4.2 Carbon and nutrient cycling in urban forests

Anna Levinsson[1]
Henrik Sjöman[1], Tobias Emilsson[1], Johannes Edvardsson[2], Anna Lund[1], Johanna Deak Sjöman[1], Per-Anders Hansson[3]
[1] Department of Landscape Architecture, Planning and Management, Swedish University of Agricultural Sciences
[2] Department of Geology, Lund University
[3] Department of Energy and Technology, Swedish University of Agricultural Sciences

Abstract: In the context of carbon footprints connected to urban areas, trees are often exclusively considered as carbon sinks, potentially mitigating carbon release from human activities. However, before an urban tree becomes a carbon sink it will instead contribute to carbon emission due to operations and activities in its nursery production, planting, establishment and following maintenance. The extent of the carbon emissions and the time needed for the trees to become carbon neutral depends on a large complex, where species-specific growth and carbon storage capacity, as well as spatial organisation of the trees and chosen planting bed substrate, will have great impact on the time needed to carbon neutrality.

The objective of this study was to investigate how carbon sequestration capacity and carbon storage in urban trees are affected by species selection and planting strategy, as well as to estimate the carbon footprint of an urban tree's complete life.

In this study we have made comparisons in growth patterns and carbon storage capacity between single trees and tree stands, planted either in parks or as street trees, in three species commonly used in an urban context in Sweden. We used dendrochronological sampling to evaluate growth rates in different situations, and included this data in life cycle assessments to gain knowledge of critical aspects in an urban tree's carbon budget.

The results will be discussed in relation to how planning and management of urban trees can be performed to improve sustainability in urban areas, from a carbon-perspective.

LiDAR-based allometric equations for quantifying urban tree aerial biomass and crown traits in Canada

T4.2 Carbon and nutrient cycling in urban forests

David Grenier-Héon[1, 2, 3]
Dominic Cyr[3], Daniel Kneeshaw[1, 2], Alain Paquette[1, 2]
[1] Université du Québec à Montreal
[2] Centre d'Étude de la Forêt
[3] Environment and Climate Change Canada

Abstract: *In many cities and regions, the contribution of urban forests (UF) to the carbon cycle, as well as the regulation of key ecosystem services (air filtration, cooling, etc.) are still poorly understood. Allometric equations used for quantifying these elements are often not representative of local species and environmental conditions. Additionally, little is known on the effects of growing site conditions (e.g., streets, parks) on tree allometric relationships within urban settings. Particularly, in Canada, most allometric equations comes from United States data or from natural forests, casting a large uncertainty and potentially significant bias on both carbon and ecosystem services estimations for the UF. Focusing primarily on Montreal and its most abundant species, this study addresses the current lack of models and knowledge gaps by 1) developing allometric equations quantifying aerial biomass and tree crown traits for Canadian urban trees using a novel LiDAR-based method and 2) evaluating the effect of species identity and growing sites on the allometry of these trees. Data were mainly acquired from a terrestrial and mobile LiDAR inventory (2021-2023). Tree biomass was estimated combining tree individual volume (estimated from LiDAR-derived 3D models) with their wood density (obtained with local samples). Leaf area index of each tree were derived from LiDAR point clouds validated with in situ measurements. Non-linear models were generated to obtain allometric equations using diameter at breast height (DBH) and crown dimensions as predictive variables. Preliminary results suggest a high divergence of street trees allometry in comparison to analogue equations from natural forests in Canada. Notably, at equal DBH, broadleaf species in cities tend to have a higher predicted biomass than those of natural forests. Overall, these results corroborate numerous studies demonstrating the importance of allometric equations that are representative of urban tree growing patterns.*

Spatial patterns of topsoil macronutrients in urban forests across eastern China

T4.2 Carbon and nutrient cycling in urban forests

Enzai Du[1]
Nan Xia[1], Xinhui Wu[1]
[1] State Key Laboratory of Earth Surface Processes and Resource Ecology, Faculty of Geographical Science, Beijing Normal University, Beijing 100875, China

Abstract: Macronutrients (e.g., nitrogen, N; phosphorus, P; potassium, K; calcium, Ca; magnesium, Mg) have important biological and ecological functions that support crucial ecosystem services. However, little is known about the large-scale patterns of soil macronutrient concentrations across urban forests. By measuring concentrations of macronutrients in topsoil samples (0-20 cm) from forest patches in 27 urban parks across nine large cities in eastern China, we analyzed their spatial trends and main drivers. Topsoil N concentrations, P concentrations, and N:P ratios in urban forests showed no significant latitudinal trends. Compared with natural forests, urban forests showed lower coefficients of variation of topsoil N concentrations, P concentrations, and N:P ratios. The spatial variation in urban topsoil N and P was mainly explained by climatic drivers and simultaneously mediated by pedogenesis and/or park age. Topsoil K concentration in urban forests showed a decrease from cities in the north to cities in the south, while topsoil Ca and Mg concentrations both showed a unimodal trend along with the latitude. The spatial trend of topsoil K concentration was mainly explained by mean annual temperature (MAT) and preurban soil order, while the spatial variations of topsoil Ca and Mg concentrations both were controlled by mean annual precipitation (MAP) and MAT. Our findings highlight the distinctive patterns of topsoil macronutrient properties across urban forests in the world's most rapidly urbanized region.

Vegetation structure, composition and carbon storage in three sub-urban areas of Harare, Zimbabwe

T4.2 Carbon and nutrient cycling in urban forests

Lizzie Mujuru[1]
Best Muchenje[2], Anna Choruma[1], Admore Mureva[1]
[1] Bindura University of Science Education
[2] Forestry Commission Zimbabwe

Abstract: Urban trees and forests provide important ecosystem services for urban residents including maintaining urban biodiversity, carbon sequestration, regulation of microclimate, regulating air pollutants and supporting human health. A study was done to assess structure, composition and carbon storage potential of trees in three sub-urban types (high, medium and low density) of Harare, Zimbabwe. Transects were made in each sub-urban type where the trees were identified and height (m) and diameter at breast height (cm) were measured. Height and diameter were used to estimate biomass and above ground organic carbon stock. Results showed that a total of 56 tree species were growing in the three suburban types of Harare. Fruit trees were more (60%) than indigenous (20%) and ornamental (20%) trees. The fruit trees were significantly more in high density suburbs than low and medium density suburbs whilst ornamental trees were more in low density than medium and high density suburbs. The structure of trees showed diameters and heights ranging from 5cm to >100 cm and 1.5 m to 20 m respectively. Species diversity was statistically similar for all suburbs. Tree biomass carbon stocks were more in indigenous trees than exotic species, with low density suburbs having significantly more biomass (7.09Mg^{-ha}) than medium density (4.7Mg^{-ha}) and high density suburbs (2.56Mg^{-ha}). Similar differences were in carbon storage. Urban households should be encouraged to play their role in climate change mitigation through planting trees around their homesteads. Furthermore, peri- urban farming should discourage tree destruction for agricultural purposes and promote agroforestry.

T4.3 Climate solutions by the forest sector: Opportunities, challenges, and responses

Evaluating forest carbon leakage under different protocol designs in the U.S. voluntary offset market

T4.3 Climate solutions by the forest sector: Opportunities, challenges, and responses

Gregory Latta[1]
Justin Baker[2], Sara Ohrel[3]
[1] University of Idaho
[2] North Carolina State University
[3] U.S. Environmental Protection Agency

Abstract: Forest carbon offsets can play important role in climate mitigation policies for governments and companies in the U.S. and around the world. For these offsets to be widely adopted they must be quantified using a methodology that ensures the integrity of the emissions reduction. An important component of an effective carbon offset methodology is the treatment of leakage, or the change in greenhouse gases (GHGs) outside of an accounting system due to GHG changes within the accounting system. Despite the known importance of accounting for leakage, few studies exist that have attempted to quantify it in a manner that could be adopted by an accounting methodology. We modify an intertemporal partial equilibrium model of the U.S. forest sector to assess the market, land use, and greenhouse gas (GHG) implications of a voluntary carbon offset program for improved forest management. Recent work has found that these voluntary market responses can differ from mandatory participation in ways that previous work had ignored. We improve upon past studies by differentiating leakage rates from offsets derived by leaving forest stocks intact thus avoiding emissions and offsets derived from removals from the atmosphere through tree growth. We then apply that standard to evaluate the impacts to both offset market participants and non-participants across a range of carbon prices. Results include marginal abatement costs (MAC) curves for each group individually allowing comparison of emissions profiles over the range of carbon prices. The difference between these two MAC curves provides insight into forest landowners' responses within the market equilibrium context. In addition to quantifying potential GHG additionality and leakage impacts of landowner participation in a voluntary carbon offset market in the U.S. forest sector, our results also highlight the complexity of accounting for those policy impacts within a consistent market equilibrium framework. This complexity is evident by evaluating the impacts of the voluntary carbon offset program on commodity prices, forest products manufacturing, and harvest levels in addition to GHG fluxes.

Examining Wild Food Sources in Mount Makiling Forest Reserve, Philippines to Promote Global Climate Regulation and Forest Financing Mechanisms

T4.3 Climate solutions by the forest sector: Opportunities, challenges, and responses

Joylyn Bon O. L. Yu[1]
Lerma SJ. Maldia[1], Crusty E. Tinio[1]
[1] Department of Forest Biological Sciences, College of Forestry and Natural Resources, University of the Philippines Los Baños

Abstract: Food insecurity and climate change are prevailing issues of the 21st century. These issues are interconnected with one another and have adverse impacts on other sectors of the world. Thus, proposed solutions need to take into account multiple factors surrounding the issues and address them in a manner that does not exacerbate existing problems. The use of wild food sources such as fruit trees, can be a viable method to increase food availability, diversify diets, and decrease carbon emissions. This study assessed the productivity of wild food sources by estimating the food sources' biomass from the 10 randomly selected plots within the 2-ha permanent biodiversity monitoring area (PBMA) at Mount Makiling Forest Reserve, Philippines. The biomass values were calculated using the allometric formulae from Brown (1997). Following the methodologies of Diamante et al. (2019) and Zeng et al. (2019), these were subsequently converted to carbon sequestered to estimate the economic value of the global climate regulation service of the food sources. There were 434 tree individuals inventoried across the 10 plots, however only 33 wild food sources had a dbh ≥5 cm. The food sources in the 1000 square meter area studied were found to store 28.57 tonnes of carbon. Additionally, these wild food sources can be leveraged to develop finance mechanisms for forests. The estimated monetary values range from $342.79 or PHP 17,948.27 to $3,513.56 or PHP 183,969.79 when taking into account both the shadow price and the social cost of Carbon. The lack of human presence on the site (unmanaged) suggests that good management can lead to greater carbon offsets. This study only estimated the economic value of the global climate regulation service, however, other ecosystem services such as water regulation and aesthetic value may be considered. More importantly, assessing and monitoring the carbon offsets from wild food sources in forest projects and communities can be a flexible and effective way to expand their funding sources while addressing challenges with food insecurity and climate change.

Keywords: above ground biomass, carbon sequestration, ecosystem services, food insecurity, wild food sources

Forest management strategies from climate mitigation and adaptation perspectives

T4.3 Climate solutions by the forest sector: Opportunities, challenges, and responses

Bishnu Chandra Poudel[1]
Johan Bergh[1]
[1] Department of Forestry and Wood technology, Linnaeus University, Sweden

Abstract: Setting forest management strategies has become increasingly important in current climate change discussion. Forests are seen as one of the alternatives to enhance carbon stock within forest's ecosystem and as product because of their ability to store carbon and substitute other carbon intensive products. Enhancing carbon storage in the forest and harvesting of products require substantial changes in management regime. This poses the challenges in the integration of mitigation and adaptation strategies in forest management. Little is described yet about the effectiveness of implementing strategies from both mitigation and adaptation perspective. To address this need, we aim to explain the complexity in timber production, carbon dynamics and its relation to species composition, forest structure, ecological and economic indicators, extent of disturbance and vulnerability in managed clear-cut, selection, and set-aside forests.

