Abstract: The productivity of Indian forest is 1 cu m/ha/year as compared to global average of 3 cu m/ha/year. It supports different industries like handicraft, pulp, paper, plywood, veneer, etc. There is a large gap in demand and supply. Scientific intervention is required to improve their economic traits like growth rate, stem form, wood quality, etc. Use of genetic markers like SNPs and analysis tools like Association mapping can help in dissecting complex traits and identifying the responsible individual genes and alleles. Association mapping in plants was pioneered by Bartlen *et al.* AM is a method used to determine the relationship between phenotypic variation and genetic polymorphism based on Linkage Disequilibrium. The concept was described by Jennings in 1917. Its quantification was given by Lewtonin in 1964. Candidate gene association mapping and genomewide association mapping are two different approaches of association mapping. Various models from fixed model to mixed model are used in association mapping. A recently developed unified mixed model can even analyze multiple levels of relatedness. In general, feasibility of AM is appropriately measured by Fisher`s exact test. Candidate gene mapping is more feasible technically and financially in case of tree species having large genome size like conifers. GWAS mapping is more useful in dissecting the complex quantitative traits but it is not feasible everywhere. However, compared to linkage mapping, it is a better alternative even in tree species having large genome size as it has the ability to identify individual genes and alleles. The significant QTL associated with tree height, diameter at breast height and stem volume have been successfully mapped in *Populus* sp, etc. With the advancement in high throughput sequencing methods and development of integrated mapping approach, mapping can be done effectively even in non-model perennial tree species. Development of proper statistical tools, design of experiment and interpretation methods may even help in identifying all individual genes responsible for quantitative traits also. AM appears to be a promising tool to accelerate the advancement in the field of tree genomics, breeding, tree improvement, understanding the evolutionary process and exploiting the economic value of forest trees sustainably.

Breeding for Boundaries: genomic variants controlling the formation of defensive barriers against necrotrophic stem decay pathogens in Norway spruce

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: Trees must cope with the attack of multiple pathogens, often simultaneously during their long lifespan. In Northern Europe. *Heterobasidion* root- and stem-rot is a major disease of Norway spruce (*Picea abies*) causing vast economic losses. The disease is caused by *Heterobasidion parviporum* and its sympatric congener *Heterobasidion annosum s.s*. While a lot of wok has been done to understand and identify resistance to *H. parviporum* in Norway spruce it is unclear to what extent these resistances are effective also against *H. annosum s.s*. The objective of this work is to compare the genetic component of resistance in Norway spruce to *H. annosum s.s*. with the resitance to *H. parviporum.* To achieve this resistance to either or both pathogens relative resistance was measured using artificial inoculations in half-sib families obtained from the Swedish breeding program. The genetic component of resistance was analysed using genome-wide exome-capture sequenced SNPs and multitrait genome-wide associations. No correlation was found for resistance to the two pathogens in this particular breeding population; however, various associations were found between genomic variants and resistance traits with synergic or antagonist pleiotropic effects to both pathogens. Several of the pleiotropic genomic variants appear to be connected to processes leading to compartmentalization of the pathogen including variants in the Norway spruce *laccase PaLAC5*. Expression analyses showed that *PaLAC5* responds specifically and strongly in close proximity to the *H. parviporum* inoculation. Thus, we hypothesize that *Pa*LAC5 and pleiotropic genome variants with similar expression patterns may be associated with the lignosuberized boundary zone formation in bark adjacent to the inoculation site. We will present further analyzes of allelic variants at the pleiotropic loci and their connection to the formation of defensive barriers using inoculation experiment with *H. annosum s.s*. and *H. parviporum*.

Broad genomics applications in host-pest/pathogen interactions: from tree breeding targets, biosurveillance tools to biopesticide development

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Ilga Porth[1]
[1] Université Laval, Département des Sciences du Bois et de la Forêt, Canada

Abstract: Healthy trees can act as a local climate buffer, reducing energy costs. Physiologically stressed trees, however, have a reduced carbon storage capacity or even become net carbon emitters due to biochemical limitations on carbon uptake. Therefore, it is critical to address *at multiple levels* the current threats to planted and natural forests caused by biotic agents. Different actions need to be taken depending on the type of biotic threat (local, expanding, invasive) and the goal of its management. Assisted gene flow and targeted breeding of host trees for resistance alleles are feasible if the breeding target is already known (e.g., increasing the production of certain chemical resistance compounds). Yet, knowledge of the biology of the pest/pathogen itself can be translated into its successful containment by developing a biopesticide or a tool that allows for biological monitoring. For native species, the preliminary work is certainly easier, since in many cases prior knowledge is already available. However, for alien invasive species, especially those of highest priority due to their aggressiveness, task forces are firstly needed to conduct rapid and in-depth surveys of the species throughout their geographic range within an applied empirical framework (collaborative science).

In my talk I will present three examples of my latest research that all use the power of genomics and molecular biology to: (a) identify top susceptible hosts among the 10 commercially most valuable Canadian conifer species against an invasive polyphagous herbivore (*Lymantria dispar* spp.), unravel the transcriptomics foundation of the high detoxification potential of the pest, and deduce the most promising chemical defense compounds (among foliar terpenoids, phenolics) from extensive host utilisation experiments. Findings are supplemented by genetic parameter estimations for host defense compounds that we found to be improvable through phenotypic or genomic selection; (b) address species identification (taxon), source, route of invasion, invasion history, and traits of invasiveness (cold adaptation, host shift) for the Asian longhorned beetle under a biosurveillance framework; (c) develop a phytoprotective agent against the native spruce budworm based on large-scale production of recombinant budworm DNA and the development of a methodology for encapsulating these DNA fragments.

Can pathogen 'omics' and model plant hosts help improve forest tree resilience to Phytophthora pathogens?

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

[4] Scion, Rotorua, New Zealand

Abstract: Pathogens in the genus *Phytophthora* are notorious killers of forest trees, causing diseases such as sudden oak death, jarrah dieback and kauri dieback. In efforts to understand these pathogens and to ultimately determine the molecular basis of how they cause disease, genome, transcriptome and proteome datasets have been generated for many *Phytophthora* species. These datasets have enabled the identification of proteins that are produced and secreted *in planta*. Many of these proteins, termed effectors, are of potential importance in interactions with the plant host. Analysis of effector function is required to determine what those interactions are, but that can be problematic when dealing with a slow-growing and complex gymnosperm host. Thus, in some cases, the use of a model angiosperm plant host is a useful tool for functional analysis of plant-pathogen interactions. The highly destructive pathogen *P. agathidicida* causes kauri dieback, killing *Agathis australis* trees that are of immense cultural and ecological significance in New Zealand. We assembled the genome of *P. agathidicida* to chromosome-level and identified effector candidates. Due to limitations in working with kauri trees, we used *Nicotiana benthamiana* as a model plant host to help analyse the roles of effectors *in planta*. Expression of *P. agathidicida* genes was compared on the two hosts and effector functions determined by infiltration into leaves. Comparison of the *P. agathidicida* gene expression patterns in kauri and *N. benthamiana* highlighted similarities as well as host-specific differences. Functional studies in *N. benthamiana* identified a *P. agathidicida* effector that suppresses defence responses elicited by a wide range of pathogen molecules and thus might be an important virulence factor. Other effectors were identified that appear to be recognised by *N. benthamiana* immune receptors that trigger defence responses. The importance of immune receptors was highlighted by greatly increased growth of *P. agathidicida* on *N. benthamiana* lacking SOBIR1, an immunity co-receptor for extracellular effectors. Identification of effectors with important roles in disease could ultimately lead to management solutions for gymnosperm diseases, for example by identification of pathogen targets for RNA silencing or by identification of host immune receptors for use in breeding for improved disease resistance.

Comparison of defensive lncRNA expression profiles of Pinus spp. with different susceptibility to Fusarium circinatum using a dual RNA-seq approach

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: Understanding the complexity of the plant transcriptome that underlies pathogen defence would greatly facilitate the development of an accurate breeding programme for resistance. This is essential in the case of forest diseases for which there are no viable eradication measures, and the use of genetically resistant material seems to be one of the most promising strategies. Pine pitch canker (PPC), a pine disease caused by the invasive pathogen *Fusarium circinatum*, is one such example where, once established, no control methods are available. Although a number of genes associated with resistance to *F. circinatum* have been identified in pine species, the non-coding part of the host transcriptome is still poorly understood. Long non-coding RNAs (lncRNAs) are emerging as important transcriptional regulators under biotic stress in plants, *cis*-regulating the transcription of genes around their transcription site or leaving their sites to exert their function elsewhere as *trans*-acting transcripts. In this study, lncRNAs from the highly susceptible *Pinus radiata* and the resistant *Pinus pinea* inoculated with *F. circinatum* were identified and characterised at an early stage of infection. Overall, 8,783 and 5,255 lncRNAs were predicted in *P. radiata* and *P. pinea*, respectively, using a comprehensive bioinformatics approach. Among them, 37 and 34 lncRNAs were differentially expressed (DE) in *P. radiata* and *P. pinea*, respectively, in response to *F. circinatum* infection. The predicted *cis*-regulated target genes of these pathogen-responsive lncRNAs were related to defence mechanisms, which was consistent with the results of the co-expression network analysis. The dual approach allowed the identification and characterisation of lncRNAs in *F. circinatum* for the first time. Our findings reveal the expression of pathogen-responsive lncRNAs in both pine species and provide new insights into the connection between lncRNAs and key pathways in the regulation of plant disease resistance. In addition, the different lncRNAs used by *F. circinatum* infecting each pine species were identified and will help us to better understand the strategies of this serious pathogen.

Disentangling the origin of an emerging Araucaria araucana pathogen in the Chilean Andes

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: *Araucaria araucana*, commonly known as the monkey puzzle tree or pewén, is an ancient conifer species occurring in the mountain ranges of Chile and Argentina. These trees grow naturally in high altitude environments where they are exposed to extremely cold winter conditions, including long periods of snow cover and dry hot summers. During 2015-2016, *A. araucana* trees were observed displaying severe die-back symptoms in several locations within their natural distribution. Field surveys and monitoring of symptomatic trees revealed a serious canker disease associated with the death of branches. The lesions girdled the branches and, in some cases infected young stems resulting in copious amounts of resin being exuded and ultimately leading to the death of the affected organs. Four fungal species belonging in a novel genus described as *Pewenomyces* (*Coryneliaceae*) were discovered in association with these cankers. Long-term pathogenicity tests under field conditions showed that one of these species, described as *P. kutranfy*, was capable of reproducing these lesions, thus leading to the conclusion that this is the causal agent of the disease. Based on current knowledge, it is suspected that *P. kutranfy* is a native pathogen and the associated disease has arisen due to changes in climatic conditions. An alternative hypothesis that the pathogen has been introduced remains a possibility. To address this knowledge gap, the genome of *P. kutranfy* was sequenced with the objective of developing molecular markers to study the genetic diversity of the pathogen. Illumina sequencing of the ex-type culture of *P. kutranfy* resulted in the assembly of a 29,59 Mb genome and ten microsatellite (SSR) markers were developed using these sequences. The markers were tested on a small subset of isolates, and studies with isolates from two *A. araucana* populations are underway. Results of these studies will provide genetic insights as to whether the pathogens might be native to the area or introduced, its mechanisms of reproduction and its patterns of spread. This study will also aid in determining key areas of research needed to develop disease management strategies.

Dual RNA-seq and host whole genome sequencing provide genetic insights into the sudden oak death host-pathogen interaction

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Zachary Foster[1, 2], Caroline Press[2], Valerie Fieland[2], Kelsey Søndreli[1], Niklaus Grünwald[2], Jared LeBoldus[1]
[1] Department of Botany and Plant Pathology, Oregon State University, Corvallis, OR 97330, USA
[2] Horticultural Crops Research Laboratory, USDA Agricultural Research Service, Corvallis, OR 97330, USA

Abstract: The sudden oak death epidemic in the coastal forests of Oregon and California has been characterized by multiple outbreaks over the last three decades, the establishment of 638 square miles of quarantine and generally infested areas in Oregon, and more than US$34 million allocated to control programs in Oregon between 2001 and 2021. In addition, habitat loss and forecasted local extinctions are predicted to have long-term consequences for the ecology of the mixed conifer forests of the region. To date, management efforts have focused on preventing epidemic spread through host removal and sanitation measures, but gaps in our understanding of the host-pathogen interaction during infection and disease prevent the development of new management strategies, such as host resistance. The causal pathogen, *Phytophthora ramorum*, is a generalist oomycete with a hemibiotrophic habit. This trophic strategy results in a dynamic disease cycle, with each phase characterized by unique patterns of gene expression. In pursuit of understanding this host-pathogen interaction, tanoak (*Notholithocarpus densiflorus*) leaves were inoculated with *P. ramorum* and mRNA was extracted from leaf lesions at 2, 7, and 14 days post inoculation (dpi) (n = 12 x 3) and then sequenced. Mock inoculations (n = 3) and pure *P ramorum* cultures (n = 14) were used as controls. 13,821 unique NA1 transcripts and 13,182 unique EU1 transcripts were detected in vivo following sequencing and mapping. Differential gene expression analysis was conducted with the overall goal of identifying genes upregulated during disease development, with specific interest in RXLR and CRN effector proteins, necrosis inducing proteins, and proteins implicated in infection and biotrophy. Analysis was structured to compare: 1) the transcriptomes of NA1 and EU1; and 2) the transcriptomes of each respective lineage among the three dpi time points. In addition, a haplotype-phased reference genome was constructed for tanoak, which is the primary driver of the epidemic in Oregon forests. The genome was constructed using a combination of short and long-read sequencing technologies. The combined genome size of both haplotypes was 1,506.1 Mb with main genome scaffold N50 lengths of 30.1 and 25.4 Mb.

Enhancing Tree Resilience to Climate Change: Biotechnological Strategies and Genome Editing

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Tobias Bruegmann[1]
Alexander Fendel[1], Virginia Zahn[1], Matthias Fladung[1]
[1] Thünen Institute of Forest Genetics, Grosshansdorf, Germany

Abstract: Various breeding and silvicultural strategies are being pursued to adapt forest tree species and even entire forests to climate change. In particular, traits such as drought stress tolerance and resistance to already existing but also novel pathogens are two major tree breeding objectives. However, the velocity of climate change is a major problem that is difficult to reconcile with the long generation cycles of forest trees. Here, the implementation of biotechnology provides promising approaches. Plant biotechnological tools, such as tissue culture, genetic engineering and genome editing, as part of plant breeding, can contribute to a rapid climate change adaptation of forest trees. Advantageously, biotechnological treatments are not dependent on flowering and fruiting.

New possibilities and great potential are offered by genome editing techniques such as CRISPR/Cas, which are already being used intensively in crop research and for an increasing number of tree species. Some methods already developed for crop species have yet to be transferred to forest tree species. Even though the basic CRISPR/Cas mechanism seems to be rather universal, the insertion of the Cas nucleases needs to be further addressed when working with different tree species. In addition to classical, gene technology-based approaches to research, DNA-free approaches are also being pursued to generate nature-identical genetic modifications.

Genome editing is being used to characterize the function of genes and to unravel biochemical pathways. A better understanding of the genetic basis of morphological and physiological traits can support genotype-based breeding. Although most of the abiotic and biotic traits are encoded by numerous genes, modifying a few genes can quantitatively increase the resilience against the effects of climate change. However, at least in Europe, regulatory aspects have to be considered when dealing with genome editing.

Evaluating the Effects of Gibberellic Acid Treatment on Cone-Setting Frequency in Picea abies Genotypes: Insights from the Nässja Mini-Seed Orchard

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Laxmi S. Mishra[1]

[3] MSc student at Lund University, Faculty of Science, Department of Biology

Abstract: The Nässja mini-seed orchard, established in 2008, serves as a research facility encompassing seed orchard management and field trials. Comprising 18 distinct clones, the orchard originated from the late 1980s to early 1990s as part of an indoor seed orchard in 100 L pots before being transplanted to the Nässja site. The primary focus of our field trial is investigating the impact of gibberellic acid (GA) injections into tree trunks. The injections are timed using a formula incorporating temperature sums, with June 22nd as the reference date. Three treatment conditions are examined: control, annual GA injections, and biennial GA injections. The trial consists of 14 rows, with 40 trees per row. The outermost rows act as windbreaks and are not included in the analysis, leaving 12 rows for investigation. Each row uniformly receives a specific treatment regimen. Since 2009, meticulous recording of female and male cone data has been conducted. Female cones are quantified through direct counting, while male cones are classified as present or absent within the designated observation period.

Our research aims to assess the impact of GA treatment on cone-setting frequency in different genotypes of Picea abies. To achieve this, mRNA was extracted from buds growing in expected female cone positions on the Norway Spruce trees in the Nässja field trial, both before and after GA treatment. Subsequently, RNA sequencing was performed at National Genomics Infrastructure, part of the Genomics Platform at SciLifeLab in Sweden to identify and analyze differentially expressed genes between the two treatment conditions. Additionally, in collaboration with the Swedish Metabolomic Centre in Umeå, we are assessing the presence and abundance of gibberellic acids (GAs) in trees before and after GA treatment, to establish a correlation between differentially expressed genes (DEGs) and GA levels. Furthermore, we are exploring potential associations between variations in the member of the SQUAMOSA BINDING PROTEIN-LIKE (SPL) gene family, PaSPL1 locus, expression of different miR156 variants, and observed differences in cone-setting frequency among *P. abies* genotypes. This multi-faceted approach aims to enhance our understanding of the intricate relationship between gene expression, GA presence, and cone-setting frequency in our study system.

Evolutionary consequences of ash dieback in natural populations of Fraxinus excelsior

Abstract: Common ash (*Fraxinus excelsior* L.) is a tree species with ecological, economic and cultural importance, which is considered a species with high adaptive potential to climate change, as it can tolerate a wide range of environmental conditions. However, ash dieback, a fungal disease caused by an invasive ascomycete, *Hymenoscyphus fraxineus*, is provoking a sharp decline in common ash populations throughout Europe. Common garden experiments have shown that susceptibility to ash dieback is a heritable trait but only a low proportion of ash trees show low susceptibility to the disease. Taking advantage of trees growing in clonal plantations of common ash (in Denmark, Sweden, Germany, Austria, Ireland and Lithuania) affected by the pathogen, a previous genome wide association study revealed many associated loci with rather small effects. Using 25k loci we could predict up to 63% of variation in disease susceptibility.

Here we collected a total of 246 leaf samples from 19 natural common ash populations from Spain, France, Switzerland, Germany, Poland, Scotland, Denmark and Lithuania. We randomly sampled leaves from young trees, over 2.5 m height that had already survived several years under disease pressure. The health status of young trees was worst in recently affected regions and better in regions with longer pathogen presence. From five locations, we had additional samples from adult trees collected in 2001 before any severe ash dieback damage was visible. Using whole genome sequencing and based on the loci identified in the genome wide association study, we will generate polygenic risk scores to assess pathogen susceptibility in the young and old tree cohorts in order to test if selection in response to ash dieback can already be detected. Furthermore, our approach will allow predictions of susceptibility to ash dieback also in natural populations not yet affected by ash dieback, e.g. in northern Spain.

Experiences from 15 years of genetic research on European common ash (Fraxinus excelsior L.)

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

[2] Katholische Universität Eichstätt-Ingolstadt, Physische Geographie/Landschaftsökologie und nachhaltige Ökosystementwicklung, Ostenstraße 14/201A, 85072 Eichstätt

Abstract: Common ash is an ecologically valuable tree species found both on soils of floodplain forests and on moderately dry lime-weathered calcareous soil. For this reason, it has long been considered an important tree species for climate smart forestry on base-saturated sites. However, ash dieback largely limits their use, especially in moist locations. Since 2009, the Bavarian Office for Forest Genetics (AWG) has been involved in various projects to detect the disease, monitored its effects and progress, and investigated its genetic aspects and conservation measures thereof.

Soon after the first detection of the disease we observed loss of genetic diversity along with the decline of vitality in natural stands as well as in a provenance trial. Driven by field observations of individual differences in susceptibility, a common garden experiment with the clones and progenies of vital and susceptible mother trees was established and regularly monitored in terms of disease symptoms. After eight years of assessment, few clones still showed significantly higher vitality. In all progenies, healthy individuals were present. Paternity analyses in a natural stand and a seed orchard suggest that high vitality has a positive effect on reproductive success and effective pollen transport can occur over long distances. Therefore, for in-situ conservation of ash, less susceptible trees should not be cut in order to maintain the connectivity among ash individuals. Forest management activities in ash stands should promote natural regeneration of healthier adults to potentially favour healthier progeny. Genetic diversity in stands should be kept as high as possible by means of healthy adult trees as well as by high numbers of offspring in the first years to provide a basis for evolutionary forces to act on. For ex-situ conservation and resistance breeding, healthy ash trees were selected throughout Bavaria and propagated. The results of population genetic analyses and a genomic selection method for less susceptible individuals, which will be used to assist final tree selection for seed orchard establishment, will be shown.

Fast identification and selection of Scots pine trees with greater resistance to multiple pathogens using infrared spectroscopy

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Patrick Sherwood[1]
Mateusz Liziniewicz[2], Michelle Cleary[1]
[1] Swedish University of Agricultural Sciences, Southern Swedish Forest Research Centre, Sweden
[2] Skogforsk (the Forestry Research Institute of Sweden), Sweden

Abstract: Scots pine (*Pinus sylvestris*) is one of the most economically and culturally important trees in Europe. It is the second most abundant tree in Sweden and is a vital component of its plan for sustainable forestry. However, the health of Scots pine is threatened by a number of current and on-the-horizon diseases that can significantly reduce productivity and outright threaten tree survival. Many of these pathogens are already established, and future management options must find ways to mitigate losses. Exploiting natural host resistance in tree breeding programs is the best method for future-proofing our forests, but phenotyping for resistance is a slow and expensive process. Sustainable quantitative resistance to pests in trees typically involves and array of defensive chemicals and anatomical structures. Recent advances in infrared spectroscopy have made it possible to get a “chemical fingerprint” of whole living tissues that can be used in chemometric analyses to identify plants with desirable properties like resistance.

The objective of this study is to use a handheld Fourier transform infrared (FTIR) spectrometer as a rapid phenotyping tool to massively accelerate the selection process of resistant Scots pine genotypes. To achieve this objective, young saplings from several families of Swedish Scots pine trees will be analyzed with the FTIR scanner and then artificially infected with *Diplodia sapinea* or *Gremmeniella abietina*. Trees will then be classified as either relatively resistant or susceptible based on resulting lesion lengths. Using the FTIR data, training and testing chemometric models for predicting tree resistance will be built that can then be applied to naïve trees to facilitate selection efforts of breeding programs.

First application of Near-infrared spectroscopy as a field predictive phenotyping tool for susceptibility of Fraxinus excelsior to ash dieback

[3] Plant Breeding, Wageningen University & Research, Wageningen, The Netherlands

Abstract: Ash dieback caused by the invasive fungus *Hymenoscyphus fraxineus*, threatens common ash trees (*Fraxinus excelsior*) in Europe. Identifying ash trees with tolerance to ash dieback is one of the key priorities to set-up breeding programs. So far, this is hindered by the very low proportion of tolerant trees, which make it necessary to develop efficient tools for high throughput disease phenotyping. In this study we aimed at implementing NIR spectrometry to predict ash dieback susceptibility in naïve ash trees.

We used a miniaturized handheld near-infrared (NIR) spectrometer to fingerprint leaves and bark to classify 103 grafted ash trees that were subsequently inoculated with *Hymenoscyphus fraxineus*. Based on sig. differences in downwards lesion length and dieback of leader shoots, genotypes were assigned to three phenotype classes. We compared partial least squares-discriminant analysis (PLS-DA) models with the machine learning algorithms, Support Vector Machine (SVM) and Random Forest (RF), and were able to identify tolerance to ash dieback in naïve trees with an accuracy ranging from 0.75 to 0.90.

Our study shows that NIR spectroscopy is a promising tool to identify in situ tolerant ash trees at an early stage before they become infected, making it possible to study thousands of trees at a reasonable cost.

First insights into genetic structure and diversity of Corylus colurna L.

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: Genetic diversity is the basis for adaptation and survival of tree species under changing environmental conditions representing the key issue of stability and productivity of forest ecosystems. The first step was the selection of appropriate populations of Turkish hazel for genetic characterization in the countries of origin or within its natural distribution range. Turkish hazel is naturally distributed on the Balkan Peninsula (Bulgaria, Bosnia and Herzegovina, Romania, Serbia, FYR Macedonia, Kosovo, Montenegro, Albania and Greece), Asia Minor, Caucasus and Afghani-stan. Because of its valuable wood, this tree species was overused in all countries. Now Turkish hazel is present only in small isolated populations and is protected under IUCN. For the genetic characterization we collected samples from 25 populations within the distribution range from Bosnia and Herzegovina (west border) to Georgia (east border).

The poster introduces the project “Suitability for cultivating Turkish hazel (*Corylus colurna* L.) under climate change” and its first results of genetic characterization of sampled populations. A clear separation of populations of *C. colurna* from Balkan, Turkey and Georgia were found and confirms the differentiation of gene pools within the natural distribution range of Turkish hazel. Based on our findings, the Bavarian Office for Forest Genetics (AWG) has established a provenance trial in Bavaria and Baden-Württemberg. Therefore, valuable information on trees adaptation and growth from differ-ent provenances will be obtained in the future from such experimental plots. Overall, our results highlight needs to delineate provenance regions, identify conservation units and seed stands for Turkish hazel which are essential for species conservation, provenances research and possible assisted migration attempts.

Genetic and morphological diversity in populations of Annona senegalensis Pers. occurring in Western (Benin) and Southern (Mozambique) Africa

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: Understanding morpho-genetic diversity and differentiation of species with relatively large distribution is crucial for the conservation and sustainable management of their genetic resources. The present study focused on *Annona senegalensis* Pers., an important multipurpose wild plant, distributed exclusively in natural ecosystems but facing several threats. The study assessed the genetic and morphological diversity, structure, and differentiation of the species among populations from Western (Benin) and Southern (Mozambique) Africa. The material was evaluated to ascertain the environmental (climatic) determinants of the variation within this species. Four sub-populations comprised of 154 individuals were phenotyped based on nineteen plant, fruit, and leaf morphological traits and further genotyped using ten polymorphic nuclear microsatellite (nSSR) markers. The results indicated strong differences in plant, fruit, and leaf morphological traits between Western and Southern populations. Furthermore, the studied populations were characterized by high genetic diversity, with an average genetic diversity index of 1.02. The Western population showed higher heterozygosity values (0.61-0.71) than the Southern population (0.41-0.49). These two regions were clearly differentiated into two different genetic groups, with further genetic subdivisions reflecting the four sub-populations. Genetic variation between regions (populations) was higher (69.1%) than among (21.3%) and within (9.6%) sub-populations. Four distinct morphological clusters were obtained, which were strongly associated with the four genetic groups representing each sub-population. Climate, mainly precipitation and temperature indexes, explained the relatively higher variation in morphological traits in Western (40.47%) than in Southern (27.98%) populations. Our study provides crucial information for the sustainable management of this species.

Keywords. *Annona senegalensis*; bioclimatic variables; genetic diversity; morphological diversity; tropical plants

Genetic basis of resistance to ash dieback in narrow-leaved ash in floodplain forests of Europe

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: Narrow-leaved ash (*Fraxinus angustifolia* Vahl.), one of the keystone tree species of floodplain forests in Europe, is rapidly declining due to highly pathogenic ash dieback caused by the fungus *Hymenoscyphus fraxineus* (formerly *Chalara fraxinea*). We examined the molecular basis of disease resistance at nearly 10,000 genome-wide SNPs (selected in genes showing disease resistance in previous common ash studies, after filtering for minimum allele frequency and linkage disequilibrium) in five narrow-leaved ash populations in the wider area of the Mura-Drava-Danube Transnational Biosphere Reserve. Thirty to 40 adult trees and 30 saplings up to 2 m tall were sampled per population. For each adult tree, health status was assessed on a scale from 1 (healthy) to 5 (only a small part of the crown remaining, 81-99% defoliation). There was no evidence that genetic diversity estimated as heterozygosity decreased in regeneration despite ash dieback. Trees with higher DBH tended to be healthier. Disease resistance had high heritability in field conditions (0.84, CI 0.22-0.93), although it did not appear to be a polygenic trait. Rather, lasso regression using binomial and Poisson models explained approximately 45% of the variance and identified 15 SNPs (common in both models) associated with resistance to ash dieback. Analysis of the transmission of SNPs showing putative resistance to ash dieback from adults to progeny is ongoing.

Genomic signals of adaption among fungi causing Annosum root rot

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Mikael Durling[1]
Jan Stenlid[1], Åke Olson[1]
[1] Swedish University of Agricultural Sciences, Department of Forest Mycology and Plant Pathology, Box 7026, 750 07, Uppsala, Sweden

Abstract: Annosum root rot disease causes severe losses to northern hemisphere forestry due to loss of timber, tree mortality and decreased carbon sequestration. The disease is caused by species from the *Heterobasidon annosum s.l.* species complex consisting of five species with different but overlapping conifer hosts. Two species, *H. anosum* and *H. irregulare*, prefer pine hosts, whereas *H. occidentale*, *H. parviporum* and *H. abietinum* prefer non-pine hosts (e.g. spruce and fir). In this study, we contrast the genomes of the pine type species to the genomes of the non-pine type species in a phylogenetic context with *Stereum hirsutum* as outgroup in order to infer evolutionary differences associated with host adaption. We sequenced and assembled the genomes of the *Heterobasdion* species. Gene predictions with MAKER2, functional annotations with InterProScan, carbohydrate active enzymes (dbCAN), transporters (TCDB) and peptidases (MEROPS), were carried out. We used OrthoFinder to infer gene families and single copy orthologous genes across the study species. Modelling of gene family copy number evolution with CAFE 5 revealed that the spruce and pine type genomes are highly similar with only 20 gene families showing significant, but small changes in gene family size. A majority of the gene families with significant changes in size appears to be involved in secondary metabolism and/or cyclic compound metabolism. No significant changes in gene family sizes between pine and non-pine species were found among neither carbohydrate active enzymes, transporters nor petidases. Single copy orthologous were highly conserved with a median non-synonymous to synonymous (dN/dS) ratio of 0.05 as estimated with the PAML package. However, 146 out of 1304 single copy orthologs show a significantly better fit for PAML model allowing sites with positive selection rather than only negative selection or neutral. Among genes where we observe possible positive selection, GeneOntology terms related to cyclic and aromatic compounds are overrepresented. Our results indicate that adaption to different host types among *Heterobasidion* species appears to be a matter of adaption through changes related to secondary metabolism. This would enable the fungus to cope with the biochemical environments and/or produce defence substances, rather than adapt to actual substrate differences.

Identification and characterization of PaSPL1 gene targets and promoter regulatory elements in the Nässja seed orchard

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: One of the most significant foundational industries in Sweden is the forestry sector. In 2008, the Nässja mini-seed orchard was established as a field trial and seed orchard. The field trails, consist of 18 different genotypes and a total of 500 *Picea abies* trees, where flowering data has been recorded since 2009. In this trial, we have found clear differences in cone-setting frequency between the different genotypes. Due to Norway srpuce's infrequent and hard to predict flowering, it is critical to understand the pathways that lead to cone production. We have previously shown that cone-setting in Norway spruce is regulated by a SQUAMOSA BINDING PROTEIN-LIKE (SPL) transcription factor, *PaSPL1*.

As an initial step to identify natural sequence variations that could explain genotype dependent difference in cone-setting frequency, we sequenced the putative promoter, *i.e.* 3000 base pairs upstream of the translational start codon in the 18 genotypes. Further, we compared the sequences to identify short nucleotide polymorphism (SNPs), indels, and regulatory elements that could be correlated with cone-setting frequency. We will evaluate the functional significance of the identified regulatory elements and binding sites in order to understand the potential function of the components in gene regulation. Additionally, predicted regulatory elements in the promoter of *PaSPL1*, genes that target *PaSPL1,* and genes targeted by *PaSPL1* will be validated experimentally using techniques such as Y1H, reporter gene assays, promoter deletion, and site-directed mutagenesis. The findings of this work will contribute to our knowledge of gene regulation and reproductive shift in plants as well as offer potential applications in the manipulation of plant development and flowering pathways. Utilizing the most advanced molecular and genomic technologies, we will work together to create a model for future forest breeding that will ensure productivity, biodiversity, and climate stability for Swedish forest owners.

Identification of genes and pathways involved in the defence response of Pinus nigra to Diplodia sapinea by combining transcriptomics and metabolomics

Abstract: The European black pine (*Pinus nigra* J.F. Arnold) is a conifer of great economic and ecological importance and is widely used for afforestation and reforestation in Central Europe as a potential substitute for native species threatened by global warming. Unfortunately, the fungus *Diplodia sapinea* (Fr.) Fuckel is causing severe damage and worldwide economic losses to this and other *Pinus* host tree species. The lack of genomic resources and the scarce knowledge of the induced molecular defence responses limit breeding perspectives. In the present study, we investigate for the first time the molecular responses of two *P. nigra* provenances (representing two subspecies) to *D. sapinea* infection using a combined transcriptomic (RT-qPCR, RNA-Seq) and metabolomic (terpenoids, phenolics, hormones) approach in a greenhouse controlled infection experiment over a period of 21 days with the aim to identify genes and pathways involved in the induced defence response. In the absence of a complete *P. nigra* reference genome, we used two strategies to establish an appropriate standard RNA-Seq protocol, firstly by using the only publicly available *P. nigra* reference transcriptome and secondly by using the most complete available reference transcriptome of the closely related pine species *P. sylvestris*. The combined transcriptomic and metabolomic approach suggests that the response of *P. nigra* to *D. sapinea* infection becomes systemically activated 21 days post infection. This activation is characterised by a significant increase in key signalling hormones associated with plant defence, including jasmonic acid, abscisic acid, and salicylic acid. This coincides with the most notable differential gene expression, primarily involving the major pathways associated with plant defence mechanisms. As a result, the induction and release of several phytoalexins and defence-related proteins were observed. Furthermore, we show that some of these systemically induced responses are provenance specific. Finally, this study identifies the key genes and pathways involved in the defence response of *P. nigra* to *D. sapinea*, providing a solid basis for further characterisation of its variation in natural populations with different susceptibilities, as a prerequisite for any association studies to better elucidate the resistance mechanism and to select improved reproductive material.

Interaction between Scots pine, Melampsora pinitorqua, and Diplodia sapinea; does M. pinitorqua leave trees more vulnerable to Diplodia tip blight?

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Matilda Stein Åslund[1]

[2] Max Planck Institute for Chemical Ecology, Department of Biochemistry, Hans-Knöll-Straße 8, 07745 Jena, Germany

Abstract: Recent reports have highlighted the occurrence of young Scots pine stands infected by both *Melampsora pinitorqua* (pine twisting rust) and *Diplodia sapinea (*Diplodia tip blight*)* in various locations in Sweden. *M. pinitorqua* is a rust pathogen that alternates between Scots pine (*Pinus sylvestris* L.) and European aspen (*Populus tremula)*, causing bending or breaking of the pine's annual shoots. The pathogen *D. sapinea* causes economically significant infections on conifers across the globe. The dominating pine species in the Nordic countries, Scots pine, is among the species susceptible to *D. sapinea*. The pathogen can persist in a susceptible host without causing apparent disease, with an onset of disease symptoms when the host is subjected to abiotic stress. In this project, we study the ecological, physiological, and genetic aspects of the interactions between Scots pine and these fungi. We hypothesise that trees severely affected by *M. pinitorqua* will exhibit a higher frequency of *D. sapinea* infections and that the abundance of *D. sapinea* will increase in *M. pinitorqua*-infected tissue. We also hypothesise that the allele frequencies and expression of cellular and metabolic defence responses will correlate with differences in the expression of disease upon infection with *M. pinitorqua* or *M. pinitorqua* and *D. sapinea*.

Phenotyping was conducted on 567 trees to assess symptoms caused by *M. pinitorqua* and *D. sapinea*. Tissue samples from healthy trees, *M. pinitorqua*-infected trees, and trees showing symptoms of both pathogens were collected for metabolite profiling, gene expression analysis, and quantification of the pathogens. Genotyping was performed on the studied trees and their parents to investigate the genetic architecture of disease resistance.

This study contributes to a better understanding of the complex interactions between tree hosts and pathogens, aiding in disease management and tree breeding programs. The results have implications for enhancing resistance to multiple pathogens and improving strategies for sustainable forest management.

Interaction of Douglas fir provenances with environmental conditions in two IUFRO provenance tests in Bosnia and Herzegovina

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Mirzeta Memisevic Hodzic[1]
Dalibor Ballian[1, 2, 3]
[1] University of Sarajevo, Faculty of Forestry, Bosnia and Herzegovina
[2] Slovenian Forestry Institute, Slovenia
[3] Academy of Arts and Sciences of Bosnia and Herzegovina, Bosnia and Herzegovina

Abstract: This study aimed to examine the interaction between the effects of the genetic structure of provenances and two localities of provenance tests in Bosnia and Herzegovina. The results will be used for the selection of best provenances for further use in wood production.

Two IUFRO provenance tests of Douglas fir (Goleš Radalje – Travnik, and Zavidovići Gostović), with different environmental conditions, were established in 1972. Seedlings 2+2 years old were planted in three blocks, total 192 plants per provenance. Six provenances were represented in both tests (1029 - Thasis, Canada, 1036 – Alberni, Canada, 1060 – Sequim, Washington, 1090 – Cougar, Washington, 1099 – Pine Grove, Washington, 1100 – Grand Ronde, Oregon). Diameters at breast height and heights of all survived trees were measured in 2022 (56 year-old trees). The variances of traits caused by provenance tests, provenances, and interaction of provenance tests and provenances were examined using multivariate analysis.

Test of Between-Subjects Effests showed statistically significant differences in diameters at breast height caused by provenance tests but not caused by provenances or interaction between provenance tests and provenances. Test of Between-Subjects Effests showed statistically significant differences in heights caused by provenance tests, provenances, and by interaction of provenance tests x provenances. Provenance 1029 had the best growth in height in provenance test Goleš Radalje but the worst in Zavidovići Gostović. All provenances showed better growth in height in Goleš Radalje provenance test, and better growth in breast height diameter in Zavidovići Gostović provenance test.

The obtained results can be used for the selection of the best provenances for afforestation at predefined habitats that correspond to the conditions of the experimental plots, as well as for raising clone plantations or seed plantations of the species.

Lessons learned from successful conifer resistance breeding program in the United States

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Richard Sniezko[1]
Angelia Kegley[1]
[1] USDA Forest Service, Dorena Genetic Resource Center

Abstract: Forests deliver a wide array of essential ecosystem services. However, throughout the world, pathogens and pests, many of them non-native and invasive, continue to cause high mortality to forest tree species. Breeding to develop populations of trees genetically resistant to these deadly pathogens or pests can be a powerful tool to help retain the utility of affected species. The USDA Forest Service has been active in resistance breeding for more than 60 years, with several notable successes that make it a world leader in this area. Programs to develop resistance to white pine blister rust (caused by *Cronartium ribicola*) and to Port-Orford-cedar (POC) root rot (caused by *Phytophthora lateralis*) are the two most successful examples. Dorena Genetic Resource Center (DGRC) has evaluated resistance to white pine blister rust in all nine 5-needle pine species native to the U.S. as well as *P. lateralis* resistance in POC. DGRC uses traditional selective breeding methods in all its programs, incorporating the naturally occurring resistance present within those species. The resistance programs also emphasize incorporating wide genetic diversity and associated field trials serve as sentinels to durability and stability of resistance as well as to monitor species adaptability under climate change. Resistant seed is now available for three of the pine species as well as POC and are being used for restoration and reforestation by multiple organizations. Continuity, staffing, facilities, and partnerships have all been essential components of these operational programs. A sustained focus on the applied output (resistant seedings for planting) rather than basic research has also been key. With examples of successes in tree resistance breeding now available, there is renewed interest world-wide in undertaking similar work. Studying what has worked in these programs should help increase the efficiency and likelihood of success in other resistance programs. As a complement to the applied resistance programs, a look at information from sentinel plantings is underway to help identify potential future threats to U.S. forests.

Looking for resilience? Who you gonna call? Abies pinsapo Boiss!

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health
Irene Victoria Blanca Reyes[1]
Concepción Ávila Sáez[1], Francisco Miguel Cánovas Ramos[1], Vanessa Castro-Rodríguez[1]
[1] University of Malaga, Department of Molecular Biology and Biochemistry, Spain

Abstract: Currently, little is known about the molecular response to climate change-related stresses in the Spanish fir (*Abies pinsapo* Boiss), a conifer species of great ecological relevance, which is in danger of extinction. Furthermore, the lack of available complete genomes as well as standardised protocols for handling biological samples makes the study of molecular responses in conifers a difficult task. In this context, our group recently achieved the complete transcriptome assembly of *A. pinsapo* (Ortigosa et al. 2022), enabling functional genomic studies in this species.

Our study aims to shed light on molecular mechanisms governing the response to abiotic stress in *A. pinsapo* within its natural ecosystem by identifying gene families associated with the response to increased temperature and water stress. Our investigations have already identified candidates' genes and revealed their differential seasonal expression patterns across various tissues in *A. pinsapo* from distinct geographical areas and with diverse weather conditions. These findings hold the potential to significantly enhance our understanding of how *A. pinsapo* adapts to environmental stressors. Moreover, the acquired knowledge will provide important information for the development of sustainable forest management strategies in the vulnerable forest of the southern Iberian Peninsula, combating the adverse impact of climate change.