This study aims at evaluating the consequences of forest management strategies implementation from climate mitigation and adaptation perspectives. We select four different forest stands managed for long time under selection cutting system to simulate production and other properties of forests under different type of management regimes. We aim to describe forest management system from forest growth, harvesting potential, carbon balance, and ecological and economical perspectives. We apply a comprehensive analysis approach to relate resulted forest conditions into the forest dynamics and its complexity to explain production, ecological, economical and forest disturbance indicators.

We use first-hand inventory database to implement forest management strategies in the Heureka system. Heureka system is equipped with forest growth model, forest planning model, carbon accounting in both below and above ground biomass, and is integrated with Q-model to describe soil carbon. Further, based on prices of forest products, it is able to evaluate the land expectation value. Our evaluation on four different forest stands from different geographical locations in southern Sweden describe the complexity of management decisions in terms of mitigation of climate change and economic returns. Pay back calculations for carbon and economic returns are compared with industrial and ecological perspective. We aim to present results for maximum potential harvest, carbon sink and adaptation strategies.

Key-words: continuous-cover forestry, Heureka, carbon benefits, net present value, ecosystem-services.

Forestry and climate change mitigation: Experiences from Quebec (Canada)

T4.3 Climate solutions by the forest sector: Opportunities, challenges, and responses

Evelyne Thiffault[1]
Lucas Moreau[1], Robert Beauregard[1], Isabelle Ménard[1], Mélina Thibault[1], Gabriel Landry[1], William Côté[1], Marilou Yargeau[1]
[1] Renewable Materials Research Centre, Department of wood and forest sciences, Université Laval, Quebec City, Canada

Abstract: The IPCC recognizes forestry as a critical element for climate change mitigation. We have estimated that for Quebec, a province of eastern Canada that possesses a large, primarily boreal, forest territory and a well-developed wood industrial network, an ambitious portfolio of actions mobilizing the forest lands and the wood processing industries could generate annual reductions varying from 0.5 to 6.7 Mt CO_2 eq/year by 2030. Implementing these actions requires detailed knowledge of the dynamics of forest ecosystems and the links between forests and societal needs for materials and energy. In this context, our results suggest that partial-cut harvesting, when used as an alternative to clear-cut harvesting in the boreal forests of Quebec, can be a promising way of supplying high-quality wood products to markets, maintaining carbon stocks in ecosystems and contributing to the resilience of boreal forests under a changing climate. Conversely, afforestation measures such as tree planting on abandoned agricultural lands do not appear to provide benefits in the context of Quebec. Most of these agricultural lands supported forest ecosystems before their clearing for cultivation, and field data suggest that they can revert relatively quickly to natural succession leading to a forest cover and sequestering large quantities of carbon without the need for artificial plantation. Moreover, the decrease in surface albedo and associated increase in radiative forcing incurred by the establishment of a coniferous plantation on a previously non-forested land can be substantial due to the high latitude and long snow-covered winters of Quebec; the deciduous-dominated natural succession (or plantation of deciduous species) can mitigate this effect. Nevertheless, our research demonstrates that improving the management of the end-of-life of wood products by preventing their landfilling (which is still very common in Quebec) through increased wood cascading use (for example, through a more extensive deployment of panel manufacturing based on recycled wood) or increasing the recovery and use of landfill methane would yield significantly higher climate benefits than any forest management action.

T4.4 Closing the forest transition theory – forest restoration policy and practice gap

Analysis of the environmental Kuznets Curve for forest transition: the case of Fujian province in China

T4.4 Closing the forest transition theory – forest restoration policy and practice gap

Lingchao Li[1]
Jinlong Liu[2]
[1] School of Economics and Management, Beijing Forestry University
[2] School of Agricultural and Rural Development, Renmin University of China

Abstract: In recent decades, the international community has become increasingly concerned about several important environmental challenges including deforestation and forest degradation. Based on the remote sensing image data and socio-economic statistics of 32 sample counties in Fujian province, we investigate the impact of socio-economic and institutional factors on forest transition. We use a panel threshold regression model to group sample counties and examine the link between forest transition and economic growth at various economic development levels in the BTH region based on the environmental Kuznets Curve (EKC) theory. In the sample counties with various levels of economic development, we found different relationships between forest transition and per capita GDP. "N" and inverted "N" shapes represent the EKC of forest transition in the low- and high-income groups, respectively, and most data show that deforestation reduces with economic growth. Policy changes to reduce deforestation are recommended to promote coordinated and environmentally friendly development in the region.

Carbon fluxes in World´s forests: Losses of tropical intact forests and C gains predominantly elsewhere

Abstract: Terrestrial carbon (C) sinks have persistently removed about 30% of the carbon dioxide (CO_2) emitted from burning fossil fuels and land-use change over the last three decades. Forests are critically important in modifying the carbon budget of the atmosphere.

In 2011 Pan et al. published the article *A large and persistent carbon sink in the world's forests* in *Science*; a global research paper. We will present an update of those estimates as well as a critical reflection of the methods behind these estimates. Latest results indicate fluctuations of the forest carbon sink, continued losses of intact tropical forests, and resilience of the global forest ecosystems in so far despite emerging changes in the global climate. Some large regions like Europe and Canada are starting to show sink saturation effects or acting as a source.

These estimates are to large extent based on national forest inventories. Do they still suffice with long data release times? Will national forest inventories develop next to remote sensing? Forest inventory methodologies have evolved since 2011. In this presentation Yude Pan and co-authors discuss applications of forest inventory methods in carbon budget research. Can remote sensing and modelling approaches replace or complement field observations of Net Annual Increment and biomass drain? Clearly in assessing disturbances remote sensing has evolved rapidly. Also, other methods will be discussed to assess the forest carbon sink.

All methodologies confirm significant historical losses of tropical intact forests. New scientific results show both increases and decreases of forest carbon stocks depending on World regions. The

credibility of forest inventory data varies between biomes inviting other methodologies to support forest inventory approaches and to make scientific contributions. Reverting deforestation and degradation of World´s hot-spot forests represent ultimate challenges in efforts to prolong the era of forest carbon sinks.

Forest transitions, causal explanations, and reforestation policies

T4.4 Closing the forest transition theory – forest restoration policy and practice gap

Bradley Walters[1]
[1] Mount Allison University

Abstract: The idea that our understanding of forest transitions (FTs) and forest transition theory (FTT) might inform reforestation policies is intriguing, but far from straightforward. The coherence and meaning of FTT is much debated and fast-evolving, so offers little concrete guidance to policy makers and practitioners. Understanding the causal dynamics of land-use changes that lead to reforestation in specific places is thereby essential for policy prescriptions in those places. Yet this too raises a variety of causal-analytic (i.e., methodological) challenges - the focus of this paper - for both researchers and policy makers. So-called 'forest transitions' reflect a complex interplay of socio-economic and biophysical causes in which local and/or regional contexts and contingencies may be decisive. We need clear-eyed explanations of these changes and the human and geographical contexts within which they occur to identify opportunities for constructive policy intervention. Drawing from recent research in the Eastern Caribbean, I describe and illustrate how causal explanations of land use change and reforestation can be done well and with an eye to informing policy. In short, this entails starting with a clear specification of on-the-ground changes of interest (e.g., expanding or contracting forest cover; agricultural land abandonment; etc.) and then seeking to explain these changes by following chains of causation outward in space and backward in time, accounting for policy influences if and where relevant. The explanatory role of general theories, causal mechanisms and causal histories is examined in relation to current philosophical views about explanation and with reference to the Caribbean case study. The importance of precise 'event specification' for delineation and evaluation of causes is also highlighted and illustrated. Specific policy recommendations based on the case study are considered, and general suggestions then made to guide explanatory research in ways that might better inform effective policy and other practical interventions. The paper concludes with an appeal to epistemic humility: in a world characterized by complex and fast-changing human-environment interactions, even good causal explanations should not imbue overconfidence in what can be predicted or controlled in practice.

From Sustainable Development to Inclusive Development: Understanding just transition in forest carbon sequestration project.

T4.4 Closing the forest transition theory – forest restoration policy and practice gap

Feng Ba[1]
[1] China Agricultural University

Abstract: Since the first period of the Kyoto Protocol, developing countries such as China, India, and Brazil have conducted more than 3,500 CDM projects through the United Nations Framework Convention on Climate Change (UNFCCC) platform (UNFCCC, 2023b). However, an increasing empirical studies have identified livelihood risks associated with CDM projects, such as ecological displacement caused by restrictions on traditional livelihood practices caused by afforestation projects. These examples underscored the results of CDM projects that often do not meet the design goals and the sustainable development goals of host countries during the project implementation process, so that it is needed for an alternative understanding of the core concepts and methodology - that is, in light of the trade-offs between economic growth and ecological sustainability in global climate cooperation and their implications for developing countries, it is important to adopt a multi-dimensional approach to achieving more inclusive development goals.The concept of just transition has gained increasing attention in the global climate cooperation framework since the Paris Agreement was adopted in 2015 and widely applied in addressing climate change issues in developing countries. This article which analyzes the just transition in international climate cooperation and focuses on three questions: (1) addresses the issues of unequal rights between developed and developing countries in international climate cooperation which constructed under the Western discourse and technology; (2) uses the emerging concept of just transition to provide a new perspective on the differences between the design and the reality of international climate cooperation projects in developing country; (3) combing the concept and research framework of ID, this research considers an addtional demention of political relations and its influence on the just tansition progress in developing country. To reach the ends mentioned above, this article employs the just transition framework to analyze the participation process of China in the CDM international emissions trading mechanism, uses the Qualitative Comparative Analysis (QCA) method on 4 project communities and 22 households to identify the key combinations of conditions required for the farmer housholds to achieve a just transition in domestic contexts under the CDM mechanism.

How Spatial Pattern of Population Distribution drive forest cover changes: case of China

T4.4 Closing the forest transition theory – forest restoration policy and practice gap

Jinlong Liu[1]
Weiping Shi[1]
[1] Renmin University of China

Abstract: Over centuries, urbanization and rural depopulation have been prevailing across the world, but how to impacts to global forest cover change has been in questioning. This research took China as a case to examine interrelationship between population spatial pattern and forest cover changes in over 50 years. The results are: 1) migration of rural population are not necessarily lead to the forest cover increase; 2) however, over 50 years, distance between population and forest distribution gravity gradually enlarged in China, reducing dependence rate of rural people's livelihood on forests; 3) there is great variation among regions, and forest policy and proper enforcement are dominant factors to nurture forest cover increasing while rural depopulation. Population increase contributes to forest loss in large extent, and stabilization of world population and proper policy in depopulation are essential to achieve global forest transition.