Master regulator of alkene biosynthesis pathway mediates disease resistance in Populus trichocarpa to Sphaerulina populicola

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

[3] Center for Bioenergy Innovation, Oak Ridge, Tennessee, USA
[4] Oregon State University, Forest Engineering Resources and Management, Corvallis, Oregon, USA

Abstract: A genome-wide association study was conducted on a population of 917 unrelated *P. trichocarpa* individuals and phenotyped for *Sphaerulina populicola* leaf spot. Using high-coverage whole-genome sequences the analysis revealed a single locus on chromosome 10 that exhibited associations with *S. populicola* leaf spot (P<0.001). This association revealed PotriKCS1, an alkene biosynthesis gene, was significantly associated with leaf spot. PotriKCS1 elongates monounsaturated fatty-acids and is responsible for the recruitment of unsaturated substrates during cuticle development. Trees with a functional copy of PotriKCS1 have been shown to accumulate a variety of alkenes in their cuticular wax; whereas trees lacking PotriKCS1 do not accumulate these alkenes in their cuticular waxes. The presence of the alkenes in the epicuticular wax of *P. trichocarpa* leaves is correlated with increased susceptibility to the co-evolved leaf-spot pathogen *S. populicola*. Gas chromatography–mass spectrometry (GC-MS) was conducted on three biological replicates of 24 genotypes of *P. trichocarpa* to determine the composition of leaf cuticular waxes. Pentacosene was among the top alkenes detected with a strong correlation (r=0.66533) to susceptibility. Chemical complementation of the trees lacking pentacosene in their cuticular waxes increased susceptibility in two greenhouse experiments. These results support our hypothesis that the presence of specific cuticular wax components promotes susceptibility to leaf spot disease in some genotypes of *P. trichocarpa.*

Multitrait GWAS and supervised machine learning reveal the genetic architecture of Fraxinus excelsior tolerance to ash dieback in Europe

Abstract: European ash (*Fraxinus excelsior*) is under intensive attack from the invasive pathogenic fungus *Hymenoscyphus fraxineus*, causing ash dieback at epidemic levels throughout Europe. Previous studies have found that host phenology, such as autumn yellowing, are correlated with susceptibility of ash trees to *H. fraxineus*; however, the genomic basis of ash dieback tolerance in *F. excelsior* remains poorly understood. Here, we integrate GWAS (genome-wide association study) with machine learning to reveal the genetic architecture of ash dieback tolerance and its relationship to phenological traits. We confirm genetic correlation between ash dieback crown damage and intensity of autumn leaf yellowing, within multiple sampling sites in six European countries (Austria, Denmark, Germany, Ireland, Lithuania, Sweden). A relatively small number of single nucleotide polymorphisms (SNPs) explained a large proportion of the variation in both disease tolerance and autumn leaf yellowing with 25k SNPs explaining 63% of variation in ash dieback

crown damage and 10k SNPs explaining 63% of variation in leaf yellowing. We identified 8 SNPs encoding non-synonymous substitutions within genes related to plant defence (6 SNPs) and phenology (2 SNPs). These 8 SNP variants have relatively high explanatory power of the observed traits and are functional homologs of pathogen defence genes (pathogen triggered immunity, pathogen detection), and phenological variation (regulation of flowering and seed maturation, auxin transport). Overall, our results suggest a multifactor defence response, according to which a combination of direct defence mechanisms and phenological avoidance of severe disease constitutes tolerance to ash dieback.

Negative effects of warm winters on dormancy release and apical dominance of seedlings from continental and maritime populations of Scots pine

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Darius Danusevicius[1]
Ruta Kembyte-Ilciukiene[1]
[1] Faculty of Forest Science and Ecology, Vytautas Magnus university

Abstract: Negative effects of warm winters on dormancy release and apical dominance of seedlings from continental and maritime populations of Scots pine

Darius Danusevicius (presenter) and Ruta Kembryte

Our aim was to study the differential effects of variable chilling on dormancy release and apical dominance of Scots pine seedings from northern Finland, continental Russia, Lithuania, Czech Republic, and Spain. We applied 10 chilling treatments from 0 to 12 weeks of chilling on one year old seedlings starting from 1st of September 2015 in a climatic chamber. A single treatment simulated weekly temperature fluctuations from +5C to +15C during a 12-week period from the 1st of September. After the chilling treatments the seedlings were moved to forcing conditions at +15C. We used 20 seedlings per population and treatment. He results showed that increased chilling markedly decreased the heat requirement for budbust for all populations. The continental populations required markedly less amount of chilling and were more sensitive to the temperature fluctuations during the chilling period than the maritime populations. Most defects related to apical dominance loss were observed in continental populations. We also found that the warm spells during chilling period may partially cancel the effects of chilling. Warm spells may disturb apical dominance of Scots pine seedlings by causing latent/ abnormal budburst of top bud on the leader.

New and Emerging Insect Pest Tragocephala nobilis Fabricius threats domestication of multipurpose tree Tetrapleura tetraptera a (Schum and Thonn.)

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Emmanuel Opuni-Frimpong[1, 2, 3]
Asamoah Adu-Gyamfi[1], Kwabena B Sarfo[1], Linda Archibrah[1], Adams Mohammed[2]
[1] CSIR-Forestry Research Institute of Ghana, Kumasi Ghana
[2] University of Energy and Natural Resources, Sunyani, Ghana
[3] Michigan Technological University, Houghton, MI USA

Abstract: Tragocephala nobilis an insect pest was recently found on a multipurpose tree species, Tetrapleura tetraptera in Ghana. Although the pest has been previously reported on other tree crops such as cocoa and Coffea arabica, this is the first report on *T. tetraptera. T. tetraptera* is a deciduous tree crop with numerous nutritional and medicinal benefits. The pest is found to attack *T. tetraptera* tree and damage is first observed as die-back of twigs and branches leading to the formation of a witches broom in the crown. This is followed by a series of tunnels created by the larvae on the main stem resulting in branch death and tree mortality. Given the threat posed by the pest to *T. tetraptera*, a broader study has been commissioned looking at genetics selection and other management tools that could contribute to developing an integrated pest management strategy for this pest in *T. tetraptera* plantations.

New genomic resources to assist breeding for Dutch elm disease resistance

Abstract: Elms were once common trees in Europe and North America. They were key members of riverine and montane habitats and commonly used in urban landscaping. They had substantial ecological, cultural and ornamental value. Unfortunately, a series of pandemic waves of the so-called Dutch elm disease, caused by fungi from the genus *Ophiostoma*, wiped them out from most of these areas.

Ulmus minor, a species found all over Europe except further North, was specially affected. Several entities initiated conservation actions along breeding programs, although, in the latter, success has been limited to the date. The main reason was the low natural resistance of most European elm populations, mustering a poor pool of founding individuals to kick off breeding programs. Nevertheless, in Spain, an appreciable number of trees with high and moderate resistance was found, leading to the establishment of a low-input breeding program (also known as Spanish elm breeding program). However, the program is facing the limitations inherent to breeding undomesticated, not economical organisms: lack of investment from industrial sector and reduced scientific information to guide it. That knowledge scarcity is even more pronounced in the genetics of the resistance.

Obtaining more insights into the genomics of the genus and the disease would surely speed up breeding. On that ground, several research initiatives, brood from the collaboration of several public institutions, have emerged: (1) a draft reference genome for *U. minor* using Illumina and PacBio sequencing platforms and state-of-the-art assembly software, attaining an acceptable genome quality (N50 > 1 Mbp); (2) combining it with whole-genome sequencing of 12 other genotypes to create several lists of SNPs amenable for target genotyping; (3) also, by means of restriction enzyme Genotyping-by-Sequencing, studying the population genetics of the species in Spain and evaluating interspecific introgression; (4) through genotyping and phenotyping crosses, analysing Quantitative Trait Loci (QTL) associated with resistance; (5) and finally, applying that information to the genomic prediction of the Mendelian sampling of the resistance in the crosses, to effectively accelerate breeding and reduce costs.

New pathogen, Diplodia sapinea, in Finland: genetic tools aiming to determine the factors leading to increased virulence of the pathogen in Scots pine

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Eeva Terhonen[1]
Tuija Hytönen[1], Katri Leino[1], Suvi Sutela[1]

Abstract: *Diplodia sapinea* is a new pathogen of Scots pine (*Pinus sylvestris* L.) and juniper (*Juniperus communis* subsp. *communis*) in Finland. It has a harmless endophytic lifestyle in its cycle, but various environmental factors (drought, elevated temperature, radiation) are assumed to launch its pathogenic mode, causing disease called "Diplodia tip blight". Based on our findings, *Diplodia sapinea* is currently distributed on the south-west coastal area of Finland. Citizen science was successfully utilized in the definition of the *D. sapinea* distribution: up to 30% of the received samples were found positive for the fungal pathogen. The genetic structure of Finnish *D. sapinea* subpopulations was examined using novel *D. sapinea* culture collection, complemented with isolates extracted from specimens originating from citizen observations. Preliminary results generated with ten newly developed nuclear microsatellite markers show that Finland harbour unique genotypes but also share same genotypes with other European countries. The impact of abiotic factors to *D. sapinea* virulence was studied experimentally using three-year-old half-siblings of Scots pine originating from four geographical location. The host-pathogen interaction (necrosis) will be phenotyped in order to uncover possible variation in the *D. sapinea* tolerance of different Scots pine provenances. Furthermore, fungal differential gene expression will be examined to define the effects of abiotic disturbances to the virulence of *D. sapinea*. Diplodia tip blight is a challenging disease to manage, and early detection and prevention are essential to limit its spread. The goal of this work is to increase awareness of *D. sapinea* impact on pine trees in Finland and promote further research into sustainable management strategies to combat this fungal pathogen.

Nuclear technologies to improve the resilience of forest species in the face of climate change

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: Nuclear technologies have multiple applications in the area of medicine, industry, agriculture and energy. In the forestry field, its application is unknown, although ionizing radiation is a tool widely used in agricultural genetic improvement, generating genetic diversity and improving variety productivity throughout the world with 3,275 mutant cultivars registered in 224 species. Nuclear technologies could be of great importance in the new scenario of climate change that is affecting native forest ecosystems and the significant reduction in production of plantations. The application of low doses of sublethal gamma radiation known as "hormesis" have short-term metabolic and physiological effects, increasing seed germination and initial plant growth, and there is a relationship with epigenetic effects that manifest as adaptive responses in the irradiated species. The higher doses of gamma radiation, known as mutagenesis, generate heritable mutations on DNA, and allow them to be included in conservation and genetic improvement programs in fast-growing native or exotic species that require adding an adaptive and/or commercial characteristic of interest that cannot be be achieved by conventional systems. Since 2020, INFOR and CCHEN have been developing the CHI5052 project for mutagenesis of forest species affected by climate change with funding from the International Atomic Energy Agency (IAEA), which includes in a first stage the determination of LD30 and LD50 doses in Eucalyptus globulus. and Quillaja saponaria for the generation of M1 populations. and the phenotyping and genotyping of M1 plants. This paper provides the strategy of the program and the preliminary results of the effect of 0, 10, 20, 30 Gy gamma doses on the germination and initial growth of Eucalyptus nitens.

Pan-genomes for exploring genetic variation beyond SNPs - examining the role of structural variants in resistance to ash dieback disease

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

[3] University of Nottingham

Abstract: Characterizing the full spectrum of genetic variants across individuals is crucial for genome-assisted breeding and understanding forest genetics more broadly. Substantial progress has been made using reference genomes from a single individual and short-read population resequencing data, which allows the identification of thousands of single nucleotide polymorphisms (SNPs). However, this approach often fails to capture another important class of genetic variants commonly associated with pathogen resistance - structural variants (SVs). These include inversions, deletions, insertions and rearrangements of large regions of DNA sequence between individuals. Pan-genomes, which integrate genome assemblies from multiple individuals, provide an improved approach for genotyping SVs from short read data at a population scale. In this study, we constructed a pan-genome for *Fraxinus excelsior* (European ash) - a keystone European tree species currently under severe threat from ash dieback disease (ADB), caused by an invasive fungal pathogen. Whilst SNPs associated with ADB resistance have been identified, preliminary evidence from short reads mapped to a single reference genome suggested SVs associated with resistance may also exist in *F. excelsior* populations. Using Oxford Nanopore Technologies long-read sequencing, we constructed *de novo* genome assemblies from 50 *F. excelsior* individuals of geographically diverse origins, used these to construct a pan-genome for the species, and characterized the landscape of SV variation. We are using this pan-genome to genotype short-read sequence data from large-scale field trials of *F. excelsior* phenotyped for ADB damage, to identify SNPs and SVs associated with resistance. This will allow us to explore the potential impact of pan-genomes on tree breeding and understanding forest genetics more broadly, as well as the genetic basis of resistance and potential for rapid adaptation in *F. excelsior* in response to an acute pathogen threat.

Pathophysiology and transcriptomic analysis of Pinus armandii inoculated by ophiostomatoid fungi associated with Dendroctonus armandi

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Huimin Wang[1]
Ya Liu[1], Quan Lu[1]
[1] Key Laboratory of Forest Protection of National Forestry and Grassland Administration, Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Beijing, China

Abstract: *Pinus armandii* is extensively abundant in western China and, as a pioneer tree, prominently influences local ecology. However, pine forests in this region have been significantly damaged by *Dendroctonus armandi* infestations closely associated with ophiostomatoid fungi. Herein, the aims of this study were to identify the diversity of ophiostomatoid fungi associated of *D. armandi* infesting *P. armandii* in western China. Subsequently, a subset of those strains was inoculated to determine the pathological physiology and molecular changes of *P. armandii*. A total of 695 ophiostomatoid fungi strains were isolated from 1,040 galleries and 89 adult beetles, at four sites. Seven species belonging to five genera were identified: two novel taxa, *Graphilbum parakesiyea* and *Ophiostoma shennongense*, a reassigned neotype, *Leptographium qinlingense*, three known species, and an unidentified *Ophiostoma* sp. 1. *Ophiostoma shennongense* was the dominant taxon in the ophiostomatoid community, with an abundance of 78.99%. Four representative ophiostomatoid species (*L. qinlingense*, *O. shennongense*, two dominant and widespread species, as well as *Gra. parakesiyea*, *Ophiostoma* sp. 1, two less frequently obtained but widely distributed across the sampling area) were selected for artificial inoculation to verify their virulent. The results of this research showed that *L. qinlingense* produced the longest lesions while *Gra*. *parakesiyea* produced the shortest. All strains could induce monoterpenoid release and the monoterpene contents in *P. armandii* were positively correlated with fungal virulence. Co-inoculation of two dominant highly and weakly virulent pathogen reduced the pathogenicity of highly pathogenic fungi. Transcriptomic analysis of *P. armandii* (CK, LQ, QS and OS) showed that many important chemical defenses in conifer such as terpenoid biosynthesis, flavonoid biosynthesis, MAPK signaling pathway and plant-pathogen interaction were activated. Compared with the control, the number of differentially expressed genes (DEGs) of co-inoculation (QS) was less than that of highly virulent pathogen (LQ) and more than that of weakly virulent pathogen (OS). The expression (LQ vs. QS) of flavonoid biosynthesis genes, phenylpropanoid biosynthesis genes and plant-pathogen interaction genes were downregulated. Co-inoculation decreased the expression of host-related defense genes. This study provides a valuable scientific theoretical basis for the management of ophiostomatoid fungi associated with *D. armandi*.

Phyllosphere microbiome assembly of susceptible and resistant Norway spruce genotypes against Heterobasidion

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Wenzi Ren
Zilan Wen[1], Fred Asiegbu[1]
[1] University of Helsinki

Abstract: Microbiome ubiquitously inhabits the plant endophytically or epiphytically. They play significant roles in plant growth and health, and have been considered as the extension of the host genome. Plant microbiome assembly could be a reflection of the plant's genetic background, plant behaviors, and environmental changes. Phyllosphere microbiome has been shown to have a close link with the plant immune system as well as the host's genetic background, and in turn, correlates with the host's health. Phyllosphere has also proved to have potential in plant adaptation to drought through microbial engineering. However, Norway spruce, as one of the most important tree species in the timber industry, its phyllosphere microbiome and the correlation with host genetic background have been very little studied. Our objectives are to identify and characterize the phyllosphere microbiome assembly of Norway spruce resistant and susceptible to *Heterobasidion* infection. Secondly to identify if there is vertical transmission of microbiome from seeds to seedlings. Thirdly to evaluate the impact of seasonal variations on the microbiota. In this study, the five most resistant and susceptible two-year-old seedlings were selected out of 402 Norway spruce genotypes. Four replicates of each genotype were planted in southern Finland. Needles from each biological replicate were collected in May, July, and September. Seeds of each genotype were also collected. DNA of needles and seeds were extracted. The Fungal ITS region as well as the bacterial 16S region were amplified. The results provided insights into the phyllosphere microbiome structure, interaction pattern, and functional composition. The results also highlighted the differences in core microbiota between the two resistant groups as well as the seeds.

Population genetic structure of the rare pine wood-living longhorn beetle in Sweden: effects of forest composition and management history

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

[3] Helsinki Institute of Life Science, University of Helsinki, Helsinki, Finland
[4] Centre for Ecological Genetics, Aarhus, Aberdeen, Helsinki Universities

Abstract: Forestry is a source of renewable raw materials and bioenergy but also has a key role in the conservation of insects and other organisms attached to dead wood. However, the Swedish Forestry Agency's forecasts showed that many biologically valuable forest types, including older pine forests, risk being displaced by more homogeneous forest landscapes dominated by younger, dense stands of spruce. Wood-living insects represent excellent indicators of biodiversity in forestry and nature conservation. In pine forests, the rare pine wood-living longhorn beetle *Tragosoma depsarium* has great potential as a signal species for valuable habitats. It has specific habitat requirements, especially in sunlit older pine forests, developing on coarse, dead pine logs and has an important role in the ecosystem by breaking deadwood. However, little information is known on the distribution and the genetic diversity of this rare species in Sweden. Genetic markers are useful tools to study species evolution and demographic events that have happened over time, shaping species distribution. Thus, we aim to describe the genetic diversity and population structure of *T. depsarium* in Sweden, and determine if populations have suffered loss of genetic diversity due to forest management and isolation. For this purpose, the geographic distribution of the beetle in Sweden was assessed at a large scale through extensive pheromone trapping, and several populations were sampled along its distribution range. to be sequenced by RADseq. DNA was extracted for each individual and sent for RAD sequencing. The sequencing results will be analysed using a population genomics approach.

Progress in Breeding Pinus radiata for Resistance against Invasive Dothistroma Needle Blight Fungal Pathogens in Kenya

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Joram Mbinga[1]
Jane Njuguna[1]
[1] Kenya Forestry Research Institute

Abstract: *Pinus radiata* (D. Don) is a fast growing high altitude commercial plantation tree species native to California-USA but successfully introduced and widely planted in many parts of the world. In Kenya it was introduced in 1930s as an industrial species for timber, plywood, pulp and paper markets. However, the species' susceptibility to *Dothistroma* blight disease led to a restriction in its planting on large scale. Dothstroma blight control measures initially tried in Kenya involved the use of copper based fungicides which were later abandoned due to environmental concerns. Control of the blight by breeding the trees for disease resistant was initiated as a viable long-term way of managing the disease. Research to develop *P. radiata* resistant to *dothistroma* blight has been undertaken by selecting among local populations *P. radiata* genotypes which show blight-resistant and higher growth. This initiative was supplemented by infusing new *P. radiata* germplasm from New Zealand. Both sets of material were planted in progeny trials to test their growth within *dothistroma* blight infested environments. The performance of the trials was evaluated by assessing growth parameters of tree height, diameter at breast height-DBH, and *Dothistroma* disease severity on all the material tested. Results show significance variation in growth performance among the different selected and introduced progenies. The best performing among the infused progenies attained a mean height, DBH and tree volume of 34m, 43cm, 2.2m^3/tree respectively after growing at the test site for 30 years. Among the local selections, the best progenies attained a mean height, DBH, and tree volume of 30m, 35cm and 1.3m^3/tree respectively after 24 years. Assessment of disease severity levels among the progenies was in the range of 0-50% infection. The growth and productivity of the trees in these trials compares to the commonly grown *Pinus patula* species which at 30 years in Kenya grows to means of 35m and 45cm height and DBH respectively. These results shows that the breeding programme for *P. radiata* resistance to Dothistroma disease in Kenya is achieving progressive results that will enable the species to be successfully grown in Kenya for commercial purpose.

Recurrent events of hybridization helped range expansion and climate change resilience in two conifers

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Piyal Karunarathne[1, 2]
Qiujie Zhou[2], Martin Lascoux[2], Pascal Milesi[2]
[1] Heinrich-Heine University, Düsseldorf, Germany
[2] Uppsala University, Uppsala, Sweden

Abstract: The current global climate change is expected to affect biodiversity negatively at all scales leading to mass biodiversity loss. Population-level changes in allele frequencies provide species to innovate adaptation to changing climates and prevent extinction. However, populations' responses to changing environmental conditions are heterogeneous across different ecosystems. This is often exhibited through adaptations of species to their local environment and reflects their potential for future climate change resilience. Detecting such environment-associated alleles requires whole genome sequencing of many populations and/or long-running common garden experiments. However, this is far from being practical for species with long generations. Here, in the present study, using exome capture genomic sequences, we tested multiple methods to assess local adaptation and climate change resilience in two widely distributed conifers, Norway spruce (*Picea abies*) and Siberian spruce (*Picea obovata*). We show that local adaptation in conifers can be better detected through a combination of allele frequency variation, population-level ecological preferences, and historical niche movement. Moreover, we integrated both genetic and ecological information into genetic-offset predictive models to show that hybridization plays a central role in expanding the niche breadth of the two conifer species and may allow both species to cope better with changing future climates. Further, the recurrent gene flow between the two species during many cycles of glaciation allowed the hybrid populations in the contact zone of the two species to acquire intermediate allele frequencies; this intern provided them with enough standing genetic variations to quickly adapt to changing climate. Therefore, hybrid populations are more likely to persist through future climatic changes. Integrative analysis of genomics and ecology, also allowed us to identify genetically isolated populations that are at risk under current climate change.

Resistance breeding programme of black alder (Alnus glutinosa) to Phytophthora ×alni in the Czech Republic

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Kateřina Novotná[1]
Petra Štochlová[1], Marek Štochl[1], Karel Černý[1]
[1] Silva Tarouca Research Institute for Landcape and Ornamental Gardening, Publ. Res. Inst.

Abstract: One of the most important species of riparian stands and carr habitats is *Alnus glutinosa* (AG). This autochthonous tree growing all over Europe is strongly threatened by *Phytophthora ×alni* (PA), an oomycete pathogen that cause rapid destruction of the riparian and alder carr ecosystems. In 2009, research of AG susceptibility against the pathogen has started. 90 healthy AG genotypes originated from different regions of the Czech Republic were used for in vitro susceptibility tests (branch inoculation). Best of them were vegetatively propagated and preserved in our stoolbed.

From their maturity, for the last 5 years, the trees have been used in controlled crossings to obtain progenies (open pollination of respective mothers have been used as a control). All obtained seedlings are artificially inoculated several times per year with several highly aggressive PA isolates. More than 40 different combinations have been tested up to now. The differences in susceptibility among tested progeny were found. Progeny of genotypes with higher resistance to PA have a higher proportion of surviving plants compared to progeny of susceptible genotypes. After the first artificial inoculation three quarters of seedling from susceptible trees died while the mortality in progeny of more resistant trees was around 30-40%. After two vegetation periods most of the descendants of susceptible trees died. Survival rates of progeny from more resistant trees were around 15 %.

Nowadays, there are some highly resistant AG seedlings that could be used in further resistance breeding or as a source for vegetative or generative propagation. Selected trees could be planted in riparian stands and could increase the stability of the carr and riparian ecosystems.

Secondary metabolites for decay resistance in Finnish forests: disclosing the stilbene biosynthesis pathway in Scots pine and Norway spruce

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Steven Taniwan[1]
Renata Ndah[1], Tanja Paasela[1], Teemu H. Teeri[1]
[1] Viikki Plant Science Centre, Department of Agricultural Sciences, University of Helsinki, 00790 Helsinki, Finland

Abstract: Scots pine and Norway spruce are the two most economically important tree species in Finland. This study investigates the stilbene biosynthesis pathway in these tree species as a source of secondary metabolites against decay and diseases. Scots pine accumulates stilbenes in the heartwood in the form of pinosylvin and its monomethyl ether, which are derivates from cinnamic acid. However, the enzyme that catalyses the reaction from cinnamic acid into the intermediate cinnamoyl-CoA, possibly an acyltransferase related to 4-coumarate:CoA ligase (4CL), remains unknown. Using transcriptome data from Scots pine under pinosylvin forming conditions, we identified four candidate 4CLs, of which one (Ps4CL2) showed strong cinnamic acid activation. We propose that Ps4CL2 is involved in pinosylvin biosynthesis in Scots pine. Contrary to Scots pine, Norway spruce accumulates stilbenes in the bark and in the form of resveratrol and its derivatives (e.g. the hydroxylated piceatannol and the methylated isorhapontigenin). Current observations from our transcriptome data of Norway spruce bark reveals several candidates responsible for hydroxylation and methylation of resveratrol.

The gene flow between Araucaria angustifolia populations through coalescent theory

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Bruno Marchetti de Souza[1]
João Ricardo Bachega Feijó Rosa[2], Evandro Vagner Tambarussi[1], Valderês Aparecida de Sousa[3], Dario Grattapaglia[3], Orzenil Bonfim da Silva Junior,[3], Miguel Luiz Menezes Freitas[4], Ananda Virginia de Aguiar[3]

[2] UniLaSalle Institut Polytechnique
[3] Empresa Brasileira de Agropecuária
[4] Instituto de Pesquisas Ambientais

Abstract: *Araucaria angustifolia* (Brazilian-pine, araucaria) is a conifer tree of high ecological and social value in Brazilian subtropical region due to its high-quality wood and pine nuts production used for feeding. However, the species have been heavily exploited. The remaining populations are isolated and may encounter difficulties adapting to climate change. So, this study examined the gene flow between populations of araucaria across its geographical natural range through a coalescent approach. Genomic DNA samples were collected from 185 trees in a provenance and progeny test sampled from 15 natural populations. The genotyping was performed using a 3K Axiom SNP array (2022 SNPs) and 28 microsatellites. Gene flow demographic models among the populations were tested to verify the direction (North or South) of the migratory flow between neighboring populations. All models were run at MIGRATE-N software. The migration rate, the effective number of migrants per generation (xNimij), and the effective population size (Ne) were estimated. The mean Ne observed using the SNPs markers for populations further north (959.02) is slightly higher than that southern (893.61). We identified neighboring populations with more intense migratory flows than the others and the general tendency of migratory flow between these populations. Thus, we identified populations that stand out as the main sources of migrant individuals showing a negative migration balance; and the ones that receive a high migration flow. We also noticed populations that stand out for their weak connection with others. By correlating the migration parameters with climatic variables, we observed that the minimum average temperature in the coldest month, and the amount of rain in the driest month present a high and significant correlation with xNimij. A negative correlation was observed between the rainfall regime and xNimij. So, the greater the amount of rain in drought period smaller the number of migrant individuals. About temperature, we observe a positive correlation between migration and average minimum temperature up to a specific temperature, after which the regression curve inflects. In general, the observed gene flow suggests a connection between the remained populations, being the greatest sources of genetic diversity of the species found in southern Brazil.

Towards the integration of disease resistance in tree breeding, can genomic selection support early selection of Heterobasidion-resistance?

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

[3] Umeå Plant Science Centre, Department of Forest Genetics and Plant Physiology, Swedish University of Agricultural Sciences, Umeå, Sweden
[4] Forestry Research Institute of Sweden (Skogforsk), Ekebo, Sweden

Abstract: *Heterobasidion* root- and stem-rot is a major disease of Norway spruce (*Picea abies*) in Europe causing significant economic losses as well as reduced carbon sequestration by infected trees. The disease is caused by *Heterobasidion parviporum* and its congeners in the *Heterobasidion annosum s.l.* species complex. The potential to improve Norway spruce for resistance to *H. parviporum* through breeding has been well established in several previous studies for backward selection of the best parental trees or the forward selection of the best progeny. However, the bottleneck in applying such resistance selection in the breeding operations is the requirement of disease exposure either through natural infection or artificial inoculation. Such processes require long-term testing or come with high costs. To develop reliable methods for early selection of resistant trees without inoculation based testing, we explore the possibility to use genomic selection (GS) to identify resistant trees in the Swedish breeding program. To achieve this, resistance was measured using artificial inoculations in progenies from 50 full-sib families in each of two Norway spruce breeding populations with 10 connecting families in the Swedish breeding program. In total 1920 plants were both phenotyped and genotyped on the 50 K Norway spruce SNP chip. GS models are built for each population and the models and phenotypic data will be used to test if the prediction accuracy based on genomic information can match the prediction accuracies in phenotypic selection, within and across populations. The results from the phenotyping work, GS model building and testing will be discussed as well as the potential applications of this work in the Nordic breeding and deployment chains.

Unlocking the genetic diversity of timber species in Terengganu Forest Reserves, Malaysia

[4] Department of Forestry Science and Biodiversity, Faculty of Forestry and Environment, Universiti Putra Malaysia, 43400, Serdang, Selangor, Malaysia.

Abstract: Terengganu, a state in eastern Peninsular Malaysia harbors numerous valuable and highly endangered timber species. Approximately 544,000 hectares have been designated as Permanent Reserved Forests. To date, Terengganu has 45 forest reserves, predominantly made up of dipterocarp woods. However, there is very little information on the genetic variation of timber species occupying these Permanent Reserved Forests. Genetic diversity is vital to ensure the success of the rehabilitation in the forest areas. It reflects the reservoir of a species for short-term ecological adaptation and long-term evolutionary change. Low genetic diversity can threaten the long-term viability of the restored forests. Balancing sustainable logging with biodiversity protection is crucial, considering the state's reliance on forestry revenue and the inherent dangers of illegal logging and processing activities to endangered species and environmental health. This study aimed to assess the genetic diversity within 12 timber species in Terengganu Forest Reserves, Malaysia using inter-simple sequence repeat (ISSR). This study improves our understanding and provides new insight into the genetic diversity of timber species inhabiting Terengganu Forest Reserves of Malaysia. The data from this study is essential in designing effective conservation strategies for Terengganu timber species. The results will be presented and discussed during the congress.

Keyword: Timber species; genetic diversity; ISSR; Terengganu Forest Reserves

Using a common garden experimental trial to reveal tree disease dynamics

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Abstract: Predicting how trees will respond to disease is vital for the management of both natural and planted forests. However, understanding tree disease dynamics is often limited by the lack of robust estimates of variation in host susceptibility and tradeoffs with other traits. Scots pine (*Pinus sylvestris*) is the most widely distributed pine species and is economically and ecologically valuable. It is impacted by the foliar pathogen *Dothistroma septosporum,* the causal agent of Dothistroma needle blight (DNB).This causes distinctive lesions on needles often resulting in needle loss and growth retardation. We evaluated genetic variation in DNB susceptibility in a multisite progeny-provenance trial of Scots pine planted in Scotland and genotyped using a 50k SNP array. The trial was surveyed regularly over eight years for DNB symptoms and duration of needle retention. DNB susceptibility over multiple years was associated with the climate at the site of provenance origin. Trees originating from hyper-oceanic sites in the west of Scotland, where conditions were warmer and wetter (i.e. environments expected to favour pathogen growth and dispersal), showed evidence for local adaptation to the pathogen, with lower levels of susceptibility compared to populations from the cooler, drier east of the country. Trees with higher levels of susceptibility showed lower growth than those that were more resistant, although the growth differential was apparent many years prior to exposure to DNB, indicating that it was not entirely a consequence of infection. Association analyses identified a set of SNPs which show promise in their ability to predict susceptibility to DNB in Scots pine. Our findings will help in early identification of Scots pines that are vulnerable to DNB, guide conservation of the ecologically important Caledonian pinewoods, and improve the economic viability and resilience of breeding programmes.

Variability of morphological traits of pedunculate oak in changed environmental conditions (in situ and ex situ)

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Mirzeta Memisevic Hodzic[1]
Dalibor Ballian[1, 2, 3]
[1] University of Sarajevo, Faculty of Forestry, Bosnia and Herzegovina
[2] Slovenian Forestry Insistute, Slovenia
[3] Academy of Arts and Sciences of Bosnia and Herzegovina, Bosnia and Herzegovina

Abstract: Pedunculate oak is an economically and ecologically very valuable species at the European level as well as specifically for Bosnia and Hercegovina, and research into variation of this species is very important.

In 2007, pedunculate oak leaf material was collected in 27 populations in Bosnia and Herzegovina along with seeds, which were used to establish a provenance trial. In the trial, leaves were collected in 2021, and 14 morphological traits were measured in both types of material. Descriptive statistics by populations and provenances were calculated, and correlation coefficients between leaf traits for populations and provenances.

Analysis of variance showed generally non-significant differences between generations, but significant variation among populations and population-by-generation interactions. However, the correlations between generations were non-significant for most traits, and neither were the correlations with climatic parameters. The results indicate both genetic and environmental effects on leaf morphology. The utility of leaf morphology for gene conservation is shortly discussed.

Variation in phenology traits and growth in a multi-site provenance trial of wild cherry (Prunus avium L.) in the Netherlands, Belgium and Germany

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

[3] Research Institute for Nature and Forest Belgium
[4] Thünen-Institut für Forstgenetik

Abstract: There is a need for forest managers to diversify forest stands in order to increase resilience to climate change and upcoming pests and diseases. Wild cherry (*Prunus avium*) is seen as one of the candidate species, due to its superior wood quality, relatively fast growth, silvicultural value, and high litter quality. The objective of the study is to investigate provenance performance under different environmental conditions with the ultimate aim to identify seed sources that are well-adapted to the present climate but can also deal with the predicted climate change. The results from these provenance trials may guide forest managers in their decision whether to use local or more southern seed sources from warmer or drier areas. For this, we established a wild cherry provenance trial network in the Netherlands, Belgium, and Germany with two trials per country. Seventeen provenances from five Western European countries were planted. All provenances were from approved seed sources either seed orchards (Qualified) or seed stands (Selected). We did repeated assessments of budburst, leaf fall, survival, and height growth. We analyzed differences between provenances by modeling spatial trends using the 'SpATS' R-package and using a multi-site approach. In general, we observed consistent differences in adaptive traits like budburst and leaf fall. Based on the results, recommendations for seed transfer will be discussed.

Yellowhorn Xso-miR5149 targeting XsGTL1 enhances water-use efficiency and drought tolerance by regulating leaf morphology and stomatal density

T1.12 Forest genetics tools to improve forest resilience to climate change and forest health

Chengjiang Ruan
Jingbin Li[1], Qixia Hu[1]
[1] Dalian Minzu University

Abstract: Yellowhorn (*Xanthoceras sorbifolium*) is a unique edible woody oil tree species in China. Drought stress is the

major yield-limiting factor of yellowhorn. MicroRNAs play an important role in regulating the response of woody

plants to drought stress. However, the regulatory function of miRNAs in yellowhorn remains unclear. Here, we

first constructed coregulatory networks integrated with miRNAs and their target genes. According to GO function

and expression pattern analysis, we selected the Xso-miR5149-*XsGTL1* module for further study. Xso-miR5149 is

a key regulator of leaf morphology and stomatal density by directly mediating the expression of the transcription

factor *XsGTL1*. Downregulation of *XsGTL1* in yellowhorn led to increased leaf area and reduced stomatal density.

RNA-seq analysis indicated that downregulation of *XsGTL1* increased the expression of genes involved in the

negative control of stomatal density, leaf morphology, and drought tolerance. After drought stress treatments,

the *XsGTL1*-RNAi yellowhorn plants were less damaged and had higher water-use efficiency than the WT plants,

while destruction of Xso-miR5149 or overexpression of *XsGTL1* had the opposite effect. Our findings indicated

that the Xso-miR5149-*XsGTL1* regulatory module plays a critical role in controlling leaf morphology and sto

matal density; hence, it’s a potential candidate module for engineering enhanced drought tolerance in

yellowhorn.

Analysis of Forest Sector Management Strategy Using Korean Dynamic Stand Growth Model to Achieve Carbon Neutrality in South Korea

T1.13 Forest management for climate change mitigation

Mina Hong[1]
Moonil Kim[2], Youngjin Ko[3], Eunbeen Park[1], Jiwon Son[3], Woo-Kyun Lee[3]
[1] OJEong Resilience Institute (OJERI), Korea University
[2] ICT-Integrated Environment, School of ICT-Integrated Studies, Pyeongtaek University
[3] Department of Environmental Science and Ecological Engineering, Korea University

Abstract: Since the Paris Agreement, the role of forests as a source of greenhouse gas sink has been emphasized, and each country has decided to submit an NDC to respond to the new climate regime. South Korea also plans to achieve NDC (Nationally Determined Contributions) in 2030 (25.5 million tons in the forest sector) and carbon neutral policy in 2050 in line with the international situation, and is making efforts to find management plans for forest sinks. Using the Korean dynamic stand growth model, this study sought strategic measures to solve problems like age class imbalance and expand sinks through forest biomass. As a result, the climate scenario is SSP1, the forest management scenario is when clear-cut harvest according to the legal final cutting age and thinning is implemented about 200,000 ha, reforestation of appropriate species to respond to climate change, and access to the forest road is within 1km, it was found that the overall sequestration of the forest increased. The current sequestration of 40.52 million tCO_2 yr^{-1} will decrease to 23.03 million tCO_2 yr^{-1} in 2050 but is predicted to increase to 35.24 million tCO_2 yr^{-1} in 2100 through growth of climate-appropriate species and age-class balance. Furthermore, it was analyzed that HWP (Harvested Wood Products) also contributes to its role as a carbon substitute with 7.73 million m^3 per year. In conclusion, this study is meaningful in that it presents a future strategy for responding to the new climate regime by reflecting the environmental and ecological characteristics of South Korea. Furthermore, these results can contribute to the forest sector's plans and policies for sustainable development.

Ash fertilization as a tool to achieve carbon neutrality: Long-term effects on tree growth and carbon balance of peatland forests

T1.13 Forest management for climate change mitigation

Päivi Väänänen[1]
Paavo Ojanen[1], Päivi Mäkiranta[1], Raija Laiho[1]
[1] Natural Resources Institute Finland

Abstract: For Finland to achieve carbon neutrality by 2035, the land use sector is expected to achieve an annual impact of 3 Mt CO2 eq. Ash fertilization of drained peatland forests, which has been practiced in Finland for decades, is considered one of the most cost-effective ways to increase carbon sequestration through its profound and durable effect on tree growth. The effect on growth is stronger in sites with high soil nitrogen availability, but which lack potassium and phosphorus. However, estimations of the climate effect of ash fertilization are based solely on the stand growth. The critical question is whether ash fertilization enhances soil processes in a way that results in increased soil emissions, undermining the positive climate impact of increased tree stand carbon sink. Fertilization could decrease methane (CH_4) emissions because increased tree growth may lead to decrease in water table level (WT). We studied the long-term effect of ash fertilization of forestry-drained peatlands on the ecosystem carbon exchange, including soil, tree and ground vegetation components, and accounting for CO_2 and CH_4. Research questions were: 1) Does fertilization cause a long-term increase in heterotrophic soil respiration (R_h) in drained peatland forests and is this increase associated with an increase in litter production? 2) What is the ecosystem carbon balance and how is it affected by ash fertilization? 3) Do responses to ash fertilization vary between nutrient rich and nutrient poor sites? The experimental setup included 8 sites that were selected from the population of ash fertilization experiments established between 1937-2014, and fertilized with doses currently applied in practical forestry. R_h and CH_4 fluxes were measured with closed chamber method biweekly throughout two growing seasons, and WT and soil temperature throughout the study period. Tree biomass production, and above- and belowground litter production was determined. Based on these field measurements, annual fluxes were calculated, soil carbon balance, CO_2 sink due to tree growth and ecosystem carbon balance were determined. We will represent results of the long-term effects of ash fertilization on nutrient availability, tree growth, heterotrophic respiration, and carbon exchange of drained peatland forests with varying fertility.

Assessment of biomass flow in agroforest parklands in south-central Sahelian part of Niger.

T1.13 Forest management for climate change mitigation

[3] University Abdou Moumouni of Niamey

Abstract: Agroforest parklands in the Sahel offer many goods and services, knowledge of which in terms of flow, in particular productivity, removal and the input of organic matter, remains limited. This study, carried out in central southern Niger following north-south agroecological gradient, aims at providing knowledge on biomass flows for better formulation of management policies for its forest ecosystems. The methodology was based on socio-ecological surveys of 184 households and the ground inventory of vegetation through 240 plots for trees and 80 plots for herbaceous plants. The indirect method was used to assess tree biomass and integral harvest for herbaceous plants.The surveys focused on the amount of biomass taken for the different needs coupled with the measurements of wood per household. Productivity was estimated at 11.411±8.377 t/ha (north) and 16.44±8.544 t/ha (south) (P = 0.000). The total biomass harvested was estimated at 2.11 ± 0.83 t/ha (north) and 3.01 ± 0.98 t/ha (south) (P=0.000). The annual input was estimated at 1.424 ± 0.15 t/ha (north) against 1.714 ± 0.311 t/ha (south) (P = 0.08). The flow was equal to -0.692±0.681 t/ha (north) and -1.292±0.67 t/ha (south). The results of this study could be a database for future formulations of policies for the management of agroforestry parklands in central southern Niger.

Assessment of masting behavior in a tropical wet forest in Puerto Rico.

T1.13 Forest management for climate change mitigation

Evald Maceno[1]
Jess K. Zimmerman[1], Miguel Leon[2]
[1] University of Puerto Rico, Rio Piedras Campus
[2] University of New Hampshire and Luquillo Long-Term Ecological Research Information Manager

Abstract: Large pulses of seed production occur in many tree species every few years in many forest types. This study examines the interannual patterns of reproduction in the Luquillo Experimental Forest in Puerto Rico focusing on evidence of masting behavior. We analyzed 30+ years (1992-2022) of fruit and seed production records in the 16 ha Luquillo Forest Dynamics Plot using 120 0.5 m^2 traps visited biweekly. The community was composed of 70 species of shrubs, trees, and climbers of various types. We used the coefficient of variation (CV > 1) to identify potential masting species in the community. Our findings indicate that more than 50 percent of the community exhibit masting behavior by this standard. No species, however, exhibited negative autocorrelation of seed production, indicative of synchronized endogenous (e.g., resource-based) reproductive cycles. This suggests the importance of disturbance events or other environmental triggers of masting behavior. We then identified years of high seed production in individual species using the deviation from long-term mean method. All species exhibited masting by this standard, even those with a CV < 1. However, only a handful of peaks among species fell within four years of major disturbance events (two hurricanes [1998, 2017] and one major drought [2015]). Overall, pairwise synchronicity among all species was skewed positive. However, this appeared to be a result of a general negative trend in reproduction in many species rather than synchronized masting behavior. This may be due to the effects of Hurricane Hugo (1989) before the start of the time series. This was the first major hurricane to strike the region in 57 years, before the more recent ones, thus having lag effects on the entire community. Beyond this, we suggest that other unidentified environmental conditions may be critical to triggering peaks of seed production in this tropical forest.