Key word: Forest transition, Zero forest cover loss at 2030, rural depopulation, forest policy

Land- use histories of planted tree cover caution international agenda promoting reforestation

T4.4 Closing the forest transition theory – forest restoration policy and practice gap

Sean Sloan[1]
Bruno Locatelli[2], Matthew Fagan[3], Adia Bey[4], Patrick Meyfroidt[4]
[1] Vancouver Island University, Department of Geography, Canada
[2] CIRAD, Forests and Societies, France
[3] University of Maryland - Baltimore County, Department of Geography and Environmental Systems, USA
[4] University Catholique de Louvain, Earth and Life Institute, Belgium

Abstract: Multiple national and multi-national schemes promote extensive tropical reforestation under the auspices of climate-change mitigation and environmental remediation. The necessity of economic incentive and public participation in such schemes has meant that such reforestation has generally taken the form of commercial tree plantations as well as agroforestry. The history of such tropical planted tree cover does not bode well for the desired environmental outcomes of such schemes in the absence of strict oversight. Here, the land-use histories of 5000 1-ha plots of planted tree cover were reviewed via visual interpretations of satellite imagery over 1990-2015. Plots were sampled pantropically within the extent of current (2015) planted tree cover and represent all major tropical plantation regions. Visual interpretations allowed for unprecedented scrutiny of the frequency by which planted tree cover – including sparely-treed lands or temporarily-cleared lands otherwise dedicated to planted tree cover – replaced natural forest cover versus managed scrublands or similar, as well as the timing and nature of land-use transitions culminating in planted tree cover. A very small proportion of plots had planted tree cover continually since 1990. Most plots were initially natural forest. Land-use transitions from natural forest to planted tree cover rarely featured intermediate stages of managed lands (e.g., agriculture) and, where they did, managed land uses were typically fleeting. Overwhelmingly, therefore, planted tree cover has replaced forests of greater environmental value, and done so relatively directly. Landsat vegetation indices of the plots, observed at roughly monthly intervals over 1985-2020, affirm consequently how vegetation coverage declines, and soil exposure increases, for years or decades following transitions to planted tree cover. The logical policy response to prevent such historical trends from repeating is to strictly limit incentivized reforestation to verifiably long-cleared lands, invariably being grazing lands on the spatial and economic peripheries. The recent and arguably successfully implementation of such a scheme in Panama will be outlined. The practicality of such an administrative approach to incentivized 'forest' production, given ambitious reforestation targets, remains uncertain and ultimately recalls debates over the relative merit and simplicity of ‘doing nothing’ to allow natural reforestation instead.

Tree-planting assistance and forest transition of communal lands: Implications for integrated land restoration and development projects

T4.4 Closing the forest transition theory – forest restoration policy and practice gap

Wil De Jong

Abstract: Local communities, living in or near forests and dependent on forests and other natural environments to meet livelihood needs are often mentioned as beneficiaries and protagonists of forest and land restoration. In forest transition debates the same communities are also recognized as contributing to forest recovery when land use intensification and forest restoration of communal lands takes place. Our paper disentangles how communal forest transition and communal endogenous or externally supported forest restoration interact. Forest transition on communal lands are long term processes resulting from multiple intra and extra communal drivers. Externally supported communal forest restoration usually is only one of those drivers, and such restoration is more likely to be successful and will contribute to sustained communal forest transition if it concurs with other, positive communal forest transition drivers. This insight has implications for forest transition theory, but also for how and where communities may be involved in forest and land restoration efforts.

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Gamified learning of long-term opportunities and limitations of forests in climate change mitigation

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Lauri Mehtätalo[1]
Ville-Veikko Uhlgren[2], Nikoletta-Zampeta Legaki[2], Daniel Fernández Galeote[2], Juho Hamari[2]
[1] Natural Resources Institute Finland (Luke), Finland
[2] Tampere University, Finland

Abstract: The biological growth dynamics of trees (growth curve) and the age structure of forests essentially determine the current level of forest growth at the area level on a certain site, whereas long-term cutting possibilities are determined by the growth curve and total area of forests. Cuttings affect growth mainly through manipulating the age distribution, either between stands in even-aged systems or within stands in uneven-aged-systems. In the long term, the difference between cuttings and removals, which is very closely connected to carbon balance of forests, necessarily approaches zero regardless of the selected level of cuttings. Furthermore, the growth at the area level has an upper limit, and reaching that requires maximum sustainable level of removals. However, especially in boreal conditions, forests grow slowly and these basic principles of growth dynamics are poorly understood, e.g., by policymakers and the general public. Based on gamified visual analytics, we present an interactive tool that allows exploring how the forest age structure, growth, removals and the difference between cuttings and growth develop over several centuries under different simple cutting scenarios set by the user. The tool illustrates forest dynamics by animating the age distribution of forests over time. For example, we allow scenarios where the difference between growth and removals has been set (fixed carbon sink scenario) and scenarios where cuttings are restricted to any level, including those that exceed the maximum sustainable level. The input data for simulations includes the age distributions and growth curves based on the National Forest Inventory data of Finland. The tool has been recently used in demonstrating growth dynamics to forest researchers, forestry students and policymakers in Finland.

"Can Social Media Revolutionize Forest Ecosystem Service Marketing? Unlocking Potential through Networks and Influencers!"

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Mona Nazari
Nicolas Bilot[1], Julia Ramsauer[2], Harald Vacik[3]
[1] Association Des Hommes et Des Arbres, Nancy, France
[2] La Manchuela por el Clima, Minglanilla, Spain
[3] Institute of Silviculture, University of Natural Resources and Life Sciences, Vienna, Austria

Abstract: Payments for ecosystem services (PES) schemes are considered a promising economic instrument for diversifying the income of forest owners and rural communities while supporting biodiversity and climate mitigation. Social networks and social media influencers (SMIs) possess the ability to establish credibility with their large audiences through perceived expertise, sharing personal experiences, and opinions. As a result, they hold influence over consumers' decisions. Therefore, modern world business and society hold great expectations of social media`s impacts. This study aims to find which social media-related techniques, methods and instruments support the process of forest ecosystem service (FES) marketing to change the behavior of the local providers and consumers of PES programs, facilitate engagement, particularly with rural participants who otherwise would not have been aware, trusted, able, or willing to join the program.

A literature review established a framework of key factors related to social media (SM) and SMIs. The interaction of these factors was analyzed by a network graph using Gephi software. A survey of three PES case studies in Europe provided an overview of the importance of these factors and insights into PES actors' behavior on social networks. Considering the actors` characteristics, the framework identified influential factors like SM platforms, content types, SMIs characteristics, and socio-economic impacts on environmental services consumption. Survey results showed that almost half of the participants confirm the positive role of social media tools for promoting the forest ecosystem services provision. YouTube emerged as the preferred platform for forest owners, regardless of their role as buyers or providers of FES. Short videos and live interviews garnered significant attention across all the actors regardless of age and gender. Additionally, 45% of respondents considered reliability as the key characteristic of SMIs.

By understanding the impact of SM and SMIs and addressing the identified barriers, it is possible to foster greater participation and engagement in PES initiatives, leading to a more sustainable and environmentally conscious society. Although, further research and practical implementation contribute to enhancing the effectiveness of SM on PES programs and accelerating their adoption.

Assessing the value and transparency of eco-labels: Contrasting business and consumer perspectives

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Venla Wallius[1, 2]
Ronak Batra[3], Anushree Tandon[1, 4], Diana Tuomasjukka[1], Yitagesu Tekle[1]
[1] European Forest Institute
[2] University of Jyväskylä
[3] PwC Middle East
[4] University of Eastern Finland

Abstract: Eco-labels have been hailed as an essential communication tool that enables consumers, both individual and organizational, to assess the environmental performances of various products and services – thus playing a critical role in informing their decisions. This apparent usefulness of eco-labels has led to the development of multiple labelling schemes, but the global market is now inundated with over 450 eco-labels covering various sectors and products. However, majority of eco-labelling programs fall short of providing credible and transparent information regarding producer's compliance, or which sustainability criteria are covered. Another key question is whether consumers (both individual and organizational) recognize and trust eco-labels – and if so, what are the parameters that sets one eco-label apart from others. In particular, there seems to be a lack of robust methodology in assessing the transparency, democracy, impartiality and sustainability impacts of eco-labels. Our study takes an initial step toward answering these problems. We explore the possibility of developing a scale that organizations (through agents such as procurement/supply chain or environmental officials) and consumers could use to assess the viability and utility of adopting or purchasing products and services through an ecolabel evaluation. Our initial findings from interviewing such agents and consumers suggest major differences in how the performance and trustworthiness of existing eco-labelling schemes are evaluated. Subsequently, we indicate the need for developing a standardized rating scale for eco-labels that accounts for both organizational and individual perspectives and facilitates a coherent evaluation of these labels by multiple stakeholders. We also raise the call for enhancing the transparency of eco-labels which may be key to increasing consumer and producer confidence in them – thus paving the way for their increased utility as a decisional and informational tool in sustainability transition.

Don’t let them fall behind – the value of real life connections in a digital world of forest communication

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Viktoria Valenta[1]
Anna-Maria Walli[1], Silvio Schüler[1]
[1] Austrian Research Centre for Forests BFW

Abstract: There is no one size fits all when it comes to communicating forest science. In Austria, the transition to climate-smart forests heavily depends on the involvement of private forest owners as they manage more than 80% of the forested area. But there is not “the traditional forest owner” who can be reached in one specific way. Societal changes affect forest ownership, shifting it from mainly farm- or family-owned business to a more diverse set of “new forest owners”, which include a lot of “non-farming” and urban forest owners. With the ownership not only the connections to and demands on the forest change, but also the position of the owners in the forestry community.

This requires novel and user-centric ways of communicating new findings and to help practitioners develop their understanding of climate-smart forests and their management. The Austrian Research Centre for Forests BFW set up several projects focused on science communication for different target groups – from traditional practitioners to middle school students.

Since many of the new forest owners are forestry laypersons, the forest information platform www.klimafitterwald.at was created as a one-stop shop with information and tools like an advisor search and a tree species traffic light system, providing an initial assessment of appropriate tree species for one's own forest. Another main output is a series of light-hearted informative videos about what to do when inheriting a forest. For more traditional forest practitioners regular practice days have been integral for knowledge sharing in the community. Transferring them into a virtual environment with sessions streamed from the forest to the comfort of living rooms across the country enabled us to reach many more people from diverse and non-forestry backgrounds than before the pandemic.

Even though the use of podcasts, social media, and videos has become a key branch of communicating forest related information, it is still vital to forge real life connections between practitioners and scientists. Therefore, a fundamental part of our work is face-to-face communication, with communities and organisations requesting our experts for events and personal advice on the ground on topics such as tree species selection and biodiversity conservation.

Exploring Public Perceptions of Forestry and Ecosystem Services: Insights into Scientific Knowledge Communication and Strategy Development

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Marcel Riedl[1]
Vilém Jarský[1]
[1] Czech University of Life Sciences, Prague

Abstract: Recognizing the significance of effective external communication and the sharing of scientific knowledge, this study emphasizes their critical role in garnering long-term support from society and policymakers to achieve the goals of multifunctional forestry, foster the development of ecosystem services, promote resilient forests, and effectively address the challenges of climate change.

By utilizing participatory methods and conducting problem tree analysis through focus groups, the study successfully identified the central problem associated with the public perception of the forestry sector, notably the need for a comprehensive long-term communication strategy.

Extensive qualitative research involving over 3,000 respondents confirmed that the forestry sector is predominantly viewed negatively, particularly among urban populations and young individuals. This negative perception was further amplified during the bark beetle calamity. The sector is often perceived as outdated, focused primarily on economic concerns, struggling to address the bark beetle calamity effectively, and failing to implement scientific knowledge and methods in practice.

To address these challenges and improve the public image of the forestry sector, a communication strategy has been developed. This strategy aims to reshape the forestry sector's positioning in the public perception map and challenge negative stereotypes. Key elements of the strategy include implementing a quintuple helix platform and fostering collaborative engagement among academia, government, industry, civil society, and the public.

The research was supported by the NAZV project QK23020008.