Can woodlands and shrublands contribute to Kenya's national carbon accounting?

T1.13 Forest management for climate change mitigation

John Kigomo[1]
Tito Mbuvi[1], Kyle Dexter[2], Lorena Benitez[2], Chemuku Wekesa[1], Solomon Kipkoech[1], Collins Masinde[1], Rufo Jillo[1], Linet Muindi[1]
[1] Kenya Forestry Research Institute (KEFRI)
[2] The University of Edinburgh, UK; School of Geosciences

Abstract: Woodlands and shrub lands, which occupies about half of Kenya's forested area plays a critical role in climate change mitigation and adaptation. Due to increasing levels of degradation attributed to anthropogenic activities and climate change, there is a need to assess and monitor dynamics of biomass for sustainable management. Furthermore, the carbon offset projects and calibration of remote sensing models require local ground data. Previous carbon accounting studies have mainly concentrated on closed canopy forests with the exclusion of woodlands. Studies were carried out in Tiva research station and Kibwezi woodlands under the Socio-Ecological Observatory for Studying African Woodlands (SEOSAW) network to estimate above ground biomass (AGB), which is the most affected carbon pool. The study also determined the contribution of tree species and size to the AGB. The sites were stratified into dense, moderate and open vegetation. Within each stratum Permanent Sample Plots (PSPs) of 0.5 ha and 1.0 ha were established in Tiva and Kibwezi, respectively. Sub-plots of 0.02 ha were laid for trees species identification and measurement of Diameter at Breast Height (DBH) and total height (H). Our findings identified 30 and 26 tree species in Tiva and Kibwezi, respectively. The tree density ranged from 58 to 682 stems ha^{-1} in Tiva and 60 to 658 stems ha^{-1} in Kibwezi. The mean AGB within Tiva was 9.3 ± 5.46 ton ha^{-1} while in Kibwezi; it was 52.0 ± 7.43 ton ha^{-1}. The species contribution to AGB was dominated by *Adansonia digitata* (42%) *Commiphora africana* (30%) and *Sterculia stenorcapa* (11%) in Kibwezi while in Tiva, *C. Africana* (46*%), Acacia mellifera* (13%) and *Commiphora eminii* (9%) had the highest proportion of AGB. The tree species and its size had significant contribution on the AGB as attested by the dominant tree species recorded. Woodlands have a potential in contributing to national carbon accounting if more effort can be directed towards sustainably managing them. Periodical studies are recommended to determine carbon storage potential and changes over time due to changing dynamics in land use practices within the drylands of Kenya.

Abstract: *Calophyllum inophyllum* is a multipurpose tree species that has recently been proven to be effective source of biodiesel, with reported huge CO2 sequestration potential. Besides that, the species has a wide natural distribution; it bears fruit throughout the year, with high productivity, and the seeds can be harvested non-destructively. *C. inophyllum* is able to grow in a variety of sites, including degraded lands, thus avoiding competition with food production on arable land. In this study, we quantified carbon sequestration and storage in plant biomass and soil organic carbon of *C,inophyllum* provenances from eight islands in Indonesia, conducted in a Calophyllum Provenance trial plots in Gunungkidul, Java Island, Indonesia. Tree component and soil samples were collected from 32 sample plots on a provenance trial area covering 3 hectares. Analysis of variance was used to determine variations in carbon stock between different provenances. Allometric equations were modelled to estimate total biomass carbon (tBC), and redundancy analyses (RDA) were used to determine the effects of soil physicochemical properties and litter fiber on carbon stock. These were followed by a variation partitioning analysis (VPA). The results showed that the average of tBC was 18.21ton ha^{-1} ranging from 13.66 ton ha^{-1} (Selayar) to 27.50 ton ha^{-1} (Bali Timur) and tSOC was 75.91 ton ha^{-1} ranging from 32.84 ton ha^{-1} (Ketapang) to 120.27 ton ha^{-1} Yapen). No significant variations found in tBC, carbon content by component, or total soil organic carbon (tSOC) between provenances. A polynomial regression equation based on coefficient of determination (R2) and root mean square error (RMSE) was used to estimate tBC. Most variations (76%) were affected by soil chemical properties. tSOC was strongly affected by soil thickness, C:N ratio, and total P rather than other soil physicochemical properties. Sand content, hemicellulose and base saturation all had inverse correlations with tSOC. tBC had a strong positive correlation with exchangeable P, total K, NH4 and DOC and negative correlations with aggregate stability index. This study is useful for evaluating and improving forest soil management, monitoring ecological and environmental conditions, and formulating climate policy.

Carbon stocks of homestead forests have a mitigation potential to climate change: A case from Chittagong Hill Tracts, Bangladesh

T1.13 Forest management for climate change mitigation

Tarit Kumar Baul[1]
Tajkera Akhter Peuly[1], Lars Holger Schmidt[2]
[1] Institute of Forestry and Environmental Sciences, University of Chittagong, Chittagong 4331, Bangladesh
[2] Department of Geoscience and Natural Resource Management, University of Copenhagen, Rolighedsvej 23, 1958 Frederiksberg C, Denmark.

Abstract: Homestead forests of Bangladesh (0.27 million ha land) have potential of providing co-benefits of conserving biodiversity and storing carbon (C). The study aimed to estimate C stocks and how stand structure affects the tree biomass C in homestead forests of the Chittagong Hill Tracts (CHT), Bangladesh. A total of 176 homestead forests at three altitudes in the CHT were randomly surveyed. All woody vegetation were measured, and litter and soil (0–30 cm depth) were sampled. The results show that the above- and below-ground tree biomass C stock in the top two altitude forests was up to 37–48% higher than in low altitude, due to significantly higher tree density and species diversity. An increase in species diversity index by one unit increased the biomass stock by 23 Mg C ha^{-1}. The C stock of litterfall in low altitude forests was 22–28% higher than in the top two altitudes owing to the deposition of litters downslope by gravity and deliberate use of pruned materials as mulch for soil improvement and conservation, resulting in up to 5% higher total soil C. The topsoil C was 10–25% higher than the deeper soil, depending on the altitude. The forest stored a total of 71 tree species and 89 Mg C ha^{-1}, which can contribute to climate change mitigation while conserving biodiversity, moisture, and hill soil in small-scale forests. This study would help policymakers to strengthen the recognition of small-scale forests for mitigation in REDD+ (reducing emissions from deforestation and forest degradation, the role of conservation, sustainable management of forests, and enhancement of forest carbon stocks) by generating C credits for owners from sustainably managed forests.

Climate change and local adaptation in forest trees - can maladaptation to future climates influence carbon sequestration belowground?

T1.13 Forest management for climate change mitigation

Theresa S. Ibáñez[1]
Michael J. Gundale[2], María Rosario García-Gil[3], Petter Axelsson[1]
[1] Swedish University of Agricultural Sciences, Department of Wildlife, Fish and Environmental Studies, Sweden
[2] Swedish University of Agricultural Sciences, Department of Forest Ecology and Management, Sweden
[3] Swedish University of Agricultural Sciences, Department of Forest Genetics and Plant Physiology, Sweden

Abstract: The urgent need to sequester atmospheric carbon dioxide (CO_2) in forests to mitigate climate change and support sustainability goals is widely recognized. While the potential of fast-growing tree populations for aboveground carbon (C) sequestration has been extensively studied, less attention has been given to understanding how these locally adapted tree populations influence plant-soil interactions and subsequently impact belowground C sequestration. Such knowledge gaps are crucial to effectively address the complexities of carbon dynamics in forest ecosystems.

In our project, we are quantifying the belowground C sequestration in relation to the aboveground tree biomass increment, in a 70-year-old *Pinus sylvestris* provenance trial in the boreal forests of Sweden. To simulate the impact of climate change, we are examining the effects of a southern transfer distance variation of up to 5 latitudinal degrees. We have estimated soil respiration, soil C and nutrients content, tree mortality, litter input, vegetation and microbial biomass and analyzed the soil microbial communities. By integrating and analyzing these variables, we aim to gain novel insights into the mechanisms underlying belowground C sequestration in areas where *P. sylvestris* trees of varying provenances have been planted. This knowledge is valuable when making decisions about forest management practices that could increase forest resilience to climate change. For instance, an increase in tree growth enhances the uptake of atmospheric CO_2 but may also simultaneously accelerate root respiration, leading to a net release of C from the system. Further, there is a risk of negative feedback loops that could impair forest capacity for C sequestration, because as the climate changes, it may make locally adapted tree populations maladapted to future climates. The outcomes of our research hold significant potential to inform the development of sustainable forest management practices in the face of a changing climate.

Combing multiple feature selection methods and structural equation modelling for exploring factors affecting stand biomass

T1.13 Forest management for climate change mitigation

Xiao He[1]
Xiangdong Lei[1], Qigang Xu[2], Jie Lan[3], Biyun Wu[1], Hong Guo[3], Wenqiang Gao[1], Di Liu[1]
[1] Institute of Forest Resource Information Techniques, Chinese Academy of Forestry, Beijing 100091, People's Republic of China.

[3] College of Forestry, Beijing Forestry University, No.35 Qinghua East Road, Beijing 100083, People' s Republic of China.

Abstract: Recognition of biotic and abiotic factors affecting biomass in natural mixed forests is of great importance for forest biomass estimation and management. However, the results obtained from different variable selection methods are often inconsistent and there is lack of the systematic analysis. The objective of this study was to combine multiple feature selection methods with structural equation modelling to identify more representative variables for better stand biomass estimation. Seven methods were applied to test the differences for variables affecting stand biomass based on data from 286 permanent sample plots in natural coniferous-broad leaved mixed forests in northeast China. They included Pearson correlation analysis, principal component analysis (PCA), stepwise regression, redundancy analysis (RDA), generalized additive model (GAM), random forests (RF), and boosted regression tree (BRT). Totally there were 64 candidate variables covering stand, biodiversity, climate and soil features. We found that there were significant differences in variables selected among feature selection methods. Variables common to all methods were the species diversity (*N_Sp_Div*), stand structural diversity (*N_ Size_ Div*), nearest taxon index (*NRI*), community weighted mean based on dry matter mass of leaves (*CWM.LDMC*), soil pH, degree-days above 18°C (*DD18*). These variables were included into the structural equation model (SEM) to further explore the direction and magnitude of the impact on stand biomass. The SEM results showed that stand average age and stand density had the greatest positive influence and that structural diversity had a significant positive effect on stand biomass. *DD*18 affected stand biomass directly and indirectly, but the total effects were negative. Soil pH affected stand biomass indirectly via additive stand density index (*aSDI*). The combination of multiple feature selection methods and structural equation modelling was an effective for understanding factors affecting stand biomass. The study provides a generic method framework for exploring the influencing factors of biomass at large scale.

Comparative Assessment of Jurisdiction-based REDD+ Benefit Sharing Policy Options in Indonesia

T1.13 Forest management for climate change mitigation

Riko Wahyudi[1, 2]
Christian Silangen[1], Muis Fajar[1]
[1] Research Centre for Climate Change - University of Indonesia
[2] Indonesia Expert Association for Climate Change and Forestry

Abstract: Mechanisms to share sharable benefits of jurisdictional-based REDD+ in incentivizing beneficiaries, particularly at site level, have become an essential and simultaneously one of the most challenging parts of REDD+. Public finance approaches through the intergovernmental fiscal transfer (IFT) system have been proposed to channel the REDD+ shareable benefits. However, the public finance approach has also its challenges such as a long-process of bureaucracy, needed interventions in the aspects of collection, allocation and distribution, and inflexibility of fund utilization. In the context of Ministry of Finance (MoF) and Ministry of Environment and Forestry (MoEF) have established a public service agency for environmental fund management (BPDLH) as a non-structural institution to manage funds for the environment, including REDD+. As a nascent institution, BPDLH is constantly looking for the best mechanism for distributing REDD+ benefits to beneficiaries in subnational jurisdiction i.e.: through provincial budget (APBD); using intermediary agency; and direct to beneficiaries. This paper will be looking into the three currently available options for benefit sharing by the BPDLH and evaluate the effectiveness, efficiency, equity, and feasibility of these options. Analyses will be made in regard to the advantages and disadvantages of each option in achieving the intended targets, thus determining the best policy approach that can be implemented sub-nationally. The paper also delivers a set of recommendations of what is the best approach is for policy makers, in this case is BPDLH, in sharing the benefit of jurisdiction-based REDD+ to achieve its overarching goals.

Development of soil greenhouse gas fluxes in former croplands: the role of tree species, the environment and the soil microbiome.

T1.13 Forest management for climate change mitigation

Karelle Rheault[1]
Jesper Riis Christiansen[1], Ludovica D'Imperio[1], Per Gundersen[1], Lars Vesterdal[1], Klaus Steenberg Larsen[1]
[1] Department of Geosciences and Natural Resource Management, University of Copenhagen, 1958 Frederiksberg C, Denmark

Abstract: Greenhouse gas (GHG) emissions, in the form of CO_2, CH_4 and N_2O, from land use change and agriculture are responsible for up to 20% of anthropogenic emissions, mainly due to deforestation, livestock production and crop fertilization. Afforestation is proposed as an effective means to sequester atmospheric carbon in biomass and soils. However, there is a lack of knowledge about the resultant soil GHG fluxes from temperate afforested ecosystems and how it develops with time. Furthermore, tree species choice (deciduous/conifers) may impact the soil biogeochemistry differently through the soil physicochemical properties and the soil microbiome with a currently uncertain outcome in relation to GHG fluxes and the climate mitigation potential.

In this study, we are investigating the development of soil GHG fluxes, soil physicochemistry, and the soil microbiome on arable land using a well-established forest chronosequence (Vestskoven, Denmark), which is a former cropland area afforested over the last 50 years with Norway spruce (*Picea abies*), oak (*Quercus robur*) and beech (*Fagus sylvatica*). The total of 14 selected sites in Vestskoven includes 4 stand ages per tree species. We measured GHG fluxes (N_2O, CH_4 and CO_2) *in situ* once a month for a period of 13 months, and sampled soil for physicochemical and molecular analyses.

Preliminary results show that net soil CO_2 fluxes increase with stand age due to higher soil C content and heterotrophic respiration and net CH_4 uptake increases due to more porous soil. We compared our chronosequence data with similar data from old growth forest soils with the same tree species. In addition to tree species and age, soil water content and temperature content are the key drivers of change in GHG fluxes 50 years after afforestation. Finally, soil fungal and bacterial community composition is changing over time, especially ectomycorrhizae, which could explain some of the variation in GHG emissions from the different tree species over the chronosequence.

Development stage mediates the effects of diversity on aboveground biomass in Northeastern China's temperate forests

T1.13 Forest management for climate change mitigation

Wenqiang Gao[1]
Xiangdong Lei[1], Maowei Liang[2]
[1] Institute of Forest Resource Information Techniques, Chinese Academy of Forestry, Beijing, China
[2] Department of Ecology, Evolution, and Behavior, University of Minnesota, St. Paul, MN 55108, USA

Abstract: Biodiversity and ecosystem functioning relationships (BEFs) has been extensively studied in various ecosystems. However, these relationships can change as forest matures (i.e., forest development stage), and the underlying mechanisms remain underexplored. Using a large temperate forest dataset with 2,392 permanent plots in northeastern China, we examined the relationships between multidimensional diversity (i.e., tree species richness, functional diversity, and functional composition) and aboveground biomass (AGB) across the five development stages (< 30, 30-50, 51-70, 71-100, and > 100 years). We found the positive BEFs using both species richness and functional diversity, but these positive effects decreased with increasing forest development stage. However, the relationships between community-weighted mean (CWM) and AGB showed two peaks in young (< 30 years) and mature (71-100 years) stands. Interestingly, the stronger effects of CWM on AGB compared to functional diversity in mature stands revealed that BEFs are driven by mass-ratio effects (i.e., dominant species) rather than niche complementarity, the average effects of CWM on AGB were significantly greater than the average effects of functional diversity. Our findings how the stand developmental stage influences the effects of biodiversity on ecosystem functioning in natural forests which could help identify effective strategies for maintaining or enhancing ecosystem services in forests at different stages of succession.

Does CDM Regenerated Forest Accumulate more Carbon Stocks in the Soil than the Biomass? The case of Humbo in Ethiopia

T1.13 Forest management for climate change mitigation

Wondimagegn Amanuel[1]
Moges Molla[1], Chala Tadesse[1], Musse Tesfaye[2], Zenebe Mekonnen[1]
[1] Ethiopian Forest Development, Addis Ababa, Ethiopia.
[2] Leibniz-Zentrum für Agrarlandschaftsforschung (ZALF), Müncheberg, Germany

Abstract: Investigating the amount of carbon pools in forest ecosystems makes it possible to understand different carbon stocks in the forest ecosystem. Humbo CDM naturally regenerated forest is managed through direct involvement of the local community and funded by World Vision Ethiopia and the Canadian government through a global carbon credit framework. Therefore, the aim of this study was to quantify the amount of biomass and soil carbon stocks along altitudinal gradients in the Humbo CDM forest in southern Ethiopia. A total of 54 nested sample plots of 20 m by 20 m were established on transects of elevation gradients with a spacing of 100 m between plots. Inventories of woody species and soil samples (010 and 1020 cm depth) were collected within each nested sample plot. Soil organic carbon was analyzed using the Walkely-Blacks method, while above-ground biomass was estimated using the Chave method. To analyze equality of means, ANOVA was used for multiple comparisons between height classes at =0.05. Total carbon stocks decreased significantly ($p<0.05$) between the three elevation gradients. The total carbon stocks significantly ($p < 0.05$) differed among the three altitudinal gradients. The biomass carbon stocks are not significantly different between middle (1610–1750 m.a.s.l.) and lower (1470–1610 m.a.s.l.) elevations but both of them significantly ($p < 0.05$) differed from higher (1750–1890 m.a.s.l.) elevation. The results show an increasing total carbon stock, particularly soil organic carbon, from lower to higher elevations. It was concluded that CDM-regenerated forest ecosystems have the potential to accumulate higher soil carbon stocks than biomass, which varies significantly along elevation. The highest ecosystem carbon stock was contributed by SOC. We recommend that carbon-related awareness raising for local people and promotion of local knowledge can be considered as a possible option for sustainable forest management and climate change mitigation.

Does the mechanical site preparation used in Fennoscandia today really increase soil carbon losses?

T1.13 Forest management for climate change mitigation

Monika Strömgren[1, 2]
Riitta Hyvönen[2], Lars Högbom[1, 2], Kristina Mjöfors[3], Bengt A. Olsson[2], Eva Ring[1]
[1] Skogforsk (The Forestry Research Institute of Sweden)
[2] SLU (Swedish University of Agricultural Sciences)
[3] RISE (Research Institue of Sweden)

Abstract: The carbon content in the soil of northern forests exceeds twice the amount stored in tree biomass. Concerns have arisen that soil disturbance, such as mechanical site preparation, could lead to a depletion of the soil carbon stock, thereby impeding climate change mitigation. However, these concerns were based on a few studies conducted in different forest ecosystems worldwide and encompass a wide range of site preparation practices.

Later research from about 15 forests on mineral soil on the two most commonly used mechanical site preparation practices in Fennoscandia, patch scarification and disc trenching, has shown that these practices do not significantly affect soil respiration during the first two years. A temporary increase in soil respiration immediately after site preparation was observed, but this disappeared after two weeks. While soil respiration from mounds and tilts were generally higher than from undisturbed soil during the first year, the respiration from pits and furrows were significantly lower, resulting in a lower overall average compared to undisturbed soil. These findings suggest minimal impact on soil carbon stock in the initial years.

Long-term studies assessing the effects of site preparation on soil carbon stock after decades are scarce. Existing studies on site preparation methods used in Fennoscandia on mineral soils do not indicate significant loss of soil carbon; instead, they suggest no substantial change after 10 and 25 years. Studies on stump harvest, which involve extensive soil disturbance, have shown similar results after 20-30 years, despite expectations of more severe soil disturbance and increased biomass harvest.

When considering climate change mitigation, both soil and biomass carbon stocks must be considered. Mechanical site preparation promotes tree growth. Thus, if the effects on soil C stock are minor, site preparation on mineral soils may contribute to climate change mitigation rather than causing adverse effects. Ongoing analyses and soil carbon inventories from additional site-preparation experiments on mineral soils aim to provide further insights into the long-term effects on soil and biomass carbon stocks approximately ten and seventeen years after treatment.

Estimated biomass carbon in thinned Cunninghamia lanceolate plantations at different stand-ages

T1.13 Forest management for climate change mitigation

Xie Zhang[1]
[1] Hunan Academy of Forestry

Abstract: Chinese fir (*Cunninghamia lanceolate* [Lamb.] Hook.) is a fast-growing species which is not only important as a timber-supplier, but also as an available sink for carbon (C) storage in biomass. Stand age and density are two critical factors that can determine tree C sequestration as interrelated drivers through natural self-thinning. *C. lanceolate* were planted using 1-year-old bare-root seedlings at the initial density of 1800 stems ha^{-1} in a 15-ha montane area of Hunan Province, China in 1987. The plantation was thinned twice 10 and 20 years after planting to leave trees of 437.5 ± 26.6, 675.0 ± 155.2 and 895.8 ± 60.1 stems ha−1 as low, medium, and high densities, respectively. Tree height and diameter at breast height (DBH) were measured every 2 years beginning from 23 years (2009) to 31 years (2018) after establishment, timber volume (TV) and biomass C were estimated accordingly. We did not find any interactive effect of age and density on any variables except for height. Both TV and biomass C increased with stand age or decreased in higher densities. The allometric height- DBH relationship can be fitted by an exponential rising- to-maximum model with higher maximum value over time. The decline of biomass C along density fit with the inverse first-order polynomial model which indicated that at least 1300–1500 stems ha−1 may be needed to maximize TV and biomass C for a longer term over 20 years. Therefore, to control the density to a reasonable level, over 1300 stems ha−1 in a rotation over 20 years old will be practical for tree biomass C in Chinese fir plantations.

Estimates of forest biomass carbon using region-specific biomass equations and volume-derived biomass relationships

T1.13 Forest management for climate change mitigation

Chao Zhang[1]
Shuirong Wu[1]
[1] Research Institute of Forestry Policy and Information Chinese Academy of Forestry

Abstract: Forest biomass and carbon content factor (*CCF*) are essential parameters in carbon accounting, thus, accurate estimates of forest biomass are of great importance for the assessment of carbon storage and carbon budget at large scales. In this study, tree sample data and national forest inventory (NFI) data were used to estimate forest biomass carbon in the Three Gorges Reservoir Region (TGRR), China. In order to estimate the biomass of each tree, above- and below-ground biomass equations were explored for six dominant tree species in TGRR based on 892 harvested sample trees. The aboveground biomass equations were both compatible with tree volume equations and additive system of biomass equations (including stem wood, bark, branches and foliage). Biomass and volume at stand-level were calculated by summing the biomass and volume of all single trees within each plot. Using the continuous biomass expansion factor (*BEF*) method and 2178 sampling forest plots of TGRR, the relationships between biomass and volume were developed for nine forest types. The *CCF*s of different components were measured for six dominant tree species in TGRR by using the dry combustion method, and a weighted CCF of whole tree was obtained. By applying the volume-derived biomass relationships and *CCF*s for different forest types, total forest biomass carbon and its dynamics were assessed in TGRR from 1999 to 2013. The results showed that, 1) The *CCF*s were 0.5490, 0.5223, 0.5142, 0.4914, 0.4779 and 0.4471 respecticely for *Pinus massoniana*, *Cunninghamia lanceolata*, *Cupressus funebris*, *Quercus*, *Betula* and *populus*; 2) The aboveground biomass equations obtained good model fitting and prediction, of which the coefficient of determination ranged from 0.912 to 0.980 (except *Betula* 0.801–0.812), and the total relative error and the mean prediction error were less than 3.0% and 10.0%, respectively; and 3) The estimate values of total forest biomass carbon were 39.328, 52.781 and 68.066 Tg for different periods, with an annual increase of 5.64%. The average total forest biomass carbon density were 27.262 Mg/ha in 1999–2003, 32.665 Mg/ha in 2004–2008, and 36.991 Mg/ha in 2009–2013. Our results can contribute to more accurate estimates of forest biomass and carbon stocks at local level.

Explicit Modelling of Uneven-Aged Stand Dynamics to Improve GHG Emissions Estimates in Eastern Canada

T1.13 Forest management for climate change mitigation

Dominic Cyr[1]
Yan Boulanger[2], Evelyne Thiffault[3], Lucas Moreau[3], Gabriel Landry[4]
[1] Environment and Cliimate Change Canada - Science and Technology Branch
[2] Natural Resources Canada - Canadian Forest Service - Laurentian Forestry Centre
[3] Université Laval
[4] Ministère des ressources naturelles et de la forêt du Québec

Abstract: Canada developed the Carbon Budget Model of the Canadian Forest Sector (CBM-CFS3) for national-scale accounting and reporting of GHG emissions and removals in managed forest, which meets Tier-3 standards for international reporting. CBM-CFS3 adopts an age-based yield curve approach that represents well the even-aged stand development typical of a vast portion of the Canadian boreal forest. Significant portions of the Canadian managed forest, however, are characterized by uneven-aged stand dynamics, which may not be adequately represented by current monitoring tools and carbon budgeting framework.

Here we investigate the potential of landscape model LANDIS-II combined with the Forest Carbon Succession (ForCS) module, which allows for an explicit representation of uneven-aged stands and associated silvicultural practices. 1- We assess the mitigation potential of forest management scenarios typical of deciduous, mixedwood and boreal forests of eastern Canada, 2- we present a calibration and validation exercise conducted in Montmorency teaching and research forest of Laval University, and 3- we compare CBM-CFS3 outputs with those obtained from LANDIS-II/ForCS.

Our results suggest that temperate and boreal forests of eastern Canada react differently to a forest management intensity gradient with regard to their respective capacity to act as carbon sinks. Net GHG capture is increased by an intensification of forest management in temperate hardwood forests, while less productive boreal forests, on the contrary, improved their net balance under longer harvesting rotations and conservation scenarios.

Using modelling tools that explicitly represent uneven-aged stand dynamics allows for improved assessments of the impacts of partial harvesting on net carbon balance, and those of climate change, which alters interspecific interactions and successional patterns. A considerable amount of uncertainty remains, however, and additional work is required before such an approach can become operational for accounting and reporting of GHG emissions and removals at national scale.

Facilitating forest carbon sequestration through increasing forest biomass and forest soil protection

T1.13 Forest management for climate change mitigation

Abstract: Diversity of objectives for sustainable forest management covering climate change mitigation, biodiversity, and bioeconomy may lead the operational forestry into diverging directions. The key question appears to be whether forests should be managed to increase the yield of forest biomass or limit the release of carbon from forest ecosystems aiming to improve the balance of greenhouse gases. The presentation aims to introduce key findings of a study conducted in Lithuania, with the primary objective to identify potential solutions to increase carbon sequestration potential of national forests. There were two parts of the study. Firstly, we conducted a qualitative analysis of the situation, by: (1) using in-depth interviews to disclose the positions of key forestry stakeholders regarding the role of forestry in carbon management and the instruments to improve it; (2) analysing relevant provisions in existing and proposed EU legal basis; (3) making an overview of the initiatives to accumulate carbon through forest management in other countries; (4) and making a meta-analysis of other studies relevant to the subject, conducted in the past in Lithuania and some in the EU. More than fifty potential forest management methods to facilitate carbon sequestration in Lithuanian forests were identified. Secondly, all the proposals were assessed for their performance using available forest decision support tools, SWOT, in-depth economic analyses for their robustness against the main principles of the proposed carbon sequestration certification schemes. The potential of each solution was compared with the expectations of forestry stakeholders, identifying and explaining the gaps between expectations and feasibility.

Facilitating wildfire mitigation strategies on Wildfire Crisis Strategy landscapes

T1.13 Forest management for climate change mitigation

Jaana Korhonen[1, 2]
Jeffrey Prestemon[2], Jill Derwin[2], John Coulston[2]
[1] ORISE / Oak Ridge Science and Education,
[2] Southern Research Station, USDA Forest Service, United States of America

Abstract: Understanding when, where, and how to intervene in forests to reduce overall economic costs and losses from wildfires is a crucial question with significant implications for forests managed by the U.S. federal government. The effective management of wildfires, including the removal of hazardous fuels that contain potentially marketable biomass products, is a high priority, as is demonstrated by new efforts on a subset of western U.S. federal land parcels defined by the 2022 Wildfire Crisis Strategy (WCS).

This study aims to address this challenge by quantifying and characterizing the biomass available within these landscapes and assessing the market impact of predicted biomass outputs using updated spatial equilibrium models and tools used for socio-ecological analysis of wildfire management.

The research project has several objectives. Firstly, an existing model will be modified to accurately quantify biomass for potential removal and explore innovative uses that are currently not considered in the selected forest. Secondly, the capacities of forest products facilities, such as mills, will be mapped and assessed to determine their capacity to process the identified biomass removals. Additionally, the project will quantify expected volumes and values of the removals, taking into account factors such as budget, treatment objectives, employment, market supply and demand dynamics, and local mill capacity.

Furthermore, the study will evaluate the potential for new uses of treatment products derived from biomass while considering the associated costs, revenue generation, job opportunities, and the impact of wildfires under different conditions and assumptions related to the demand for treatment products. By exploring alternative assumptions and scenarios, the research aims to provide a comprehensive analysis of the economic and environmental aspects of fire mitigation strategies specifically in the WCS landscapes.

Overall, this study aims to enhance our understanding of how economic variables intersect with fire resilience and management, bringing novel insight into the socio-ecological impacts of wildfire management.

From source to sink – recovery of the forest carbon balance after harvest

T1.13 Forest management for climate change mitigation

Achim Grelle[1]
Johan Bergh[1]
[1] Linnaeus University

Abstract: In Sweden, >80% of the productive forest is managed by clear-cutting, plantation of coniferous monocultures and rotation periods of 60 – 120 years, usually with some thinnings. The carbon losses after clear-cutting are intensively debated and it has been suggested to take a long time before the re-growing forest becomes a net carbon sink again. We analyzed ecosystem carbon fluxes from eddy-covariance measurements in five young forests in southern Sweden where the previous stand had been harvested by clear-cutting or wind-felled: three stands with Norway spruce (*Picea abies* (L.) Karst.), one with Scots pine (*Pinus sylvestris*) and one with Larch (*Larix x eurolepis* A. Henry). Among the spruce stands, one had the stumps harvested, one was fertilized and one received no special treatments. The observed stands transitioned from annual carbon loss to annual carbon gain 8–13 years after disturbance, depending on site productivity and management. This duration corresponds to approximately 15% of the rotation periods at these sites. The lowest carbon emissions and shortest recovery time was observed in the stand where the stumps of the trees, in addition to the stems and logging residues, were removed after harvest. This stand not only returned to a carbon sink within this time period but the total carbon gains since disturbance also equalled the total losses after only 11 years. Among the other stands, the highest carbon uptake was observed in the fertilized spruce stand. On a seasonal basis, the onset of net carbon uptake in spring was usually 1 month later in the larch stand than in the other stands because of phenological differences.
Extrapolation in combination with chronosequence data suggests that conventionally regenerated stands reach a neutral carbon balance after approximately 30% of the rotation period, i.e., when the carbon losses after clear-cutting are balanced by subsequent uptake. These findings highlight that production stands in southern Sweden act as carbon sources during a relatively small part of the rotation period, and that this period can be significantly reduced by implementing measures that enhance productivity or minimize the amount of woody debris remaining after disturbances.

Futures scenarios for sustainable forest management on forest potential: Balancing Carbon Sequestration and Sustainable Resource Utilization

T1.13 Forest management for climate change mitigation

Serban Chivulescu[1]
Raul Gheorghe Radu[1], Mihai Hapa[1, 2], Diana Pitar[1], Stefan Leca[1], Luminita Marmureanu[1], Stefan Petrea[1], Alexandru Claudiu Dobre[1], Ionut Silviu Pascu[1], Robert Pache[3], Ovidiu Badea[1, 2]

[2] Faculty of Silviculture and Forest Engineering, "Transilvania" University of Brașov, 500123 Brașov, Brașov, Romania
[3] Romanian National Forest Administration – Romsilva, 023841 București, Romania

Abstract: Recent climate policy advancements at the European Union level have led to more focused and definitive strategies for addressing climate change, with specific reduction targets assigned to countries, particularly in the forestry sector. On the way to 2050 EU climate neutrality, the focus is increasing on Land Use, Land Use Change, and Forestry (LULUCF), particularly within the forestry sector, which highlights the importance of forest management practices (FMPs) as effective tools for balancing carbon sequestration and the provision of forest services.

The study examines FMPs applied to over 3.5 million hectares of public forests in Romania, encompassing a wide range of forest types. By analyzing the impact of these practices on forest structure over a 35-year period, this research models the potential for carbon removal by 2050 based on different mitigation strategies. Forest management plans in Romania, revised every decade, adhere to silvicultural principles that promote a balanced distribution on age classes of forest and a controlled harvesting of wood resources. Sustainability indicators, including natural regeneration promotion and extended rotation ages of up to 140 years, ensure a balance between wood resource harvested and carbon removal from the atmosphere.

To facilitate emissions modeling, a comprehensive database of forest management practices implemented in Romania since 1984 has been compiled, incorporating stand and tree species data. Evaluating carbon balance in different types of forest management practices over time, the research modeled future carbon reduction strategies using the EFISCEN and CBM carbon budget and generate scenarios for forest dynamic characterized by varying harvest intensities trough FMPs approaches.

The study provides a deeper understanding of the often-overlooked impact of these practices on carbon sequestration and greenhouse gas emissions. It highlights that long-term conservation or non-intervention may not necessarily lead to higher annual carbon stocks removal potential due to factors like increased mortality and decreased yield, underscores the role of strategic forest management in reducing greenhouse gas emissions and combating climate change. Example of FMPs close to nature approach on a temperate forest type offers comprehensive and valuable insights into the consistent and sustainable forest management measures that can be adopted to meet climate neutrality.

HOW DO DIFFERENT SOURCES OF UNCERTAINTIES AFFECT VOLUME AND BIOMASS ESTIMATES?

T1.13 Forest management for climate change mitigation

Franciele Alba Da Silva[1]
Gabriel Agostini Orso[1], Rubén Manso[2], Alexandre Behling[1], Sylvio Péllico Netto[1]
[1] UFPR
[2] Forest Research - UK

Abstract: Estimates of population parameters in forestry are fraught with uncertainties that should always
be assessed and reported so that the accuracy of the results is known and understood. The aims of this study were (i) to quantify the total uncertainty on volume and biomass estimates and the share of this total due to different sources of uncertainty, such as design-related uncertainty, modelling-related uncertainty – including that emerging from an embedded height-diameter model– and that due to measurement errors, and to (ii) explore the economic implications of ignoring uncertainty in volume and biomass estimates. For these purposes, we used the case study of Acacia mearnsii stands in the South of Brazil. To evaluate how the above uncertainty propagates, we defined five scenarios where the different sources of uncertainty are progressively and incrementally added. Scenarios 1, 2, and 3 focus on the impact of height models on the uncertainties of volume and biomass estimates. We assume that in these scenarios the explanatory variables dbh and h were measured error free. In scenarios 4 and 5, in addition to continuing with the effect of the height equation, we added systematic and random errors on dbh in plots. We fitted Spurr model in linear fashion with mixed-effects to predict individual tree volume and biomass. The greatest uncertainty occurred when we used all predicted heights, both to fit the model and to
estimate the volume and biomass in the plots. The systematic error in the inventory plots led to the second largest uncertainty. In the third place is the uncertainty due to random errors in the explanatory variables used in volume and biomass models. One of the main conclusions of this study is that uncertainty sources interact in different ways and are propagated in the final uncertainty calculations in terms of volume and biomass. These sources of uncertainty may be more significant in the model or inventory, but they directly influence the total uncertainty. Understanding the effect of multiple sources of uncertainty in any estimate helps identify the most effective way to direct monitoring efforts to improve confidence in those estimates.

Impact on soil functions and soil greenhouse gas emissions by harvesting technologies on compaction-prone forest soils

Abstract: Temperate forests are a significant sink for the greenhouse gases (GHG) methane (CH_4), carbon dioxide (CO_2) and soil emissions of nitrous oxide (N_2O) are low. However, forest management can have a significant long-term impact, and soil compaction caused by heavy forest machine operation, in particular, can be a driving force. Especially silty and clayey soils are compaction-prone and have a low recovery capacity. These changes may affect the soil microbial community and influence soil respiration, methane uptake, and nitrogen turnover.

Results of a one-year measurement campaign in an Austrian beech forest catchment on Stagnic cambisol over Flysch sediments (N 48°07'16", E 16°02'52'', 510 m MASL) revealed a significant reduction in the CH_4 uptake rates and increased soil CO_2 and N_2O emissions at skid tails, six years after harvesting. Compared to the forest stand annual global warming potential (GWP_{100}) was 58% higher at skid tails.

The objective of the current project HoBo (Securing the Sustainability of Forest Soil Functions via Optimized Harvesting Technologies, https://dafne.at/projekte/hobo) is to determine the effects of harvester-forwarder use with/without tracks (HF/HFt) and cable-yarding with motor-manual-felling (CMM), on several soil functions to provide further recommendations for a site-adapted technology use for heavy soils.

We will present results from currently performed measurements at three forest stands on heavy soils, at the Flysch zone and the Molasse basin (North Alpine foreland basin), recently thinned by HF, HFt and CMM techniques. To gain insights into the effects on soil chemistry and microbiology, and changes in microbial community, we conduct soil analysis at 6-week intervals for nitrogen

availability, microbial carbon and nitrogen biomass, and phospholipid fatty acid (PLFA) analysis. Impacts on soil GHG flux rates of CO_2, CH_4, and N_2O are measured with trace gas analyzers (Li-Cor 7810 and 7820), either manually (Li-Cor Smart Chamber 8200-01S) in a 3-weeks interval at the recently thinned stands, or continuously (5-minute interval) with automatic chambers at the plots that were harvested seven years ago, at the LTER-CWN research site Klausen-Leopoldsdorf (https://deims.org/bb472a51-f85f-4de0-8358-f21ecbe2a102).

Intensive forest harvest increases N2O emission from soil: A meta-analysis

T1.13 Forest management for climate change mitigation

Yixiang Wang[1]
[1] Zhejiang A & F University

Abstract: A comprehensive evaluation of the impact of forest harvest on soil N_2O flux at the global scale is currently
unavailable. In this study, by using a global meta-analysis of 64 observations from 29 peer-reviewed publications
over the last 30 years, we elucidated how forest harvest impacted soil N_2O flux and related soil properties.
Intensive forest harvest significantly increased soil N_2O flux with a mean effect size of 0.85 and the increase was
associated with elevated soil temperature, increased concentration of NO_3^--N and decreased soil pH. The effect on
soil N_2O flux lasted for around six years, and soil N_2O emission depended on existing forest types in the late stage
(the recovery period >6 years) after harvest. Forest harvest clearly increased soil N_2O flux, with effect size
ranging 0.73–2.12, in broadleaf forests but did not significantly affect it in coniferous and mixed broadleaf-
conifer forests. In addition, the time required for the complete recovery from harvest in terms of N_2O flux
was difficult to define because of the scarcity of long-term experiments. Overall, this study provides the first
formal global-scale assessment on how forest harvest intensity, forest types and the time since harvest affect soil
N_2O flux. The findings of this study help to narrow the knowledge gap regarding the effect of forest harvest on
soil N_2O flux, and to facilitate decision making to decrease soil N_2O emission post forest harvest.

Is the tree health visible in the satellite signal? Relating tree growth, environmental data, and satellite imagery

T1.13 Forest management for climate change mitigation

Tamalika Chakraborty[1]
Marco Bobinger[1], Christopher Schiller[1], Jonathan Költzow[1], Fabian Fassnacht[1]
[1] Institute of Geographical Sciences, Free University of Berlin, Berlin, Germany

Abstract: Rapid global warming due to climate change and associated extreme weather events, such as storms, heavy rainfall, and prolonged dry periods, is the biggest threat of this century, causing pre-mature forest decline. The long drought of recent years has led to massive forest damage. According to the Forest Condition Report 2020, only "21% of the examined trees in our forests are still without crown damage", which is a clear sign of the catastrophic condition of the forests. In this condition, forests must be adapted to the new climate change conditions, and long-term climate-adapted forest conversion is required. In this study, we want to develop a decision support system to foster climate-adapted forest conversion. This would be based on tree species composition and vitality data, soil conditions, and climate data, which are harmonized and analyzed using Artificial intelligence (AI) methods. Two main objectives are: 1) monitoring near real-time forest decline, 2) building a link among environmental variables, tree health indicators (through tree growth), and remote sensing data. AI methodologies will be used for pattern recognition in satellite imagery to generate a high-resolution tree species map using a combination of Sentinel-2 time-series data and high-resolution orthophotos. Based on satellite imagery, a forest condition monitoring system will be developed to detect deviations from the current vegetation state as observed by satellite systems from expected vegetation conditions. The monitoring will be supported by semi-automated data collection of local conditions with a sensor network in the field. A mixed forest stand in Landshut, Germany, has been selected for conceptualizing, installing, and measuring LoRaWAN-based sensor network. LoRa-based sensors, including dendrometers, soil sensors, air temperature, and humidity condition sensors, are installed locally at the trees to provide additional parameters besides the available extraterrestrial data. Moreover, canopy cameras have been installed in the trees to understand the eco-physiological behaviors of the trees as a proxy of health parameters. Results will show how tree species combinations determine ecological indicators (tree growth) of the temperate trees under the climate change condition following the recommendation of suitable tree species combinations at the right place.