Films as human rights: through the lens of Indigenous peoples in post pandemic era

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Purabi Bose[1]
[1] Swedish University of Agricultural Sciences

Abstract: Films as human rights: through the lens of Indigenous peoples in post-pandemic era

Among various forms of communication, a combination of audio-visual formats like films is increasingly used in promoting human rights. Indigenous Peoples' rights to forest food in India are being amplified through a film, TARA *Alpinia nigra*. This article examines how common resources, such as wild edible forest food, when turned into commodities violate basic human rights to the culture and health of India's Indigenous Peoples. When a human rights violation happens, it means that person's humanity has been denied. Often, human rights violation is expressed in statistics (numbers) or via legal bindings (treaties, policies), which fail to have a human touch. Filmmaking on human rights violations touches that human element by shedding light, camera, and action by amplifying the voices of the 'human beings', the real protagonists. This article demonstrates the role of film in documenting the 'way of living and traditional right to sustainable forest food for Assam's – North-East province in India – hunting-gathering Indigenous communities. It elaborates how films can become a powerful medium when the human 'rightsholders' are given a space to voice their opinions in front of the lens. The conclusions point out two ways forward as a post-pandemic approaches: (a) the films become a lens of justice by letting real people talk in front of the camera rather than voice-overs by the 'beholders' of human rights, and (b) Indigenous Peoples are aware of their traditional rights to forest food as commons.

This abstract is published as a book chapter (Bose, 2023), and the presentation will be modified to only highlight the dimension of how filmmaking could be a powerful tool for Indigenous people's human rights to forest food and resources and governance. The presentation could be adapted to a short 5 min speed-talk to a normal presentation talk of 15min depending upon the need of the session.

Forest Fires and Forestry Communication: Lessons from the Largest Forest Fire in Slovenia

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Boris Rantaša[1]
Aleš Poljanec[2], Tina Dolenc[2], Branka Gasparič[2], Marija Kolšek[2], Boštjan Košiček[2], Hojka Kraigher[1]
[1] Slovenian Forestry Institute
[2] Slovenia Forest Service

Abstract: Large-scale forest fires are increasingly common in Central and Southern Europe due to the impact of climate change. In this presentation, we provide an overview of the communication response to a forest fire that occurred in the Goriški Kras region of Slovenia in July 2022. Effective communication, media engagement, and stakeholder relations played a vital role in the forestry sector's response to the fire. Daily press releases, press conferences, and social media platforms were utilized to keep the media and the public informed. Communication activities also facilitated emergency logging efforts, which involved over 500 volunteers to assist in the response and prevent the fire from spreading.

Moreover, this event represents the most significant incident in Slovenian forestry to date in terms of media response and engagement. Communication activities were crucial in securing funding, volunteers, and other forms of assistance for post-fire restoration efforts. They also facilitated coordination among the public forest service and numerous affected forest owners. The involvement of the local community and various expert services in the post-fire forest management plan was facilitated by these communication efforts. The presentation also addresses the challenges and obstacles encountered during the response.

Finally, we present empirical guidelines and lessons learned for coordinating communication responses to forest fires, which can serve as a reference for future incidents.

Forests and transformative governance - Insights from TRANS-lighthouses

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Gerd Lupp[1]
Isabel Ferreira[2], Nathalie Nunes[2], Beatriz Caitana[2], Eduardo Marques[3], Gonçalo Canto Moniz[2]
[1] Technical University of Munich
[2] Centre for Social Studies, University of Coimbra
[3] University of the Acores

Abstract: The project TRANS-lighthouses aims to gather evidence on material and immaterial results of nature-based solutions in order to rethink and reframe how social and ecologically just solutions are created. TRANS-lighthouses integrates a network of nature-based solutions' lighthouses for urban, rural, coastal and forested areas. Lighthouses is a metaphor for a set of local arrangements and instruments grounded on a concerted and networked group of multiple actors committed to enhancing the contributions of nature-based solutions towards interlinked ecological, social and economic targets. This will be done by testing new governance models and co-creation approaches and tools. One of the Lighthouses with two case studies from Lagoa (Azores) and Upper Allgäu (Germany) is dedicated to solutions in, around and with forests and co-designing the solutions in an inclusive, just manner and analyzing the mechanisms of co-creation and their governance.

The assessment case of the Upper Allgäu will examine the success factors and lessons learned from the Mountain Forest Initiative. The initiative was started by the local forest administration in 2008. It tries to tackle to support owners to adapt their forests to climate change to secure multiple ecosystem services provided by multifunctional forestry. An increasing share of forest owners have lost skills and awareness for forest management and are unaware of the urgency to act. The goal is to work together as equals with forest owners to enhance the situation of the forests by co-creating solutions.

The pilot case of Lagoa (Azores) will work in an inclusive way to increase the sustainable recreational use in the unique forests in the area. Facing health issues in the local population, the idea is to jointly develop, co-create as well as unlock the potential of forests not only for tourism, but to enhance and stimulate physical activity of the local population to increase health and wellbeing together with a broad range of stakeholders stretching from land management, schools, citizens, NGOS to hospitals.

With the project start on May 1, 2023, we intend to present first outcomes and results with a focus on forest landscapes after one year of intense work in the study cases.

Hackathon: An innovative combination of forestry, forest technology and health care

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Dominik Muehlberger[1]
Christine Orntesmüller[1]
[1] Austrian Research Centre for Forests (BFW), Forest, Society and International Affairs

Abstract:

In the post-pandemic era, with communication and exchange being more crucial than ever, innovative methods are making their way into the forestry, forest technology, and healthcare sectors. One remarkable example is the Hackathon, traditionally associated with the IT industry. However, it has now ventured into the realm of forests and health, bringing together professionals from diverse fields. This exciting competition aims to foster communication, collaboration, and interdisciplinary learning, creating a platform where novel ideas can flourish at the intersection of technology, forestry, and healthcare.

The Austrian Research Centre for Forests (BFW) organized a hackathon at the Benedictine Abbey of Göttweig in Austria as part of the Erasmus+ -Project Green4C. The hackathon brought together 19 young experts from different disciplines, aged between 15 and 35. Four teams, consisting of students from the fields of wood technology, forestry and health science, worked together for 24 hours to design health stations in the healing forest using only natural materials, without screws or glue to connect the elements. These stations should offer preventive health services and therapies. The aim was to promote interdisciplinary cooperation and learning among the participants.

The hackathon promoted exchange between disciplines and allowed participants to learn from and work with each other. The intensive collaboration accompanied by a design thinking process led to the development of detailed and holistic wooden models that included sound elements, various seating and resting options, meditation places and therapeutic games. These models were masterpieces that combined the three disciplines of wood craft, forestry and therapeutic science, with the forest serving as a unifying element.

A ten-member jury evaluated the models based on criteria such as innovation, overall concept and implementation. After the evaluation, it was decided that all four therapeutic health stations would be implemented in the healing forest of the Benedictine monastery of Göttweig. The hackathon not only offered the opportunity to practically apply the multifunctionality of forests, but also promoted a new and unique exchange between experts from the fields of health, crafts, art and forestry, who acted as mentors and provided valuable impulses.

Lessons in Podcasting

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Jennifer Hayes[1]
Jose Bolaños[2]
[1] USDA Forest Service, Office of Sustainability and Climate
[2] International Union of Forest Research Organizations

Abstract: In this interactive session, the presenters will demonstrate effective techniques for podcast interviewing, describe techniques for podcast script development using a real-life example, suggest ways to approach podcast recording to engage diverse global audiences, and share tips on podcast dissemination. Why? Because podcasting is a great way to share science!

In today's busy world, more and more people are turning to podcasting as a form of entertainment and information-gathering. The world of podcasting has bloomed in the last several years, with an estimated 424 million global listeners in 2022[1]. According to one survey, 32% of 18+ listen to podcasts during their commutes[2]. Podcasting is a way to bring science in a digestible format to a broad set of listeners. While podcasting could be as simple as recording yourself talking on your telephone, that is not exactly a best practice. Competition for listenership is high. Quality podcasting is required if you want to retain a listener-base.

Hayes and Bolanos recently teamed up on the launch of IUFRO's Branching out: the Forest Podcast[3]. They will draw from this experience and working on other successful podcasts to provide insights on making your own podcast a success.

TREEgital: Digital knowledge transfer about forests

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Irene Gianordoli[1]
Franziska Krainer[1]
[1] Austrian Research Centre for Forests (BFW), Communication Department

Abstract: The Corona pandemic has given a strong boost to digitalization in school education. With the project TREEgital we are embracing this development by providing knowledge about forests for schools, using digital tools to explore the importance of forests as living, recreational, and economic spaces, as well as to emphasize their role in climate and biodiversity protection. The thematic focal points of TREEgital are biodiversity and climate change, as well as career guidance for young people regarding green and sustainable jobs in the broad environmental and forestry sector. Additionally, we impart digital competencies to equip students with the skills needed in today's digital world.

To achieve these goals, we develop methods and digital educational products for school use: One of these methods is the utilization of augmented reality (AR) in the developed app "Öswald." AR technology enhances the learning experience by overlaying virtual elements onto the real-world environment, allowing students to interact with and explore the forest in a dynamic and engaging way. Another method is the creation of career guidance YouTube videos with a specific focus on STEM subjects. These videos aim to inspire and inform students about potential career paths forest-related fields. By showcasing real-life professionals and their work, students gain valuable insights into the diverse opportunities available in these areas. Furthermore, the project features a video-podcast called "TreeCast", in which forestry scientists are invited to share their research and experiences. Topics covered in the podcast range from climate change and biodiversity to pest management and soil health. The social media series "Ask the Expert" gives insights into the professional world of scientists and forest research.

Through these methods TREEgital seeks to leverage digital tools and resources to foster meaningful and interactive learning experiences, making forest knowledge accessible and engaging for students in the digital age. The educational materials not only impart knowledge about biodiversity, but also focus on Education for Sustainable Development (ESD) and the implementation of the Sustainable Development Goals (SDGs). This takes a sustainable approach to teaching, providing students with knowledge and skills to take responsibility in a globalized world.

What is considered good written communication about forest? Issues, concerns and practices revealed by a systematic review

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Isabelle Paré[1]

[1] Université Laval

Abstract: To better address questions related to how we communicate forest science into the future and take informed, evidence-based decisions, it can be insightful to examine what has been done up to now, how it has been done and why. Moreover, if to move away from a « content paradigm » towards a « performance paradigm » of communication, the understanding of what audiences expect, need and want is an essential component to any action-oriented, user-centric communication initiatives.

Stakeholders communicating about forest rely on a variety of written material to deliver their messages. Those messages, designed to be published and read in order to reach a variety of readers in a broad range of situations, can aim to inform, educate, support decision-making or ensure accountability, for example. How are those stakeholders communicating about forests? What are their main concerns? What do they consider to be effective, successful written communication about forests, or indicators thereof?

To comprehensively grasp how written communications about forests is appraised, we conducted a mixed-method systematic review of research papers published between January 1989 and March 2020. To retrieve those papers from 14 selected electronic databases, the search words Forest* AND Communication, combined with one or more of 27 specific keywords shared with adjacent disciplines (linguistic, composition studies, information design, among others) were used. The material was evaluated for eligibility, focusing on professional or technical documents designed in a workplace context for an adult readership, and coded according to a predetermined set of criteria.

The results show a growing but limited interest in understanding what makes written communication about forest effective, and barely any explicit definitions of what a good performance should entail. Almost half of the papers analyzed were only tangentially focused on the documents for their communication purposes. Recommandations, when formulated, mainly focused on content, content delivery and the process which may facilitate or impede content quality. A small number of mostly quantitative user-focused studies were conducted almost exclusively by practitioners working in an extension or outreach communication setting.

Those results call for a more systematic and sustained efforts into taking the user experience into account.

What the bug?! Cross-generational storytelling: Innovative methods for science communication about forest insects

T4.5 Communicating and Connecting: Post-pandemic approaches to sharing scientific and traditional forest knowledge to inspire trust, engagement and positive change

Irene Gianordoli[1]
Franziska Krainer[1]
[1] Austrian Research Centre for Forests (BFW), Communication Department

Abstract: Topics such as the biodiversity crisis are often hard to communicate, leading to a dwindling awareness and even increasing levels of scientific skepticism among the general public. The project "What the bug?! Cross-generational Storytelling" focuses on accessible science communication around forest research, with a special emphasis on forest insects. The aim of the project is to explain forest research processes in a participatory way. By using modern storytelling methods, the project aims to reach different target groups, including young people and senior citizens, enabling the cross-generational transfer of knowledge.

An interactive science quiz is designed to introduce young people to forest insects and their importance in a globalized world shaped by climate change. Phenomena such as the flight technique of click beetles or the perception of forest fires by the black pine beetle are illustrated interactively and participative in experiments. Science in miniature format can be experienced: The formulation and testing of hypotheses is tried out.

In science storytelling cafés we create spaces and opportunities for exchange about this multi-layered topic that affects us all more than we might think. The storytelling café is a low-threshold and participatory method of biography and memory work that focuses on autobiographical narratives and promotes dialogue between the participants rather than discussion. The science storytelling café can also be used as a method for raising awareness by enabling participants to draw attention to societal challenges such as climate change, insect decline and globalization, and to address possible solutions.

The project aims to improve science communication about the forest, raise awareness for forest research, fosters species knowledge among the population and teaches why this knowledge is important. The project thus contributes to education for sustainable development (SDG 4) and the protection of life on land (SDG 15).Through cross-generational knowledge transfer and innovative methods, young people and seniors are addressed to raise interest in scientific processes and to reduce science skepticism.

T4.6 Conflicts in Forest Settings

Analysing conflicting stakeholder perspectives in multifunctional forest landscapes using a complex systems approach

T4.6 Conflicts in Forest Settings

Lucas Dawson[1]
Per Angelstam[1, 2]
[1] School for Forest Management, Faculty of Forest Sciences, Swedish University of Agricultural Sciences
[2] Department of Forestry and Wildlife Management, Inland Norway University of Applied Sciences

Abstract: Background: Climate change and biodiversity loss, along with long-term urbanization trends and a societal-scale transition towards renewable materials and energy, threaten the world's forests. In addition, natural and cultural values associated with forests have become key selling points for nature-based tourism and recreation. Policy responses at multiple levels therefore increasingly stress the need for multifunctional forest landscapes (MFLs) to supply an increasingly diverse suite of ecosystem services. However, a key challenge remains the perceived incompatibility among different stakeholder interests.

Aim: In a new 4-year transdisciplinary research program we aim to improve understanding of the complex, dynamic factors that influence what different stakeholders want from forest landscapes, and how these factors interact to constrain or enable a shift towards MFLs.

Methods: We use place-based landscape studies in Sweden, where stakeholder positions are polarized by deeply entrenched conflicts and by a desire for competing functions and benefits from forests. A complex systems approach, using qualitative modelling, spatial and network analyses, allows us to map and analyse key factors and core system dynamics (including feedback loops) and to identify constraints and opportunities influencing attempts to overcome conflicts in forest landscapes towards MFLs.

Results: Our recent and ongoing studies indicate that conflicting economic considerations continue to dominate different stakeholder perspectives. In particular, perceived threats to natural and cultural values of forests resulting from intensive forest management practices were shown to drive multi-stakeholder coalitions in support of a transition to MFLs. Further, we identified several institutional, socio-cultural and environmental drivers that influence conflicting management objectives and practices. These drivers interact to steer emergent conflict-resolution processes relating to a shared vision, support, learning, and new management practices. Key constraints included lack of trust, power imbalances and weak links between governance levels.

Conclusions: Our results make important contributions to the development of a causal model for exploring the drivers, impacts and solutions to conflicts in forest settings. However, the success of MFL initiatives in Sweden depends on a shift away from intensive forest management. Further research is therefore needed concerning the causal mechanisms supporting and/or constraining transition pathways from clear-felling to clear-cut free forest management.

Applying machine learning to media analysis improves our understanding of forest conflicts

T4.6 Conflicts in Forest Settings

Isabella Hallberg-Sramek[1]
Simon Lindgren[2], Jonatan Samuelsson[3], Camilla Sandström[4]
[1] Swedish University of Agricultural Sciences (SLU), Department of Forest Genetics and Plant Physiology, Sweden
[2] Umeå University, Department of Sociology, Sweden
[3] Umeå university, Department of Historical, Philosophical and Religious studies, Sweden
[4] Umeå University, Department of Political Science, Sweden

Abstract: Conflicts over the management and governance of forests are increasing. Previous media studies in this area have largely focused on analysing the portrayal of specific conflicts. This study aims to review how a broad range of forest conflicts are portrayed in the Swedish media, analysing their temporal, spatial, and relational dimensions. We applied topic modelling, a machine learning approach, to analyse 53 600 articles published in the Swedish daily press between 2012 and 2022. We identified 916 topics, of which 94 were of interest for this study. Our results showed that media coverage of forest conflicts is increasing, and that the conflicts receiving the most coverage relate to hunting and fishing (35 % of total coverage), energy (24 %), recreation and tourism (11 %), nature conservation (8%), forest damages (6%), international issues (5%), forestry (5%), reindeer husbandry (4%), media and politics (2%), and mining (1%). Some of these conflicts were continuously reported upon, while the coverage of others exhibited seasonal or event-related patterns. Four conflicts received most of their coverage in specific regions, while others were covered across the whole of Sweden. Several of the conflicts related to each other, forming three clusters of issues focused respectively on industrial, cultural, and conservation conflicts. Our results emphasise the value of using topic modelling to review the temporal, spatial, and relational dimensions of how conflicts are reported upon in the media.

Climate adaptation of biodiversity conservation in managed forest landscapes

T4.6 Conflicts in Forest Settings

Caroline Greiser[1, 2]
Ditte M. Christianssen[2, 3], Irena A. Koelemeijer[2, 3], Kristoffer Hylander[2, 3]
[1] Department of Physical Geography, Stockholm University, Sweden
[2] Bolin Centre for Climate Research, Stockholm University, Sweden
[3] Department of Ecology, Environment and Plant Sciences, Stockholm University, Sweden

Abstract: Biodiversity conservation in managed forests needs new complementing approaches given the threat from rapid climate change for which we present two main strategies: (1) The *resistance* strategy focuses on actions to increase the capacity of species and communities to resist change. (2) The *transformation* strategy includes actions that ease the change of communities to a set of species that are well adapted to the novel environmental conditions. We suggest a number of concrete tools for policy makers and managers. Tools from the resistance strategy include: identifying and protecting climate refugia for cold-favoured species; reducing the effects of drought by protecting hydrological networks; and actively removing competitors threatening cold-favoured species. Under the transformation strategy, we suggest tools like: enhancing establishment of forest species favoured by the new climate, but currently disfavoured by forest management, e.g. by planting them at suitable sites outside their main range; and increasing connectivity across the landscape to support the expansion of warm-favoured species to new suitable sites. Finally, we suggest applying a landscape perspective and managing for both retreating and expanding species in parallel. The two different strategies (resistance and transformation) should be seen as complementary ways to maintain a rich biodiversity in future forest ecosystems.

Conflicting forest discourses in journals and amongst professionals

T4.6 Conflicts in Forest Settings

E. Carina H. Keskitalo[1, 2]
Gun Lidestav[2], F. X. Aguilar[2]
[1] Umeå university
[2] SLU Umeå

Abstract: The academic literature is rich in varying and divergent understandings of forest, and it has been observed that discourses around forestry and forest use are often highly national- and sectoral-based. This means that not only is there a variation between countries in how forest is treated, but there is also a variation amongst how different disciplines treat forest issues within a country. In many cases, there may also be conflicting understandings expressed between those focusing more on production and those focusing more on protection. To study the potential variations in present literature in the case of the relatively strongly forest focused country Sweden, this study investigated material found in a structured literature review on forest management. Results illustrate the more limited variation between articles classified as Agricultural and Biological sciences (where Forestry is a sub-category) and Environmental science. However, they also illustrate a variation in how forestry is treated in specific articles across categories, which corresponds with a more production-oriented perspective versus one focused on environmental considerations. These results were followed-up in focus groups with participants from forest production- and environmental-oriented sciences.

Conflicts about clearcutting: an opportunity to question the forest social order

T4.6 Conflicts in Forest Settings

Philippe Deuffic[1]
[1] Inrae, Bordeaux, France

Abstract: Protests and conflicts against clearcutting have increased tenfold in the last ten years in France. NGOs and citizen movements are so active that they are succeeding in suspending and even stopping many harvesting operations in the most productive forest regions. How did this social movement emerge and how are forest owners' associations reacting to this strong social mobilization against clearcutting? Is it just a difficult period to get through, or a transformative moment that is here to last? Using a socio-constructivist theoretical framework to analyze the rise and fall of social problems, we will show that clearcutting conflicts are not new but often go back several centuries. We will also show how ENGOS and local citizens' movements are joining forces today to put clearcutting regulations on the political agenda through highly effective grassroots and internet communication campaigns. Conflicts are also stimulated by the "greening" and "climatisation" of social debates, which means that every logging action should be evaluated according to its ecological and climatic impacts. Clearcuts illustrate these conflicting views by questioning the impact of forest management operations - whether logging or reforestation - on the landscape, ecosystem services and the ambivalent role of forestry in the economic development of remote rural areas. More generally, these protests are putting into question the forest social order that usually prevails in the forest sector Despite some moments of violence, and according to Georg Simmel' approach of conflicts, we show thatconflicts can be a positive moment to discuss the social contract between citizens, forest owners' organizations and forest policy makers. Finally, we will show how these conflicts lead some forest owners to reconsider certain forestry techniques such as clearcutting.

Conflicts arising from green infrastructure plans in Swedish forest: how reactions to maps affect and impede soft policy implementation

T4.6 Conflicts in Forest Settings

Luis Andrés Guillén[1]
Vilis Brukas[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Alnarp, Sweden

Abstract: Sweden has a long tradition of forest ownership with strong property rights over resource management decisions. Private owners also manage more than half of Sweden's forest area. Under Sweden's liberal forest governance, forest stakeholders' acceptance is crucial for implementing novel instruments to landscape management, such as green infrastructure plans. Involving industrial and non-industrial private forest owners is, however, not a simple task. Based on analyses of green infrastructure plans and interviews with officials in charge of coordinating the plans at County Administrative Boards, the study aims to explore (i) the act of mapping areas with a high amount of key habitats and nature values and (ii) the resulting conflicts and the hinders to implementation of governmental tasks. The green infrastructure plans aimed at gathering knowledge, mapping nature values and listing actions to guide all stakeholders on how to include green infrastructure in their managing decisions. We examine how maps tend to be conceptualized as solely the creation of new knowledge, supposedly scientific and objective in its nature. Yet, there was an underlying realization that maps are able to indirectly affect resource distribution for nature conservation or limit forest owners' decision space. Further, we explore how coordinators adapt to the opposition by forest stakeholders of the actual maps and the concept of a government mapping their private property. Our discussion centers on how maps, albeit considered pure spatial knowledge, represent a soft policy instrument for environmental governance and resource prioritization in forest settings. Our study underscores how different departure points to knowledge and its significance create conflicts and subsequent adaptations in working strategies or the stagnation of environmental initiatives

Diverse human values combined and reflected in the modern forest policy and education system in East-Asian countries

T4.6 Conflicts in Forest Settings

Yuichiro Hirano[1]
[1] Forestry and Forest Products Research Institute

Abstract: Conflicts in forest settings arise from the recognition of diverse human values and benefits of forests. However, viewing historically, the forest policy and education system in modern period had been formed with the combination and reflection of those multiple values in East-Asian countries.