Methane oxidation in forest soils under different thinning intensity

T1.13 Forest management for climate change mitigation

Hojeong Kang[1]
Jaehyun Lee[1]
[1] Yonsei University

Abstract: Forest thinning is a widely employed management practice aimed at increasing tree biomass. However, its potential impact on methane oxidation, a valuable aspect of forests in terms of climate change mitigation, has yet to be assessed. In this study, we conducted a comparative analysis of methane oxidation rates, the abundance of methanotrophs, microbial enzyme activities, and soil chemical properties in temperate forests subjected to varying degrees of thinning over 2 years. In contrast to previous findings, we observed that soils exhibited the highest methane oxidation rates under moderate thinning intensities. Our analysis suggests that the active development of understory vegetation resulting from moderate thinning provides a substantial supply of organic matter to the soils, thereby facilitating methane oxidation. This study unveils a previously unrecognized influential factor, organic matter availability, in methane oxidation, offering new insights into forest management strategies for effective climate change mitigation.

Modeling vertical distribution of soil organic carbon in Zhejiang Province of China

T1.13 Forest management for climate change mitigation

Zhibin Sun[1]
Lin Meng[1], **Yixiang Wang**[2]
[1] Nanjing Normal University
[2] College of Environment and Resource Sciences, Zhejiang A&F University, Hangzhou 311300, China

Abstract: Exploring the distribution characteristics and influencing factors of soil organic carbon in the mesoscale range are of important theoretical and practical significance for the measurement of soil organic carbon content and agricultural production management. This study selects 838 distributed soil samples with different depths from Zhejiang Province in China. In the vertical direction, a vertical model of soil organic carbon density (SOCD) is established from five typical forest types. The relationship between SOCD and soil depth follows an exponential regression model. With the increase of soil depth, the unit SOCD continues to decrease, and the decline rate gradually slows down. The proposed vertical model combines MGWR model and exponential model, and it can well predict SOCD in soil layers with different depths.

Native, drought tolerant tree species as valuable option to enhance resilience of Central European forests to climate change

T1.13 Forest management for climate change mitigation

Julia Schmucker[1]
Enno Uhl[2, 3], Jens Peter Skovsgaard[4], Gerhard Schmied[2], Hans Pretzsch[2]
[1] Swedish University of Agricultural Sciences, Sweden
[2] Technical University of Munich, Chair for Forest Growth and Yield Science, Freising, Germany
[3] Bavarian Forest Institute, Freising, Germany
[4] Southern Swedish Forest Research Centre, Alnarp, Sweden

Abstract: Recent climate models predict an increase in hot, extremely dry summers in Central Europe. Currently predominant species differ in their capability to cope with those conditions. Especially on marginal sites, coniferous species showed a severe decrease in vitality during the last years. Therefore, the composition of Central European forests is expected to change drastically in the next decades. Under these circumstances, the introduction and promotion of alternative admixed species is a viable option to increase forest stability. Particularly, native and drought resilient species may be a reasonable option to complement present prevailing species and to maintain a close to nature composition. In our study we assessed the growth and drought reaction of five rare native tree species, i. e. European hornbeam (*Carpinus betulus* L.), European white elm (*Ulmus leavis* Pall.), field maple (*Acer campestre* L.), true service tree (*Sorbus domestica* L.) and wild service tree (*Sorbus torminalis* (L.) Crantz). Based on tree-ring data we I) evaluated their species-specific dendrometric growth characteristics and variability and examined the influencing site and tree variables on annual growth. II) We quantified their reaction to single drought events, also depending on site and tree variables. III) We compared the species-specific reaction of the focus species to oak (*Quercus robur* L., *Quercus petraea* (Matt.) Liebl.) and European beech (*Fagus sylvatica* L.). They are abundant species in Central Europe, and their growth dynamics under drought stress are well-known by forest managers. Our results show, that besides European white elm, the rare species have on average a lower annual growth, but a higher growth variability than European beech and oak. However, especially field maple and wild service tree appeared to be better adapted to drought than European beech and partially even recovered better than oak. Combining the aspects of growth stability and drought tolerance, we conclude that rare native tree species are well suited to drought conditions. Admixtures of those species may play an important role in forest stand transformation towards more climate resilient forests. However, this also requires adjusted silvicultural concepts that consider the species-specific allometric characteristics and allow the promotion of the rare species.

Pilot construction of national forest management aimed at improving forest quality and carbon sink capacity

T1.13 Forest management for climate change mitigation

Xianzhao Liu[1]

[1] Research Institute of Forest Resource Information Techniques, Chinese Academy of Forestry

Abstract: As the largest terrestrial ecosystem, forests play a variety of service functions in carbon sequestration and sink enhancement to cope with climate change, wood products supply, health and entertainment improvement, as well as ecological protection. The Plantation area of China is 1.314 billion mu, which ranks first in the world. In the past 10 years, China has replanted 960 million mu, contributing about a quarter of the new green area of the world, and becoming the country with the fastest growth in forest resources. However, the forest quality of China, especially the quality of plantation forest is not high, which influence the full play of a variety of functions, China is shifting the direction of forest development from increasing green space to improving quality and efficiency. This paper reviews the relevant work in forest management in China in the past 20 years, and emphasizes on the policies, funds, technology and other aspects of the pilot work of sustainable forest management launched in 2023. Through the multi-level and continuous promotion of forest management work by the state, province, city and forest farm, the researchers attempt to realize the conviction that Lucid Waters and Lush Mountains are Invaluable Assets, and ensure that the forest can play the role of "four reservoirs".

Pinus pinea circadian cycle monitored through high-resolution dendrometers across seasons

T1.13 Forest management for climate change mitigation

Veronica Loewe-Muñoz[1, 2]

[3] CONICET - Universidad Nacional de Córdoba. Argentina.

Abstract: Stone pine has relevant socio economic impacts, with increasing interest by establishing productive plantations in several countries. Stem diameter variations (SDVs) result in reversible depletion and replenishment led by the tree water status, and in irreversible diameter growth. The intra-daily temporal monitoring of hourly SDVs contribute in understanding the tree's response to changes in environmental conditions. The goals of the study were to describe the stem circadian cycles monitored with high-resolution band dendrometers during one year in adult stone pine trees growing in a semi-arid coastal environment, and to describe the category of stem cycles and their seasonal frequency. To study stem circadian cycles, the hourly SDVs were accumulated and splitted into three phases covering approximately 24 hours: contraction (P1), expansion or swelling (P2), and stem diameter increment (P3). In all seasons, the time of onset and duration were calculated for each phase. Results revealed that short cycles (<21 h) and long cycles (>28 h) were few; most of the circadian cycles were regular (24±3 h). P1, the daily shrinkage, occurred in the afternoon, when transpiration is higher than the root water uptake; P1 also included the night during winter. The maximum P1 was observed in summer. P2, the daily water uptake that follows P1, occurred in nights and mornings in winter and autumn, and mostly in nights of spring and summer. P3, the irreversible growth, in summer and autumn occurred mostly during mornings, and in spring, the fastest growth period, during nights and mornings. Time series of mean circadian cycle SDVs during one month of spring, summer, autumn and winter are presented. The highest stem diameter accumulation occurred in spring, and the lowest in autumn. Growth-temperature relationships, interesting to understand growth processes and environmental drivers, were studied. The temporal variability pattern showed lower growth under higher daily temperature across seasons. A Spearman correlation was found among SDVs and air temperature throughout the year (ρ ρ=-0.43, $p<0.0001$), and in every season. Our results add new insights into daily growth-climate relationships, especially important to face climate change challenges in semi-arid environments.

Potential reductions in carbon emissions from Indonesian forest concessions through use of reduced-impact logging practices

T1.13 Forest management for climate change mitigation

Hermudananto Hermudananto
Francis E. Putz[1, 2]
[1] Department of Biology, University of Florida, Gainesville, FL 32611, USA
[2] Tropical Forests and People Research Centre, University of the Sunshine Coast, Maroochydore DC, QLD, Australia

Abstract: To estimate how implementation of reduced-impact logging (RIL) practices could reduce carbon emissions from selective logging in Indonesia, we compiled data from 15 concessions in Kalimantan and 10 in the Papuan provinces, including data from 2010-2012 and new data from 2020. Data were collected harvested timber as well as on collateral damage caused by felling, skidding, and clearing for haul roads and log yards. Emissions data, expressed per cubic meter of wood harvested, per area harvested, or per Mg of timber harvested (i.e., the Carbon Impact Factor) were 1.30 ± 0.30 Mg C m^{-3}, 27.52 ± 8.70 Mg C ha^{-1}, and 6.88 ± 1.65 Mg Mg^{-1}, respectively. Felling, hauling, and skidding caused 43-59%, 24-36%, and 17-21% of these emissions, respectively. Potential emissions reductions calculated as the difference between observed emissions and those of the five best-performing concessions are 0.66 ± 0.30 Mg C m^{-3}, 20.85 ± 8.70 Mg C ha^{-1}, and 4.14 ± 1.65 Mg Mg^{-1}, which represent overall reductions of 51%, 76%, and 60%, respectively. Extrapolating these estimates to all forest concessions in Indonesia using average log production data from 2018-2021 results in an estimated annual emissions reduction of 14.47 Tg CO_2 from adoption of RIL, which is 2.9% of Indonesia's nationally determined contribution (NDC) from the forestry sector.

Prolonged rotation in combination of forest drainage – a solution to increased carbon storage in hemiboreal coniferous forests on organic soils?

T1.13 Forest management for climate change mitigation

Valters Samariks[1]
Ieva Jaunslaviete[1], Daiga Zute[1], Āris Jansons[1]
[1] Latvian State Forest Research Institute "Silava"

Abstract: Forests are expected to play an important role to achieve global climate change mitigation goals by increasing carbon removal from the atmosphere and reducing greenhouse gas emissions. Forests contain several carbon pools (i.e. tree biomass, soil, deadwood, etc.). Old-growth (prolonged rotation) forests are recognized as significant long-term carbon storages, however carbon stocks in such forests vary significantly due to site type, tree species, species structure, and natural disturbances. Even though tree biomass is a significant and dynamic carbon pool that can be managed, natural disturbances can notably deplete the carbon stock. An important management practice in hemiboreal region is forest drainage to enhance tree growth. Therefore, the aim of this study is to compare the carbon stocks in drained and undrained Scots pine forests on organic soils.

The study object is Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*) forests on organic soils (71 to 188 years old), where tree biomass and deadwood carbon stock was evaluated. The selection criteria for the old-growth forests (representing prolonged rotation) included the actual presence of the chosen forest type, an age group of over 130 years, a dominant target species representing over 60% of the basal area, and no evidence of prior logging activities.

Coniferous forests on drained organic soils have significantly higher carbon stock compared to undrained stands. This indicates that stand drainage enhances tree growth and carbon storage, and highlights the potential of forest management to improve carbon stock of periodically wet forest stands on organic soils. The deadwood carbon stock in coniferous stands was small, yet significantly higher for drained sites, and did not differ between tree species of the same forest type. The annual carbon stock difference in drained forest stands is significantly greater than in sites without drainage systems; however the carbon stock difference decreases with age. The decreasing trend of carbon storage efficiency (annual carbon stock difference) with age suggests the potential for forest management with shorter rotation cycles to mitigate climate change, while increasing the carbon removal from atmosphere and storing it in the wood products (boost land use efficiency).

Risk Assessment of the Forest Sector as a Carbon Sink According to Climate and Land Use Changes

T1.13 Forest management for climate change mitigation

Jiwon Son[1]
Mina Hong[2], Cholho Song[2], Woo-kyun Lee[1]
[1] Department of Environmental Science and Ecological Engineering, Korea University, Republic of Korea
[2] OJEong Resilience Institute, Korea University, Republic of Korea

Abstract: South Korea is facing problems due to climate change, leading to significant changes in land use. Meanwhile, two-thirds of the national territory is covered with forests, and they play a major role in carbon sequestration. This emphasizes the need to evaluate the risks in forest areas as a carbon sink. Moreover, there have been limited studies conducted in Korea on the changes in land use under climate change. This study aims to assess the effects of forest management and land use changes on the carbon sequestration of the forests under extreme climates. Land use simulations, the extreme climate scenario, and the forest management options were used in this study. Land use simulations included the following types: a condition where forest area decreases, a condition with maintaining the current status, and a condition with increased forest area. The climate scenario used in this study was the Shared Socioeconomic Pathways (SSP) 5-8.5, which assumes high greenhouse gas (GHG) emissions. The overall scenario with each of simulations integrated were as follows: 1) no human intervention in forest management with the land use scenario of decreased forest areas, 2) maintaining the current status both on forest management and land use, and 3) implementing optimum forest management with the land use scenario of increased forest areas. The scenario involving larger forest areas and optimal management (scenario no.3) exhibited the lowest risks, demonstrating significant differences from the first and second scenarios. Also, areas with high age-class came out to have higher risks when evaluated at the region level, including areas such as Gangwon-do, a typical region experiencing a reduction in northern temperate forests, and Gyeongsangnam-do, a distinctive region transitioning to warm-temperate forests. Therefore, forests should be managed not only according to policies but also considering changes in land use. This study contributed to understand and evaluate the capacity of forests sequestrating carbon in the future. Furthermore, this study may contribute to the development of the next National and Regional Forest Plans.

Seasonality of albedo and FAPAR in the temperate secondary forest ecosystem: A comprehensive observation using Qingyuan Ker towers

T1.13 Forest management for climate change mitigation

Shuangtian Li[1, 2, 3]
Tian Gao[1, 2], Qiaoling Yan[1, 2], Fengyuan Yu[1, 2], Jinxin Zhang[1, 2], Jiaojun Zhu[1, 2]

[3] University of Chinese Academy of Sciences

Abstract: Reforestation have been highlighted as a significant intervention for climate change by altering the land surface albedo and vegetation productivity. Previous studies have reported the effect of land-use/cover change on the land surface albedo, yet few studies have examined how changed understory and canopy structures derived from reforestation contribute to forest albedos and further influence fraction of absorbed photosynthetically active radiation (FAPAR, a proxy of gross primary productivity). Using the Qingyuan Ker Towers (three towers in a watershed; natural mixed broadleaved forest, T1-MBF; natural Mongolian oak forest, T2-MOF; larch plantation forest, T3-LPF), albedos for three spectral regions (global solar radiation, SR; photosynthetically active radiation, PAR; near-infrared radiation, NIR) and FAPAR were monitored. We continuously measured canopy effective leaf area index (LAI_e) and understory greenness, and examine their relationships to albedos in a temperate secondary forest ecosystem. The result showed that SR and NIR albedos of MBF and MOF were greater than those of LPF, and their PAR albedos were comparable. SR and NIR albedos were comparably and positively correlated with canopy LAI_e and understory greenness, while PAR albedo was negatively correlated with canopy LAI_e and understory greenness. Understory greenness explained 75.6% of changes in NIR albedo of LPF in the peak growing season, indicating a strong control of understory vegetation on the albedos. In addition, SR albedos were significantly correlated with FAPAR, with stronger correlations in MBF (r = 0.69) and MOF (r = 0.93) than that in LPF (r = 0.3), showing a co-benefit of carbon uptake and albedo in broadleaved stands, but the co-benefit was weakened in coniferous plantation stand. These findings suggested that increasing vegetation green biomass and introduction of broadleaved trees into monocultural coniferous plantation may increase forest albedo and co-benefit of albedo and FAPAR to combat climate warming.

Site index estimation for China fir plantations in china based on spatial clustering of environmental variables

Absract:The environmental uncertainty derived from climate change suggests that some commonly used empirical indicators of forest productivity, such as site index, may not be suitable for future growth prediction in the following decades. As a consequence, the development of statistical models that relate these indicators with environmental variables may be a crucial support resource for practical forest management.In this research, we tested three different statistical learning techniques for estimating site index of Chinese fir(Cunninghamia lanceolata) stands in fifteen province in the south of china.The predictors used for this task were a set of 43 physiographic, soil, and climatic variables obtained from available raster maps for this region, whereas the site index data came from the sixth and seventh national forest resources continuous inventory data, with a total sample size of 23 239.The proposed learning techniques produced models of easy interpretation in comparison to other "machine learning" approaches, and accounted for up to 45% of the response's variability. The random forest,GAM,GLM provided models with high performance but at the expense of including a large number of predictors. Using the group analysis in ArcGIS, the plots in the study area was gruoped according to the environmental similaruty and spatial proximity. The GAM with spatial clustering seemed to be the most suitable technique, as it explained above 40% of the site index variability with a reduced amount of predictors, and did not show undesirable patterns in the residuals and predicted values. Besides, the growth-environment relationships represented by this model seemed to be ecologically coherent.

[3] National Laboratory for Health Security, Centre for Ecological Research, Hungary

Abstract: Forests and their special microclimates are key elements in the mitigation of climate change and biodiversity loss worldwide. The relevance of forests in biodiversity and biogeochemical processes is shaped by microclimates, which can be described as stable, buffered, cooler and more humid than those of the adjoining open habitat. Tree-related microhabitats are especially important substrates and structures for biodiversity in forests but their effects on local microclimates in temperate regions are largely unknown. Water-filled tree holes (WHs) are special microhabitats, "aquatic islands on trees", that are important for insect larvae and mesofauna colonizing these waterbodies and feeding on the detritus. These temporary microhabitats can sustain water throughout dry periods for many vertebrate species as well.

In an abandoned Turkey oak-dominated coppice stand, in Northern Hungary, the microclimatic conditions of 80 WHs and adjacent forest plots were measured at the peak of the growing season of 2021. While closed forests could cool down air temperatures up to 5°C, WHs had an additional negative offset of 2.5°C and could increase air humidity by extra 15 percentage points (5 vs. 20%). The local microclimate of WHs and the adjacent closed forest differed significantly for means and extremes of all tested variables (air temperature and humidity, vapour pressure deficit), which was mainly driven by WH entry area, WH volume, and water amount.

Besides their substantial effects on the local microclimate, WHs are the only known habitat of European red-listed bryophyte species *Codonoblepharon forsteri* (Dicks.) Goffinet). Systematic mapping of the species showed that Turkey oak is an important host tree species (87 records). The main drivers – bare surface on the WH periphery, distance from the closest occurrence, and diffuse light – of the colonization of the species were also unfolded.

Moreover, by camera trapping, we could gain the first insights into the WH-use of vertebrate species – such as *Felis silvestris, Vulpes vulpes* or *Coccothraustes coccothraustes* – in oak-dominated forests.

We can conclude that the importance of microhabitats and habitat trees as climatic refugia increases, and the need for active protection is essential facing global climate change to mitigate its negative effects on forest biodiversity.

Soil CO2 fluxes and stocks in two typical Mediterranean oak-dominated ecosystems

T1.13 Forest management for climate change mitigation

[2] Forest Research Institute, Hellenic Agricultural Organization Dimitra, Vassilika, 57006 Thessaloniki, Greece

Abstract: The concentration of CO_2 in the soil is approximately four times larger than in the atmosphere, and minor changes in soil respiration may significantly impact the balance of atmospheric CO_2 and its effect on climate change. This work studies the mechanisms of soil respiration and C cycling in oak-dominated deciduous and evergreen Mediterranean forests and aims to: i) assess the difference in soil CO_2 emissions among the two types of ecosystems, ii) investigate the seasonal variance of carbon fluxes in those ecosystems, and iii) determine the effect of soil temperature and humidity, as well as of inputs from litterfall, forest floor and roots on soil respiration. The methodological approach of this work quantifies the contribution of the two independent processes that cause soil CO_2 efflux: i) root-derived C breakdown (autotrophic respiration of roots) and ii) soil-derived C decomposition (heterotrophic respiration of litter and SOM). Thus, the following treatments were applied: control [C] (undisturbed), no-litterfall [NL] (aboveground litterfall excluded) and no-litterfall -no-roots [NLNR] (both litterfall and roots excluded). In the NLNR treatment, roots were excluded by putting 20–25 cm deep trenches (20 cm wide) and placing fiberglass sheets to prevent root access. Three monitoring plots were established in each of the two ecosystem types. Every plot included three replicate measuring points for each of the three treatments. In total 54 polyvinyl chloride (PVC) collars were established for the performance of soil respiration measurements once every three months for one year, using a Li-8100 automated soil CO_2 efflux system. At the same time, soil temperature (°C) and volumetric soil moisture content (%) were determined. Here we present the preliminary results of soil respiration differences among two representative oak-dominated Mediterranean ecosystems and we attempt to identify the effects of climatic drivers and of litter inputs on the seasonal fluctuation of soil CO_2 fluxes, in order to enhance our understanding of C cycling in these forest types.

Stand biomass and productivity under future climate change varied among larch plantations in north and northeast China

T1.13 Forest management for climate change mitigation

Xiangdong Lei[1]
Yalin Xie[2]
[1] Institute of Forest Resource Information Techniques, Chinese Academy of Forestry, Beijing 100091
[2] Natural Resources Comprehensive Survey Command Center, China Geological Survey, Beijing 100055

Abstract: Understanding the effects of climate change on forest biomass and productivity is vital to adaptive forest management. In the present study, the 3-PG$_{mix}$ model was parameterized to simulate the effects of climate change on stand biomass and productivity of four types of larch plantations (*Larix olgensis, Larix gmelinii, Larix principis-rupprechtii* and *Larix kaempferi*) using 552 sample plots collected from the 6th, 7th and 8th National Forest Inventories north and northeast China. The 3-PGmix model is suitable for simulation of growth and yield of larch plantations, and the simulated and measured values of stand variables were consistent with each other (R^2 was between 0.71 and 0.96). Future climate change (increased temperature, precipitation and CO_2 concentration) could promote the growth of four larch species. Compared with the current climate, the stand variables showed an increasing trend in the 90 year simulation period with the same trend of RCP8.5 > RCP 4.5 > current climate. Furthermore, the response of larch plantations to climate change varied with tree species and site levels. With the exception of *Larix kaempferi*, the increased size of stand growth at low site levels was larger than that of high site level; but the increased mortality at high site level was larger than that of low site level. Implications for adaptive forest management were discussed.

The national voluntary carbon credit registry for the forestry sector in Italy

T1.13 Forest management for climate change mitigation

Saverio Maluccio[1]
Raoul Romano[1], Giorgio Vacchiano[2]
[1] Council for agricultural research end economics - CREA
[2] Department of Agricultural and Environmental Sciences-land production agroenergy of Milan State University - DISAA

Abstract: Contesto

Il crescente interesse della società civile e dei settori produttivi per gli impegni internazionali e dell'Unione Europea (UE) per combattere il cambiamento climatico e ridurne gli impatti sul capitale naturale ha portato a una maggiore attenzione politica e sociale sul ruolo svolto dai settori forestale e agricolo e dal servizi ecosistemici forniti.

Argomento

I crediti volontari di carbonio sono stati venduti nell'ambito dei Mercati Volontari in Italia e un'analisi di mercato del "Centro Monitoraggio Carbone" (NMC), gruppo di lavoro coordinato dal Consiglio per la Ricerca in Agricoltura e l'Analisi dell'Economia Agraria (CREA), mostra che raramente i crediti sono accompagnati da certificazione da parte di un organismo di certificazione esterno, nazionale o internazionale; invece, i crediti sono certificati secondo linee guida interne o talvolta venduti senza certificazione.

Grazie all'articolo 45 della legge n. 41 approvata il 21 aprile 2023, sarà istituito in Italia un registro pubblico dei crediti di carbonio generati su base volontaria dal settore agroforestale nazionale.

Metodo

Il Centro Monitoraggio Carbonio del CREA-PB, nell'ultimo anno ha istituito un Comitato Tecnico Scientifico (STC).

The STC drafted the document called Climate Credit Forestry Code (CFC 2.0) from a guideline document called Carbon Forestry Code (CFC) made in 2014 that was updated according to national and international regulations inherent to carbon removals and carbon markets. In particular, the CFC 2.0 was made consistent with the proposed regulation of carbon removals.

Results

The main requirements defined are: additionality, baseline, permanence and impacts on other ecosystem services such as biodiversity, soil and water resource.

I CFC 2.0 requires that net removals that generate carbon credits be calculated through the following general formula: Climate credits= ACt - ACb- GHG

Conclusion

L'introduzione di linee guida istituzionali riconosciute e dell'anagrafe pubblica nazionale per il settore agricolo e forestale consentirà di regolamentare il mercato anche in Italia. Pertanto, consentiranno alle organizzazioni pubbliche e private che vogliono compensare le proprie emissioni di utilizzare crediti di carbonio certificati generati in Italia dal settore forestale.

The Response Relationship between Nitrogen and Phosphorus Contents in Camellia oleifera Leaves based on Ground Hyperspectral and Machine Learning

T1.13 Forest management for climate change mitigation

Xuehai Tang[1]
Fan Kuang[1], Genshen Fu[1], Qun Cai[2], Lipeng Yan[1], Qingfeng Huang[1], Bin Wang[1], Qiangxin Ou[1]

Abstract: Abstract: Nitrogen and phosphorus are essential elements for plant growth. They play an important role in representing plant growth, physiological regulation, and fruit harvest. Hyperspectral technology provides a non-destructive, rapid, highly accurate, and cost-effective method for estimating nutrient content in plant leaves. However, there have been few reports on the remote sensing-based nutrient diagnosis of *Camellia oleifera* leaves. In this paper, 160 *Camellia oleifera* samples were used. Spectral data were obtained using a full-band ground object spectrometer. Based on preprocessing, different combinations of spectral indices were compared to reveal the spectral response characteristics of leaf nitrogen content (LNC) and leaf phosphorus content (LPC). Furthermore, spectral variables were screened, and optimal LNC and LPC estimation models based on three machine learning algorithms were constructed. The results showed that the spectral sensitive region for leaf nitrogen and phosphorus content was mainly reflected in green light, followed by red light and the long-wave direction of short-wave infrared. Savitzky-Golay first derivative (SGFD) pretreatment method was generally superior to the multiplicative scatter correction (MSC). At the canopy scale, the maximum of absolute values of correlation coefficient between LNC, LPC, and spectral transformation features were 0.56 and 0.49. The optimal LNC and LPC models were SGFD-NDSI-BPNN, with determination coefficients R^2 of 0.81 and 0.79, and RMSEP of 0.55 g/kg and 0.06 g/kg, respectively. The research results provide a reliable theoretical basis for the optical remote sensing monitoring of nutrient content in *Camellia oleifera* on a large scale.

Towards meeting net-zero emissions: carbon dioxide removal potential from Norwegian forests

T1.13 Forest management for climate change mitigation

Ignacio Sevillano[1]
Clara Antón-Fernández[1], Gunnhild Søgaard[1], Ana Aza[1], Christian Mohr[1], Knut Øistad[1], Rasmus Astrup[1]
[1] NIBIO - Norwegian Institute of Bioeconomy Research, Division of Forests and Forests Resources, Norway

Abstract: There is an increasing interest in using forests as a natural solution for enhancing terrestrial carbon dioxide removal, which is considered to have a significant potential role in climate mitigation efforts. Thus, carbon dioxide removal strategies from the forest sector might be key in achieving net-zero commitments and climate targets. Here, we assessed a range of carbon dioxide removal strategies oriented to increase carbon sequestration from Norwegian forests. These strategies include intensification of forest management (intensification of established practices in the forest sector), change in tree species (conversion from low-productive broadleaf forests to high-productive spruce forests), tree planting (spruce planting in areas currently undergoing the transition to low-productive broadleaf forests but which do not yet meet the FAO forest definition), and use of biochar from forest residues. Intensification of forest management and use of biochar would increase CO_2 removals in the short (2030), medium (2050) and long-term (2100), with very little effect in the short-term and increasing towards the end of the century. While change in tree species would increase CO_2 emissions in the short and mid-term, tree planting would have a negligible effect. Both change in tree species and tree planting (spruce conversion) would lead to an increase in CO_2 removals from the second half of this century. By the end of the century, the largest accumulated CO_2 removal potential was for tree species change and intensification of forest management strategies, following by tree planting and biochar strategies.

What alternative forest management approaches can we do to achieve carbon neutrality: A case study in Northeastern China

T1.13 Forest management for climate change mitigation

Dan Qiao[1]
Yihong Zhu[1]
[1] Beijing Forestry University

Abstract: Forest ecosystems play a pivotal role in mitigating climate change and providing essential ecosystem services (ES) to the natural biosphere. With China being the world's largest developing nation, its commitment to achieving carbon peak by 2030 and carbon neutrality by 2060 underscores the need to explore sustainable approaches for optimizing the ecological and economic benefits of forests. This study focuses on evaluating the economic value of forest ecosystem services in significant state-owned forest areas of Northeast China. Employing a comprehensive methodology combining geographic information system (GIS) modeling, scenario modeling, and economic estimation techniques, we conduct a 40-year scenario-based prediction of wood supply and carbon sequestration at representative sites to assess the impact of alternative forest management strategies on the studied services. The scenarios considered include: Scenario A, representing the prevailing management approach with logging prohibition; Scenario B, incorporating nature protection-oriented management; and Scenario C, emphasizing wood production-oriented management, both in comparison to Scenario A. Forest management scenarios are simulated over a 20-year timeframe. Our findings not only offer valuable insights for the management of China's natural forests to achieve the “dual carbon” goal, but also contribute to the ongoing discourse surrounding the trade-offs and synergies between carbon sequestration and the socio-ecological benefits associated with wood production.

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Annual flux of radiocesium from canopy to forest floor more than ten years after the Fukushima accident

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

[2] Atmosphere and Ocean Research Institute, The University of Tokyo

Abstract: More than ten years have passed since the Fukushima Daiichi Nuclear Power Plant accident, it has been pointed out that forest radiocesium (^{137}Cs) cycle is probably near the quasi-equilibrium state (^{137}Cs flux from canopy to forest floor is balanced with that of uptake from forest floor to trees). Observation of the ^{137}Cs flux from the canopy to forest floor is one of the essential attempts to improve the accuracy of prediction of ^{137}Cs activity concentration in the stem toward the resumption of forestry. In this study, we investigated the annual flux of ^{137}Cs via litterfall, throughfall, and stemflow in deciduous broad-leaved and Japanese cedar forests in Kawauchi Village, Fukushima Prefecture, from 2021 to 2022. Our observational results showed that annual flux of ^{137}Cs from canopy to forest floor in deciduous broad-leaved and Japanese cedar forests was 2600 and 930 Bq/m^2, respectively. Both of the above annual fluxes were less than 1% of the total ^{137}Cs inventory in the forest system. In addition, it was suggested that litterfall plays the most dominant role in the annual flux of ^{137}Cs from canopy to forest floor in forests more than ten years after the accident.

Availability of logs and litter of Japanese konara oak by estimation of radiocesium concentration from the leaves and the initial deposition

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Tatsuhiro Ohkubo[1]
Momo Hamagami[1], Mei Ikemoto[1], Mineaki Aizawa[1], Kazuya Iizuka[2]
[1] Department of Forest Science, Utsunomiya University, Utsunomiya 321-8505, Japan
[2] University Forests, Utsunomiya University, 7556 Funyu, Shioya-machi, Shioya-gun, 329-2441, Japan

Abstract: The contamination damage caused by cesium-137 (hereafter ^{137}Cs) released and deposited as a result of the Fukushima Daiichi Nuclear Power Plant accident has forced restrictions on the use of deciduous broad-leaved *Quercus serrata* forests in the Satoyama landscapes, which are used to produce logs for mushroom production and leaf litter for compost production for organic farming. To examine relationship between the ^{137}Cs concentrations in different parts of the tree, and the current availability of tree trunks and fallen leaves based on provisional permissible values of ^{137}Cs, we collected overstory branches, leaves, and fallen leaves by litter traps and tree trunks of *Quercus serrata* in several areas of different initial deposition levels neighbor to Fukushima prefecture, And the estimation of ^{137}Cs concentrations was made in tree trunks and fallen leaves from overstory branches and leaves and fallen leaves. The distribution of ^{137}Cs concentration in each individual *Quercus serrata* tree was highest in the overstory leaves. At the highly contaminated area both of the tree trunks and fallen leaves were unusable compared to the provisional permissible values (logs for mushroom production (50Bq/kg), leaf litter compost (400Bq/kg)), on the other hands the intermediate and low contaminated area showed the value of usable for the log and litter based compost production. Linear regression analysis showed that the best fit of the regression equation was obtained between the upper leaves and the trunk (bark) and between the upper leaves and fallen leaves, suggesting that the ^{137}Cs concentrations in the trunk and fallen leaves can be estimated from the concentrations in the upper leaves and branches. For the estimation of tree trunk and litter concentration from initial deposition for each area determined by airborne radar measurements by the Japan Atomic Energy Agency, a significant linear regression equation was obtained between initial deposition and overstory leaves. The relationship suggests that it is possible to estimate the concentration of overstory leaves from the initial deposition and of trunk and fallen leaves from overstory leaves. The results of this study will contribute to the rapid assessment of logs and litter availability under heterogeneous gradient of ^{137}Cs contamination.

Biogeochemical recycling of K and Cs isotopes in deciduous forest stands on the long term after deposition

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Abstract: Due to atmospheric releases from the Chernobyl and Fukushima accidents, Cs-137 long half-live (30y) and its incorporation into the biogeochemical cycle of elements lead to its persistence within forest ecosystems, affecting forest ecosystem services even more since their decontamination is hardly possible. Predicting its behavior and transfer dynamics over time is of key importance to help recovering benefit from forest products. Such assessment studies require the transfer processes to be documented with numerous data to encompass the variability of environmental factors (e.g. species, age, climate, deposit). To date, the root-uptake which is known to be the major process of Cs-137 intake in trees after the transition phase (>10y) couldn't be robustly assessed due to the remaining contribution of initial foliar uptake. More, data remain scarce for deciduous trees as most post-Chernobyl and post-Fukushima field studies mainly focused on evergreen species.

Relying on stands monitoring data collected during the post-accident long-term phase (>30y) in 4 various deciduous forest stands (France, Ukraine), we compared their Cs-137 concentrations and inventories distributions in trees as well as those of stable chemical analogues (Cs-133, K). To differentiate annual root-uptake from internal translocations fluxes in trees, we assessed their biogeochemical cycling fluxes (mass balance approach).

On the long-term, the Cs-137 initial foliar uptake contribution was no more visible at our sites due to biomass dilution and Tag (aggregated transfer factor) values were one order of magnitude lower than reference ones (IAEA, 2009) likely indicating a long-term decrease of Cs-137 bioavailability in soil. The concentrations of Cs-133 and Cs-137 normalized by the exchangeable inventories in soil were linearly correlated ($r>0.7$, $p<0.05$) and differences between isotopes were explained by the soil depth root density. The Cs isotopes were more sequestered than K in roots. Compared to evergreen coniferous forests, uptake rates (y^{-1}) were up to twice higher for K but up to 10 times lower for Cs isotopes, consequently exhibiting a stronger Cs/K discrimination. In a Q. serrata stand sampled in 2014-2018 (Japan, early-medium stage) where dynamics were slower than for coniferous, use of Cs-133 and K to assess the magnitude of Cs-137 root uptake rate is underway.

Comparing stable and radioactive caesium in a boreal forest landscape

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Fredrik Lidman[1]
Ulrik Kautsky[2]
[1] Swedish University of Agricultural Sciences
[2] Swedish Nuclear Fuel and Waste Management Company

Abstract: Radiocaesium was a major contaminant from the Chornobyl and Fukushima accidents, and Cs remains one of the most widely investigated elements in radioecology. The knowledge is largely based on studies of the radioactive isotope Cs-137, but Cs also occurs naturally as the stable isotope Cs-133. Because Cs-133 has been present in the environment over longer timescales than Cs-137 and has a different source – weathering rather than atmospheric fallout – it can provide additional insights into what processes govern the long-term fate of Cs in the complex boreal forest landscape.

This presentation will compare measurements on stable Cs-133 and radioactive Cs-137 from one of the most well-investigated catchments in the boreal forest region, the Krycklan catchment in northern Sweden. Measurements of Cs-137 date back to the Chornobyl accident in 1986, and sporadic measurements of soil, peat, stream water and biota have continued since then. The available research infrastructure has also been used to collect extensive data on Cs-133 in mires, soil water, groundwater, precipitation, biota and stream water from several catchments with contrasting characteristics, e.g. different catchment sizes and soil types. This has provided an overview of the natural abundance of Cs in different compartments across the forest landscape and allowed an assessment of the long-term transport and accumulation patterns of Cs. Complementary data on chemical analogues like K and Rb provides additional insights into what biogeochemical processes control the fate of Cs.

Although Cs-133 and Cs-137 chemically are identical, the results display substantial differences between the isotopes. Partly, this can be attributed to the radioactive decay of Cs-137 and its shorter presence in these ecosystems, but partly this also reflects how the two isotopes entered the ecosystems. For example, higher export of Cs-137 has often been observed from mires than from forests, but for Cs-133 the relationship is the opposite. Combined with evidence from other elements this suggests that the higher Cs-137 retention in forest soils is more related to hydrological flow pathways than higher mobility of Cs in peat. Hence, comparing these isotopes can help disentangle what processes are important for the long-term fate of Cs in the landscape.

Forest radioactive contamination: long-term dynamics and impact on ecosystem and society — Session overview

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Shoji Hashimoto[1, 2]
James Beasley[3], Gabriele Voigt[4], Mike Wood[5]

[5] School of Science, Engineering & Environment, University of Salford

Abstract: This presentation aims to provide an overview of the session and its objectives. The session focuses on sharing knowledge about forest-related radioactivity from around the world, including insights from long-term studies conducted in Chernobyl and Fukushima. Specifically, the session will explore the dynamics of radioactive materials and radiation in forest environments, encompassing all forest components, such as trees, soil, water, mushrooms, wildlife, and more. Additionally, the session will highlight the indirect impacts on forest ecosystems and society. Abandoned forests undergo changes in their biology and landscapes, which affect both society and wildlife. The potential risks of forest fires will also be addressed. Social studies will explore the effects of forest contamination on people's lives and the forest industry, as well as communication and education initiatives aimed at engaging local residents.

Further accumulation of radioactive cesium from 2014 to 2020 in the inner heartwood of trees contaminated by the Fukushima nuclear accident of 2011

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Shinta Ohashi[1]
Katsushi Kuroda[1], Hisashi Abe[1]
[1] Department of Wood Properties and Processing, Forestry and Forest Products Research Institute, Japan

Abstract: Understanding the dynamics of radioactive cesium (^{137}Cs) in stem wood containing substantial amounts of heartwood at the time of the Fukushima nuclear accident of 2011 is important for predicting the level of ^{137}Cs contamination of mature wood in Fukushima, Japan. Our previous study revealed that approximately 3 years after the accident (i.e., 2014), the amount of accident-derived ^{137}Cs that had transferred to the innermost heartwood tended to be small compared to the natural distribution pattern of stable cesium (^{133}Cs). Currently, it is unclear whether ^{137}Cs accumulates further in the inner heartwood or whether the distribution pattern of ^{137}Cs approaches that of ^{133}Cs over time. To clarify the ^{137}Cs dynamics after 2014, we conducted a follow-up investigation in 2020 at the same sites as those studied in 2014. Wood disks were collected from four cedar trees (*Cryptomeria japonica*), two trees each of cypress (*Chamaecyparis obtusa*) and larch (*Larix kaempferi*). The trees were approximately 50–70 years old. Wood disks were divided into segments every 2 cm along the radial direction from the cambium to the pith. The ^{137}Cs and ^{133}Cs concentrations were determined using a Ge detector and an inductively coupled plasma mass spectrometer, respectively. In 2014, the ^{137}Cs concentration tended to decrease from the outermost to the innermost heartwood (near the pith), while the ^{133}Cs concentration was distributed almost evenly throughout the heartwood. In 2020, the ^{137}Cs concentration in the inner and outer heartwood of many wood disks were similar, which reflected the distribution pattern of ^{133}Cs. However, in some wood disks with a relatively large heartwood area, the ^{137}Cs concentration tended to decrease slightly toward the innermost heartwood. Overall, the results demonstrate that the distribution patterns of ^{137}Cs and ^{133}Cs in heartwood become similar after several to ten years after the accident, although it may take more than a decade for ^{137}Cs to reach a steady-state distribution in stem wood with a relatively large heartwood area.

Inflow of absorbable radiocesium to forest soil at rhizosphere by stemflow

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Abstract: Evaluating the uptake mechanism of radiocesium by trees is necessary for developing the reducing method of the radiocesium concentration of trees in radioactively contaminated forests because the temporal trend of radiocesium concentration in stem wood differs depending on the tree species and standing conditions. Therefore, it is important to elucidate the dynamics of radiocesium that can be absorbed by trees in the rhizosphere where absorbing roots are distributed. This study investigated the relationship between the inflow of radiocesium by stemflow and radiocesium stocks in soils. We measured radiocesium amount by stemflow and dissolved and exchangeable radiocesium in different soil depths (0–5 cm, 5–10 cm, 10–15 cm) at four directions of trees for two Japanese cedar stands and a Konara oak forest in Fukushima prefecture, Japan. In addition, the preferential flowpaths of stemflow were detected by spraying the stems with colored dye under three rainfall conditions. Radiocesium amount by stemflow was higher for the Konara oak forest than the Japanese cedar forests. In the oak forest, dissolved and exchangeable radiocesium stocks in soil were high clearly under preferential flowpath of stemflow. In addition, on the soils of preferential flowpaths of stemflow, whereas vertical distributions of dissolved radiocesium are constant, some exchangeable radiocesium existed at deeper soils (10–15 cm). These results indicated that exchangeable radiocesium existed at the deeper soil layer because dissolved radiocesium was supplied to deeper soils by stemflow at the rhizosphere.