Taking China and Japan as examples, this research focused on the values and footprints of those who greatly contributed to the formation of the modern forestry administration and education in these two countries.

Not only did they aim to establish a sustainable timber production system, but they also recognized the importance of forests from the perspective of water and soil conservation based on local circumstances. The significant connections with landscape architecture, botany, and tree taxonomy were also confirmed. Having these roots, the modern forestry and public foresters, sometimes regarded as having simplified scientific viewpoints, played the remarkable roles to harmonize and resolve conflicts based on local human actors with different values and benefits of forests in East Asia.

Forest restoration paradigms and conflicts in Europe

T4.6 Conflicts in Forest Settings

Lyla O'Brien[1, 2]
Agata Konczal[2], Anna Begemann[1, 2], Marko Lovrić[1, 2], Nataša Lovrić[1, 3], Simon Fleckenstein[4, 5], Georg Winkel[2]
[1] European Forest Institute, Platz der Vereinten Nationen 7, 53113, Bonn, Germany
[2] Forest and Nature Conservation Policy Group, Wageningen University, Droevendaalsesteeg 3, Building 101 (Gaia Building), 6708 PB Wageningen, the Netherlands
[3] University of Eastern Finland, Faculty of Science, Forestry and Technology, School of Forest Sciences, Yliopistokatu 7, 80101, Joensuu, Finland
[4] University of Freiburg, Chair of Forest and Environmental Policy, Tennenbacher Straße 4, 79106 Freiburg im Breisgau, Germany
[5] University of Helsinki, Faculty of Agriculture and Forestry, Department of Forest Sciences, FI-00014 Helsinki, Finland

Abstract: Forest landscape restoration (FLR) is gaining importance in Europe. This study aims to analyse how forest restoration is understood in a European context, identify forest restoration conflicts, and explore the relationship between both understandings and conflicts. To achieve this, 46 semi-structured interviews were conducted with stakeholders in 12 FLR case studies in 12 different European countries. The results show three distinct ways in which forest restoration is understood, i.e., 'forest restoration paradigms', which arise from how different actor groups problematize forests and their management. Looking deeper, these 'forest problematizations' are determined by the ecological and socio-ecological context and the collective values, beliefs, and knowledge of actor groups. In addition, when these underlying values and interests clash in a certain context, forest restoration conflicts emerge. For effective FLR implementation in Europe and decision-making processes, it is important to understand how stakeholders perceive forest restoration and the contexts in which different understandings emerge.

How to Frame Bengal Tigers: Conservation Narratives and State Politics versus Local Ecosystem Ethos and Livelihood Realities in Bangladesh's Sundarban

T4.6 Conflicts in Forest Settings

Sujoy Subroto[1]
Conny Davidsen[1]
[1] Department of Geography, University of Calgary, Canada

Abstract: The Sundarbans mangroves are a world-famous Bengal tiger habitat and home to a complex social-ecological system with a long history of colonial exploitation, exclusionary forest governance and systematic marginalization. The region's global ecological significance has driven conservation- and climate-focused development interventions, among which the tiger/wildlife-human strategy needs a critical re-assessment of their effectiveness. Drawing on political ecology and grounded in qualitative methodology, this exploratory case study examines the dominant narratives and national policy discourses surrounding the tiger and *de facto* local social-cultural context in the Bangladesh Sundarbans to understand how conservation crises are framed, conflicts are presented/constructed, and solutions are devised.

The study illustrates overlapping and contradicting discursive representations of tigers as a central and dominant theme in policy discourses, both materially and symbolically, across various levels of governance. Two major findings: First, we outline the region's layered popular tiger narratives (e.g. globally endangered, national pride, climate victim), and argue why the state-donor coalition tends to simplify the region's complex human-wildlife interaction into a binary Tiger-Human conflict centered around instrumental competition over resource extraction. Secondly, this study highlights shortcomings in the state's official record of tiger attack fatalities compared to community-level recorded causalities and explains this gap through conflicting interests and visions between the regional forest department and community's de facto livelihood risk strategies.

Our analysis examines Sundarban's wildlife narratives and livelihood-related stories embedded in social-cultural contexts with local perceptions, knowledge bases, cognitive framing, power relations, and moral values. It argues that transregional politics of framing tiger conflict in a monolithic way have overshadowed or sidelined the root causes for local wildlife conflict. This has legitimized band-aid solutions such as territorial compartmentalization, stricter law enforcement and restrictions on livelihood activities although they are ineffective or inappropriate to local socio-spatial-cultural tiger-related perceptions and ecological values. Moving beyond the central binary of tiger narratives, this study offers a re-interpretation of tiger perceptions and strategies, embedded in a thorough understanding of the underlying political-economic drivers, resource governance interests and rural power dynamics to address the Sundarban's conservation-development conflict more effectively, and sustainably.

Private forest owners' acceptance of breeding and regeneration strategies for increasing the share of broadleaves in Sweden

T4.6 Conflicts in Forest Settings

Louise Eriksson[1]
Caroline Rapp[1]
[1] Umeå University

Abstract: There are divergent opinions on the management of forests among rightsholder and stakeholder groups, politicians, and in the general public. When management changes to meet challenges associated with increases in forest damages associated with climate change and still deliver a range of ecosystem services, it is especially important to understand peoples' opinions. To outline legitimate management strategies, there is a need to understand opinions that differ between groups, opinions shared between different groups, but also the heterogeneity within groups. When stakeholder groups learn how another group is endorsing different opinions, rather than one coherent view, or get a better understanding of why a particular opinion is being endorsed, there may be a basis for dialogue.

Diversification of forest management strategies and tree species is an approach to handle future challenges to forests. Forests currently dominated by conifers may be diversified by adopting broadleaves, but this can be done in different ways using different breeding and regeneration strategies, including traditional breeding, assisted migration, planting non-native hybrid tree species, or genetically modified tree species. While studies have revealed that acceptance towards breeding strategies in the public vary, little is known about forest owners' views on their place in the current diversification of management to adapt to climate change. This study examines private forest owners' (also called family forest owners) acceptance of breeding and regeneration strategies to increase the share of broadleaves based on data from a large survey of a random sample of forest owners in Sweden (n = 5000). Analyses focus on the within-group variations on acceptance, and considers for example the place-based, social and psychological variables that may be used to explain varying levels of acceptance. By analysing these attitudes of private forest owners – a key rightsholder group in Sweden – it is possible to identify both mean level of acceptance but also within-group variation as a basis for an improved understanding of how this group differ from, or overlap, with other stakeholder groups in this context.

Social representations and social licence in emerging climate adaptations for fire-affected forests

T4.6 Conflicts in Forest Settings

Rebecca M Ford[1]
Prativa Sapkota[1], Andrea Rawluk[1], Kathryn JH Williams[1]
[1] the University of Melbourne

Abstract: Forests are changing with increased fire frequencies that are linked to climate change. Managers seek a social licence for new types of interventions to support forest resilience. However, this is made complex by differing views among the public and stakeholders about how humans should relate to 'natural' forest ecosystems. We investigated support for practices such as forest thinning and restoration and explored nuances in people's thinking about forests through the concept of social representations. These are systems of values, beliefs, norms and practices that are thought to emerge through informal social interactions and are drawn on as people respond to new situations such as climate change. We conducted ten focus groups with members of interest groups and the public to identify responses to forest change and components of social representations. We then conducted a survey of 475 residents to characterize social representations and measure support for practices. Four main social representations were identified and named for the values and human-forest relationships which helped define them: Shaping forests; Partnering forests; Defending forests; and Relating forests and society. Participants appeared to draw on these in forming views about unfamiliar forms of management. The practice of thinning for ecological resilience originates within the 'Shaping forests' social representation, which includes the belief that people should intervene to improve forests, but is not a good fit with other social representations, such as 'Defending forests', in which human intervention is believed to be detrimental to forests. Overall, gentler interventions were more supported, however participants also recognized the need to experiment with many different methods, acknowledging that one approach would not fit all contexts. They urged governments to incorporate local, Indigenous and scientific knowledge in the development of new practices, alongside professional expertise. There is now a window of opportunity to build new relationships and social licence as new adaptive practices are trialled and as members of the public are still forming their views about them.

The conservation effort response to the incursion of armed group into protected areas: insights from the W-Arly-Pendjari Complex in West Africa

Abstract: The sudden incursion of armed groups in 2017 into the W and Arly parks, located respectively in Niger and Burkina Faso, poses a serious threat to conservation efforts in one of West Africa's largest transboundary natural world heritage sites the W-Arly-Pendjari Complex (WAP). Responding to such a conflict requires quick adaptive management for conservation managers, who are often unprepared and have no clear strategies to such threats. The question is therefore how conservation managers respond to such situations in practice. Using disaster response as an analytical framework, this paper aims to describe how conservation managers have dealt with these issues in order to assess their performance in tackling them. Our results show that conservation responses to the security crisis have been multi-faceted, depending on the WAP countries. It ranges from a withdrawal of conservation actors from the parks (Niger and Burkina Faso) to a continued active management in the Benin component. The resistance of Benin can be to some extent associated with the fact that solid foundations were put in place before the crisis. A focus on a community strategy that met the needs of the forest dependent communities to reduce their vulnerability is a clear key factor in building a local alliance in the face of such a disaster. The main challenges for conservation managers are their limited capacity to tackle the new problem but careful attention needs to be paid on the false perception of addressing the crisis solely from a military point of view. The emergency response is often weak as it depends on what external support can or is willing to offer. Such an approach easily falls into symbolic gestures far from eliminating the issues.

Unravelling Tensions: Analysing Social Networks of Forest Biodiversity Conservation Implementors

T4.6 Conflicts in Forest Settings

Theresa Klara Loch[1]

[1] Faculty of Environment and Natural Resources, Chair of Forest and Environmental Policy, University of Freiburg

Abstract: In Germany, the recent impacts of drought, heat and related bark beetle outbreaks have brought conflicts over multifunctional forest management into view. In the negotiation process between management, use and protection of forests, biodiversity conservation is a crucial endeavour to achieve the conservation of species, habitats and ecosystems. Respective biodiversity cartas and policies have been formulated on international, national and regional levels, but a focus on problems of ground-level implementation is lacking.

Overall, policy implementation has had a secondary role in policy analysis, attributing a higher importance to policy formation. Nevertheless, policy implementation is a highly interactive process, determined by implementors themselves, their knowledge and social networks. The latter of these are an important variable in the decision-making process and provide a first explanation for (non-)collaborations within the implementation process. To gain a better understanding of social networks in these processes, social network analysis provides a language and methodology to make relationships visible. Thereby, a special interest is placed on negative or 'difficult' ties, which have been described as particularly harmful, as they can lead to high levels of disappointment, frustration and anger – hindering the implementation of conservation measures. With the exception of extreme cases, social networks are combinations of positive and negative interactions, incorporating material, emotional and reputational aspects. Most focus has been placed on positive ties, analysing different forms of relational states and events, while research on negative and 'difficult' ties has been lacking. Social negativity ranges from behaviours that provoke conflict, over insensitive behaviours, to behaviours that interfere with a person’s ability to achieve goals. Difficult ties are generally described as another form of social negativity, in which the presence of people is felt to be difficult.