Influence of slope positions on Cs-137 uptake by trees in Japanese steep mountain forests

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Abstract: In Japanese steep mountain forests, the degree of organic layer development and soil physico-chemical properties change depending on the slope positions. This may also affect the dynamics of ^{137}Cs originating from the Fukushima Daiichi Nuclear Power Plant (FDNPP) accident in the forest ecosystem. In this study, we investigated the aggregated transfer factors (T_{ag}) of Japanese cedar needles, branches, barks, and stem woods along the slope in a Japanese cedar forest, which is located around 20 km northwest of the FDNPP. Additionally, air dose rates and soil properties (including exchangeable potassium which inhibits the ^{137}Cs absorption by plants) were also measured. Our results indicated that there were no significant differences in the ^{137}Cs inventory in forest soils (organic and mineral soil layers) and air dose rates among slope positions, suggesting that the initial ^{137}Cs deposition was almost equal regardless of the slope positions. However, ^{137}Cs activity concentrations in needles, branches, and stem woods tended to be relatively high at the ridge, and all maximum concentrations were found at the ridge. T_{ag} values in needles, branches, and stem woods also were higher at the ridge than those at the middle and low positions. There were no differences in bark between slope positions. The exchangeable potassium in the surface mineral soil layers (0–5 cm) did not vary depending on the slope positions. At the ridge, large amounts of ^{137}Cs were retained in the organic layers (about 25 times that at the low position), which were thick and the lower part of the organic layers was covered by dense fine roots. Oppositely, at the low position of the slope, the organic layers were thin and the dense fine roots were rarely observed. Therefore, large T_{ag} values at the ridge could be explained by that 137Cs are retained in the thick organic layers and are absorbed by the trees through the dense fine roots. We concluded that great attention should be paid to the slope positions to interpret soil-to-tree transfer of ^{137}Cs in mountainous forested areas in Japan.

Influences of Rooting Activity by Wild Boar on Cesium-137 soil profile after the Fukushima Daiichi Nuclear Power Plant accident

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Abstract: Cesium-137 (Cs-137, physical half-life of ca. 30 years) was a main anthropogenic radiological contaminant released from the 2011 Fukushima Daiichi Nuclear Power Plant (FDNPP) accident in Japan. Initially, contaminants from the accident were deposited on the surface soil layers in the terrestrial ecosystem surrounding Fukushima, but over time vertical migration of Cs-137 in the soil has occurred, with most Cs-137 now distributed a few centimeters below the soil surface. Wild boar (*Sus scrofa*) are present in the FDNPP region and impact the landscape and ecosystem, particularly through rooting behavior that can significantly disturb the soil. Soil disturbance caused by wild boar rooting likely alters the distribution of Cs-137-contaminated soil profiles, especially around the FDNPP area given the regional population increase of wild boar following the FDNPP accident. Our objective was to determine whether rooting by wild boar alters the distribution of Cs-137 contamination within soil profiles through collection of soil cores from control sites and two different types of rooting samples, new depressions and old (i.e. several months old) depressions, within the difficult-to-return zone surrounding the FDNPP. The mean soil migration depth of Cs-137 was 7.1 ± SD 2.3 cm across all rooting sites and 4.0 ± SD 1.2 cm across all control sites. The Cs-137 ratio [activity concentration of Cs-137 at each depth / the maximum activity concentration of Cs-137 in each core sample] was highest in the 2-4 cm soil profile and immediately decreased after 4 cm depth at the control sites. However, the ^{137}Cs ratio in soil layers at sites disturbed by wild pig rooting was deeper (i.e., 6-10 cm) than control sites, more dispersed throughout the soil profile, and decreased more slowly than control sites. There was no difference in the soil profiles between new and old rooting sites. These results demonstrate that soil disturbance from wild boar rooting can directly influence the distribution of contaminants within soil profiles. However, the extent to which deeper layers are affected by contamination depends on the unique characteristics (i.e., depth of rooting) of each wild boar rooting disturbance.

Inter-specific characteristics and intra-municipal variation of 137Cs concentrations in wild mushrooms after the Fukushima nuclear accident

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Masabumi Komatsu[1]

[1] Forestry and Forest Products Research Institute

Abstract: Due to radioactive contamination following the Fukushima Daiichi Nuclear Power Plant accident in 2011, shipping restrictions have been imposed on wild mushrooms in a wide area of eastern Japan. The shipping restrictions on wild mushrooms in municipalities are made without distinguishing between species, and because of the wide variation in concentrations from sample to sample, lifting is done on a species-by-species basis based on a large number of tests. In order to contribute to more efficient restriction and its lifting, I focused on the variation of radiocesium (^{137}Cs) concentration for each species obtained within the same municipality, and 7,920 sample data collected in prefectures in eastern Japan from 2014 to 2019 were analyzed. The ^{137}Cs concentrations of mushroom species collected in municipalities could be regarded as a lognormal distribution. The geometric standard deviation (GSD) for each species and municipality, which is an indicator of the variability of the lognormal distribution, tended to converge as the number of samples increased, while the values were considered to vary to 2–3 by species. The ratio of the geometric mean (GM) of ^{137}Cs concentrations for each species was constant regardless of the sampling municipality, suggesting that the trend in species concentrations is common regardless of the region. The concentration distribution considering the variation of species showed that there were cases where the concentration distributions overlapped even when the geometric mean concentrations differed by a factor of 10. On the other hand, there were cases in which the concentration distributions were very similar even though the species differed (e.g., *Pholiota microspora* (nameko) and *Panellus edulis* (mukitake), or *Mycoleptodonoides aitchisonii* (bunaharitake) and *Pleurotus ostreatus* (hiratake)). Such information is important when considering shipping restriction or its lifting.

Long term effects of ionising radiation in the Chernobyl Exclusion zone on DNA integrity and chemical defence systems of Scots pine

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

[5] Department of Plant Sciences, Faculty of Biosciences, Norwegian University of Life Sciences, P.O. Box 5003, NO-1432 Ås, Norway

Abstract: The Chernobyl Nuclear Power Plant (ChNPP) accident in 1986 resulted in extremely high levels of acute ionising radiation, that killed or damaged Scots pine (*Pinus sylvestris*) trees in the surrounding areas. Dead trees were cleared and buried, and new plantations established a few years later. Today, more than three decades later, gamma and beta-radiation near the ChNPP is still elevated compared with ambient levels but have decreased by a factor of 300 and 100, respectively. In the present work Scots pine-trees growing at High (220 μGyh^{-1}), Medium (11 μGyh^{-1}), and Low (0.2 μGyh^{-1}), of chronically elevated ionising radiation in the Chernobyl Exclusion zone were investigated with respect to possible damage to DNA, cells and organelles, as well as potential increased levels of phenolic and terpenoid antioxidants. Scots pine from the High and Medium radiation sites had elevated levels of DNA damage in shoot tips and needles as shown by the COMET assay, as well as increased numbers of resin ducts and subcellular abnormalities in needles. Needles from the High radiation site showed elevated levels of monoterpenes and condensed tannins compared with those from the other sites. In conclusion, substantial DNA damage and (sub)cellular effects, but also mobilisation of stress-protective substances possessing antioxidant activity are observed in Scots pine trees growing at elevated levels of ionising radiation more than three decades after the ChNPP accident. This demonstrates that the radiation levels in the Red Forest still significantly impact the plant community.

Low-dose-rate radiation effects on tree mutations: Insights from mutation surveys in Japanese cedar and flowering cherry

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Saneyoshi Ueno
Yoichi Hasegawa[1], Shuri Kato[1, 2], Hideki Mori[1], Hirofumi Tsukada[3], Hajime Ohira[4], Shingo Kaneko[4]

[3] Fukushima University, Institute of Environmental Radioactivity, Japan
[4] Fukushima University, Faculty of Symbiotic Systems Science, Japan

Abstract: Understanding the impact of low-dose-rate radiation on genetics, especially in natural settings, remains a significant scientific challenge. Following the Fukushima Dai-ichi Nuclear Power Plant disaster, naturally occurring lands became contaminated. This study investigates de novo mutations (DNMs) in germ line cells of Japanese cedar and flowering cherry trees exposed to ambient dose rates ranging from 0.08 to 6.86 $\mu Gy\ h^{-1}$ and distributed inside and outside the "Difficult-to-return Zone." Both tree species are extensively cultivated in Japan for forestry and horticultural purposes. In the case of Japanese flowering cherry, artificial crossing was performed to produce 69 seeds/seedlings, and only two potential DNMs were detected in uncontaminated areas. For Japanese cedar, 146 haploid megagametophytes were utilized as samples for the next generation. The use of megagametophytes from open pollination provided several advantages, including reduced radiation exposure in contaminated zones due to the elimination of artificial crossings and simplified data analysis owing to the haploid nature of megagametophytes. By directly comparing nucleotide sequences between parent trees and megagametophytes, an average of 1.4 candidate DNMs per megagametophyte sample (range: 0-40) was identified after optimizing filtering procedures through validation via Sanger sequencing. Interestingly, no correlation was found between observed mutations and ambient dose rates or the concentration of ^{137}Cs in cedar branches of the mother trees within the growth areas. Moreover, our findings suggest that mutation rates vary among genetic lineages and are influenced by the growing environment. Remarkably, the results indicate that the germplasm of Japanese cedar trees growing in contaminated areas did not exhibit a significant increase in mutation frequencies. These findings emphasize the complex nature of genetic responses to low-dose-rate radiation and underscore the importance of considering both species-specific differences and environmental factors.

Phytoremediation of heavy metal polluted gold mining sites

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

John Otuoma[1]
Mary Gathara[2], James Ndufa[2]
[1] Kenya Forestry Research Institute, P. O. Box 5199 - 40108, Kisumu, Kenya
[2] Kenya Forestry Research Institute, P. O. Box 20412 - 00200, Nairobi, Kenya

Abstract: Mining is a key economic activity in Kenya, contributing 1% of the country's GDP and 2% of export earnings. Since it is largely artisanal, it is a major source of pollution in which associated heavy metals end up contaminating the top soil and surface water resources. We assessed heavy metal contamination levels in Macalder, a major artisanal gold mining site in western Kenya. The concentration of lead (3,773 ppm), chromium (1,093 ppm), zinc (4,443 ppm) and Arsenic (3,363 ppm) were significantly higher than WHO recommended levels (Pb – 300 ppm), (Cr-1,500 ppm), (Zn-100 ppm) and (As-10 ppm). Following a survey of naturally growing plant species in the area, we tested the phytoremediation potential of six woody species from the area for a period of 60 days. The species were *Albizia coriaria, Senna siamea, Ficus sur, Ficus benjamina, Jatropha curcas* and *Euphorbia tirucalli.* We added two bamboo species to the list, namely: *Bambusa vulgaris* and *Bambusa blumeana*. There were three treatments for this assessment: highly contaminated soils, moderately contaminated soils and pure sand, which served as a control. The results indicated that all the species were able to grow in the pure sand throughout the period of 60 days. *Albizia*, *Senna*, and *Jatropha* could not grow in both highly contaminated and moderately contaminated soils beyond the first 7 days. *Ficus* was able to grow in the moderately contaminated soil for the 60 days, but did not manage more than 7 days in the highly contaminated soil. The two bamboo species managed to grow in all the soils for the 60 day period. This experiment is proceeding to the stage of analyzing the concentration level of heavy metals in the tissues of the woody species that were able to grow in the contaminated soils. The results suggest, however, that not all plant species that grow in heavy metal contaminated soils have the capacity to support phytoremediation of such sites. The expectation of the study is to end up with plants species with the capacity to not only grow in the contaminated soils but also mop up the heavy metals.

Radioactive contamination and radiation protection in Fukushima forests

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Satoru Miura[1]

[3] National Food Research Institute, National Agriculture and Food Research Organization

Abstract: After the Fukushima Daiichi Nuclear Power Plant accident, which resulted in a Level 7 nuclear disaster, the Japanese government promptly established regulatory limits in various fields. It put in place measures to protect people against radiation exposure to radioactive materials released into the environment. Most of the regulatory limits were established within one year of the accident, and restrictions on food distribution and access to forests are still in place. In this study, we estimated the additional exposure dose due to the nuclear accident based on the long-term monitoring data conducted in the forests, and discuss the optimized countermeasures to be taken in the event of a nuclear disaster. Air dose rates related to external exposure in forests sometimes changed significantly depending on the forest type during the first year or two after the accident; however, they continued to decline at a constant rate generally according to the rate of radioactive decay over a long period in most forests. Therefore, external exposure associated with forest activities can be accurately estimated based on the air dose rate and time spent. Internal exposure, on the other hand, was mainly caused by ingesting wild edible forest products with high radiation levels, but the standard limit of 100 Bq/kg of radiocesium applied to general food products keeping those products from the market makes the exposure risk extremely low. It should be noted, however, that eating large quantities of wild animals, wild vegetables, and mushrooms for private consumption in mountain village areas could be a potential internal exposure risk. Most measures taken against radioactive materials after the nuclear power plant accident have focused on specific activities of forestry workers and mountain village inhabitants. As a result, the concept of monitoring and controlling total annual exposure doses, considering both external and internal exposure, has not been widely adopted. Now that the contamination situation has settled down, it would be a lesson to make the most of the severe nuclear accident by reviewing more than ten years of monitoring data and considering preparedness for future accidents from the perspective of optimizing radiation protection of people.

RADIOECOLOGY OF PALM FOREST

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society
Gabtiele Voigt[1]
Natalia Semioshkina, Prasoon Taj[2], Nemeer Padiyath[2], Francois Foulon[2]
[1] RadCon GmbH, Am Mittleren Moos 46 a, 86167 Augsburg, Germany
[2] ENTC Khalifa University, UAE

Abstract: Palm forests, also known as palm groves or palm plantations, cover large areas in tropical and sub-tropical regions. There are often other vegetation types present, such as undergrowth plants, shrubs, and vines. These forests provide habitats for a wide array of animals, including birds, insects, reptiles, and mammals. Palm forests are economically significant in many regions. Palm trees produce valuable resources such as coconuts, palm oil, dates, and palm wine, which have various commercial applications. Palm oil, in particular, is extensively used in food products, cosmetics, and biodiesel production. With global warming the role of palm trees as a source of various product could grow.

With the development of nuclear energy in countries with an arid climate, there is a need to analyze possible emergency situations and their consequences, including identifying ways of food contamination with radionuclides and their spread through the food chain. Since palm trees play an important role in the nutrition of the population of countries with an arid climate, experiments were carried out at the Khalifa University of Abu Dhabi to determine the coefficients of transfer of radionuclides from soil to palm fruits, leaves, and bark. These experiments represent the first step in preparing a radioecological base, and the results will be presented.

Redistribution of the soil 137Cs inventory through litter and sediment transport on a hillslope covered by deciduous forest in Fukushima, Japan

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

[4] USDA-ARS National Soil Erosion Research Laboratory (NSERL)
[5] Kyoto University

Abstract: The long-term behavior of radiocesium (^{137}Cs) activity concentrations in forest ecosystems and their downstream impacts remain important issues in the deciduous broadleaf forests of Fukushima, Japan following the Fukushima Daiichi Nuclear Power Plant accident. To predict ^{137}Cs cycling and discharge in the forest ecosystem, it is important to understand the spatial dynamics of the ^{137}Cs inventory and transport along hillslopes. Therefore, we observed the spatial distribution of the ^{137}Cs inventory and ^{137}Cs transport via sediment and litter of a deciduous forest hillslope in Fukushima, Japan in 2016 and 2017 and examined how the spatial distribution of ^{137}Cs inventory was formed using a mass balance model. In 2017, the ^{137}Cs activity concentration was significantly greater in the downslope riparian area (455 kBq/m^2) than in the upslope ridge area (179 kBq/m^2). Annual ^{137}Cs transport within litter and sediment contributed < 0.5% to the current ^{137}Cs inventory, and cannot explain the current spatial variation of ^{137}Cs inventory on the hillslope. The mass balance model results showed that if the initial ^{137}Cs deposition was distributed uniformly in 2011, the spatial distribution of the hillslope ^{137}Cs inventory was influenced mainly by the movement of leaf litter with a high ^{137}Cs activity concentration.

Releases of 137Cs and 210Po by combustion of boreal peat and forest soil samples contaminated by Chornobyl fallouts

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Guillaume Pédehontaa-Hiaa[1]
Vilhelm Malmborg[2], Dan Madsen[3], Christopher Rääf[1], Johan Martinsson[1]
[1] Medical Radiation Physics Malmö, Medical Faculty, Lund University, Sweden
[2] Ergonomics and Aerosol Technology, LTH Faculty of Engineering, Lund University, Sweden
[3] Division of Fire Safety Engineering, Lund University, Sweden

Abstract: After the Chernobyl accident in 1986, the environment of the region of Gävle, Sweden (about 150 km North of Stockholm) was contaminated by radioactive fallouts. With a warming climate, an increasing number of wildfires in such a boreal environment is expected. A forest fire event would result in the redistribution of man-made and natural radionuclides like ^{137}Cs and ^{210}Po in the local environment as aerosols or ashes with potential negative effects on human health. Samples of forest litter, soil, peatbog litter and peat were collected on two sites of this contaminated area. The samples were dried and combusted in a small-scale experimental set-up to investigate the fire-induced resuspension of radionuclides. The samples were combusted at different temperatures and oxygen concentrations to simulate flaming and smouldering conditions. Aerosol fractions of various particle sizes were collected on filters using an impactor system and the remaining ashes were also recovered for measurement by radiometric techniques.

Gamma spectroscopy measurements showed that an average of 71% of the combusted samples ^{137}Cs 71% remained in the ashes after the combustion. The influence of the oxygen concentration was also investigated. Calculations based on the measured activity indicate that up to 7 TBq of ^{137}Cs could be released from the peat and soil by a wildfire in this contaminated region of about 100 km^2. Measurable amounts of ^{210}Po were also observed by direct alpha spectroscopy measurement of filters recovered from the impactor containing the smallest fraction of aerosol (> 0.2 µm) which corresponds to the breathable fraction. The highest values were observed in filters of combusted forest soils which could be explained by a higher fraction of inorganic materials.

More research is currently ongoing currently in Sweden to obtain experimental results in the field using the opportunity of prescribed burns to estimate the radionuclide redistribution in boreal forests. The comparison of field and laboratory combustions will allow to assess the performances of the laboratory-based approach.

Seasonal change of concentrations of radioactive cesium and various elements in leaves of Chengiopanax sciadophylloides grown in Fukushima, Japan

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Masazumi Kayama[1]
Satoru Miura[1], Yoshiki Shinomiya[1]
[1] Forestry and Forest Products Research Institute

Abstract: *Chengiopanax sciadophylloides* is a woody species for the utilization of mountain vegetables in Japan. After the Fukushima nuclear disaster in 2011, a higher accumulation of radioactive cesium (Cs-137) within the plants of *C. sciadophylloides* were shown. Concentrations of Cs-137 in leaves of general woody species decreased gradually year after year; however, *C. sciadophylloides* was not decreased. Moreover, although the concentration of Cs-137 of *Quercus serrata* showed a seasonal pattern of the highest value in early spring and then decreasing gradually, the trend of C. sciadophylloides were unrevealed. The objective of this study is to elucidate the seasonal absorption pattern of Cs-137 concentrations and other elements in leaves of *C. sciadophylloides*.

Four study sites were set in Tamura City, Fukushima Prefecture, where many *C. sciadophylloides* were distributed. Based on the preliminary research, concentrations of Cs-137 were different along the slope position and accumulated more at upper slopes. We established the sites on the upper, middle, and lower positions of the slopes, and five individuals (over 3 m) of *C. sciadophylloides* were selected. From the survey in 2021, leaves of *C. sciadophylloides* were collected from the flushing to the defoliation seasons and analyzed Cs-137 and various elements.

The Cs-137 concentrations in leaves of *C. sciadophylloides* were the highest in April, especially in the upper slopes. The Cs-137 concentrations decreased in the samples after June, but a further decrease was not observed in the samples from November 1st, when the yellow leaves were just before defoliation. In addition, the concentration of stable isotope of cesium (Cs-133) showed a similar tendency. Similarly, the concentration of potassium (K), which is an alkali metal like Cs, was the highest in the sample in April and decreased in the samples after June. The value of the concentration of K in April was quite high (over 1500 $\mu mol\ g^{-1}$) compared with other plant species. Therefore, Cs and K may have similar mechanisms of absorption, and the active uptake of K may be concerned with the co-uptake of Cs-137.

Sensitivity to gamma radiation of Scots pine seedlings grown from seeds developed under elevated levels of ionising radiation

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Abstract: The Chernobyl Nuclear Power plant (ChNPP) accident in 1986 resulted in extreme levels of ionising radiation resulting in massive death of Scots pine (*Pinus sylvestris*) trees in the "Red forest" area and damage to trees in surrounding areas. The gamma and beta radiation in the Chernobyl exclusion zone have decreased by a factor of 300 and 100, respectively, but the radiation levels are still elevated and impact on Scots pine trees that were planted or regenerated naturally after the accident. The aim of the current work was to test whether elevated radiation during the seed development can possibly result in rapid adaptation or alternatively, increase the susceptibility of the progeny to radiation. Seeds were collected in 2019/20 from Scots pine trees growing in High (near Trench #22 of Red forest), Medium (near lake Glubokoye) and Low, background (Ivankiv forestry) level radiation sites. In the High and Medium radiation sites, the seeds received total dose rates of 48 and 10 $\mu Gy\ h^{-1}$, respectively. Six days old seedlings grown from these seeds were exposed under controlled conditions to 144 h of gamma radiation from a ^{60}Co source, with dose rates ranging from 1-100 $mGy\ h^{-1}$, followed by assessment of DNA damage (COMET assay), phenotyping and analyses of expression of cell cycle- and DNA damage repair genes. Interestingly, at $\geq$ 40 $mGy\ h^{-1}$ there was significantly less DNA damage in the seedlings from seeds from the High and Medium radiation sites as compared to those from the low radiation site seeds. All seedlings showed gamma dose rate-dependent growth inhibition but no significant phenotypic differences between seedlings from the different seed development sites were observed. Also, no significant effect of seed origin on expression of the cell cycle and DNA damage repair genes analysed so far has been found. Taken together, the results indicate lower radiosensitivity at the DNA level in seedlings from seeds developed at elevated radiation levels as compared to low radiation, but the consequences and background of the differences in DNA damage remain to be elucidated.

Soil-to-plant transfer of 40K, 238U and 232Th and radiological risk assessment of selected mining sites in Nigeria.

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Muyiwa Michael Orosun[1]
Mojisola Rachael USIKALU[2]
[1] University of Ilorin, Ilorin, Nigeria
[2] Covenant University, Ota, Nigeria

Abstract: *One of the major route through which humans are exposed to ionizing radiation is via food chain, which is consequent of soil-to-plant transfer of radionuclides. This work reported the activity concentrations of ^{40}K, ^{238}U and ^{232}Th in samples of water, soil and guinea corn grains collected from Beryllium and Gold mining sites in Kwara, Nigeria. In-situ measurements at approximately 1 m in the air was carried out using a well-calibrated portable Gamma Spectrometer (Super Spec RS-125), while the soil, water and the guinea corn samples were analyzed using a '3 x 3' inch lead-shielded NaI (Tl) detector. The measured activity concentrations of the natural radionuclides in the soil from both mines are lower than the in-situ measurements. This was attributed to the contribution from other terrestrial materials on-site. The estimated mean transfer factors (TFs) for ^{40}K, ^{238}U and ^{232}Th are 0.21, 0.17 and 0.31, and 0.46, 0.19 and 0.28 respectively for the Beryllium and Gold mining sites. While the TFs for ^{238}U and ^{232}Th exceeds the mean value of 0.0062 and 0.0021 for ^{238}U and ^{232}Th respectively, the TFs for ^{40}K are well below the 0.74 for cereals grains provided by International Atomic Energy Agency (IAEA). The radiation impact assessment using the Monte Carlo simulations reveals values that were generally less than the global average values provided by the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR). Hence, the risk of cancer inducement due to radiation exposure is within the acceptable limits for both mining sites.*

Ten-year monitoring of vertical distribution of radiocesium in Fukushima forest soils and tasks for future decades

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

[4] Hokkaido Research Center, Forestry and Forest Products Research Institute
[5] Principal Research Director, Forestry and Forest Products Research Institute
[6] Kansai Research Center, Forestry and Forest Products Research Institute (Retired)

Abstract: The accident at Fukushima Dai-ichi Nuclear Power Plant resulted in the release of a large amount of radiocesium in March 2011, and forest areas were contaminated, especially in Fukushima, Japan. There is great concern about the long-term effects of ^{137}Cs remaining in forest ecosystems due to its long half-life (30 years). We have conducted continuous monitoring of forest soils (both organic and mineral soil horizons) at 10 plots with different ^{137}Cs deposition levels and dominant species, for up to 10 years after the accident. Here, we describe the temporal trends of ^{137}Cs inventories in each soil horizon, and statistically evaluate the phase shift of ^{137}Cs distribution in forests.

In the organic horizon, the ^{137}Cs inventories were exponentially decreasing at most plots. In the mineral soil horizon, most of ^{137}Cs remained in the surface layer of the mineral soil horizon (0–5 cm). In this layer, the inventories first increased and then became relatively constant. By applying several regression models for the temporal trends of ^{137}Cs inventories in this layer, the exponential offset model was selected at most plots, and we suggested entry into the "quasi-equilibrium steady-state", a relatively stable ^{137}Cs distribution in each forest compartment, over the observation period. Although we also observed exponentially increasing trends of ^{137}Cs in the lower layer (5–10 cm) of the mineral soil horizon, we concluded that the downward migration of ^{137}Cs is not significant in terms of the balance of the ^{137}Cs distribution in the entire mineral soil horizon.

Overall, most ^{137}Cs from the accident should be retained in the surface mineral soil horizon over future decades, and we should still pay attention to external exposure from ^{137}Cs radioactivity in this layer. This point is comparable to forests in Chernobyl, although climate and soil conditions were significantly different between Chernobyl and Fukushima. Meanwhile, we also observed significant spatial heterogeneity of ^{137}Cs inventories. We highlight the importance of plot- to subplot-scale (or smaller) environmental factors such as quality of organic matter in the forest floor as well as continuous multi-point investigations, to improve predictions of ^{137}Cs distribution in forests.

The effect of the suspension of potassium fertilization on the radiocesium uptake suppression by hinoki cypress

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Keizo Hirai[1]
Masabumi Komatsu[1], Junko Nagakura[1], Takuya Manaka[1]
[1] Forestry and Forest Products Research Institute, Tsukuba, Japan

Abstract: The effect of potassium fertilization on the suppression of radiocesium（^{137}Cs） root uptake by hinoki cypress seedlings, which were not directly contaminated, was continuously investigated in 2014 after the Fukushima accident. We reported at the IUFRO Brazil Congress that continuous fertilization was effective in suppressing ^{137}Cs uptake, based on investigations up to the third year（2017）, fertilization was suspended in half of the fertilized plots since 2017 and in all plots since 2021.

The study site is located in Kawauchi, Fukushima Prefecture with a deposition of ^{137}Cs of 360 kBq m^2 based on the third monitoring, and the soil type is Cambisol. We established eights plots of, 50×50 m in 2014; two were fertilized three times until 2016, two were fertilized seven times until 2020, and the remaining four were not fertilized as a control. Fertilization was started at 2014, and applied in spring before the start of tree growth at 100 kg K_2O (83 kg as K) per hectare with 60% KCl fertilizer ever year. Tree height and diameter were measured each year the end of tree growth, and needle leaf and soil samples were collected for analysis.

The exchangeable potassium content of the soil tended to be higher in the fertilized plots than in the unfertilized plots during the fertilization period, but decreased to pre-fertilization levels in the year following the suspension of fertilization. The concentration of ^{137}Cs in needles in the fertilized plots was significantly lower than in the unfertilized plots during the fertilization period, indicating an inhibition effect of absorption. The concentration of ^{137}Cs in the needles increased when fertilization was suspended, but the concentration of ^{137}Cs in 2022 was one-eighth and one-third of that without fertilization in the seven and the three times fertilization treatments, respectively. Similar results were obtained for the transfer factor.

It was concluded that the effect of ^{137}Cs uptake suppression continued even after the suspension of fertilizer application.

The importance of forests in the dose assessments of radioactive repositories the next 1000-100 000 years

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Ulrik Kautsky[1]
Peter Saetre[1], Olle Hjerne[1], Sari Peura[1]
[1] SKB, Swedish Nuclear Fuel and Waste Management Co., Sweden

Abstract: In the safety assessment of Swedish geological waste repositories forest are assumed to be the dominating ecosystem above repositories during terrestrial periods. The main reason why forest was expected is that the present and future land area consists in large extent of glacial till unsuitable for agricultural land. In the timeframe of 100000 year it is assumed that the climate will temperate or warmer but still temperate. However, in this timeframe it cannot be excluded that cooler periods will occurs with a shift to a more boreal climate still forested. Even substantial cooler periods were analysed with periglacial and glacial periods partly submerged under the sea without forests.

The fate of hypothetical released radionuclides (e.g. C-14, Cl-36, Mo-93, Ni-59) from a repository were evaluated with a combined transport and exposure model (BioTEX). Even if forests dominate the landscape the major dose was obtained from mires that have accumulated radionuclides and then are drained for agriculture, because the discharges from a geological repository were simulated to be at low lying areas, i.e lakes and wetlands. The agriculture pathway also gave higher exposure because of the higher productivity potentially feeding a larger population in a concentrated area, while hunter and gatherers needed to scavenge larger areas for game, berries and mushrooms to be sustainable. This study also pinpointed that the interesting forest for dose assessment are on or close to wetlands, thus not the well-studied productive forests on tills.

Transfer of radiocesium through food webs in forest and river ecosystems

T1.14 Forest radioactive contamination: long-term dynamics and impact on ecosystem and society

Minato Kakuma[1]
Masashi Murakami[2], Toshihiro Wada[3], Nobuhito Ohte[1]
[1] Kyoto University
[2] Chiba University
[3] Fukushima University

Abstract: The disastrous earthquake and subsequent tsunami on March 11, 2011, caused the Fukushima Daiichi Nuclear Power Plant to lose power and release enormous amounts of radionuclides. Of the variety of radionuclides deposited on land, ^{137}Cs is the most worrying radionuclide in the environment due to its relatively long half-life and bioavailability. The transfer of ^{137}Cs through the food web into the bodies of animals in Fukushima's forest and river ecosystems has been confirmed since the early post-accident period.

Although the transfer of ^{137}Cs through food webs focusing on either forest ecosystems or river ecosystems has been investigated, there are few examples of comprehensive investigations of these ecosystems connected by water systems. The objective of this study was to monitor the process of transfer and redeposition of ^{137}Cs accumulated in forest soils through the food web in the biocoenosis of forest and river ecosystems and to understand the amount and pathways of such transfer and redeposition.

We have collected various samples, including freshwater fish, insects, spiders, and plants in terrestrial and aquatic environments in three river basins (Ukedo River, Takase River, and Kuma River) in Fukushima Prefecture since 2020. Those river basins contained the evacuation zone.

We measured ^{137}Cs concentrations in the samples collected with germanium detectors and analyzed their feeding habitat using carbon and nitrogen stable isotope ratio analysis and DNA metabarcoding methods.

The detection of DNA from a variety of aquatic insects in the bodies of terrestrial predators suggests that insects that live in water as larvae have the ability to transport ^{137}Cs to the terrestrial food web. Carbon stable isotope ratios, an indicator of food resources, differed depending on the location of fish sampling (upstream or downstream) and fish species, and individual fish with stronger ties to the forest ecosystem via food webs tended to have higher amounts of radiocesium retained in their bodies.

The findings from this study will provide a more detailed understanding of the ^{137}Cs concentration characteristics of each species. It will be necessary to continue monitoring ecosystems in order to understand the dynamics of ^{137}Cs accurately.

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Biological legacies as nature-based solutions to maintain protective effects in alpine mountain forests

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Paul Richter[1]
Tommaso Baggio[1], Davide Marangon[1], Lorenzo Faes[1], Frédéric Berger[2], Emanuele Lingua[1]
[1] Department of Land, Environment, Agriculture and Forestry, University of Padova, Legnaro (PD), Italy
[2] National Research Institute for Agriculture, Food and the Environment (INRAE), France

Abstract: Protective forests play a fundamental role in mountain areas. Natural disturbances are affecting their stability and the provision of essential ecosystem services. Assessing the residual protection provided by biological legacies and forest recovery dynamics in the context of climate change is thus of extreme relevance.

A multiscale approach, from tree to landscape, adopting different techniques and data sources (field, lidar, satellite and UAV data) is implemented in this research. The aim of this study is a better understanding of the influence, potentials and actual service-life of natural disturbance legacies in protective forests against rockfall and a better knowledge towards a more ecological and effective post-disturbance forest management. The study areas are located in the North-East of Italy, which was severely affected by storm Vaia in October 2018, that caused large windthrows.

5 Years after the event, field investigations are being carried out to asses the decay status of the existing deadwood under specified conditions (altitude, species, soil). This includes applying sensors for a long term-monitoring of moisture, water content of the logs and soil, climate data, sampling of the dry-matter content and the decay status of deadwood. The final goal of this research is the enrichment of scientific data about decay-conditions, towards well-founded, practice-oriented knowledge of the “service-lifetime” of biological legacies after a disturbance event in protective forests.

Contrasting impacts of climate change on protective functions in mountain forests of the Alps

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

[5] Centre for Climate Change and Transformation, Eurac Research, Bolzano, Italy

Abstract: Protection forests play a key role in protecting settlements, people, and infrastructures from gravitational hazards such as rockfalls and avalanches in mountain areas. Rapid climate change is challenging the role of protection forests by altering their dynamics, structure, and composition. Information on local- and regional-scale impacts of climate change on protection forests are critical for planning adaptations in forest management.

We used a model of forest dynamics (ForClim) to project the future development of mountain forests in the Eastern Italian Alps and their capacity of protecting against gravitational hazards, namely rockfall and avalanches. We investigated eleven representative forests along an elevational gradient (950-2000 m a.s.l.) and locations covering wide differences in tree species structure, composition, and site exposition under multiple climate change projections and current management scenarios. In additon to assessing future changes in forest structure and composition, we evaluated protective performance using protection indices.

Our findings showed that climate warming had a contrasting impact on the montane and subalpine forests. Forests in lower-montane elevations with a mild to warm climate and those located in dry continental valleys showed drastic negative changes in forest structure and composition, triggered by drought-induced mortality and maladaptation of current tree species to future climatic conditions. Subalpine forest, instead, profited from rising temperatures and longer vegetation periods with an increase in forest growth. However, impacts were highly contingent to the magnitude of climate warming, with increasing criticality under the most severe climate projections. Increased warming and drought-stress also impacted the protective functions of forests, decreasing rockfall and avalanche protection indexes for montane sites while increasing them for subalpine forests. In some cases, the most severe climate change scenario induced a complete loss of the ability of the forest to protect against gravitational hazards.

Forest management strategies require prompt adaptations to counteract the effects of climate change if protective functions are to be maintained in mountain forests of the Alps. Given the contrasting impact of climate warming, silvicultural planningt can be aided by model-based projections and local-scale assessments.

Detection and management of degraded forests to preserve protective functions: a transnational case study from European Western Alps

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Cristian Accastello[1]
Evelyn Joan Momo[1], Lucia Caffo[1], Alberto Dotta[1], Simon Brochier[2], Pascal Frbezar[2], Roberta Berretti[3], Renzo Motta[3], Davide Ascoli[3]
[1] Consorzio Forestale Alta Valle Susa (CFAVS), Italy
[2] Office National des Forets (ONF), Hautes-Alpes Regional Agency, France
[3] University of Torino (UniTo), Department of Agriculture, Food and Forest Sciences, Italy

Abstract: Since the last few decades, in the European Alps global change has posed a severe threat to the functionality of mountain ecosystems due to an increase in the frequency and intensity of natural hazards. Furthermore, conflicting trends of depopulation of marginal areas on the one hand and mass tourism on the other pose new problems of spatial planning and management. In this context, sustainable management of mountain forests appears as a 'wicked problem', due to the multiplicity of conflicting interests that involves. Forests, due to the services they provide, are an essential element for the liveability of mountain territories: nonetheless, their slow natural dynamics can result insufficient to cope with the speed with which the climate crisis effects are manifesting themselves.

In this context, ALCOTRA project 'SylvAFoRes' (Adaptive Forestry for a Resilient Forest) promotes an approach of analysis, planning and management that increases the resilience of forests to climate change in order to ensure the provision of ecosystem services to society. The study area covers around 2100 km^2 between Italy and France (respectively in Susa and Durance valleys), in a mountain environment inhabited by more than 45 000 people.

Through a transnational approach, the project focuses on the identification of stands exposed to degradation and on their interactions with those natural hazards that increase the vulnerability of fundamental ecosystem services (protection, production, biodiversity, tourism). Early detection of degraded forests has been achieved through the application of a protocol (FORDEAD) based on open-source satellite images, which has been validated for mountain forests. Afterwards, their development trends were monitored and considered in the light of possible interactions with fire and other hazards (e.g. avalanches). From the results of the analysis, areas at greater risk of loss of functionality have been identified. Subsequently, adaptive and climate-smart silvicultural treatments will be defined and tested in several pilot forestry sites in order to slow down or prevent the degradation process.

Therefore, the results of this project will provide practical tools and experiences to replicate innovative silvicultural solutions in other mountain areas, minimizing the drawbacks of global change.

Ecology of Protective Forests

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Jiaojun Zhu[1, 2, 3]
[1] Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang 110016, China
[2] Qingyuan Forest CERN, National Observation and Research Station, Liaoning Province, Shenyang 110016, China
[3] Key Laboratory for Management of Non-commercial Forests, Liaoning Province, Shenyang 110016, China

Abstract: Forests, as the main body of terrestrial ecosystems and important natural resources, play a vital role in maintaining the earth's ecological balance. All forests have certain protective functions, e.g., water and soil conservation, preventing wind erosion, stabilizing mobile dunes, and carbon sequestration. However, with the development of human society, forests have been severely damaged, destroying the ecological balance of nature. To meet the needs of protective functions due to the reduction of forest resources, protective forests, whose basic management purpose is to provide protective functions, have been planned or planted in ecologically fragile areas or areas with natural hazards or adverse climates. Protective forests, including natural and plantation forests, can be divided into shelterbelts and non-belt forests according to their shapes. The final goal of constructing and managing protective forests is to ensure efficient, stable, and sustainable ecological protection functions. From an ecology perspective, protective forest programs no longer take a single “protective forest” but a “protective forest ecosystem” as the main body. Therefore, developing the “Ecology of Protective Forests” discipline is necessary.

For natural protective forests, it should be regionalized based on the principles of dominant protection functions. However, in the ecologically fragile areas that need to be afforestation, it involves site classification, planning, and design of planted protective forests. Protective forest management should follow ecological principles to ensure the protective functions efficiently and continuously over a long time, which include the theory of protective maturity and phase-directional management, structures optimization and configuration, renewal, and mechanism underlying decline and restoration. As a bridge between the construction and management of protective forests, the assessment of protective forests can be applied to evaluate the protective forests in time to determine the degrees of protection function, identify the problems existing in the processes of construction and management, and provide feedback to the construction and management, respectively. Consequently, this can ensure the final goal of protective forest construction. Based on over 30 years of systematic research, the disciplinary frameworks of Ecology of Protective Forests have been established, including the theories and technologies of construction/regionalization, operation/management, and ecological service function assessment of protective forest.

Exploring the Influence of Vegetation Dynamics on Soil Erosion, Flood Peaks, and Landscape Dynamics in Alpine Watersheds under Climate Change

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Louis A. König[1]
Peter Molnar[2], Brian McArdell[3], Harald Bugmann[1]
[1] Forest Ecology, Department of Environmental Systems Science, Institute of Terrestrial Ecosystems, ETH Zurich, Universitätstrasse 16, 8092 Zurich, Switzerland
[2] Department of Civil, Environmental and Geomatic Engineering, Institute of Environmental Engineering, ETH Zurich, Laura-Hezner-Weg 7, 8093 Zürich, Switzerland
[3] Mountain Hydrology and Mass Movements, Torrents and Mass Movements, Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Zürcherstrasse 111, 8903 Birmensdorf, Switzerland

Abstract: Alpine watersheds are complex and highly engineered systems designed to mitigate flooding and debris flow risks, safeguard downstream areas, and support arable land. However, these engineered solutions often come with significant financial costs and environmental challenges. This study proposes a novel approach to investigate the influence of vegetation dynamics on soil erosion, flood peaks, and subsequent landscape dynamics in alpine watersheds, with the aim of identifying less engineered options that can yield effective results.

To achieve this, we developed an integrated modeling framework that combines a dynamic vegetation model (LandClim), the Revised Universal Soil Loss Equation (RUSLE) for soil erosion estimation, and the landscape evolution model HAIL-CAESAR. By employing this comprehensive framework, we simulated and analyzed the effects of climate change and vegetation dynamics on sediment transport and landscape evolution processes.

Our findings suggest that landcover changes have significant effects on the sediment cascade within alpine watersheds. Through simulations and scenario analyses, we observed that alterations in vegetation patterns can influence the magnitude and distribution of sediment transport, thereby impacting soil erosion rates and flood peak intensities. Additionally, considering the effects of climate change on vegetation dynamics, we found that shifts in species composition and growth patterns can further contribute to these effects.

Our results indicate that, by implementing appropriate management strategies, less engineered options have the potential to yield favorable outcomes in terms of flood mitigation and soil conservation in alpine watersheds. By recognizing the potential of natural processes and incorporating ecological considerations into watershed management, decision-makers can optimize resource allocation, reduce costs, and minimize the environmental footprint associated with conventional engineering solutions.

The implications of our research underscore the importance of considering vegetation dynamics and the impacts of climate change in the planning and implementation of strategies for alpine watershed management. By adopting a holistic perspective that integrates ecological factors, decision-makers can develop sustainable management approaches that aim to balance flood risk reduction, soil conservation, and the preservation of natural systems. While our study provides valuable insights,

further evaluation and cautious interpretation of the results are necessary to refine our understanding of the complex interactions within alpine watersheds.

Forest-based solutions for reconciling natural hazard reduction with biodiversity benefits

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Freddy Rey[1]
Sylvain Dupire[1], Frédéric Berger[1]
[1] Univ. Grenoble Alpes, INRAE, UR LESSEM, 2 rue de la Papeterie, BP 76, F-38402 St-Martin-d'Hères

Abstract: Nature-based solutions (NbS) offer a way to preserve, restore and manage ecosystems to meet today's societal challenges by combining benefits for society and biodiversity. They incorporate natural features and processes into projects to ensure their sustainable development while investing in the integrity of ecosystems. Forests can be a good solution to achieve this goal. "Forest-based solutions" (FbS) can then be identified as NbS using forests for providing both human well-being and biodiversity benefits. In this paper, we intend to consider FbS as solutions reconciling natural hazard control with biodiversity benefits, and especially highlight the practice and research needs in this field. FbS correspond specifically herein to forests used or managed for mitigating natural hazard linked to gravity (rockfalls and avalanches) or to water (floods and drought), while preserving, restoring or managing biodiversity. Firstly, we review the definition and development of FbS applied to natural hazard reduction, while stressing issues concerning the design, implementation, and monitoring of these kinds of actions. Secondly, we point out the need to combine natural hazard control with restoration, preservation and management of ecosystems, by posing novel practice and research questions.

Impacts of climate change on the mechanical properties of standing trees

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Abstract: The role of forest stands in reducing natural gravity hazards has been studied for several decades and at different scales ranging from the tree to the role of the forest cover on a complete territory. At the tree level, previous studies have focused solely on the mechanical response of the trunk during an impact.

A non-destructive protocol called "Pull-Release" test has been developed to measure the mechanical properties of the different compartments of a standing tree (roots, trunk and crown). This experimentation opens new fields of research both on the role of the anchorage on the stability of the tree but also on the complete response of a standing tree to the mechanical solicitations related to various hazards. Moreover, it could allow to evaluate the effect of different types of natural disturbances (fire, pest attacks, droughts...), whose frequency and intensity should increase with climate change, on the protection capacity of a tree.

This protocol was applied on different standing trees of healthy forest stands located on an altitudinal gradient in the French Alps and on trees having undergone a disturbance (mainly fire). Seasonal variations of mechanical properties were also analyzed.

The presentation will describe the protocol used, the results of the first year of measurements and the first conclusions to account for in the management of protective forests under a changing climate.

Improving the prediction of forest wind disturbances in the alpine region by remote sensed data

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Abstract: Windstorms are natural disturbances that are expected to increase both in frequency and magnitude as a consequence of climate change. In the Alps, windstorms are responsible for severe damage to forest stands, which in many areas provide fundamental protection against natural hazards. Therefore, the assessment of the vulnerability of forests toward windstorms is fundamental in the alpine region to improve forest management and avoid future losses. Different models are present in the literature assessing the critical wind speed (CWS) of a certain forest stand. However, one of the main issues in their application at a wide scale concerns the creation of the input data both in terms of stand characteristics and species-specific parameters. In this study we address such a gap in knowledge (i) developing an algorithm to derive single trees and stand characteristics from LiDAR data and (ii) improving the species-specific parameters for the most widespread forest species of the alpine region. We take advantage of one the most advanced models ForestGALES (implemented in the R environment, so-called fgr). The developed algorithm (written in the R environment) calculates the tree characteristics (height, DBH, crown radius) to create an input database for the fgr model. The stand characteristics of distance to any gap and gap size are automatically derived at a resolution of 20x20m while stem density and dominant height are calculated at the same resolution but using a moving window either of 3x3 or 5x5. Such values are associated with the tree input database (based on the tree location) and the CWSs are directly computed through the fgr model. The species-specific parameters of the most common forest species for the alpine region are derived from literature and specific tree pulling experiments, improving the representativeness of the investigated forest. The procedure has been applied in the Alto Agordino area (IT), showing promising results. The developed methodology can substantially advance the usability and accuracy of forest wind susceptibility since it requires as input the canopy height model and the species distribution. Therefore, practitioners can enhance forest management by increasing the resistance of protective forests against future windstorms.

Knowledge transfer through power strategies: the example of two EU projects on ecosystem-based and climate-adapted natural hazard management

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Michael Kirchner[1]
Max Krott[1], Tabea Victoria Schaefers[1]
[1] aChair Group of Forest and Nature Conservation Policy, Georg-August-University of Göttingen, Buesgenweg 3, 37077 Göttingen, Germany

Abstract: In the efforts to maintain and improve the protective effect of alpine mountain forests against natural hazard risks for people and objects, current research results can make a decisive contribution to a risk-based and climate-adaptive protective forest management. However, the promotion and development of innovations through applied research programmes, such as the EU Alpine Space Programme, is not yet a guarantee for a successful implementation of ecosystem-based and climate-adaptive risk management of natural hazards in practice. Rather, the practical impact of such EU projects is low, as the implementation of research results by policymakers and practitioners fails due to the interests of the actors. To integrate such results more successfully into practice, the study aims to identify additional factors of knowledge transfer beyond participation and communication of scientific information, which the transdisciplinary approach of EU research programmes places at the centre of its selection process and project implementation. In the study, the "Research-Integration-Utilisation" (RIU) model of knowledge transfer is applied in the EU Alpine Space projects "GreenRisk4Alps" and "MOSAIC", which elaborated innovative eco-system-based and climate-adaptive natural hazard management strategies. The RIU model assumes that scientific information must be actively taken up by practitioners or policy actors and integrated into their practice, which is done in "integration forums" by interest driven actors within power networks. Within the study a mix of qualitative and quantitative methods were applied to identify additional success factors of knowledge transfer. The study examines whether the project proposal formulated in the EU Alpine Space Programme contains links to the interests and power of actors. Our results show that the transdisciplinary model of knowledge transfer in the Alpine Space Programme ignores the selection processes of scientific results by powerful actors and thus disregards highly relevant factors for the transfer of scientific knowledge. The effective use of these factors is possible in the identified and described integration forums. Based on robust data, these offer a solid foundation for the design of knowledge transfer processes by selecting the most promising integration forums. The likelihood of application of research results from EU or other research fundings could thus be significantly increased.

Long-term monitoring in the forested headwater catchment Rindbach, Austria, as a basis for an integrated natural hazard management.

Abstract: As part of an action program launched by the Austrian federal government that specifically addresses challenges regarding protective forests, a case study has been established in the Rindbach watershed near Ebensee (Upper Austria) for long term monitoring, research and training. This torrential-model catchment will serve as a natural laboratory and as a training area for practical courses with a long-term perspective (>30 years). It is managed and organized in close cooperation with the Austrian Protective Forest Hub (https://www.protective-forest.at/protectiveforesthub.html), which serves as a competence center for nationwide coordination, exchange of information and knowledge transfer, bringing together various interest groups. The main objective of the experimental catchment Rindbach is to gain understanding about geological, hydrological, hydraulic, forestry and engineering interrelationships under natural conditions. For this purpose, also two meteorological as well as a water level and discharge measuring stations were set up in the catchment area.

Within a three-year pilot project funded by the Austrian Waldfonds (https://www.waldfonds.at/), necessary baseline data are gathered by an interdisciplinary team of scientists. The compiled data includes information on geology and hydrogeology, soil and site conditions, hydrological conditions, natural hazard processes, forest conditions and dynamics as well as technical infrastructures. In addition to the provision of all collected data, the project will further conduct "best-practice" models and first order simulations of the above-mentioned interrelationships to maintain the protection function of the forests besides other ecosystem services. The final data collection will enable comprehensive analyses of future challenges in forested catchments, for example due to climate and/or land use changes, characterised by increase in the frequency of critical precipitation events, occurrence of natural disturbances (e.g. windthrow, bark beetle infestations), influence of forest and

game management, changes in sediment availability as well as changes in the soil water balance, nutrient supply and carbon sequestration.

Maintaining the protective function of mountain forests under climate change by the concept of naturalness in tree species composition

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Daniel Scherrer[1]

[1] Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Switzerland
[2] ETH Zürich, Switzerland

Abstract: In Swiss mountain areas, the protective function of forests is the predominant ecosystem service having high cultural and economic significance. It is assumed that natural forests or close-to-natural forests, i.e. forests being in the equilibrium with environmental conditions are the most resilient and resistant in regard to disturbances and hence best protecting people and assets on the long run. Here, we estimated the naturalness of the tree species composition by comparing Swiss National Forest Inventory (NFI) data with current and future potential Natural forest Site Types (NST). Based on this analysis, we identified species that are under or over-represented in protective mountain forests and derived the subsequent potential for management interventions. The urgency of management interventions is expected to be small if all predominant tree species of the idealized potential natural forests are present and only their relative portions in the stand need adjustment. In contrast, interventions are advisable, if predominant tree species of the current and future potential natural forests are absent. Based on NFI data, the tree species composition of 47% of the protective mountain forests were classified as 'natural' or 'close-to-natural', while the remaining 53% were classified as 'not natural' or 'partly natural'. Norway spruce (*Picea abies* (L.) H. Karst.) and European larch (*Larix decidua* Mill.) were the two most over-represented species under current and even more so under predicted future climatic conditions. To date, silver fir (*Abies alba* Mill.) and European beech (*Fagus sylvatica* L.) were the two species most frequently absent in protective mountain forests, in which they should prevail. Apart from European beech, the most prominent increase in prevalence is predicted for oak (sessile oak and pubescent oak; *Quercus petrea* Liebl., *Q. pubescens* Willd.) and small-leaved lime (*Tilia cordata* Mill.). These species were currently missing from more than 75% of the stands, in which they are expected to be dominant under future conditions. Our analysis indicates the need to transform tree species compositions of protective mountain forests to optimize fitness under future climates. Some of these transformations will take place naturally, incited by disturbances, others – the majority of them – will need active management interventions.

Mapping the natural disturbance risk to protective forests across the European Alps

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Ana Stritih[1]
Cornelius Senf[1], Rupert Seidl[1, 2]

[2] Berchtesgaden National Park, Germany

Abstract: Mountain forests play an essential role in protecting people and infrastructure from natural hazards. However, forests in the European Alps are currently experiencing an increasing rate of natural disturbances (including windthrows, bark beetle outbreaks and forest fires) that may jeopardize their capacity to provide this ecosystem service in the future.
Here, we map the risk to forests' protective service across the Alps by integrating the risk components of hazard (in this case, the probability of natural disturbances), exposed values (current protective forests that protect people or infrastructure), and vulnerability (the probability that the forests' protective capacity is maintained or recovered after a disturbance).To map disturbance probability, we use satellite-based data on forest disturbances from 1986-2020 and fit an ensemble model predicting windthrow, bark beetle and fire occurrence based on topographic and climatic predictors. To assess forests' protective capacity, we analyze the recovery of key forest structural parameters (cover and height) over time after disturbance using spaceborne lidar (GEDI) data. Over 35 years after a disturbance, most forests maintain or recover sufficient cover and height for providing protection from natural hazards, but recovery is limited at warm, dry sites that are also particularly exposed to forest fires. Forest management interventions to reduce forest susceptibility and/or alternative protection measures should be prioritized in areas where disturbances are likely to occur, forest recovery is slow, and where people rely on forests for protection. Integrating information on disturbance probability, recovery, and demand for protection can thus help identify priority areas for risk reduction under an intensifying disturbance regime.

Planning with limited resources in mountain forests: Decision support for spatial prioritization of management activities under future uncertainties

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Abstract: Mountain forest management is extremely important in Switzerland for providing protection against natural hazards and multiple other ecosystem services. Many mountain forests are however spruce-dominated and under high risk of large-scale, climate change-enhanced disturbances. Forest managers are thus challenged with allocating their limited resources (operational capacity) for an efficient management of mountain forests considering both their future protective function as well as their resistance and resilience. Because it is not possible to access an entire forest area within a planning period, a prioritization of forest areas with respect to the largest long-term management impact is urgently required.

We present a novel approach for prioritizing forest areas for management activities in mountain forests in a Swiss case study. We combine various spatial information on topography, truck accessibility of the forest road network, important areas for protection services, and new developed predisposition maps that indicate forest areas particularly vulnerable to disturbances (windthrow, bark beetle, and snow breakage). This information is used to automatically subdivide the case study into forest management units (FMU). FMUs represent spatially contiguous areas combining homogenous harvest operational aspects and management planning objectives. Based on current forest conditions and field measurements, mid-term management scenarios are defined for the main forest types. Further, the management impact is assessed on the harvestable timber amounts, the potential to mitigate disturbances and to reduce the risks for natural hazards. This allows an assessment of the potential long-term management benefits and costs of harvesting operational activities.

The gained information on benefits and economic consequences will provide a holistic assessment of management consequences on the level of each FMU. Based on cost-benefit relations a prioritization of the spatially defined FMUs will be possible for the next planning period (usually 10 years). Outcomes are aimed to support the order on how the FMUs should be accessed depending on the main management objective. Our hypothesis is that the largest long-term impacts on resistance and resilience will be achieved if management is targeted to promote mixed forests with a high structural diversity. However, this might cause trade-offs with economical management objectives.

Preserving the protective function of forests in Switzerland's high mountain regions: the crucial role of forest management

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

[4] Swiss Federal Institute of Forest, Snow and Landscape Research WSL, Birmensdorf, Switzerland

Abstract: In densely populated mountain regions such as the European Alps, forests provide a fundamental protective function against multiple hazards such as snow avalanches and rockfall. However, climate change and natural disturbances pose a significant threat to the protective function of forests in these areas, as they often lead to decreased stand density and reduced stability. Forest management can play a crucial role in countering these challenges and enhancing forest resilience. By reducing the growing stock and promoting forest regeneration, forest management can bolster the ability of forests to maintain their long-term protective role against gravitational natural hazards.

In this contribution, we investigate the future effectiveness of forest protection in a mountainous area in the region of Davos, Switzerland, which is largely covered by Norway spruce and serves primarily as a protective function. To assess future forest dynamics, we utilize a dynamic process-based model at the landscape scale (LandClim), which is initialized with current climate data, forest structure data from stand maps and high-resolution remote sensing data. Forest structure data are derived using a representative stand type approach, where forest stands are populated with locally adapted individual tree datasets using a statistical method based on the fourth Swiss National Forest Inventory.

The model is run until 2080 under two climate change scenarios (moderate and strong), different disturbance regimes (windthrow, and bark beetle), and a suite of management scenarios, allowing tree species to migrate to potentially suitable areas. We compare two management scenarios (business as usual, and adaptation with a focus on increased resilience), defined together with local stakeholders. Additionally, we explore the impact of three levels of ungulate browsing pressure (low, medium, and high) on regeneration dynamics.

Our findings indicate that by the end of the 21st century, at these high elevations, Norway spruce will mostly persist and even expand to higher elevations, potentially maintaining the long-term protective effect against rockfall and avalanches. However, there will likely be increasing shares of deciduous tree species, especially in the valley bottom, suggesting the need for different management interventions at these locations

Prioritizing forest management under global change: a stakeholder-driven approach in spruce-dominated mountain forests in Switzerland

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

[6] Technical University of Munich

Abstract: The vulnerability of mountain forests to natural disturbances is expected to rise with climate change along with increased disturbance frequency and severity. The damage caused to mountain protective forests may have negative repercussions on their ability to safeguard human lives and infrastructures. As resources for interventions are limited, prioritizing management interventions becomes crucial to anticipate and plan for potential disturbance and damage scenarios.

This study presents an approach developed together with stakeholders, aiming to provide guidance for management prioritization in spruce-dominated mountain forests under anticipated exacerbating disturbances (windthrow, snow breakage, and bark beetle) and natural hazards (snow avalanches and rockfall).

A comprehensive set of 20 spatial layers was generated to identify ‘hotspots’ for intervention for two regions in Switzerland (cantons of the Grisons and St. Gallen). Spanning approximately 1’600 km^2 (30 % forested), these layers encompassed high-resolution (10 x 10 m) forest structure parameters, and various site characteristics derived from airborne LiDAR data. The influence of each variable on each disturbance agent was weighted using the outcome of an expert survey, resulting in the assignment of predisposition values to each landscape pixel. These values were reclassified to predisposition classes and aggregated to spatially continuous disturbance predisposition maps. Map validation was conducted using stakeholder input, field forest stand data, and remote sensing disturbance data. Additionally, avalanche and rockfall models were employed to simulate large-scale hazard scenarios considering different forest covers, including disturbed forests derived from the predisposition maps. This allowed to assess the impact of disturbances on hazard potential. The simulation results were combined with data on economical and individual damage potential to perform a quantitative risk assessment at the building level.

Such predisposition maps may serve as an input to cost/benefit analyses to formulate and prioritize management actions. The expert-driven approach presented in this study serves as a model for the effective integration of research and practice, ultimately enhancing the resilience of mountain forests in the face of global change.

Quantifying drought conditions in Swiss protective forests based on 40-years inventory and satellite data

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Estelle Noyer[1]
Luuk Dorren[1], Christine Moos[1]
[1] Bern University of Applied Sciences (BFH)

Abstract: Mountain areas are one of the many regions that are strongly impacted by climate change, leading to growing concerns about increasing frequencies and intensities of natural hazards. Thanks to the presence of forests, risks emanating from these can be avoided or reduced to an acceptable level. However, these so-called protective forests are themselves affected by climate change as well due to the intensification of disturbances such as droughts, windstorms, and bark beetle infestations. Consequently, critical changes in their protective effect are to be expected. To maintain forest resistance and resilience for the mitigation of natural hazards, forest acclimation to new and fast changing climatic conditions is the cornerstone for a successful hazard management strategy. The capacity of a forest to acclimate are determined by prior climatic regime as well as by forest dynamics legacies and related to site conditions, forest structure and species composition. In this study, we aim at characterizing the past and current status of protective forests in Switzerland in response to drought episodes by studying time-series from 1984 to 2022 of forest structure and climate parameters. Two main hypotheses will be tested: (1) relationships between forest structure and drought indicators differ with stand elevation and forest composition, (2) forests in higher elevation have been exposed to less intense drought episodes in the past and result in greater sensitivity to recent drought episodes.

Historical climatic conditions, field data from the Swiss National Forest Inventory (NFI) and forest indicators assessed by satellite data (Landsat and Sentinel) will be used to compute climatic drought indicators, forest drought tolerance proxies and forest structural parameters related to the protective effect (*i.e.* dominant species, basal area, stem density, mortality rate).

Based on observations, we will classify forest stands as acclimated and non-acclimated to drought episodes in mountain areas. Quantification of the drought legacy effect on forest structure and composition will bring insights about protective forest dynamics and their potential development in the future. Furthermore, the analysis will help identifying forest areas requiring active management to sustain their protective effect against natural hazards, visualized using maps that provide support to forest management practitioners.

Towards improved early detection of bark beetle infestations in Swiss mountain forests

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Theresa Banzer[1, 2]

[5] Forestry and Natural Hazards Office AWN Canton of the Grisons

Abstract: The European spruce bark beetle (*Ips typographus*) has wreaked havoc on European forests in recent years, also thanks to the dry and warm conditions that have prevailed. These outbreaks have caused significant damage to large portions of Norway spruce forests. Rising temperatures and increasing drought frequency cause an accelerated development of *Ips typographus* while also increasing the susceptibility of spruce trees to bark beetle attacks. Consequently, spruce forests are becoming more vulnerable, raising concerns about their protective function against natural hazards, and other ecosystem services. Given these circumstances, timely planning and effective implementation of control and adaptation measures become paramount. To assist stakeholders with their responsibilities, the development of robust methods for the early detection of both vulnerable and infested trees is essential.

To address this challenge, the earlyBEETLE project focuses on improving the early detection of bark beetle damage in mountain spruce forests in the canton of the Grisons in Switzerland. The project aims to (i) Conduct a retrospective analysis and interpretation of spatio-temporal bark beetle infestations using tree rings and remote sensing; (ii) Identify suitable indices, utilizing remote sensing and field data, for the early detection of bark beetle infestations; (iii) Develop an ad-hoc database to optimize the long-term monitoring of bark beetle infestations; (iv) Evaluate and optimize management interventions and determine the most effective timing for their implementation in six different study regions.

The project utilizes satellite data to identify past patterns of 'dead' pixels and detect potential correlations with various indices related to tree stress (e.g. NDVI). Additionally, drones equipped with multispectral cameras provide individual-tree resolution images. Field observations of forest characteristics (e.g. tree height, crown length, and health status) provide ground-truthing for satellite and drone data. Pheromone traps are regularly monitored to inform management decisions and determine the appropriate timing for drone flights. Real-time data on new infestations are collected and stored in the database, which is used to inform and validate remote sensing data.

In this contribution, we will present the latest findings of the project and discuss their relevance in the context of global change impacts on mountain protective forests.

Transpiration and water use sources of poplar protective forests with different ages in a semiarid sandy region of Northeast China

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Lining Song[1, 2, 3]
[1] Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang 110016, China
[2] Qingyuan Forest CERN, National Observation and Research Station, Liaoning Province, Shenyang 110016, China
[3] Key Laboratory for Management of Non-commercial Forests, Liaoning Province, Shenyang 110016, China

Abstract: Poplar (*Populus × xiaozhuanica*) protective forests play an important role in the prevention and control of desertification in semiarid sandy land of northern China, however, these protective forests with different ages frequently suffer dieback and mortality during extreme drought years with decline in groundwater level. Nevertheless, the transpiration and water use sources of poplar protective forests with different ages and their response to drought and decline in groundwater level remain unclear. Here, the seasonal variations in transpiration and water use sources of the 7– and 20–year–old poplar protective forests were determined based on the thermal dissipation and stable isotopes methods. Environmental variables were measured concurrently over two growing seasons. The results showed that transpiration per unit leaf area averaged 1.6 and 2.3 mm d^{-1} for the 7– and 20–year–old trees during the measurement period, whereas it was 1.5 and 1.9 mm d^{-1} for the transpiration per unit ground area (E_s), indicating that water use of protective forests increased with stand age. Sensitivity of E_s to climatic variables increased with stand age, but the E_s of 7–year–old protective forest was more sensitive to soil drought and decline in groundwater level compared with the 20–year–old protective forest. In addition, the canopy conductance significantly increased with stand age, but the sensitivity of canopy conductance to vapor pressure deficit was sensitive to soil drought for the 7–year–old poplar protective forest, indicating a decrease in hydraulic conductance. Furthermore, the 7– and 20–year–old trees switched water sources from 0–100 cm soil layer and groundwater in spring to 0–200 cm soil water and groundwater in summer as the soil moisture and groundwater level decreased, but the contribution of groundwater to transpiration decreased from 47% to 32.3% and from 39.6% to 37% for 7– and 20–year–old protective forest, respectively. These findings indicated that decline in groundwater level reduced the contribution of groundwater to transpiration for 7–year–old poplar protective forest, and thus exacerbated the negative effect of soil drought on transpiration compared with the 20–year–old poplar protective forest.

Trends in growth and intrinsic water use efficiency of Pinus sylvestris var. mongolica trees under a warming and drying climate in Northeast China

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Jinxin Zhang[1, 2, 3]
[1] Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang 110016, China
[2] Qingyuan Forest CERN, National Observation and Research Station, Liaoning Province, Shenyang 110016, China
[3] Liaoning Key Laboratory for Management of Non-commercial Forests, Shenyang 110016, China

Abstract: Determination of the long-term trends in tree growth and physiological performance responding to a warming and drying climate is vital for protective forest vulnerability assessment and management. Here, tree growth and intrinsic water use efficiency (iWUE) of Mongolian pine (*Pinus sylvestris* var. *mongolica*) were investigated at Fujia (FJ), Zhanggutai (ZGT), Kulun (KL) and Wulanaodu (WLAD) sites with mean annual precipitation (MAP) of 554, 479, 410 and 305 mm in the Keerqin Sandy Land for the warming and drying period 1970–2019, respectively, using annually resolved tree-ring width and $\delta^{13}C$ data. Results showed that basal area increment gradually increased and then declined or maintain constant for all study sites, showing a higher growth rate at KL and FJ sites than those at sites with WLAD and ZGT sites. Tree growth was only sensitive to spring precipitation at ZGT and KL sites owing to low groundwater levels. The iWUE displayed a significant increase over time at all study sites, showing the highest extent of increase at the ZGT site. An increase in iWUE was due to increasing atmospheric CO_2 and drying influencing stomatal conductance and photosynthetic capacity at the FJ site, whereas it was because of warming and/or drying reinforcing stomatal closure at ZGT and KL sites. However, it was possibly associated with progressive nutrient limitation at the WLAD site because of the shallow groundwater level. Negative relationships between BAI and iWUE were observed for all study sites, except at the ZGT site. These findings indicated that increasing iWUE did not stimulate tree growth at all study sites, because the negative impacts of drying on tree growth have overridden the small positive influence of rising atmospheric CO_2 at the FJ site. However, it was likely that warming and/or drying reduced the stomatal conductance and thus decreased photosynthetic rates, limiting tree growth at ZGT and KL sites, whereas it may be due to progressive nutrient limitation reducing tree growth at the WLAD site. Therefore, the predicted warming and drying climate might have a more negative impact on Mongolian pine trees at sites with low groundwater levels than with high precipitation and/or shallow groundwater level.

Unveiling the Vulnerability of Tropical Montane Forests in the Face of the Climate Crisis

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Bernard Peter O. Daipan[1, 2]
Nelson M. Pampolina[2], Diomedes A. Racelis[2]
[1] Benguet State University
[2] University of the Philippines Los Baños

Abstract: Climate change has had a severe impact on the Philippine tropical montane forest ecosystem. However, limited studies have been conducted in the country on the vulnerability of these forests to the climate crisis. This paper assesses the vulnerability of the tropical montane forest of the Cordillera Region to projected climate change using geospatial techniques. Specifically, this study determines the forest areas in the region that are vulnerable to fires and landslides using open-source satellite imageries and remotely sensed datasets. The geospatial analysis reveals that approximately 116 thousand hectares or 8.5% of the forest in the region are prone to fires. The study notes an increasing trend of fire incidents and burned areas observed in both natural and plantation forests in the region. This trend could be linked to the region's rising temperatures and extended drought. In the next four decades, a projected rise in temperature of 1.9 to 2.1°C and a decrease in precipitation (-70.42 mm) during the dry season could result in more severe forest fires, larger burned areas, and longer fire durations. Furthermore, nearly 73% of the region's forests are vulnerable to landslides on a high to extremely high level. This vulnerability is reflected in the 182 landslides that occurred in the region between 2007 and 2018. The projected increase in precipitation (341.99 mm) during the wet season could further lead to an increase in landslides in the area in the near future. The output of this study could be used in the adaptation and mitigation plans, and risk reduction activities in the region. The findings of this study highlight the need for urgent action to prevent further forest degradation due to climate change. This study also underscores the importance of using geospatial techniques to identify areas that are most vulnerable to climate change and to develop targeted adaptation and mitigation strategies.

Where mountain forests meet the sea – simulating anthropogenic changes to protection forest function at northern latitudes.

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Paul McLean[1]
Kjersti Gisnås[2], Odd-Are Jensen[3], Stephanie Eisner[1]
[1] Norwegian Institute of Bioeconomic Research (NIBIO)
[2] The Norwegian Geotechnical Institute (NGI)
[3] The Norwegian Water Resources and Energy Directorate (NVE)

Abstract: Norway is defined by its fjordic landscape, with steep forested slopes rising out of the sea. Due to the northern latitude, snow is common to sea level and even low altitude forests (in absolute terms) provide many of the protective functions from gravitational mass movement normally associated with mountain forests. However, the concept of protection forest management is in its infancy in Norway, where instigating a suitable national policy is complicated by the current forest structure and ownership. Large areas of protection forest are even-aged spruce forests planted from the 1950s to restore the degraded natural forests. These forests represent a large national investment to create a timber resource that is due for harvest, though today they provide many services beyond this original intention. Notably, society and its associated infrastructure have developed both downhill of and within these forests in the 70 years since their creation. The logical solution of protecting the current and future society by setting aside large areas as protection forest is a real challenge because almost all of Norway's forests are under highly fragmented and small-scale private ownership. Through a lack of understanding, many owners or harvesting companies want to maximise their short-term economic gain and instigate large scale clearcutting, which has resulted in documented mass movement and high tensions between stakeholders.

We address a national requirement to compile knowledge in a common platform to understand the implications of forest management decisions with respect to underlying gravitational hazards and climate. We combined expertise on forest management & measurement, climate, hydrology, and gravitational mass movement to build a state-of-the-art simulation framework to quantify the effects of different forest management strategies on a given forest's protective function against gravitational mass movement.

In our scenario simulations, forest cover, climate and terrain characteristics can be manipulated to investigate changes in risk zones according to different management choices. We will demonstrate this in multiple case studies representing different levels of risk and convey the consequences of anthropogenic changes on disaster risk reduction.

Will current management practices ensure rockfall protection in mountain forests under climate change?

T1.15 Impacts of Global Change on Protective Forests in Mountain Areas

Ulrike Hiltner[1]
Timothy Thrippleton[2], Monika Frehner[1, 3], Jonas Glatthorn[2], Harald Bugmann[1]
[1] ETH Zurich, Dept. Environmental Systems Science, Inst. Terrestrial Ecosystems, Professorship of Forest Ecology, Switzerland
[2] Swiss Federal Institute for Forest, Snow and Landscape Research - WSL, Forest Resources and Management, Switzerland
[3] ETH Zurich, Dept. Environmental Systems Science, Inst. Terrestrial Ecosystems, Group of Silviculture, Switzerland

Abstract: In many mountain regions, forests have an important role for protecting human infrastructure below slopes from rockfall damages. To this end, such forests need to sustainably fulfill certain requirements, e.g., in terms of the stem number distribution over stem diameter classes and stand basal area, both of which are required to dissipate the energy of falling rocks (so-called "target profiles"). Established management practices exist to date to achieve these target profiles. However, it is unclear whether forest management will need to be adapted to sustainably maintain the protective function of mountain forests in the future under climatic change conditions.

We anticipate that key parameters of current best practice forest management can be adjusted to maintain the protective function of mountain forests without having to introduce an alternative management regime. To test this based on many simulation scenarios, we apply the dynamic, individual-based forest model ForClim to representative stands at four elevational zones in the Swiss Alps. For each stand, we first determine a sustainable achievable stem number distribution and the corresponding stand basal area, and then optimize multiple model parameters considering different climate change assumptions (current climate, RCP 4.5, and RCP 8.5). By combining dynamic forest modeling with heuristic optimization, we implement a novel method of autonomous learning. We use Simulated Annealing to estimate the extent to which adjustments of management parameters (e.g., target diameter, harvested timber volume, and intervention cycle) may be required to achieve the target profiles under climate change. We discuss the trends for each stand as proposed by the optimizer. When comparing all simulation scenarios, preliminary results indicate that the recommended adjustments to management parameters exhibit heterogeneous trends depending on the elevation and severity of climate change. In order to sustainably maintain the protective function against rockfall, the management parameters must be subsequentially adjusted several times during a simulation period.

This method of autonomous learning provides forest practitioners with a useful decision support tool. It allows to test a wide range of silvicultural options in a non-destructive manner while considering environmental changes such as climate change at long-term.

T1.16 Implementing fire-resilient landscapes

A landscape-scale spatio-temporal forest treatment and wildfire scenario model for California

T1.16 Implementing fire-resilient landscapes

Carrie Levine[1]
David Schmidt[1], Kyle Woodward[1], Anna Talucci[1], Thomas Buchholz[1], David Saah[1]
[1] Spatial Informatics Group

Abstract: In 2020, the state of California signed a memorandum of understanding with the US Forest Service to increase the pace and scale of forest health and fire resilience treatments throughout the state. In order to achieve the goal of reducing the impacts of catastrophic wildfires, the entities agreed to a target of 1 million acres treated per year over twenty years, beginning in 2025. Determining how to allocate treatment acres in an equitable way across an incredibly diverse socio-ecological landscape requires an extensive cost-benefit analysis based on modeled treatment impacts on forest structure and composition, fuel loading, wildfire behavior, and benefits to communities.

We developed a methodology for modeling the effects of annual forest, shrubland, and rangeland treatments on vegetation growth and change over a 20-year period. The core set of modeled scenarios consisted of a combination of three variables: treatment intensity (the number of acres treated per year), treatment prioritization (where treatments were allocated on the landscape), and treatment type (how vegetation was impacted). These variables guided the development of 108 unique treatment scenarios. The treatment scenarios were developed regionally to account for varying fire management goals and objectives across the state.

We created a reproducible workflow in Google Earth Engine to allocate the treatments on the landscape for each scenario. Next, we transitioned the forested vegetation in 5-year timesteps using the Forest Vegetation Simulator (FVS), a growth and yield model. For non-forested vegetation, we used a Google Earth Engine workflow which transitions shrub and grass vegetation over time after disturbance based on vegetation characteristics, disturbance type, and disturbance severity. We then ran a spatially explicit, probabilistic fire behavior model across the state at 1, 10, and 20-year timesteps to evaluate the impacts of vegetation treatments over time on fire extent and severity.

To evaluate the effect of the varying forest and landscape management scenarios, we use a cost-benefits framework. We provide summaries of objectives met, impacts of varying treatment scenarios, and potential workforce and funding needs to meet fire resilience goals for the state of California.

Addressing policy coherence towards integrated wildfire risk management in the European Union

T1.16 Implementing fire-resilient landscapes

Eduard Plana[1]
Marta Serra[1], Sara Nebot[1], Annick Smeenk[1]
[1] Forest Sciences and Technology Centre of Catalonia

Abstract: Although forming part of the natural ecosystem, wildfires are one of the most important threats to forest areas and adjacent values and communities. Even more so since wildfire risk (WFR) has been exacerbated across the world due to climate and land use changes, favouring more severe, damaging, and extreme wildfire events not only in traditional fire-prone areas but also in unprecedented territories, with different socioeconomic, ecological and political implications. Consequently, integrated approaches tackling the root causes related to fire spread capacity (hazard) as well as the creation of exposures and vulnerabilities become determinant. Beyond approaching wildfires as an emergency, WFR reduction needs to be integrated in all sectoral policies influencing risk "(de)construction" process, such as urban planning, bioeconomy, nature conservation, green energy or within the touristic sector.

In this context, the European Green Deal responds with policies and initiatives with objectives ranging from biodiversity conservation (e.g. EU Biodiversity Strategy for 2030) to the promotion of renewable energy (e.g. EU Renewable Energy Directive), the strengthening of the bio-based sector (EU Bioeconomy strategy) and much more, all directly or indirectly impacting forest ecosystems. Many of the policies framed under the Green Deal just vaguely mention wildfires. This can create incoherences between and within policies and strategies with respect to WFRM. Policies influence environmental and socio-economic dimensions, being able to transform a territory into a more wildfire resilient one if coherence exists or into a risk-prone one if there is incoherence.

This research identifies the landscape of policies and initiatives under the European Green Deal influencing WFR in terms of hazard, exposure and vulnerability trade-offs, and analyses up to what extend they are aligned in a (in)coherent way for wildfire disaster risk reduction. Results conclude that significant dysfunctions, but also potential synergies exist to move forward to integrated WFR management under a common policy frame supported by multi-stakeholders' risk governance bodies. Key aspects that could be approached in a more coherent way along and across the initiatives and policies analysed are suggested. Moreover, the method and results offer a general frame that may be downscaled from EU to national or regional level.

Assessing Fuel Moisture Codes Before and After Fire Events using Sentinel-1 SAR C-band imagery in the case of Mediterranean Forests

T1.16 Implementing fire-resilient landscapes

Francesco Pirotti[1]
Opeyemi Adedipe[1], **Brigitte Leblon**[2]
[1] Department of Land, Environment, Agriculture and Forestry, University of Padua, Italy
[2] Faculty of Natural Resources Management, Lakehead University, Canada

Abstract: In fire-prone Mediterranean regions, fire danger is often estimated using meteorological factors using the Canadian Forest Fire Danger Rating system. The system's fuel moisture codes are interpolated from single-point weather data. Radar remote sensing is sensible to soil and vegetation moisture content and might be a valid tool for mapping the spatial distribution of fuel moisture over time. This study investigates the sensibility of Sentinel-1 C-band backscatter values to fuel moisture over a study area of about 500 km^2 in northwestern Portugal. The fuel moisture was parametrized with the Drought Code (DC) of the Canadian Forest Fire Danger Rating System. Sentinel-1 C-VV and C-VH backscatter values from 276 images acquired between January 2018 and December 2020 were assigned to five classes depending on the Drought Code (DC) over several unburned and burned sites with full (>90%) forest cover. Confounding variables such as tree cover and incidence angle were accounted for. C-VV and C-VH backscatter values are inversely correlated ($R^2 = 0.324$ to 0.438; $p<0.001$) with local incidence angle over canopies. Correlation is significantly stronger over very wet locations (DC class = 0 to 1). C-VV and C-VH backscatter values can discriminate wet to dry forest environments, but they are less sensitive to the transition between dry (DC classes=1 to 10, 10 to 100) and extremely dry environments (DC classes=100 to 1000). C-VH is more sensible than C-VV to catch burnt areas. The VH polarization captures post-fire vegetation recovery after an average minimum period of 360 days after the fire event, although with less distinction for extremely wet fuels.

Costs, Risks, Liability and Legal Architecture of Prescribed Burns in the United States: History and Trends for the Future

T1.16 Implementing fire-resilient landscapes

Gregory Frey[1]
Changyou Sun[2], Troy Bowman[3], Iris Montague[4], Kalani Perera[2], Taylor Sanders[3]
[1] USDA Forest Service, Southern Research Station; USA
[2] Mississippi State University, Department of Forestry; USA
[3] Alabama Agricultural and Mechanical University, Department of Biological and Environmental Sciences; USA
[4] USDA Forest Service, Northern Research Station; USA

Abstract: Prescribed burns are utilized in the United States to mitigate wildfire risk as well as to enhance wildlife habitat, control pests and diseases, and provide other benefits. These burns have costs of implementation as well as risks of damage to property or personal injury. A large portion of the benefits of prescribed burns accrue broadly to society, whereas the costs and risks of burns are borne by individuals. Both the risks and the benefits of prescribed burns have become more pronounced over time with increasing population, particularly within the wildland-urban interface, and growing wildfire severity due to climate change.

This oral presentation will discuss the history and evolving trends of costs, risks, liability, and legal architecture surrounding prescribed burns on private and public lands. We will discuss long-term social trends and other drivers of the policy debate and how this has impacted the incentive structure surrounding the decision about whether or not to burn. What are the continuing challenges and what policy structure would alleviate those barriers while enhancing social benefits?

Designing Fire Resilient Landscapes in South-west France

T1.16 Implementing fire-resilient landscapes

Barry Gardiner[1]
Lucas Moreews[1], Christophe Orazio[1], Emma Hart[2], Kevin Sim[2]
[1] Institut Européen de La Forêt Cultivée, Cestas, France
[2] School of Computing, Edinburgh Napier University, Scotland, UK

Abstract: In July and August 2022 almost 30,000 ha of forest were burnt in three fires in Les Landes de Gasgone Forest in south-west France. These were the largest forest fires in the area since August 1949 due to an extremely efficient prevention system with forest owners' mandatory enrolment in municipal fire prevention associations (DFCI).

The background to the 2022 fires was a very dry and hot summer with temperatures around 40 C and humidity below 10% on occasions. These unusual conditions lasted for more than a week due to an offshore easterly wind that kept moisture from the sea reaching inland and forming clouds and rain. Under these conditions when the first two fires started, both by human activity, they proved very difficult to control. Several strategies were put in place, which proved very effective to stop the fire progression included the opening of large fire breaks, tactical fires, and backfires.

With the changing climate bringing hotter and drier summers to the south-west of France the risk of large fires is likely to increase. Improved fire fighting systems are clearly not the solution to this problem and a more fire-resilient landscape is required. In this paper we present calculations using the Prometheus fire spread model (https://firegrowthmodel.ca/pages/prometheus_overview_e.html) to investigate fire movement in the landscape and the total area burnt. We investigate different landscape designs, both human inspired, and designed using machine learning (e.g. simulated annealing), with a number of constraints such as land ownership, retention of the overall percentage of forest cover and the location of roads, railways and habitation. The modified landscapes have different patterns of forest cover and a mix of other land uses including agricultural areas, photovoltaic farms, and urban areas to help reduce fire spread. We compare the levels of damage and the rates of fire propagation from the July and August 2022 fires in the current landscape and in these modified landscapes. The results could be of benefit in helping to reduce the overall level of damage from forest fires and be part of the design of a climate-resilient forest landscape in the region.

DISRUPTED LANDSCAPES: Integrating Mediterranean Wildfires into landscape planning

T1.16 Implementing fire-resilient landscapes

Pepa Morán Núñez[1]
[1] DUTP, Department of Urbanism, Territory and Landscape. Polytechnical University of Catalonia UPC

Abstract: Wildfires are the main natural disturbance that affects the Mediterranean area, and it is expected to worsen in the global climate change scenario. The fire regime has changed, mainly due to climate and human activity. The international community specialized in wildfire management recognizes the inability to solve and treat the problem strictly from the field of emergencies. The classic prevention model is being questioned, since it is not an issue of extinction capacity or economic resources destined to extinction, but an issue of landscape's ability to integrate and modulate disturbances.

This investigation explores a representation methodology by mapping future scenarios in landscape architecture as a means of integrating wildfires disturbance in landscape planning and management. The case study of the Collserola mountain range in the Barcelona Metropolitan Area in Spain is developed, to test representation, planning and management methodology. The perception and interpretation we make of wildfires and disturbances is sociocultural, but in turn, disruptive, and this fact influences political and scientific positions that are not exempt from these assessments. The concept of loss of value, associated with disturbances, is analyzed, to resignify loss and disturbance through the characterization of the operation of the disturbance: intensity, frequency or regime, as well as the landscape's own capacities that are activated by the disturbance, such as resistance, resilience or transformability, proposing its integration into landscape planning and management through representation.

The case study develops a methodology for the integration of disturbances in planning and management in a specific territory such as the Collserola mountain range, anticipating the scenario of great wildfire and proposing the inclusion of disruptive change through management and of wildfires through fire regime management to reduce vulnerability.

This methodology incorporates the operability of wildfires to planning and decision making to resignify the concept of disturbance and join a necessarily transdisciplinary reflection on the socialization of value and risk.