Identifying such negative or difficult ties within social networks of implementors contributes to a better understanding of implementation barriers, conflicts and final outcomes. Through a case study in the Black Forest (Germany) a local social network of forest biodiversity implementors will be explored, analysing the causes of forest conflicts and identifying possibilities of developing and supporting – or even intentionally creating – relationships for the purpose of more successful forest biodiversity implementation.

Where do deer belong? Reframing wildlife management conflicts through place-based initiatives

T4.6 Conflicts in Forest Settings

Mariella Marzano[1]
Norman Dandy[2]
[1] Forest Research, Northern Research Station, Roslin, Scotland, United Kingdom
[2] Bangor University, College Road, Bangor

Abstract: The creation of new forests, agroforestry systems and urban treescapes in the pursuit of net zero will generate many more common spaces where wildlife and humans will connect. These spaces will simultaneously form new habitat for wild deer and venues for people to use and engage with. Evidence consistently shows that forests are viewed strongly as places *for* wildlife – spaces in which other species can and should thrive without human interference. This sits alongside evidence that highlights forests as sites where people seek out encounters with wildlife. Significant benefits can flow from wildlife watching and similar experiences, but wildlife management infrequently considers the promotion and enhancement of these interactions.

Whilst deer management in the UK has evolved into a more collaborative and inclusive enterprise, it remains targeted towards a relatively stable set of values, interests, and objectives oriented towards protecting productive forestry and the structural ecology of native woodlands. Narrowly constructed existing approaches frame wild deer as over-abundant with consequently negative impacts within forest settings. Arguably, inclusive place-based approaches more effectively recognise and encompass deer contributions to the desirable characteristics of, and benefits generated by, forests. Our analysis focuses on examples of place-based initiatives - that is, activities which enable communities to recognise and acknowledge the ways in which wildlife and people co-produce local places. This has considerable potential to reframe contemporary wildlife management conflicts in forests.

We will present case-study analyses that explore the potential influence of place-based initiatives on ways in which diverse stakeholders (e.g. community members and land managers) value deer, how they understand potentially problematic wildlife species and their own impacts, and their perspectives on where deer belong. Our aim is to identify place-based initiatives and actions that can build (co-create) positive relations between communities and their local wildlife. This reframing will move us beyond the core research of documenting public ‘attitudes to’ particular management methods (such as fencing, culling, etc), towards an understanding of the processes via which we can create resilient communities that have a developed consideration of the diverse and broad connections between themselves, wild deer, and their local environment.

Which characteristics support forest recreation? – A discrete choice experiment to evaluate visitors' preferences for forest recreation in Germany

T4.6 Conflicts in Forest Settings

Isabelle Jarisch[1]
Thomas Knoke[1]
[1] Institute of Forest Management, Research Department Life Science Systems, TUM School of Life Sciences Weihenstephan, Technical University of Munich, Germany

Abstract: Measuring visitors' preferences for forest recreation began to gain momentum in Germany in the 1980s, when scientific interest in recreational use of forests and society's attachment to green spaces was high. Today forest recreation is an example of cultural ecosystem services that is increasingly integrated into multi-objective forest management. When public planners ask forest managers to consider recreational value in developing management plans, foresters often fear that doing so will involve conflicting goals and a restricted decision space. But is that fear backed up by up to date research or rather the opinion of urban forest managers afraid of losing opportunities for timber production?

In comparison to other ecosystem services, forest recreation may never generate high enough payments to match the social value of this ecosystem service, at least in Germany. However, scientific studies often report high financial values based on forest recreation evaluations. Especially in urban and suburban areas, the relevance of forest recreation for multi-objective management can be very high and proved its importance in multi-objective forest management.

We use a discrete choice experiment to model a forest visitor's decision between predefined forest alternatives, to evaluate which characteristics are matter to people using forests for recreation. Moreover, due to the multi-dimensional, preference-based valuation technique, we can portray the importance of forest characteristics for visitor's utility functions. We use willingness to travel as measure to calculate financial values for forest recreation in Germany. Focus group discussions have highlighted the importance of mixed composition of single stands along a forest road. Variability of contiguous stands was valued as important characteristic for high forest attractiveness for recreation. Therefore, our study concentrates not on the attractiveness of single stands as often seen in other studies, but wants to evaluate the composition of different stand types. By selected management interventions and innovative visitor guidance concepts, forest managers can modify forest recreation and the related public perception. We believe intensified research about forest recreation helps to strengthen the connection between society, forests and supports understanding for multi-objective forest management.

T4.7 Digital transformation in forest governance – the Good, the Bad and the Ugly

And the forests tweets will echo with laughter? - German "forest death 2.0" in the hybrid media system

T4.7 Digital transformation in forest governance – the Good, the Bad and the Ugly

Philipp Mack[1]
[1] University of Freiburg

Abstract: Large-scale forest damages induced by drought, heat and related bark beetle outbreaks are some of the first signs that make the effect of climate change visible and tangible to the public in Germany. With the first damages in 2018, a heated debate emerged that was quickly framed as *forest death 2.0*. In the light of the climate crisis, actors seek to position themselves in the debate, highlighting the urgency in implementing their proposed measures to *save* German forests.

In order to understand these struggles for discursive power, my study is conceptually embedded in the complex entanglements between legacy and new media that Andrew Chadwick defines as *Hybrid Media System*. My empirical work comprises the analyses of different forms of public and political communication, including newspaper articles, position papers and twitter data. By drawing on different concepts of discourse and framing theories, the results show the multi-faceted and overlapping problematizations of the forest crisis, that is yet shaped by a structurally consolidated polarization between forestry and nature conservation discourses. In line with existing literature on social media debates, I show that this polarization is further increased in the twitter debate through the surge of a third discourse on climate scepticism, that is disregarded in media and political communication. With this contribution I seek to contribute to the understanding of the relation between digital and traditional forms of communication in forest controversies as well as the surge of polarization in times of crises. Doing so, I critically reflect on deliberative perspectives on digital media, as besides “the Good” and “the Bad” it opens up a space for “the Ugly” that might echo back in the then seemingly narrow gap between forestry and nature conservation.

Content creation and streaming by forest machine operators – current trends and impacts on forest-related discourse.

T4.7 Digital transformation in forest governance – the Good, the Bad and the Ugly

Philip Chambers[1, 2]
Heli Kymäläinen[1], Daniela Nousiainen[1]
[1] University of Eastern Finland, Finland
[2] Gamification Group, University of Tampere, Finland

Abstract: The digitalisation of forest-related discourse has transformed the way in which the sector interacts in the public sphere and has led to the creation of a distinct 'digital town square' for forestry. Moreover, with the rise of mobile applications like TikTok, video content creation and live-streaming capabilities have provided people at the operational level of the forest sector with new opportunities to present their work and talk directly with the public. Furthermore, these activities are gamified, increasingly monetised, and professionalised in a way that has led to the blurring of the lines between work and play - a phenomenon known as 'playbour.'

In this study, the experiences of forest machine operators in Finland and their motivations behind creating online video content and taking part in live streaming are examined. From previous studies, it is known that forest machine operators are attracted to the profession through factors such as the working environment, the independence of the work, seeing the immediate impact of their work, as well as having the opportunity to 'play' with big and modern machinery. However, due to the monotonous nature of the work, which is being increasingly automated, social aspects of the job, including identity, standing in the community, and well-being, are also identified as being particularly important. This, coupled with the new digitalised social-networking possibilities, has led to intrinsically playful behaviour that is also providing new streams of income.

This new paradigm is investigated through online surveys and contextual interviews. The effect that content creation is having on the forest machine operators' well-being and workability is evaluated. Furthermore, the study explores the degree to which these content creators are self-censoring as they anticipate pushback from the traditional holders of discursive power - state forestry organisations, forest managers, forest owners, machine manufacturers, and other related stakeholders.

This study provides insights into the nature of, and motivations behind, contemporary forest discourse. It highlights how developments in digital platforms are leading to the democratisation of forestry communication, and how real-time conversations may be shaping the discussion around forest conflicts and governance.

Institutional design for equitable governance of hybrid forest commons

T4.7 Digital transformation in forest governance – the Good, the Bad and the Ugly

Bob Kreiken[1, 2]
[1] Delft University of Technology
[2] Interdisciplinary Research on Digital Sequence Information (iDSI)

Abstract: Genomic technologies are crucial for the conservation and adaptation of forests in the face of numerous threats. Vast genetic databases facilitate rapid screening and international scientific collaboration. The storage of these delocalised digital resources in addition to physical forest genetic resources (FGR) has given rise to concepts like twin or hybrid commons. Commoners in both systems face unique but interrelated challenges. Whereas local FGR managers have to navigate the policy landscape surrounding a forest, forest scientists and bioinformaticians have to navigate a myriad of global regulations governing Digital Sequence Information (DSI) on genetic resources, a policy term for genetic sequence data.

Recently, Parties to the Convention on Biological Diversity decided that fair and equitable access and benefit-sharing (ABS) obligations apply to DSI. The benefits arising from the use of DSI should be directed towards the conservation of biodiversity and its sustainable use, specifically by indigenous peoples. Through this decision global data governance has been tied to local forest governance. Therefore, issues of fairness and equity are now extended **across** two commons between states, stakeholders and scientists, and between DSI users and FGR managers and stewards.

First of all, the agenda-setting power over forests is increasingly shifting towards data users with the risk of making local voices 'invisible'. On the other hand, there are opportunities to take local autonomy and discourses of FGR stewards to a global level, for example via Indigenous Data Sovereignty discourse. Secondly, although open access to DSI allows North-South collaboration, it can exacerbate existing inequities in science by excluding actors without data skills or equipment. Thirdly, because values and norms are embedded in global data, the digitalization of forests might dominate how others should understand and manage forests, replacing local ways of knowing.

There is no literature that has explored this *glocal* and polycentric governance of DSI and FGR. However, we argue that any institutional design should: 1) include value-centred approaches to research capacity-building for the use of DSI, 2) elucidate relations of environmental justice in this governance coupled system, and 3) establish duties between the DSI and FGR commoners for achieving just and equitable outcomes.

Mediated Battles for the Forest: comparing discursive power in hybrid media systems in the Baltic Sea Region

T4.7 Digital transformation in forest governance – the Good, the Bad and the Ugly

Kristina Riegert[1]
Ida Wallin
[1] Södertörns Högskola

Abstract: The increased interest in forests as the basis for a growing bioeconomy has led to an intensification of conflicts, expanded national debates and heightened media interest. Media reporting amplifies already entrenched conflicts between different users of the forest, and this is further fueled by social and digital media. Concerns about factuality and misinformation in the debate have also been raised. Media are the main sites of public discourse, and it is therefore important to analyse how digital and social media change the way debates are circulated and represented, and the potential consequences this has for governance and power relations. In this project we trace how *discursive powe*r is wielded and circulated through framing forest debates in hybrid media systems of three Baltic Sea countries - Estonia, Germany and Sweden. Around half of EU's forested area lies within the Baltic Sea region, making this a key area for a growing bioeconomy in the EU and a forest-conflict hotspot.

Mediated forest conflicts can be seen as discursive power struggles to define problems, identify relevant knowledge or arguments, and propose solutions. Previous forest research in each of the countries shows polarized and emotional debates between forestry and conservation alliances (Savioja 2017; Mack et al 2023; Jakobsson et al 2021). Theoretically we draw on the concepts of 'hybrid media systems' 'discursive power' and 'framing'. Hybrid media systems sets the focus on how the adaption between legacy and social media changes norms, logics and practices (Chadwick, 2017). Actors who harness these logics gain discursive power. This paper presents the comparative framework for locating discursive power (Jungherr et al, 2019), the motivation for studying particularly intensive peaks of mediated forest debates, and the identification of key arguments and actors. For the forest-rich Baltic Sea region, identifying how discursive power frames contributes to polarization or compromise contributes to an understanding of the media's role in the governance of sustainability transitions.

Shared resposnbility for biosecurity: Myrtle Rust in New Zealand and mainstream media framings of responsbility for action

T4.7 Digital transformation in forest governance – the Good, the Bad and the Ugly

Peter Edwards[1]
Robyn Kannemeyer[1], Gradon Diprose[1]
[1] Manaaki Whenua Landcare Research

Abstract: Globally managing biosecurity incursions, unwanted pests, and diseases are a growing concern as the climate warms. In some contexts this has resulted in shifts towards a shared responsibility between government agencies, industries, communities and Indigenous people. However, shifting responsibility can introduce new complexities in biosecurity systems at a time of significant socio-ecological change. Myrtle rust *(Austropuccinia psidii)* is a fungal disease posing a threat to plants and trees in Myrtaceae, including ornamental and culturally and economically important species. In Aotearoa New Zealand (A-NZ) this includes iconic tree and forest species like pōhutukawa, mānuka, rātā, and ramarama. Since myrtle rust arrived in A-NZ in 2017, mainstream online media reporting has covered the response to the incursion, and its ongoing spread throughout the country. To explore how 'shared responsibility' for biosecurity is framed, we have undertaken a discourse analysis of mainstream online media reporting on myrtle rust in A-NZ.

Our analysis identifies five themes; the description of myrtle rust, different conceptions of 'borders', the contested portrayal, and distribution of responsibility for decision making across different actors (government, industry, communities, and Indigenous Māori people), and the role of science and different knowledges in biosecurity. Our findings show that at the start of the incursion, media reporting was high. Myrtle rust was framed primarily through a Western science lens which emphasised the risks myrtle rust posed to A-NZ's primary sector. The Central Government was framed as being primarily responsible for managing the incursion response, with support from industry and communities (primarily in terms of following containment protocols). As myrtle rust became established and the incursion response ended, media reporting decreased, and framings began to shift. Increasingly local government, researchers, communities, and Indigenous groups were framed as being responsible for action, and having knowledge that may help inform action. The risks posed by myrtle rust also shifted to highlight more socio-cultural considerations, such as the loss of iconic native trees. These findings show how 'shared responsibility' for biosecurity has shifted over time and place and indicate the inclusion of more diverse knowledges and values in relation to biosecurity research and action in A-NZ.

Situating forest policy and governance issues through digital methods

T4.7 Digital transformation in forest governance – the Good, the Bad and the Ugly

Rina Tsubaki[1]
Liliana Bounegru[2], Jonathan Gray[2]
[1] European Forest Institute
[2] King's College London

Abstract: The web and social media platforms are increasingly becoming sites of knowing, reporting on and interacting with forest and nature conservation. This can bring opportunities for researchers to repurpose online materials to explore forest-related issues, practices, experiences and perspectives in different contexts. Yet, studying social media poses a number of challenges for researchers. For example, researchers need to adapt to changes made by social media platforms (e.g. Facebook, Instagram, Twitter and Reddit limiting API access). At the same time, social media platforms have specific features, practices and cultures that researchers must attend to and account for. How can research questions and methods be adjusted in order to study the online mediation of forest cultures and issues?

Drawing on multiple collaborative research projects with the European Forest Institute, the Public Data Lab and King's College London, this work explores the use of digital methods (Rogers, 2013, 2019) to study online engagement around forests and forest issues - and how these may enrich research on forest governance, policy and practice. Through the study of issue networks, actors and media practices, it suggests what can be learned about how forests are articulated, activated and recomposed in online spaces - and the implications of this for forest research.

T4.8 Effects and effectiveness of forest policies in developing tropical statehoods

An Indicator-based Composite Index for Assessing and Reporting on Forest Sustainability

T4.8 Effects and effectiveness of forest policies in developing tropical statehoods

Aaheli Chaki[1, 2]
Bhaskar Sinha[1], Jigyasa Bisaria[1]
[1] Indian Institute of Forest Management, Bhopal, India
[2] Forest Research Institute, Dehradun, India

Abstract: Forests are one of the world's vital terrestrial ecosystems, providing many services and benefits which support the livelihoods of about 350 million people globally. The dependency on forests for people's livelihoods in developing tropical countries like India is higher than in developed countries. This further necessitates a need for comprehensive monitoring and reporting of forest sustainability on different social, ecological and economic indicators for evidence-driven decision-making to manage forest resources effectively. However, India's current national forest monitoring is confined largely to a few ecological indicators, limiting the understanding of forest resources' social and economic contributions among policymakers and decision-makers. In this context, the current study presents a multi-dimensional perspective on forest sustainability based on a newly developed indicator-based composite index. The relevant social, ecological and economic indicators were identified through a literature survey of standardized national and international frameworks and stakeholder consultations. A total of 36 relevant indicators were selected for developing the composite index, including ecological (12), social (13) and economic (11) indicators to capture a holistic assessment of forest sustainability. The paper also highlighted the rationale for including each of the major indicators, which is critical to realize the full potential of forests through effective management. The data on these indicators have been collected from different sources and Government records to check the availability and identify existing information gaps. Furthermore, we have computed the score based on the newly developed forest sustainability index in one of the forest divisions to identify each indicator's contribution to the overall sustainability of forest resources. Thus, the study provides a data and evidence-driven decision-support mechanism for effective assessment and reporting on forest sustainability.

An Overview of Global Bamboo Forest Certification: The Status Quo, Challenges, and Prospects

T4.8 Effects and effectiveness of forest policies in developing tropical statehoods

Yanxia Li[1]
Yanjie Hu[2], Kun Li[2]
[1] International Bamboo and Rattan Organization, Beijing 100102, China
[2] Research Institute of Forestry Policy and Information, Chinese Academy of Forestry, Beijing 100091, China

Abstract: Illegal logging is one of the main causes of deforestation and forest degradation. As a voluntary market-driven mechanism, sustainable forest certification aims to reduce illegal logging in forests and promote sustainable management practices by creating a transparent, independent tracing and auditing mechanism. To date, around 11% of global forest areas have been certified under forest certification schemes. Biologically, bamboo belongs to the grass family and is classified as a non-timber forest product. Owing to its high fiber quality, many bamboo panel-based products, such as flooring, furniture, and kitchenware, are traded as alternatives to timber products in the global market. Therefore, bamboo and its products must adhere to the same legal requirements and public procurement policies as timber, such as the European Timber Regulations and the Lacey Act in the United States. Forest certification is widely acknowledged as a means of ensuring the sustainability and legality of forest sources by European countries and the United States, which are the largest importers of bamboo products. By identifying the differences between bamboo and trees in terms of their biological features and management, this paper provides an overview of the current development of global bamboo forest certification in terms of certification standards, practices, and markets; analyzes challenges and future trends; and offers recommendations for creating interest in this issue and taking further action.

Keywords: sustainable forest management, bamboo, certification, chain of custody, trade

Calibrating collaborative forest management through the lens of social, economic and ecological policy instruments in Bangladesh

T4.8 Effects and effectiveness of forest policies in developing tropical statehoods

Md. Saifur Rahman[1, 2]
Md. Nazmus Sadath[3]
[1] Ministry of Environment, Forest and Climate Change, Bangladesh Secretariat, Dhaka-1000, Bangladesh
[2] Alexander von Humboldt Postdoctoral Fellow, TU Dresden, Germany
[3] Professor, Forestry and Wood Technology Discipline, Khulna University, Khulna, Bangladesh

Abstract: Sustaining and scaling up the benefits of a pilot intervention will require a clearer understanding of the political process and a transformative national framework that may support policy and institutional governance landscapes. Policy instruments, integral to the policy-political process, set the limits and directions of policy implementation. A greater understanding of a well-known set of implementation instruments and underlying reasons for choice and actors' rules of behaviour are vital to analysing the effectiveness of policies. We witnessed a notable policy shift in the governance of community-based forest management in Bangladesh – from social forestry (SoF) – to co-management (CoM) – to a collaborative (CoL) approach. However, the question comes: why has it been crucial to making such frequent shifts, what changes happened with the policy instruments across the governance process, and how has the transformation been essential to achieve conservation and sustainable management of protected forests? Hence, the study aims to investigate the trend and fusion of policy instruments through the lens of social, economic and ecological dimensions, reasons for choices and actors' rules of behaviour to evaluate the policy effectiveness. The study, therefore, hypothesises diverse formal and informal interests and multiple actors' power capabilities determine the instrument choices that may not ensure the sustainability and conservation of protected landscapes. The study employs a mixed qualitative-quantitative research method based on content analysis of relevant policy documents and expert interviews. The theoretical viewpoints regarding interests and power discourse and the evidence-based explorative analysis would serve as a basis to draw results about the power players and the driving interests taking such a significant stake in the resources management decisions. Among others, one important finding is that powerful development actors (foreign donors) and their allies make decisions regarding choices of policy instruments utilising their expert identity and funding portfolio. Adopting and implementing policy instruments see a lack of participation of state and community actors, stagnant scale-up operations and a paucity of resource mobilisation that cannot ensure sustainability and conservation of protected landscapes. The research gives a policy direction to help manage the protected areas and support undertaking strategic development decisions (e.g., financing, cooperation and policymaking).

Customizing the political effects of international forest policies in selected developing countries

T4.8 Effects and effectiveness of forest policies in developing tropical statehoods

Lukas Giessen[1]
[1] TU Dresden

Abstract: Based on a larger collaborative research programme, this contribution aims to analyse the political effects of selected international forest governance initiatives in developing countries. It does so be employing international regime theory and combining it with the emerging concept of "customizing" international institutions during implementation or transposition into domestic national and sub-national contexts. It employs cases from Bangladesh, Indonesia, Argentina .

Determinants of benefits of Participatory Forest Management income generating activities in Upper Imenti Forest in Meru County, Kenya

Abstract: This study focused on identifying factors affecting the benefits of Participatory Forestry Management (PFM) income generating activities in Upper Imenti Forest from community perspectives and whether they are dependent on status of participation in forest management through membership of Community Forest Association (CFA) or not. Cross-sectional survey research design was applied for collecting quantitative data using a semi-structured questionnaires for 384 household stratified on the basis of PFM participation status. Using Statistical Package for Social Sciences version 25, Binomial regression with Wald Chi-square was analysed to identify factors perceived to be significantly influencing benefits for PFM participants and Pearson Chi-square to compare factors perceived to be affecting PFM and non-PFM participant.data. CFA members' participation in PFM was significantly and positively affected by benefits of PFM income generating activities and forest products accessed in the forest. Benefits linked to Plantation Establishment for Livelihood Improvement System (PELIS) for CFA members were significantly reduced by enforcement of moratorium policy since February 2018, diseases and pests, poor PELIS guideline adherence and animal damage. Benefits related to state forest access for firewood by the CFA members were negatively influenced by the moratorium policy. Diseases and pests affected benefits associated with bee keeping significantly. Comparing factors under different PFM participation status, crop production was significantly affected by policy changes, pest and diseases, animal damage and PELIS guideline adherence for CFA members than for Non CFA members. Policy changes also affected the CFA members significantly in firewood collection and access to fodder in the state forest than the Non-CFA members. Hence, sustainable community participation in Upper Imenti Forest management requires: increasing PFM benefits, addressing factors reducing benefits and enhancing active participation of CFA members in PFM related decision-making processes.

Key words: Participatory Forest Management, Community Forest Association, sustainable community participation, access to forest products, moratorium policy, income generating activities

Do incentive- or penalty-based policies better promote tropical forest conservation? Experimental evidence from Brazil

T4.8 Effects and effectiveness of forest policies in developing tropical statehoods