Keywords: Landscape management; landscape planning; wildfires; landscape representation

Economic resilience to wildfires

T1.16 Implementing fire-resilient landscapes

Elena Górriz-Mifsud[1]
[1] Forest Science and Technology Center of Catalonia (CTFC)

Abstract: Economic resilience towards wildfires is the condition of a socio-ecological system whose economic actors can continue their functions prior to the fire event. This refers to the revenue-raising function (income-generation paths through marketable products and services), but also the non-market social and ecological functions from forests and woodlands. The economic resilience requires a system that minimizes the severity of the wildfire impacts, reduces the economic impact of fire prevention restrictions, decreases the time lapse until the recovery of the economic functions, ensures the availability of restoration funds to repair the losses (e.g., insurance), or assures the feasibility of alternative methods to exert post-fire the functions.

This presentation revolves around potential and existing mechanisms that allow for static and dynamic economic resilience (*sensu* Rose, 2007), accounting for the efficient allocation of resources, to the reparation of the capital stock. This duality confronts the anticipation of future losses (avoided reparation costs or losses) with the current expenditures to achieve certain reduction in exposure or vulnerability. It follows a discussion about the acceptability of these mechanisms, confronted with the general public risk aversion and risk perception, and the current resources typically devoted to rather reactive, impact-mitigation approaches rather than to proactive, risk-reduction measures.

Normative frameworks distil the liability of each involved economic agent – from homeowner obligations (e.g. insurance), to forest manager duties, public dissuasive and punishing structures, etc. Some countries rely on subsidy schemes to landowners and/or catastrophic aids to affected agents, which reduce the incentives of agents to enter into additional pre-fire risk reduction expenses. Yet, those public funds do not arrive to the whole region, reason for efficient distribution. Businesses become disrupted both due to the wildfire impacts, but also due to losses for strict restrictions aimed at avoiding fire ignitions during the risk season. While these restrictions tend to become more frequent due to more frequent harsh summer conditions, compensation mechanisms are to be designed if these businesses are to be maintained. Also, economic opportunities emerge post-fire not only for restoration but also for the usage of the burnt material -could be channelled as chances for the disrupted businesses.

Effects of surface fire behavior on emission from Pinus koraiensis plantation–A laboratory simulation study

T1.16 Implementing fire-resilient landscapes

Guang Yang[1]
Jibin Ning[1], Hongzhou Yu[1]
[1] Northeast Forestry University

Abstract: The emission of smoke from forest fires not only affects short-term respiration health of fire fighter and public, but also poses a long-term threat to human cardiopulmonary functionality. The dead surface fuel of red pine plantation forest were collected as experimental materials, and the characteristics of forest fire behavior and the emission characteristics of particulate pollutants and gaseous pollutants during forest combustion were measured by laboratory simulated combustion experiments under field conditions as the main research means. In this study, we systematically investigated the effects of forest fire behavior characteristics on the respirable particulate matter and mixed exposure ratio, and established a forest fire smoke prediction method based on easily estimated fire behavior characteristics. The result shows that: Flame length, depth, fuel consumption loading and fire line intensity are highly significant positive correlation with $PM_{2.5}$ concentration; flame length and fuel consumption loading are highly significant positive correlation with CO concentration; residence time, flame height, fuel consumption loading and CO_2 concentration are highly significant positive correlation.Based on MLR, SVM, BPNN and RF, forest fire smoke exposure characteristics were predicted using easily estimated forest fire behavior characteristics, and RF was the optimal algorithm after screening, the R^2 of predicting $PM_{2.5}$ concentration and MER were 0.88 and 0.87, and MAPE were 16.55% and 14.84%, ; flame length had the most significant effect on $PM_{2.5}$ and MER based on RDA , and the flame length explained 15.0% and contributed 42.6% to smoke exposure; when the concentration of particle pollutant and gaseous pollutant MER were exceeded limit values, the corresponding flame lengths were 28.30 cm and 20.88 cm, respectively, and when the flame length exceeded the limit value, attention should be paid to forest fire smoke protection.In summary, the forest fire behavior characteristics measured in this study were highly correlated with the collected forest fire smoke concentrations, making it possible to realize fire environment smoke predictions based on forest fire behavior characteristics.Further optimization of laboratory data parameters using actual forest combustion data in the field will significantly improve the applicability of indoor burning experiments.

Exploring Swedish forest owners' and fire and rescue services' experiences of collaboration during forest fires

[4] Bengt Fridlund, Department of Forestry and Wood Technology, Linnaeus University, Växjö, Sweden; Centre of Interprofessional Collaboration within Emergency care (CICE), Linnaeus University, Växjö, Sweden ORCID-id: 0000-0002-5412-9497

[5] Anders Svensson, Faculty of Health and Life Sciences, Linnaeus University, Växjö, Sweden; Centre of Interprofessional Collaboration within Emergency care (CICE), Linnaeus University, Växjö, Sweden; Department of Ambulance Service, Region Kronoberg, Växjö Sweden ORCID-id: 0000-0001-7479-8092

Abstract: Forest fires are now becoming more frequent due to warmer and drier summers caused by climate change. A forest fire can have a significant impact on society as they are unpredictable and do not adhere to geographical or organizational boundaries. In such situations, forest owners and the local community often gather to help, and their assistance is highly valued. In Sweden, forest owners are legally responsible for helping the fire and rescue service during forest fires and managing the post-fire monitoring of the burnt area.

To better understand the experiences of private forest owners during forest fires and their collaboration with fire and rescue services, interviews were conducted and analyzed using qualitative content analysis and the critical incident technique (CIT). The results showed that forest fires are not only a disaster in economic terms but also have an emotional impact on forest owners. Despite this, forest owners feel a sense of responsibility and express a willingness to act, which sometimes involves putting themselves in danger. They want to collaborate with the fire and rescue services in the decision-making process, and their strong and differentiated network is mobilized to accentuate specific local knowledge proven useful in fighting forest fires. To ensure a safe work environment for all involved, the fire and rescue services need a proactive plan that involves forest owners. The fire and rescue services' view of the collaboration with the forest owners and the network that gathers has an impact on the result of the forest fire. The fire and rescue services stresses that meeting the emotional needs of the affected forest owner is a prioritized action that enhances good communication and collaboration.

While a forest fire can be a personal disaster, it can also yield a positive outcome by promoting practical and structural enhancements privately and in the local community. Collaborative efforts

between the forest owners and the fire and rescue services create security and resilience that extends beyond the forest fire area and leads to better pre-disaster planning. While the fear of new forest fires will remain for generations, disasters can be turned into proactive engagements.

Fire risks and boreal forest management

T1.16 Implementing fire-resilient landscapes

Yuval Zelnik[1]
Samuli Launiainen[2], Giulia Vico[1]
[1] Swedish University of Agricultural Sciences, Department of Crop Production Ecology
[2] Natural Resources Institute Finland

Abstract: Forests are increasingly affected by both natural disturbances and human impacts, including fires, logging and land-use change. Climate change has further altered forest dynamics, leading to novel conditions such as increased droughts and more frequent fires, making forests more susceptible to disturbances. In the boreal region, fires rank are a major factor in shaping forest dynamics, second only to human management. Millions of hectares of boreal forest burn annually, with size and frequency of wildfires increasing. Nonetheless, our understanding of how forest management effects wildfires remains limited

Intensive forest management practices, including tree planting, thinning, and clearcutting, contribute to uniform forests in terms of species and age, often disconnected from the underlying landscape. These practices, along with landscape augmentation methods such as ditching, enhance wood production but also increase the susceptibility of spatially homogeneous forests to large fires. While much research has focused on boreal forest fires in North America, where management practices are less intensive, it is crucial to expand our understanding of fire dynamics in intensely managed forests in Eurasia. As wildfires are projected to become more frequent and severe in Eurasia due to climate change, comprehending fire dynamics in these forests becomes increasingly important.

We use a cellular-automata model to simulate fire spread, combined with eco-physiological modeling for environmental factors such as fuel moisture. We consider fire spread through small regions (1-10km), and focus on two management aspects, the structuring of forest stands by logging and tree planting, and the impact of ditching on fire dynamics via soil moisture. We find that stand management, and its effect on the spatial organization of the forest landscape, greatly affects fire spread, and that small stands can be used to mitigate fire risk. This behavior interplays with other aspects of landscape management, such as augmenting the landscape to control soil moisture, and diversifying stands with different tree species. Overall we find that management practices has a substantial impact on fire risk in boreal forests, with preferable choices depending on the scale at which management choices are made.

Abstract: Fire regulation capacity (FRC) by ecosystems and landscape is an ecological function that modulates fire regimes by maintaining fire frequency, intensity and spread within acceptable thresholds and mitigates the harmful effects of fires on ecosystems and people. This study applies a modelling and simulation approach using the LANDIS-II Forest Landscape Model to assess the role of ecosystems and landscape features in regulating fire and supplying the fire protection ecosystem service (FPES) in a mountainous fire-prone area in northeastern Portugal undergoing landscape change and climate change. The study was conducted for i) 1990 -2020, where we modelled the effect of past landscape changes on fire behaviour to assess FRC (using burned area and fire intensity as a proxy) and FPES (using fire impacts on ecosystems services (ES) as a proxy), and ii) 2020-2050, where we explored the combined effect of farmland abandonment and fire management strategies (FMS): business-as-usual (BAU) based on fire suppression and fire-smart (FS) strategies focused on fire prevention, on landscape dynamics and FRC under climate change scenarios (RCP 4.5 and 8.5) to predict their effects on future fire regimes and the economic value of FPES. We found that past landscape changes promoted buildup and spatial continuity of hazardous fuels in the landscape, increasing the occurrence of large fires and areas burned above the firefighting capacity, thus indicating a reduction in FRC. From 2020 to 2050, this trend continued, particularly under the BAU strategy, where a marked decrease in FRC led to a pronounced change in the current fire regime. Still, fire-smart management fostered FRC and mitigated the effect of climate on fire activity by moderating the occurrence of large and intense fires, thus preventing fire regime intensification.

Regarding FPES, we found that from 1990 on, the value of ES supplied increased, but losses due to fire also increased, which reduced the FPES supply. Likewise, from 2020 on, although the economic value yielded by ES was positive for all FMS, FS strategies outweighed BAU in both climate scenarios and were more cost-effective than BAU.

Forest fires as a factor of ecosystem alteration in the Paraná Delta, Argentina

T1.16 Implementing fire-resilient landscapes

Mariano Ferro[1, 2]
Clara Maria Minaverry[1, 2, 3], Analia Scarselletta[1, 2]
[1] Departamento de Ciencias Sociales, Universidad Nacional de Luján, Argentina
[2] instituto de Ecología y Desarrollo Sustentable (INEDES), Argentina
[3] Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina

Abstract: The Paraná Delta is a vast network of islands, channels, and wetlands formed by the Paraná River and its tributaries. The forests settled in this area are home to a great diversity of plant and animal species, closely related to the region's wetlands. However, the pressure of various productive activities, since the 1990s, has significantly altered the forest, wetlands and produced relevant cultural and natural ecosystem services losses. In particular, deforestation, agricultural expansion, and urbanization have altered some sectors of the region, which has led to the loss of natural habitats and a decrease in biodiversity. This proposal focuses on the fire crises in the last two decades. The first of these episodes was in 2008, and the institutional response was the creation of the Strategic Plan for Conservation and Sustainable Use in the Paraná Delta (PIECAS-DP). Among its objectives, it was foreseen to solve the problems related to the DP fires and achieve a normative harmonization between environmental conservation. Between 2020 and 2022, new fire crises occurred, aggravated by an unprecedented drought, leading to conflicts in which the National Supreme Court of National Justice intervened. Also, important national and specific regulations were enacted since 2020 to reduce the situations where economic interests were behind the production of intended fires and the loss of native forests. The hypothesis put forward is that the level of institutionalization of the environmental paradigm in the Paraná Delta is low, and this is due to i) the fragmentation between divergent principles that generate tensions between individual and patrimonial interests and collective rights, and ii) the little adoption, by public institutions, of concepts and knowledge produced by laboratories dedicated to the study of aquatic ecosystems. The adopted methodology is descriptive-inductive and includes the collective case study of the Paraná Delta which has unique characteristics, natural and cultural values which must be protected for present and future generations.

Germany is becoming a forest-fire land: are we ready for that?

T1.16 Implementing fire-resilient landscapes

Somidh Saha[1]
[1] Karlsruhe Institute of Technology (KIT), Institute for Technology Assessment and Systems Analysis (ITAS), Karlsruhe, Germany

Abstract: Forest fires are not new to Germany. Forest fires were a natural part of the stand dynamics before the middle ages. Natural grassland and forest were intermixed in the central European landscape, and large herbivores such as European bison roamed before the Romans arrived in Germany along the Rhine. Forest cover was depleted significantly during the middle ages and rebounded since the industrial revolution. The first scientific forestry started in Germany in the 18th century, with sustainable timber production and hunting a primary goal. The natural grassland disappeared, either converted to cropland or forest. As a result, a cultural landscape was formed where the forest ends at the doorstep of a house. Forest turned to monocultures of a few species dominated mainly by conifers in the subsequent 19th and 20th centuries. In this new cultural landscape, forest owners tried their best to suppress fire as stand-replacing large fires contradicts the normative dogma of sustainability, which fundamentally avoids the significant natural disturbance. In this presentation, I will show how the history of forest development in Germany, in combination with anthropogenic climate change impacts and lack of public awareness, is gradually turning Germany into a forest-fire land like California and Australia. I found the burned forest areas increased 400% in the last years compared to 20 to 30 years ago. At the end of the 20th century, the average size of a burning patch was less than 5 ha, and nowadays, forest fire with more than 100 ha in size is becoming common. Due to the lack of grassland between human habitation and croplands, forest fires at doorsteps increased the vulnerability of damage to human life and properties. I have detected that northeastern Germany and Rhine Valley are highly vulnerable due to increasing dryness, sandy soil with low water storage capacity, still a large portion of conifer monoculture, and a lack of mixed forests. I detected the areas for silvicultural and infrastructure improvement so that forest owners and all stakeholders get ready for the new reality and create a future forest more resilient to fires.

Impact of wildfire severity on natural regeneration of Douglas-fir in interior British Columbia

T1.16 Implementing fire-resilient landscapes

Abstract: Wildfires are an increasingly pressing issue in British Columbia (BC) due to climate change, fuel buildup, and pest outbreaks, so understanding how forests regenerate after fire is critical for successful post-wildfire restoration. This study examines the impact of burn severity on Douglas-fir seedling natural regeneration in the Fraser variant of the Dry Cool Interior Douglas-fir biogeoclimatic (IDFdk3) subzone of British Columbia. The study site is located 10 km west-northwest of 100 Mile House (51˚ 39′ N, 121 ˚ 28 ′ W), BC. The area experienced large wildfires in 2017, resulting in mixed-severity burned stands. Plots are located in low, moderate, and high burn severity zones. Seedling regeneration data and ground cover percentages were recorded from 2019-2022, and seedling needle, twig, and soil samples were collected in each plot in late summer of 2022 for elemental and stable isotope analyses. Low burn severity plots had more seedlings per unit area, but high burn severity plots had larger seedlings. To further investigate these patterns, the results from the stable isotope analyses of needle material ($\delta^{13}C$, $\delta^{15}N$, $\delta^{18}O$) and twig and soil water ($\delta^{18}O$, $\delta^{2}H$) will be used to assess time-integrated water use efficiency, stomatal conductance, leaf nutrient status, and soil water uptake depth of seedlings. By incorporating this ecophysiological data with seedling growth and biomass measurements, we can investigate key growth-limiting factors (light, water, nutrients) and assess differences in seedling performance based on burn severity. The anticipated results of this study include insights into the effects of burn severity on post-fire natural regeneration dynamics of interior Douglas-fir that will help inform post-fire regeneration strategies. Given the economic importance of interior Douglas-fir in the region, understanding how to facilitate regeneration success after wildfires is a critical issue for First Nations, the forest industry, and management and stewardship agencies. This study will help inform the development of silvicultural strategies to create favorable regeneration conditions, ultimately facilitating the recovery of forest ecosystems following destructive wildfires.

Improving surface fuel maps integrating remotely sensed data, machine learning, and ecologically based concepts to support prescribed fire management

Abstract: Spatially explicit maps of surface fuel components (e.g., litter, duff, down woody debris–DWD) across large areas are needed to implement pre-fire fuel management strategies and predict fire behavior, effects, consumption, and emissions. Remote sensing and statistical modelling offer opportunities to capture fuel heterogeneity. Light detection and ranging (LiDAR) data, for instance, are commonly used to model forest structure attributes and predict canopy fuels. Nevertheless, remote sensing data alone are inadequate to describe the highly heterogenous surface fuelbed layer, due to the low sensitivity of both passive and active sensors to discriminate the ground from surface fuels and understory vegetation.

To overcome these limitations, we recently developed a LiDAR-based, object-oriented approach to map annual tree litterfall and litter accumulation with time since fire, exploiting the evident relationship between the litter distribution and the spatial variability of overstory inputs. In this study, we expand this methodology to describe additional surface fuel components besides litter that originate primarily from the tree crowns. We investigate the relationship between observed DWD (1 hr, 10 hr, and 100 hr fuel components) and crown biomass using tree crown maps and crown attributes derived from airborne LiDAR point clouds. Specific models of crown bulk density, volume, and branch biomass of different diameter sizes will be trained using machine learning and annual DWD fall will be predicted. On the other hand, duff (partially to fully decomposed organic material) accumulates from the breakdown of litter and DWD. Therefore, we will further use the DWD and litter maps as input to estimate annual duff formation and to simulate duff accumulation

based on fire return intervals. Study sites are fire-maintained longleaf pine forests located in Florida, Georgia, and South Carolina (southeastern USA), where remote sensing and field reference data are available for testing and validating the methodology. This integrated conceptual approach will enable mapping some physical properties of fine fuels at higher spatial resolutions, partially resolving the limitations of current methods to describe the surface fuelbed layer in a spatially explicitly manner and offering fire modelers and managers the required information to support decision-making prior to and during prescribed burns.

Information and innovative technology supporting the wildfire risk management and forest resilience – Slovak case study

T1.16 Implementing fire-resilient landscapes
Andrea Majlingova[1]
Yvonne Brodrechtova[2], Lenka Marcinekova[2], Zoltan Balogh[3]

[3] Slovak Academy od Sciences, Institute of Informatics

Abstract: The ongoing climate change creates significant risks for forests across the globe. Under these challenges, the EU launched Horizon 2020 European Green Deal Call to bridge the scientific advances in the fight against wildfires into concrete innovation opportunities. Under the topic "preventing and fighting extreme wildfires with the integration and demonstration of innovative means", project SILVANUS was launched. Its goal is to develop an integrated technology and information platform for wildfire management. The innovative technologies and stakeholders' participation solutions in lowering wildfire risk are tested in 11 countries worldwide and across all phases of wildfire risk management: prevention/preparedness, detection/monitoring, and restoration/adaptation. Slovakia has also joined the Europe-wide initiative to fight forest fires through the SILVANUS project. On April 24-26, 2023, the Slovakian project partners demonstrated innovative solutions and technological support for all phases of wildfire risk management: 1. the results of wildfire risk assessment using a holistic and integral approach for wildfire prevention/preparation phase, 2. the technologies which outputs are real-time data supporting the decision-making process of command staff in the wildfire detection/response phase, 3. the use of the SIBYLA forest growth simulator in forest recovery phase. Specifically, the possibilities of deploying the OPTIX smoke detection CCTV system operating in 24/7 mode and allowing monitoring of the territory in a 360° radius were tested. The camera output visualized in the control centre was sent to the Fire and Rescue Service's operations centre as a text message or MMS (photos). Wildfire was verified via drones operated by foresters. Drones were also deployed to monitor the territory during the fire to support the intervention commander. SWARM of drones was used to map the fire-affected area and create a continuous orthophoto map. In problematic GSM signal locations were used a stand-alone Starlink satellite internet and a drone using Starlink satellite internet to create a local GSM network. The Colossus ground robot technology was deployed to extinguish the fire and transport the firefighting assets and injured person. To suppress the wildfires, a pond system of water transport, a helicopter with a Bambi bucket in the undercarriage, which was filled from the large-capacity FIREFLEX tank.

Innovative technologies & socio-ecological-economic solutions for fire resilient territories in Europe (FIRE-RES project)

T1.16 Implementing fire-resilient landscapes

Abstract: Extreme wildfire events exceeding control capacity are becoming a major environmental, economic and social threat, not only in fire-prone regions in Southern Europe, America and Oceania, but also in new areas such as Central and Northern Europe. The EU H2020 FIRE-RES project (https://fire-res.eu/) aims to provide Europe with the necessary capacity to avoid collapse in the face of Extreme Wildfire Events (EWE), which are projected to increase as the result of a harsher climate. FIRE-RES is a 4-year project (2021–2025) whose scope is to effectively promote the implementation of a holistic fire management approach and support the transition towards more resilient landscapes and communities to EWE in Europe. FIRE-RES brings together a transdisciplinary, multi-actor consortium of 35 partners, formed by researchers, wildfire agencies, technological companies, industry and civil society from 13 countries, linking to broader networks in science and disaster reduction management. The project will deploy a total of 34 innovation actions across a set of eleven living labs representing different environments in Europe and Chile. Its final mission is to boost the socio-ecological transition of the European Union towards a fire-resilient continent by developing a stream of innovative actions.

Integrated Fire Management within ASEAN: Approaches to include community-based fire management and address climate change

T1.16 Implementing fire-resilient landscapes

Marina Tornorsam[1]
David Ganz[1]
[1] RECOFTC

Abstract: Forest fires continue to significantly impact the environment, economy, and communities around the world in both direct and indirect ways. Environmental harm caused by forest fires disturbs ecosystems and alters land use inducing significant release of greenhouse gases. Climate change affects each passing fire season intensifying the severity of smoke and haze by the increasing frequency, intensity, and duration of fires. From these smoke particulates, transboundary haze has risen across the landscape afflicting the whole ASEAN region at a worsening rate thereby threatening public and environmental health. The transdisciplinary scale and transboundary impact of wildfires requires a collective and proactive approach inclusive of diverse perspectives. A series of roundtable discussions conducted in early 2022 through the RECOFTC TFD-FLOURISH project, provided lessons learned that emphasized the need for international intervention and a shift towards long-term integrated planning involving diverse stakeholders and efforts at multiple levels. The methods within this current project focus on enhancing existing strategies and technologies for greater use and accessibility for forest communities to prepare and respond to fire risks themselves. Initial study across Southeast Asia indicated that people cause most ignitions either accidentally or intentionally in cases of agricultural burning or land clearing. In implementation, project target sites in Thailand, Laos PDR, Viet Nam, and Cambodia were selected based on a range of factors including but not limited to burn scare proximity, hot spot density, land use, and transboundary relevance. This project mobilizes on the understanding that community and landscape perspectives should be prioritized in the design and implementation of forest fire management. By building trust and applying adaptive management strategies that draw on social, economic, cultural, and ecological conditions, RECOFTC facilitates the cross-stakeholder and cross-sectoral approach needed to build resiliency in fire threatened landscapes. Application of a proactive and people centered approach benefits both ecosystem health and biodiversity while strengthening landscape connectivity and sustainability of community livelihoods. Further involvement of regional stakeholders and opportunities for knowledge sharing will address the challenge of transboundary haze from the root of problem: irregular and unpredictable burning in the region.

Integrating nature-based solutions in wildfire and disaster risk reduction strategies

T1.16 Implementing fire-resilient landscapes

[1] Forest Sciences and Technology Centre of Catalonia
[2] International Institute for Applied Systems Analysis

Abstract: Land use changes that increase biomass accumulation at landscape scale are adding to wildfire risk conditions in many regions across the world, especially and historically in rural mountainous areas. Land abandonment and other changes are resulting in landscapes becoming increasingly hazardous, both in terms of wildfire propagation (fire velocity and intensity overcoming so-called suppression capacity) and in terms of damaging impact (increased potential of wildfires to critically impact values at risk). This trend is exacerbated by the fire-prone conditions posed by a warmer, dryer and vegetation-stressing climate, jeopardizing the adaptation capacity of risk management systems. This combination of factors is increasing the risk of extreme wildfire events and shifting the perception of wildfires as mainly an ecological phenomenon to a disaster risk management issue. While nature-based solutions (NbS) are increasingly prevalent on disaster risk reduction agendas, their application to wildfire risk has been poorly conceptualized up until now. This paper explores the consequences of the evolving wildfire risk in terms of disaster risk management, both in traditional and non-traditional fire-prone areas, and how the NbS concept can be applied as part of risk-reduction strategies. Fundamentals of fire ecology and traditional sustainable forestry practices for risk reduction, climate change and biodiversity are contrasted, exploring the boundaries of concepts such as fire-smart forestry, natural-fire regime restoration or fire-resilient landscapes, as well as conservation and re-wilding, as different options for NBS policy. Theoretical, empirical, and policy aspects are considered, delivering lessons learned (also from other natural hazards) and best practices, along with technical, financial (e.g., the role of insurance) and governance options to frame different perspectives of NbS into integrated and equitable wildfire- and disaster risk reduction.

Latest scientific insights into landscape management towards fire-resilience

T1.16 Implementing fire-resilient landscapes

Marc-André Parisien[1]
[1] Natural Resources Canada

Abstract: This keynote speech will set the scene for the rest of the session, which will cover the fire-resilience topic from a multidisciplinary perspective.

This talk will review the latest advances on fire ecology, and related insights into forest management and societal adaptation and risk mitigation practices that could contribute to better prepared communities and ecosystems to tackle fire contingencies. Taking the examples from Boreal ecosystems, the talk will refer also to fire regimes and changes in the latest decades related to climate novelties. The talk will also refer to some of the following questions:

- How is the relation between fuel availability and fire severity? Which are the consequent socio-ecological impacts?
- How to achieve and maintain forest resilient structures and uses?
- How to make viable and affordable this society-forest-risk relation?
- How synergetic or competing is the wildfire risk mitigation service with other ecosystem services? (e.g. water-biodiversity-wildfire nexus).
- How to pass from effective stand-level to landscape-level measures?

Lessons from the 2023 wildfire season in Canada will be introduced as well.

Merging National Forest Inventory data with fire expert rating of fuel complexes through photo interpretation of NFI plots

T1.16 Implementing fire-resilient landscapes

Inka Bohlin[1]
Anders Granström[2]
[1] Swedish University of Agricultural Sciences, Department of Forest Resource Management, Sweden
[2] Swedish University of Agricultural Sciences, Department of Forest Ecology and Management, Sweden

Abstract: High-quality fuel maps are needed for operational fire suppression. These are typically built on satellite scenes and other remote sensing tools, which unfortunately have limited ability to detect surface fuel conditions in closed forest. In many regions there is also very limited experimental fire data to grade various fuel complexes from a fire danger perspective. Here we analyse whether standard inventory data from the Swedish National Forest Inventory (NFI) plots can be used to grade fire danger. Five fire-experts, with long experience in conducting prescribed fire in forests, were asked to interpret a series of photos we had taken at 192 different 20m-radius NFI plots in two regions in northern and southern Sweden. The experts rated the fuel complex in each plot based on the images only, which were taken from a position 5m south of the plot centre in five directions from nadir to zenith. They rated different 'fire-danger' categories: relative drying rate of the surface fuels, relative intensity of a surface fire in high-danger fire weather, risk for fire climbing into the canopy and overall risk (all on a scale 1-10), and seasonality of surface fuel flammability (on a scale 1-5).

The evaluations of the five experts were highly consistent (no statistically significant differences). We then built regression models for each fire danger category using the NFI plot data as independent variables. The most important variables indicating high fire danger were percentile cover of dwarf-shrubs (*Vaccinium vitis-idaea, Vaccinium myrtillus, Empetrum nigrum, Calluna vulgaris*) and the proportion of *Pleurozium schreberi* and *Hylocomium splendens* in the moss layer. Also the proportion of different tree species (*Pinus sylvestris, picea abies, betula sp*., deciduous mix) had significant effects. In addition, tree height, canopy cover, tree species proportions within different canopy layers were significant variables in different regression models.

Our study show that standard NFI-data can be interpreted to grade forest with regard to fuel structure. The results can be used to refine the current fuel map of Sweden and also be integrated into forest decision support systems such as HEUREKA, for combined analysis of forest resource management and fire risk.

Multi-scale laser scanning in support of prescribed fires to maintain or restore resilient forests

Abstract: Large fuel accumulations over decades of fire exclusion practices, especially in the western USA, coupled with longer fire seasons caused by a warming and drying climate, has increased wildfire activity, burn area, burn severity, and emissions. Fuel loadings and consumption are the two largest sources of uncertainty in estimating emissions, and improved fuel maps are needed for regional planning of forest and fuel treatments. There is broad consensus that more prescribed fires are needed to maintain resilient forests, reduce fuel loads, and restore forests where fire has been unnaturally excluded, leading to increased risks of severe wildfires. Laser scanning data collected on the ground and from aircraft and satellites provide state-of-the-art remote sensing capabilities for characterizing forest structure attributes, including biomass and fuel loads.

We estimated canopy and surface fuels at multiple scales using machine learning informed by a combination of field and laser scanning data and fire history records. We collected pre- and post-fire field and laser scanning data to model and map both pre- and post-fire fuel loads; by subsequently differencing these fuel maps, we could map fuel consumption to inform studies of fuels, fire behavior, emissions, and fire effects. In the southeastern USA, frequent prescribed surface fires are used primarily to maintain desirable conditions in surface fuels, shrub cover, and tree density and age structure in longleaf pine forests. In the western USA, where decades of fire exclusion have caused these variables to depart from historical conditions, prescribed surface fires have been reintroduced to restore dry ponderosa pine forests, and prescribed crown fires have been used to restore subalpine forests. We present a conceptual framework for inventory and monitoring of fuel loads, supported by published case studies conducted across these diverse forest types. Findings from these studies informs a strategic, multi-scale approach to regional forest and fuel monitoring

that will become increasingly feasible, practical, and useful with: 1) continued spatial and temporal infilling of airborne laser scanning collections, 2) increased instances of repeat airborne laser scanning coverage across the USA, 3) satellite laser scanning samples of fuel loads across a range of forest types and fire regimes.

Perceptions, knowledge and spiritual management of fire in Forest indigenous landscapes

T1.16 Implementing fire-resilient landscapes

Ana Maria Monsalve Cuartas[1]
Ignacio Sanchez[2]
[1] Lisbon University. Agronomic Superior Institute. Portugal
[2] Francisco Jose Caldas University Colombia

Abstract: Indigenous Peoples and Local Communities own approximately half of native forests in Colombia. These forests are important to safeguard biodiversity, to address the challenge of climate change and to conserve local knowledge. They may further contribute to address the increasing disconnection between humans and forests. This disconnection is not physical as human societies depend on the sustainability of the provision of forest products and services. It is emotional and spiritual. We do not perceive forests as the amazing organisms that enable our life on earth. Most people identify forests as an inexhaustible object or resource that provides us with materials to satisfy our individual and collective needs. The profound lack of interest that many individuals of our species show towards the extraordinary kingdom of trees has led us to place such complex ecosystems on the same level as plastic bags: on the shelf of the useful but inert. Many indigenous communities from Colombia don't perceive forests this narrow way. However, this truth is very hard to understand by forest scientists and policy makers , they do not understand that indigenous communities have this perception.

Forest and people need for live in this earth five elements one of them is fire. The concept and management of fire in land owned by indigenous communities encompasses a spiritual dimension, where fire is interpreted as a spirit that can help design and build new forest spaces as heal and rebuild living beings.

This article is a reflexive and critical approach to understanding the fire knowledge base as well as the fire-related management practices in forests owned by three indigenous communities in Colombia. The analysis of the perceptions, knowledge and spiritual management of fire of three communities offers a unique opportunity to study the biophysical and social materialization of complex multidimensional relationships and processes involved in the management of fire in their forests. Moreover, it is influential to design forest programs that may integrate information about ecological, cultural, and social values as well as traditional knowledge of Indigenous Peoples and Local Communities and thus design resilient landscapes

Quantifying emissions from megafires: Securing carbon market funds for fuel treatments that reduce wildfire severity and improve forest resilience.

T1.16 Implementing fire-resilient landscapes

Thomas Buchholz[1]
Carrie Levine[1], David Schmidt[1], David Saah[1, 2]
[1] Spatial Informatics Group LLC, Pleasanton, California, USA
[2] Geospatial Analysis Lab, University of San Francisco, California, USA

Abstract: Fuel treatments such as mechanized thinnings or prescribed burns are an effective tool to reduce wildfire severity and contribute to fire-resilient landscapes. The need to scale up these fuel treatments across the western US and beyond is increasing and acknowledged by a large contingent of stakeholders. However, fuel treatments can cost up to several thousand of USD per hectare treated as they focus on the removal of smaller diameter trees and understory vegetation, reducing surface fuels through chipping, piling, prescribed fire, or a combination of these activities. Hence, funding remains a major challenge.

We present on a new initiative based on decades-long research on the greenhouse gas (GHG) emissions implications of fuel treatments: tapping into the carbon market through Reduced Emissions from Megafires (REM). In 2023, the Climate Action Reserve's (CAR) Climate Forward program, approved the REM forecasting methodology. This methodology provides a novel mechanism for funding forest health projects by quantifying GHG emission savings by reducing the risk of catastrophic wildfires. Under the REM protocol, emissions are forecasted for project areas with and without treatment (the baseline scenario). By comparing projected emissions in the baseline and project scenarios, we can estimate the impact of treatments on GHG emissions measured in metric tonnes of carbon dioxide equivalents. The quantification of reduced GHG emissions from fuel treatments under this methodology includes accounting for forest carbon, emissions from fires, carbon in wood products, and mobile emissions, both within the treatment area and within the fireshed.

This methodology also provides a capable analytical backdrop to effectively design fuel treatment placement and types across hundreds of thousands of hectares. We have developed a semi-automated process relying on open-source vegetation, topography, wildfire history, and weather data as well as growth & yield and wildfire behavior models to explore fuel treatment effectiveness not only in GHG emission reductions but other forest resilience metrics as well such as temporary or permanent vegetation type change following high-severity wildfire.

Our presentation will provide the audience with insights in the REM methodology itself as well as its capacity to build stakeholder consensus around fuel treatment allocations.

Spurring rural economies while reducing fire emissions through a targeted fuel reduction thinning program in the western United States

T1.16 Implementing fire-resilient landscapes

[2] North Carolina State University
[3] Michigan State University
[4] U.S. Environmental Protection Agency

Abstract: At 64%, the Federal Government is the largest forestland owner in the Western United States. These lands provide a wide range of ecosystem services including wildlife habitat, recreational opportunities, air and water filtration as well as providing forest products and jobs in local economies. They are also the source of considerable debate as to an appropriate management emphasis. Decades of fire suppression coupled with the substantial reduction in federal harvest levels of the has led to a steady buildup of fuels, an increase in forest density, as well as escalating fire, disease, and insect epidemics. Between 1987 and 2001 the volume of timber sold from national forests dropped some 90%, followed by a modest increase since then. Mortality has increased by 388.8% in the region to the point where eight of the eleven western states are now in a situation of emitting more CO_2 than they sequester thus contributing to our national emissions. Unfortunately, the reduction of federal harvest in the 1990’s led to a subsequent contraction in regional forest products processing capacity which indirectly affects the costs and thus management opportunities of such programs. This is exacerbated by the inability to utilize any removed material as merchantability often depends on that capacity infrastructure due to the long-haul distances in the West. This study seeks to inform policy makers and market participants about the potential effects of an expansion of federal harvest in the western U.S. on national greenhouse gas (GHG) accounts and rural economies. We use spatial partial equilibrium model to explore a set of scenarios based on expanding federal harvest in the region while simultaneously expanding mill capacity to utilize the removed material. For each scenario we evaluate changes in rural economies associated with transportation logistics and merchandizing of logs throughout the region at the various manufacturing facilities. We simultaneously track GHG accounts throughout the forest and forest sector supply chain.

Stakeholder participation in fire resilient forest management and restoration outcomes in the Western Himalayan Eco-region

T1.16 Implementing fire-resilient landscapes

Shruthi Gopirajan Andaladi Thekkethil[1]
Fabian Ewald Fassnacht[2], Sebastian Schmidtlein[3], Pawan Kumar Joshi[4, 5], Somidh Saha[1, 3]

[5] Special Centre for Disaster Research, Jawaharlal Nehru University, New Delhi 110067, India

Abstract: In the Western Himalayan Eco-region (WHER), communities have historically used forest fire to shape Socio-Ecological Systems (SES). However, forest fires under climate change and socio-economic transformation pose new challenges of repeated fires, increased annual burn area, and changes in fire season. Thereby threatening adaptive capacity of various forest stakeholders to resist and manage adverse fire impact. The knowledge of preparedness and adaptive capacity of the communities to forest fire is essential for improving resilience of Himalayan SESs to future scenarios of extreme fire events and related risks. Therefore, this study aims to understand drivers, factors and mechanisms affecting various stakeholders' participation and decision making in forest fire management vis-a-vis short-term and long-term actions in fire mitigation and restoration of damaged fire landscapes in Uttarakhand. Uttarakhand is one of the Western Himalayan states in India that is prone to multitude of socio-environmental risks. The majority of the forest fires in Uttarakhand arise out of human "actions and inactions". The state has a rich and complex forest management system, controlled by government departments and decentralised community forest management groups. The diversity in forest stakeholders creates a platform for potential cross and intra-stakeholder collaborations and conflicts in managing disturbed forest sites as forest fire impact is not restricted to human-made social boundaries of the forest. The existing literature has minimally investigated such complex social-ecological interactions in forest fire management in the Himalayan region. Often, fire, forest, and people are studied in silos, creating challenges in developing effective fire management policies. This study will employ the Social Ecological System Framework (SESF) and concepts of collective action to assess the multi-stakeholder perspectives. Geospatial analysis of the fire regime and expert interviews will be used for site selection. Further, various quantitative and qualitative research methods will be used to collect the perspectives of local and regional stakeholders and the preliminary results of the study will be available before July 2024. The outcomes of the study have manifold implications for further research and policy recommendation in developing indicators of resilience in fire prone SESs.

The role of nature-based fuel treatments in mitigating wildfire risk

T1.16 Implementing fire-resilient landscapes

Xiaorui Tian[1]
Xuezheng Zong[2], Xianli Wang[3]
[1] Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Key Laboratory of Forest Protection of National Forestry and Grassland Administration, Beijing, China
[2] Key Laboratory of Land Surface Pattern and Simulation, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing, China
[3] Northern Forestry Centre, Canadian Forest Service, Natural Resources Canada

Abstract: Climate change has intensified the seasonal severity rating (SSR) of fire seasons and led to more intense wildfires worldwide. Nature-based fuel treatments (NbFT) provide an ecologically friendly strategy for mitigating increasing wildfire risks and maintaining ecosystem functions; however, their design and effectiveness are still unclear under different SSR conditions. In this study, we proposed a framework to assess the wildfire risk of various SSR conditions in Southwest China. Using percentiles of the SSR index, we divided the 2000-2020 fire seasons into three scenarios: low ($\leq 25^{th}$), normal (25^{th} -75^{th}), and high ($\geq 75^{th}$). We developed 17 NbFT designs involving one spatial arrangement, three modes, four treatment intensities (%), and two treatment geometric shapes. These designs were then evaluated for their effectiveness in mitigating wildfire risk under the above three SSR scenarios. Our results showed that the SSR scenarios had a significant influence on wildfire risk. Compared with the normal SSR scenario, the high SSR scenario resulted in over 50% of the study area experiencing an increasing trend in wildfire risk. In contrast, 97.6% of the study area showed a decreasing trend in wildfire risk under the low SSR scenario. NbFT with belt-shape treatments outperformed those with block-shape treatments in mitigating wildfire risk when other parameters remained constant, and their effectiveness was boosted with increasing treatment intensity. The optimal NbFTs design was determined comprehensively under the three SSR scenarios to be fuel breaks with a density of 3.9 m/ha while treating 20% of the area in a belt shape. Using this design, the proportions of very high- risk areas would be reduced to less than 0.1% and 0.2% under the low- and normal- SSR scenarios, respectively, but this percentage would still be high at 10% under the high SSR scenario. Overall, the NbFT showed limited effectiveness in mitigating wildfire risk under high fire weather conditions even with the optimal design.

Use of near real-time satellite data in forests: Applications for wildfire purposes and development towards resilient landscapes

T1.16 Implementing fire-resilient landscapes

Marius Hauglin[1]
Ana María De Lera Garrido[1]
[1] Norwegian Institute of Bioeconomy Reasearch

Abstract: Technological advances and developments within the field of remote sensing and data processing have opened new possibilities for the utilization of satellite data. Frequently acquired satellite data can be used for monitoring and change detection to ensure maps correspond to the current situation on the ground. In the case of wildfire events, it can be crucial for first responders to have updated information that accurately represents the actual conditions of the forest and landscape. Also, monitoring the state and change in the forest and vegetation can help guide decisions in the separate phases of wildfire mitigation and prevention. In this study we have reviewed the use of open satellite data for near real-time applications in forests. We have tested near real-time change detection methods and evaluated these in a test area in boreal forest in Norway and on the Greek island of Lesvos. We have used openly available data from satellites – such as from the Copernicus program of the European Space Agency – and made updates to existing maps, based on changes automatically detected in the satellite imagery. Detection of changes such as clear cuts, new forest roads and areas with dead trees were tested, and this information was included in existing online maps, indicating the areas with such changes. We furthermore used the detected changes to update a remote sensing-based high resolution fuel map, which serves as basis for fire simulations and provides valuable information for fire risk assessments

We assessed the accuracy by comparing a selection of the automatically detected changes to field observations and reviewed the impact of updated information on applications for wildfire prevention and the development towards fire resilient landscapes.

What has happened to the uppermost soil layer after 5 years of fire occurrence?

T1.16 Implementing fire-resilient landscapes

[3] Université Paris-Saclay, Paris

Abstract: Fires regardless of their causes are one of the important factors that affect forest ecosystem functions via their effect on soil properties. The aim of this study was to understand the fire impact on soil chemical properties. Two similar stands of Pistachio-Almond in semi dry areas of Zagros forests were selected to estimate fire impact, one of them faced fire 5 years ago. The other one in the neighborhood was used as a control stand to compare results without burning. Soil samples were collected from 0-20 cm depth. Soil chemical properties including moisture, electrical conductivity, soil reaction (pH), organic carbon, organic matter, total nitrogen, available phosphorus, and potassium were measured by the standard soil analysis methods Results indicated some chemical properties values of soil decreased after fire including pH (2%), organic carbon (12%), organic matter (12%), total nitrogen (5%), potassium (4%), and available phosphorous (61%). While the value of soil electrical conductivity (28%) and moisture (17%) was more in the burnt stand than the control one after 5 years. Soil basal respiration did not show any big difference between burnt and unburnt soils. It seems that fire impacts in different ways on different soil properties but it is obvious that it takes a long time for the soil to recover from fire impacts.

Linus Mwangi[1], Beryn Otieno[1], Jane Njuguna[1], Mercy Gichora[1]
[1] Kenya Forestry Research Institute (KEFRI), P.O. Box 20412-00200, Nairobi- Kenya

Abstract: A research conservancy of the Forest Department was established in Kenya in 1934. This was absorbed in 1948 by the East African Agricultural and Forestry Organization (EAAFRO) and only came under Kenya Agricultural Research Institute (KARI) in 1981. In 1986, Kenya Forestry Research Institute (KEFRI) took over forestry research from KARI. In this study, a desktop review was undertaken of both published and grey literature on the subject of forest pests and diseases and the evolution of management options that have been followed in Kenya. Over the years, records indicate that Kenya's forestry systems have been threatened by several insect pests and pathogens since the dawn of plantation forestry early in the twentieth century, with some causing significant economic losses and limiting productivity. On exotic trees, the major exotic insect pests so far encountered include *Gonipterus scutellatus, Oemida gahani, Pineus boerneri, Cinara cupressivora, Leptocybe invasa, Thaumastocoris perigrinus* and *Glycapsis brimblecombei*. In a few cases, like that of pines and black wattle, indigenous defoliator insects have caused problems in exotic plantations but are eventually contained by local natural enemies. Local termites also attack and cause root damage to exotic tree seedlings, mostly in the ASAL areas. The major tree diseases encountered are caused by a mixture of exotic and indigenous agents. They include damping off in tree nurseries, transplant diseases, terminal crook on pines, Armillaria root rot, and a canker on *Cupressus macrocarpa* (which eventually had to be replaced by the more disease-tolerant *C. lusitanica*). Other notable tree diseases are Dothistroma needle blight caused by *Mycosphaerella pini,* Cankers on *Eucalyptus grandis* caused by *Chrysoporthe cubensis*, and Powdery mildews on Eucalypts. Integrated pest management is considered ethical and has been Kenya's preferred strategy for containing these challenges through a combination of cultural methods, pesticides, fungicides, biological control, and selection and breeding for resistance. There need to strengthen quarantine measures persists. We benefit from engagement of citizens in pest management strategies in Kenya's forestry systems and are eager to learn lessons about successful containment of various insect pests and diseases that have been recorded elsewhere.

A Strategy for Restoration of Lantana-Infested Forest Landscape in the State of Uttar Pradesh, India

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Dinesh Kumar[1]
[1] ICFRE-Forest Research Institute, Dehradun, India

Abstract: *Lantana camara* (commonly known as lantana) is one of the most serious invasive alien species in tropical and sub-tropical areas in India and other parts of the world. The species occurs in forests, pastures, agricultural areas, roadsides and vacant lands in varying densities. Research has led to the development of cut-rootstock method for uprooting it. In order to prevent re-emergence of lantana, the plants of other species must immediately occupy the place vacated by it. Pilot studies have been carried out in the past in Jim Corbett Tiger Reserve (Uttarakhand), Kalesar National Park (Haryana) and Satpura Tiger Reserve (Madhya Pradesh) where lantana was uprooted in demonstration plots of 2-5 hectares followed by planting of rooted ramets or clumps of native grass species or by broadcasting seed pellets of grass species. Planting of trees could involve greater cost than planting of grasses. Research findings are available on use of chemical and biological weed control measures for control of lantana in some areas in India and abroad. However, possibility of harm to non-target species necessitates site-specific research before largescale application of those measures.

The cost of rehabilitation of a lantana infested area would depend on forest cover and other site condition. A landscape-level rehabilitation strategy must consider several factors since the extent and intensity of lantana infestation in India are quite large and variable.

The author has proposed a strategy for restoration of lantana-infested forest landscape for the state of Uttar Pradesh, India. Four treatment models have been suggested in forest landscape for the purpose depending upon the density of forest cover. The models include a combination of uprooting, assisting natural regeneration, grass planting and tree planting based on site-specific factors such as presence of other vegetation, herbivory, anthropogenic disturbance, presence of dependent population, local support for protection, availability of funds, etc. Recommendation has also been made for utilisation of lantana biomass for making furniture, handicraft, briquettes, etc. to support livelihood of local inhabitants.

Advancements in the study of Xylella fastidiosa vectors: biology and biometrics of Philaenus italosignus juveniles.

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Matteo Bracalini[1]
Anita Nencioni[1], Sara Campigli[1], Guido Marchi[1], Domenico Rizzo[2], **Tiziana Panzavolta**[1]
[1] University of Florence, Department of Agriculture, Food, Environment and Forestry (DAGRI), Italy
[2] Laboratory of Phytopathological Diagnostics and Molecular Biology, Plant Protection Service of Tuscany, Italy

Abstract: In this study, we explored the biology and biometrics of the spittlebug *Philaenus italosignus* (PI) (Hemiptera: Aphrophoridae), one of the confirmed vectors of the quarantine phytopathogenic bacterium *Xylella fastidiosa* (XF). PI juveniles are known to have only one host, the lily *Asphodelus ramosus*, while the nymphs of *Philaenus spumarius* (PS), the most studied XF vector, are notoriously polyphagous. Indeed, a better understanding of these spittlebugs is key for early detection of XF.

In 2019 we first reported PI in Tuscany (Italy), nearby the outbreak area of Monte Argentario in which XF subsp. *multiplex*, was found mainly associated with Mediterranean scrub. Since then, we kept studying PI's biology intending to verify its overwintering stage and the duration of the preimaginal development. Lastly, we investigated the possibility of using biometric traits of PI juveniles as an identification tool.

Insect samples, both target (PI) and non-target (PS), included nymphs collected in 2022-2023. For all five instars the head's width was measured (500 specimens for each species). Finally, DNA tests were carried out using the PI-specific Sybr GREEN qPCR assay to verify the identity of a subsample of 80 nymphs.

Our observations showed that, in Tuscany, PI first instar nymphs are found on the lily already in December and, unlike PS, they overwinter. Thus, the duration of the preimaginal development covers a total of four months, with newly emerged adults appearing in April.

Our observations on the nymphs extended the current knowledge on PS biometrics, while providing original data on PI juveniles. Moreover, by comparing measurements we showed how each instar's size differs between the two species, PI nymphs being significantly larger. Finally, molecular tests validated our claim on PI biometrics: in no case, morphological and molecular analyses gave conflicting results.

In conclusion, the size of *Philaenus* nymphs may be used to discriminate both spittlebug species. The reliability of this trait and the new data on PI's biology will allow better monitoring of the ongoing XF emergency, both in agriculture and natural environments, also in view of the prolonged timeframe during which the bacterium may be transmitted to trees by the polyphagous PI adults.

Does the immigration country determine the further spread of forest pathogens in Europe?

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Alberto Santini[1]
Luisa Ghelardini[2]
[1] C.N.R. Institute for Sustainable Plant Protection, Via Madonna del Piano, 10, 50019 Sesto fiorentino (FI), Italy e-mail alberto.santini@cnr.it
[2] University of Florence, Department of Agricultural, Food, Environmental and Forest Sciences and Technologies (DAGRI), Piazzale delle Cascine 18, 50144 Firenze,Italy e-mail luisa.ghelardini@unifi.it

Abstract: In previous works, present and historical pathways of introduction of invasive forest pathogens (IFPs) into Europe have been studied. The main means of introduction is trade of live plants which, especially in Europe, is not strictly regulated and even entry of potted plants may be allowed. IFPs enter as ‘contaminants’ or ‘stowaway’, *i.e.*, with commodities to which the pathogen is or is not biologically connected, respectively.

When plant commodities, and the organisms they harbor, cross the border, it is common that the port of entry does not correspond to the final destination: for example, most plants for planting enter Europe through the ports of Rotterdam (NL) or Antwerp (BE), but they may be immediately transported elsewhere or grown locally for a period of time and then traded abroad. In this study, based on the European IFPs database and assuming that the country of introduction corresponds to the first report country we analyzed the spread in Europe of some historical and present IFPs to discriminate whether a country-to-country pattern of spread may be identified and whether this pattern has changed over time. This information may be relevant to identify intra-European diffusion networks and take effective action on risk management in the future.

Efficacy of insecticide aerial spraying programs to reduce tree mortality during a spruce budworm outbreak (1967–1992) in the province of Quebec

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Alvaro Fuentealba[1]
Alain Dupont[2], Roberto Quezada-Garcia[1], Éric Bauce[1]
[1] Laval University
[2] Société de Protection des Forêts contre les Insectes et Maladies (SOPFIM)

Abstract: Spruce budworm (*Choristoneura fumiferana*) is the most important pest of conifer forests in North America. The main approach for protecting forests against this defoliator is aerial spraying of insecticides. Despite the crucial role of aerial insecticide applications in the global forest protection strategy, little is known about its real effects on tree mortality or the stand characteristics that may affect its long-term efficacy. We evaluated the efficacy of the protection program that was implemented during the 1967–1992 outbreak in Quebec in tree mortality reduction. We established 422 plots in eastern Quebec based upon the following parameters: insecticide application; stand composition; drainage quality; and stand age. Unprotected plots exhibited 18 to 44% greater tree mortality than protected plots. Insecticide efficacy was affected by drainage condition. For example, protected plots that were established on sites with poor quality drainage exhibited 67.53% lower balsam fir (*Abies balsamea*) mortality than did unprotected plots. Insecticide application had no substantial effect on spruce mortality (4.63 and 4.32% white spruce (*Picea glauca*) and black spruce (*P. mariana*) mortality, respectively). A lack of strong treatment effects of spraying operations on spruce mortality may simply reflect the fact that the protection program in Quebec was designed to protect balsam fir. As a result, the dosage or timing of insecticide applications might not have been optimal to protect spruce trees. Spruce characteristics may also play a role in explaining the aforementioned response. Spruce species normally sustain less defoliation than balsam fir because of their stronger capacity to re-foliate after defoliation, late phenology, and toxic phytochemistry. Our study also found that the return on protection investment in terms of mortality reduction may decline after 7 years of aerial spraying. Furthermore, we found that it is not necessary to achieve the target protection goal (50% foliage protection) every year to reduce host tree mortality. Our results may be useful for decision-makers to decide where and when to apply insecticides during a spruce budworm outbreak and may help to determine the appropriateness of treating the forest on an annual basis depending upon the protection goals.

Forest pest management through a co-operative research consortium

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Sam Van Holsbeeck[1]
[1] University of the Sunshine Coast, Forest Research Institute, Australia

Abstract: Damaging pests and diseases pose significant threats to the two million hectares of plantation forests in Australia and the cost of re-establishment due to pest attacks is significant. Access to current effective pesticides to mitigate many of these threats remains challenging in a small pesticide market, a climate of regulatory and economic changes and imposed certification requirements. This certification requires that forest managers protect forests from damaging pests while at the same time reducing the use and exposure to highly hazardous pesticides (HHPs). About 99% of the plantation forestry pesticide spend in Australia is on herbicides with only about 1% on other products, highlighting the comparatively limited options available to control damaging pests and diseases. In 2018, the Forest Pest Management (FPM) Research Consortium was established to maintain and increase the productive capacity of the Australian forest industry by reducing the reliance on HHPs, instead shifting usage to environmentally and socially acceptable control options for pests and diseases. The Consortium is a membership-based co-operative research effort, including 19 forest plantation growers and pesticide manufacturers, that ensures the continued availability of effective and safe control options for pests and diseases. The project has conducted need-based screening and operational trials since March 2018 in response to regulatory, economic and societal trends, and supports ~90% of the forest plantation industry in Australia. The FPM Research Consortium delivers whole-of-industry outcomes for considerable overall value at a fraction of the cost that individual enterprises would otherwise be required to expend. Outcomes include i) compliance with relevant weed or pest legislation and providing expert advice to regulators and certification bodies, and ii) protecting the integrity of adjacent land uses and its users through the development of advanced application technologies to reduce spray drift and human exposure.

Forest Stewardship Council – 30 years of contribution to sustainable forest management in Sweden

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Henrik von Stedingk[1]
[1] FSC Sweden

Abstract: The Forest Stewardship Council have been a tool for sustainable forest management since the foundation in 1994. One means has been the governance system based on stakeholder involvement and membership with engagement from social, economic, and environmental stakeholders. Another means has been the forest management certification, with a global framework and nationally adapted requirements. The third means is the verification system for the full value chain and a product label facilitating the market uptake and the demand for FSC material and FSC certified products.

Sweden was the first country to have a national Forest stewardship standard in 1998. A large proportion of the Swedish forests got certified early and today ca 55 % of the productive forest is certified. The FSC certification has since been a major factor in setting new practices for forest management in Sweden. The protection of Woodland key Habitats, the requirement to have 10 percentage set-asides and/or adapted management for social or environmental values, and the inclusion of prescribed burning for larger forest management units, are examples of changed practices with strong effects for biodiversity in the Swedish forest landscape.

Another example is the ban of chemical pesticides from the Swedish forestry. This was the result of FSC promoting research and the development of non-chemical treatment of seedlings to hinder damage from large pine weevil as well as encouraging integrated pest management to prevent damage from European spruce bark beetle.

FSC certification also have a strong social dimension with requirement for all workers to have collective agreements, support of the rights for the reindeer herding Sami population as well as requiring engagement with affected local stakeholders.

There are learnings to be drawn from the experiences, challenges, and development of the FSC certification scheme, how the stakeholders have been engaging in writing the standards, and how FSC certification has been a driver for change of forest management practices in Sweden.

Historical shifts in government programs for spruce budworm outbreaks in Canada

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Deepa Pureswaran[1]
Christopher Edge[1]
[1] Canadian Forest Service, Atlantic Forestry Centre, Fredericton, NB, Canada

Abstract: Spruce budworm populations are characterised by large-scale outbreaks, punctuated by periods where the insect appears to undergo local extinction. Outbreaks occur with a predictable frequency of ~30-40 years in eastern Canada, and cause widespread mortality of balsam fir and spruce. Mortality losses in eastern Canada during the 1910-1920 outbreak was estimated to be 720 million m^3. Similarly, losses in Quebec between 1967 and 1992 were ~238 million m^3 with a commercial value of $12.5 billion. When the use of spruce and balsam fir as sawlogs and pulpwood, respectively, began in the early 20th century, uncontrolled outbreaks became an economic threat to timber supply. During the outbreak of the 1940s, forest protection became a priority for some provincial governments that began large scale pesticide application programs. For example, between 1952 and 1993 97% of 6.2 million ha of forested lands in New Brunswick Canada were treated with insecticide. During this program 12 insecticides were applied as aerial sprays. The four more commonly used were DDT (1952-1968), phosphamidon (1963-1967), fenitrothion (1968-1993) and aminocarb (1970-1987). Opposition from experts, citizens and citizen groups contributed to research efforts to develop silvicultural methods to reduce stand vulnerability, behavioural and metabolic chemicals as well as naturally occurring insect pathogens to replace insecticides. Today, two insecticides are used in control programs. In 1973, broad use of *Bacillus thuringiensis* var Kurstaki (Btk), a pathogen of lepidopteran larvae, began as a foliage protection strategy to target feeding larvae in high value stands. In the early 1990s Tebufenozide, an analogue of the moulting hormone, ecdysone, was developed and is approved for use in Canada. Mating disruption from overloading male olfactory senses by spraying sex pheromone has been tested without success for practical use. Widespread moth dispersal from the current outbreak (2006-present) in Quebec into New Brunswick has put other regions at risk. An early intervention strategy (EIS), is being tested in New Brunswick since 2014 to suppress infestation hotspots with Btk and quell population growth as soon as populations begin to rise. Following eight years of tests, this strategy appears to be effective in mitigating the spread of the outbreak.

i-Tree Pest Predictor: a "crystal ball" to foretell future forest invaders?

[14] University of Maine, Orono, ME, USA

Abstract: All around the world, there has been an interest in fostering interconnectedness among continents that has led to rising rates of international biotic interchange that threaten the health and resilience of our global forest ecosystems. Though most result in little ecological impact, introduced insects pose a significant threat to forest ecosystems due to the small, but mighty, proportion that cause significant impacts, such as regional host mortality or functional host extinction. Robust forecasts of insects that are likely to cause substantial impacts have largely remained elusive, though they would improve biosecurity measures and could help prevent the introduction of some potentially catastrophic insect species akin to the emerald ash borer (*Agrilus planipennis*) and hemlock woolly adelgid (*Adelges tsugae*) in eastern North America. For this study, we used data from introduced insects currently established in North American forests to identify drivers of impact and develop models and a tool that can predict impact of insects that have not yet arrived in North America. We considered four submodels – (i) insect traits, (ii) host traits, (iii) host evolutionary history, and (iv) insect evolutionary history – and found that the significant submodels varied by insect host type and breadth but, overall, evolutionary history of the native and novel hosts was significant irrespective of insect host type and breadth. The significant submodels were consolidated into five composite models and built into an i-Tree Pest Predictor tool that can help forecast which non-native insects have a high probability of causing tree mortality on 360+ hardwood and 50+ conifer trees native to North America should they establish. Ultimately, the tool, now available through i-Tree, is being used to develop a risky insects database. Along with sentinel trees and other risk assessments, this tool will help predict the next high-impact insect invaders in North American forests before they invade, which will aid decision-making and help provide directed feedback to improve biosecurity measures. Similar tools can be developed for other countries or continents to better predict the risk that non-native forest insects pose to forest ecosystems around the world.

Learning from the past to better inform the future – interdisciplinary and transdisciplinary approaches to forest health

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Mariella Marzano[1]
Andrew Leibhold[2], Maartje Klapwijk[3]

[3] SLU, Inst för Ekologi, Box 7044 750 07 UPPSALA

Abstract: Biological invasions leave long-term (and often irreversible) landscape legacies with climate change and current global political and economic issues only serving to exacerbate the biosecurity crisis. Humans are a key driver in the movement and introduction of tree pests and diseases but also part of management solutions. A holistic and interdisciplinary approach to promoting forest health requires multiple disciplines and perspectives and acknowledgement that different societies will favour specific approaches, but we can learn from each other. There will be a number of factors affecting biosecurity decision-making of different actors including their values and motivations, how risks are perceived and acted upon and the push and pull of existing regulatory and economic contexts. Understanding these contextual factors and historical legacy is key to any future attempts to improve biosecurity policy and practice. We provide an introduction to the session and examples from across the globe of the benefits of bringing together different disciplinary and experiential expertise for addressing biosecurity threats in ethical, sustainable and socially just directions. We end with a call for collaborative and inclusive approaches to sharing knowledge and practices and for interdisciplinary or transdisciplinary processes to be considered essential by all key players in forest health.

New challenges, new TRIAD: investigating zoning-based forestry with functional enrichment to foster forest resilience

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Clement Hardy[1]
Christian Messier[1], Yan Boulanger[2], Dominic Cyr[3], Elise Filotas[4]
[1] Département des Sciences Biologiques, Université du Québec à Montréal
[2] Ressources Naturelles Canada, Canadian Forest Service, Centre de Foresterie des Laurentides
[3] Centre d'étude de la forêt, Université du Québec à Montréal
[4] Département des Sciences et des Technologies de la TELUQ, Université du Québec

Abstract: TRIAD forest management was proposed 30 years ago to reconcile conservation and exploitation by dividing the landscape into three types of zones with specific management goals: protected areas, intensive timber production areas, and extensive production areas. More recently, numerous studies in forest ecology have emphasized the importance of increasing forest resilience to uncertain future conditions by maximizing their functional diversity. In this perspective, we revisited the TRIAD management approach to add a resilience component. Using the LANDIS-II forest landscape simulation model, we tested novel TRIAD+ scenarios designed to improve forest resilience in the face of extreme disturbance events. To that end, we simulated a 4 million hectare landscape in the Mauricie region of Quebec for 200 years, with one of three extreme disturbances happening at t =100: fire, drought, or an insect outbreak. We monitored resulting changes in mature wood biomass across the landscape, and the resilience of forests impacted by the extreme disturbance via three measures: the resistance, net change and recovery time of their mature biomass and functional diversity. We then assigned to each simulation a unique combination of one of 4 management scenarios and 3 climate scenarios. The TRIAD+ management scenario used plantations to increase the functional diversity of the forests following cuts in the "extensive" zones of TRIAD. We also simulated the "classic" TRIAD and two "Business-As-Usual" (BAU) scenarios, one of which included "functional" plantations as in TRIAD+. The climate scenarios consisted of a Baseline, RCP 4.5 and RCP 8.5 scenario, impacting species growth and fire frequency in the landscape.

The new TRIAD+ resulted in a good compromise, improving the resilience, functional diversity and mature biomass of the landscape compared to the classic TRIAD and BAU without plantations, while drastically increasing the surface of protected forests. However, these improvements were relatively small, and our variables were mainly influenced by changes due to climate. As such, our study revealed important insights in the design of future forest management strategies, the practicality and efficacy of functional enrichment to improve forest resilience, and the urgent need to account for small-scale interactions at the stand level in Forest Landscape Models.

Retrospective analyses of weather-related extreme events, large-scale disturbances, and silvicultural strategies

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Alexandra Wehnert[1]
Mathias Deutsch[2], Franka Huth[1], Tobias Reeh[2], Ingolf Profft[3]
[1] TU Dresden, Institute of Silviculture and Forest Protection, Chair of Silviculture, Germany
[2] Georg-August-Universität Göttingen, Institute of Geography, Germany
[3] Forestry Research and Competence Centre Gotha, Germany

Abstract: Germany's forests have been characterized by intensive human use for centuries. This is still evident today in the tree species composition and the often uniform forest structures. Increasingly, forests are extraordinarily stressed by climatic development. Especially in spruce-dominated low mountain regions, large-scale disturbances occur due to storms, wet snow, and drought, which are additionally exacerbated by bark beetle calamities. With regulated forestry in the 19th century, precise documentation of forest management from planning to utilization began in Germany, so that the occurrence of large-scale disturbances and damages was also recorded. From today's perspective, these precise records of forestry operations form an extraordinary historical fund. In addition, meteorological measuring stations were established in many regions for the continuous recording of the climate and for weather forecasting. The current disturbances in forests caused by weather extremes have reached the most extreme proportions in the low mountain regions, so the question arises as to which silvicultural experiences and technical possibilities have been classified as particularly successful for reforestation in historical retrospect.

Our research project analyzes the silvicultural handling of disturbances in the forests of the model regions - Saxon Ore Mountains and Thuringian Forest - for a period of 200 years based on extensive regional archival records. We link the records of the meteorological measuring stations with the forestry records.

A look at history confirms that the spruce stands of the low mountain regions were particularly frequently and extensively damaged by climatic and anthropogenic factors. In both low mountain regions, for example, extreme storm events in 1868, 1876, 1903, and 1946 or the occurrence of drought years in 1800, 1893, 1904, and 1911 have been recorded. Despite enormous recurring damage and sound knowledge of the causes of disturbances, there was no consistent move away from pure spruce stand management. Our research demonstrates the early application of silvicultural treatment strategies such as tree species selection, specific regeneration procedures, optimization of measures via spatial order, and management of deadwood, associated vegetation, or pioneer tree species. These measures are frequently discussed even under current conditions.

Abstract: Populations of Sirex woodwasp (*Sirex noctilio* (Hymenoptera: Siricidae)) on *Pinus* spp. have been largely managed throughout their non-native ranges in the Southern Hemisphere using a combination of classical (parasitoid wasps, particularly *Ibalia leucospoides* (Hymenoptera: Ibaliidae)) and augmentative (the bicyclic nematode *Deladenus siricidicola* (Tylenchida: Neotylenchidae)) biological control. Performance of this nematode can be impacted by biotic interactions with the Sirex symbiotic fungus (*Amylostereum areolatum* (Russulales: Amylostereaceae)) upon which it feeds, with bluestain fungi vectored by bark beetles, as well as by temperature, moisture, nematode inoculation technique, and pine taxon. These factors, as well as a lack of genetic diversity among biocontrol populations globally, and the legacy of a "defective strain" that arose through continuous mass rearing in Australia, are thought to have additionally contributed to limitations in achieving consistent parasitism rates by the nematode across Southern Hemisphere regions.

Here, we discuss the fascinating history of the Sirex biocontrol program pioneered in Australia in the 1960s and 70s, that was subsequently disrupted by the emergence of the defective strain in the late 1980s. Nematodes then collected from an original release site in Kamona, Tasmania, returned virulence to the program, and these were adopted by South Africa and several countries in South America. This shared resource, and possible inbreeding in culture, contributed to reportedly homozygous populations across the Southern Hemisphere, and concerns for the sustainability of the biocontrol program. More recent studies have uncovered unexpected diversity in *D. siricidicola* populations in Australia and New Zealand, including the identification of a dominant cryptic field strain (Lineage D) in background Sirex populations.

The Kamona strain has been used as an augmentative biocontrol agent, while Lineage D has behaved more as a classical biocontrol agent in Australia; having possibly originated from initial Australian releases in the 1970s or by accidental introduction via infected Sirex. It was confirmed as a sterilising strain, and has a higher reproductive rate than Kamona, and is being incorporated into release programs in Australia and South Africa. The potential of Lineage D to improve biological control of *S. noctilio* illustrates the value of characterizing the applied molecular ecology in biological control systems.

The southern pine beetle monitoring and forecast team -- a community success since 1988

T1.17 Learning from the past to better inform the future: integrated approaches to increase forest health and resilience

Matthew Ayres[1]

[6] Maryland Institute College of Art, Baltimore, MD USA

Abstract: The southern pine beetle (SPB), *Dendroctonus frontalis* is among the most naturally aggressive tree-killing insects in the world. In its native regions of southeastern USA and Mesoamerica, SPB displays episodic epidemics that can kill native pines within thousands of km^2. Direct costs to forest industry are in billions of USD. Indirect effects on forests and people are profound. In 1988, Ron Billings, Texas Forest Service, organized a network of forest health professionals to sample the abundance of SPB and its specialized predator in spring with pheromone-baited traps and a common protocol. The data were mailed to Ron, who generated forecasts of outbreak risk for the participating forest areas. The forecasts were valued by participants then and now. As of 2022, even with none of the original people still active, and with no centralized financial support, the team had grown to hundreds of cooperators from dozens of state and federal institutions representing 269 forest management areas in 12 states. Now, individual cooperators enter trapping data into a cloud-based GIS system, where it is swept into www.spbpredict.com, connected with previous abundance estimates, and used to predict the probability of an SPB epidemic for each forest area in the coming summer. The growing database is publicly available and the model is open source. The system lends itself to continual improvement as knowledge of SPB population dynamics grows and data accumulate. Since inception, the model has evolved from one that emphasized cyclical dynamics due to predator-prey interactions to one that postulates alternative states of low and high abundance separated by an escape threshold. The statistical model is a zero-inflated Poisson, which matches the theoretical model of alternate states. A practical implication of there being an escape threshold is that suppression will be most effective early in a nascent outbreak, which enhances the value of short-term forecasts. Among the challenges is how to communicate and interpret forecasts that describe a statistical distribution of possible outcomes rather than predicting a specific result. A broad benefit has been to promote constructive discussions of SPB biology and management among diverse community members who bring different knowledge and perspectives.

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

A methodology to assess atypical forest stand dynamics: an application in the temperate forest of southern Quebec

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Abstract: Global changes create specific conditions that most often lead to abrupt responses of the ecosystems that, in some cases, result in an ecosystem collapse (EC). This phenomenon occurs when an ecosystem changes drastically in terms of its composition, structure and function. A major challenge for current forest management is the lack of quantitative measures required to detect the occurrence of EC. We present here a new methodological approach to quantify the EC events that have occurred over the last 50 years in the temperate forest of Quebec, using the permanent sample plots (PSPs) dating from 1970. Based on transition vectors expressing changes in the composition, the structure and the function of the PEPs, we identified trajectories which are representative of the recurrent forest dynamics, and are specific to each of the most important ecological types of temperate hardwood forest. Then, these trajectories are used to identify divergent trajectories that represent either stagnation or EC. We present an application of this approach to the case of mesic maple stands (FE3). Our findings highlight that in the recent decades, some ecosystems tend to diverge more from the trajectories of the recurrent dynamics suggesting a loss of the ecosystem identity. The tools developed by this approach can be used to guide management and conservation actions in order to maintain the identity of forests as these are subjected to changing environmental conditions.

Keywords: Global change, temperate forest, forest ecosystems, ecosystem collapse, stagnation, permanent sample plots, recurrent dynamics, divergent trajectories.

Agua Salud: A long-term Research Initiative in Panama

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Jefferson Hall[1]
Robert Stallard[1]
[1] Smithsonian Tropical Research Institute

Abstract: Long term research sites are critical to understanding global change as they allow researchers to interpret changes in reference to historical baselines and capture the effects of severe weather events like floods and droughts, events most likely to affect forest dynamics. The Smithsonian Tropical Research Institute (STRI) recently celebrated its 100-year anniversary in Panama. Under the leadership of Ira Rubinoff, STRI initiated and has maintained a tradition of long-term research sites, watersheds, networks, and plots, some for more than 40 years. The Agua Salud Project, in the center of the Panama Canal Watershed, studies the ecosystem services provided by tropical forests and how they change with land use and climate change. The project leverages basic, use-inspired, applied research, and natural history observations to address broad research questions related to land and forest management; silvicultural interventions include several forest restoration treatments targeting timber yields as well as managing for other ecosystem services. Agua Salud celebrated its 15th year of a proposed 40 plus year project in 2023. Unlike other long-term research and monitoring programs at STRI, Agua Salud is almost entirely dependent upon external resources secured through fund raising. Its core budget necessary to "keep the lights on" is $225,000 a year but could absorb over $2 million annually were it to be used to its full research potential.

In this talk we will discuss the Agua Salud experimental design and how we have leveraged extreme events and changing research emphasis towards mitigating the worst effects of global change to incorporate new research directions while still working to address the original long-term goals of the project. The necessity to remake, refocus, and repackage research questions that can be addressed in shorter time periods that will attract funders requires a full-time scientist overseeing management and the project vision, something not always recognized as valuable in the scientific community.

Digging into tree and stand dynamics: benefits from long-term yield trials – current and future perspectives

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Enno Uhl[1, 2]
Hans Pretzsch[1]
[1] Technical University of Munich, TUM School of Life Sciences, Chair of Forest Growth and Yield Science
[2] Bavarian State Institute of Forestry

Abstract: Diverse data sources facilitate the understanding of forest ecosystem functioning and development of best management options. Among them, long term yield experiments, historically forming the nucleous of systematic forest science, provide specific advantages when questions concerning tree and stand level development affected by the interaction between environment and management activities are addressed. The presentation examplarily highlights currently emerging issues in forest ecology which are dependent on long-term observations to be solved. We show how information from unmanaged plots provide insights into maximum stand density development. Maximum stand density translates into density-productivity relations along a density reduction gradient, including mortality and prethinnings, which support the assessment of long-term growth relations between species and provenances. This is a relevant asset, when it comes to both, the decision about the most suitable and resilient species and to evaluate the effect of management activities on growth dynamics and resilience. We then emphasise the benefit of long-term observations for quantifying and understanding shifts in growth dynamics in the frame of changing environments. Lastly, we present an innovative plot design for mixed species stands that build upon the lessons learned during decades of managing long-term yield experiments. The necessity of preserving existing long-term experiments, and sustaining the scope and monitoring will be discussed.

Effect of silvicultural itineraries with contrasting objective density on forest processes to mitigate soil water deficit

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Marion Jourdan[1]
Damien Bonal[1], Nathalie Breda[1], François Lebourgeois[1], Ingrid Seynave[1]
[1] Université de Lorraine, AgroParisTech, INRAE Silva, Nancy, France

Abstract: European forests are subject to climate change with uncertain consequences. Therefore, it becomes as uncertain to predict wood production, especially for not common silvicultural practices. For example, one of adaptation option is to achieve lower objective density, to reduce evapotranspiration and precipitation interception. This mitigate soil water deficit and to increase available water for remaining trees in pedoclimatic context where water is already a limiting factor. However, these managements with lower density and reduced leaf area index raise questions about impact on ecosystem functioning or wood quality. It is becoming urgent to focus on this type of management to assess their relevance, their real potential and their limits.

In our work, we chose to study the effect of silvicultural practices with contrasting objective densities on tree transpiration and carbon storage in sessile oak (*Quercus petraea*) and Douglas-fir (*Pseudotsuga menziesii*) stands. We focus on three contrasting densities which will allow us to understand the effect of increasing competition on tree and stand functioning. First, stand leaf area index is determined. Then, tree transpiration is estimated thank to sap flow, measured with Granier sensors during early summer season. Finally, we study carbon storage through non-structural carbohydrates concentration, in three compartments, at different times in the growing season. So we can estimate carbon allocation to storage function according to forest management, at tree and at stand scales.

We work on GIS Coop networks: long term silvicultural experimental French networks in regular and heterogenous forest management systems. For 30 years GIS Coop manages 1200 plots exposed to highly contrasted stand density regimes, from open growth to self-thinning, for understanding stands dynamics for new forestry practices under a changing environment. In our study the added question is: how decreasing objective density modifies stand leaf area index, tree transpiration and carbon storage? Specific data will be collected on 2 sites, in pure and even-aged Douglas fir and sessile oak stand. We expect a decreasing stand evapotranspiration and rainfall interception with decreasing density, and an increasing carbon storage with decreasing stand density, thank to hydric stress release, but not especially a difference in carbon allocation.

Exploring the relevance of the Nelder wheels design for forest research: A case study of Pinus species interaction

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

IRENE RUANO[1, 2]
AITOR VÁZQUEZ VELOSO[1, 2], FELIPE BRAVO[1, 2]
[1] University Institute for Research in Sustainable Forest Management (iuFOR), University of Valladolid, Avda. Madrid 57, 34004 Palencia, Spain
[2] Department of Plant Production and Forest Resources, E.T.S. of Agriculture Engineering, Universidad de Valladolid, Palencia, Spain

Abstract: The Nelder wheels design, originally developed for studying spacing in horticultural crops, has regained interest in forest research due to advancements in computationally affordable methods for analyzing mixed models and spatial statistics. This study examines the applicability of the Nelder wheels design to insight on intra- and inter-specific interactions among two Mediterranean pines (*Pinus pinaster* and *Pinus halepensis)* seedlings.

The experimental setup consisted of five Nelder wheels planted in Palencia, northern Spain, in 2013. This design allowed the examination of ten density levels, ranging from 1000 trees/ha to 80000 trees/ha, within a relatively small area (less than 1 ha), with the two species intercalated to create diverse mixture levels.

The advantages and disadvantages of the Nelder wheel design are evaluated, with particular attention to addressing the challenge of mortality and its impact on density analysis. Various solutions proposed by researchers to mitigate the impact of plant mortality on the experimental design are discussed, including the use of Voronoi diagrams to recalculate growing space and density.

The study also examines the survival, growth, and biomass production of the planted seedlings. Statistical models, such as Cox models, binomial logistic regressions, and mixed models, were employed to analyze the data. Findings from the study highlight the potential of the Nelder wheel design in capturing species interactions and biomass dynamics. *Pinus halepensis* exhibited higher survival rates and growth, while the mixture effects of species require further investigation to uncover the complex competition and facilitation equilibrium. Under high densities, competition and facilitation interactions were observed, with higher survival rates but reduced growth. Notably, density significantly influenced biomass dynamics for *Pinus halepensis*, with lower densities leading to higher total biomass increments but an increased proportion of root biomass compared to aboveground biomass.

In conclusion, the Nelder wheel design proves to be a valuable tool for investigating species interactions and biomass dynamics in forest research. Its ability to accommodate various density levels within a limited space offers insights into forest regeneration patterns and management strategies.

Forest conversion with beech – Back the wrong horse?

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Abstract: The summer drought in 2018/19 in Central Europe led to a massive decline in the vitality of European beech (Fagus sylvatica). Until now, European beech is the main tree species of many forest conversion programmes. Understandably, the forest administrations are very concerned about beech dieback. As a result, we want to detect the potential of European beech under rising temperature. Therefore, we use many long-term experimental plots in Germany with more than 70 years of observation. We analyze the amount of removed beech trees and the reason of removal. Based on a broad site and age gradient, we investigate the following research questions: 1. How does the amount and the proportion of removed trees changed over the time, separated by human-made thinning and natural mortality. 2. What is the influence of climatic conditions? 3. What influence does the competition have? Based on the results, we discuss possible silvicultural strategies for dealing with beech under climate change.

From evidence into practice – case Finland

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Harri Mäkinen[1]
Saija Huuskonen[1]
[1] Natural Resources Institute Finland

Abstract: The annual growth of the forests of Finland has more than doubled in less than a century. While the environment-induced increment increase is substantial, a considerably larger increase representing 2/3 of the change is attributed to growing stock volume and forest structure. They both have changed over time due to efficient forest management and new silvicultural regimes, elaborated based on long-term field experiments.

The earliest long-term plots and experiments were installed in the 1920s, before statistical thinking, to provide data on forest dynamics and for building yield tables. Some of the observational plots dating back to these days are still being monitored. Beginning from the 1960s, new types of experiments were established including plots with different thinning intensities as well as unthinned reference plots. The obtained data have been used for studying forest ecology and management, as well as developing silvicultural guidelines, models and decision support tools. In addition to the original aim of intensifying wood production, the long-term records on tree and stand characteristics have provided evidence on wood properties, mortality, woody decomposition and carbon sequestration, among other things.

In times of scarce resources, several experiments have been considered too expensive, outdated, or abandoned due to damage and land use or owner change. On top of that, transition to research projects lasting a few years makes long-term maintenance of the experiments challenging, not to mention establishing new ones. However, short-term projects on changing fashion topics have provided supplementary resources to dwindling basic institutional funding to maintain the experiments in time spans of decades or even century. Despite all the challenges, we still preserve a unique set of long-term experiments delivering information on retrospective changes in structure and functioning of managed and unmanages stands.

From fuel wood production to climate change mitigation – expected and unexpected answers from long-term forest experiments in Austria

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Thomas Ledermann[1]

[1] Austrian Research Centre for Forests (BFW), Department of Forest Growth, Silviculture and Genetics, Forest Growth Unit, Vienna, Austria

Abstract: The Austrian Research Centre for Forests (BFW) was founded in 1874 and has a long tradition in the establishment and maintenance of long-term forest experiments. At that time the experiments were mainly comprised of thinning trials in Norway spruce (Picea abies [L.] Karst.) and common beech (Fagus sylvatica [L.]) in order to study total volume production with regard to stand density. In 1892 a spacing experiment in Norway spruce was established at "Hauersteig" and measured for more than 100 years. The first results of this spacing trial were published in 1974 having a revolutionary effect on the initial spacing of newly planted stands. In 1969 the European stem number experiment was established in 14 European countries and coordinated by the International Union of Forest Research Organizations (IUFRO). In Austria this experiment was observed until 2016. Finally, at the beginning of the 1990s, a set of 5 spacing trials with cloned plant material was established in Austria. All these experiments can be considered as the core experiments of the Forest Growth Unit of BFW. They are restricted to Norway spruce, which is currently the most important tree species in Austria. In total the Forest Growth Unit of BFW is currently running 67 long-term forest experiments addressing various research questions.

The above mentioned experiments were selected because they clearly reflect how research questions evolved over a time span of approximately 100 years. Furthermore, they are imposing examples of the value and benefits that long-term experiments can have for unexpected and suddenly emerging research questions. Specifically, this contribution will show (i) how the data were used for the validation of an individual-tree growth model, (ii) how the data were used for the development of biomass equations, (iii) how the data were used for economic analyses to support decision making of forest managers, (iv) how timing and severity of thinning operations determine the vulnerability of forest stands against storm and snow damage, and (v) how wide spacing afforestation as well as thinning operations affect carbon storage and carbon sequestration of stands of Norway spruce.

Growth and yield model calibration and evaluation: the role of long-term silviculture experiment data in British Columbia, Canada

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Catherine Bealle Statland[1]
James Goudie[2], Ian Cameron[3]
[1] British Columbia Ministry of Forests, Forest Analysis and Inventory, Canada
[2] Associate of Azura Formetrics Ltd., Canada
[3] Azura Formetrics Ltd., Canada

Abstract: Since the 1970s, the Province of British Columbia (BC) has invested many resources in the design and development of the Tree and Stand Simulator (TASS), its primary growth and yield model for projecting the dynamics of regenerated and silviculturally treated forest stands. Crucial to this program has been the availability of remeasured data from long-term experiments focusing on species selection, espacement, thinning, realized genetic gain, forest health and provenance which have been established and persistently maintained by a succession of committed research staff over the years, both within BC and beyond. The TASS component functions governing height increment, bole area and volume increment, wood quality attributes and crown growth are parameterized for each tree species using data collected through the destructive analysis of stems and crowns and other measurements of individual tree attributes. In a subsequent phase of calibration, key coefficients related to volume growth and mortality are re-estimated so that the simulated trends in volume and mortality conform to the magnitude and patterns of a set of guide curves for different stand densities in each species. These guide curves are a synthesis of the stand-level trends in volume growth and mortality observed in espacement trials and other growth and yield experiments. Therefore, it is highly beneficial for these field installations to be maintained as long as possible, despite the challenges. This presentation will demonstrate various approaches to generating these benchmarks. Beyond calibration, experimental installations in stand treatments continue to support evaluation of model response to thinning, pruning, fertilization, and variable retention harvest patterns, as well as the development of modules for simulating the impacts of genetic selection, forest health agents and climate change.

Influence of stand composition and thinning on drought resilience in mixed forests

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Kathleen Donaleshen
Jodi Axelson[1, 2], Ignacio Barbeito[2]
[1] Forest Science, Planning and Practices Branch, British Columbia Ministry of Forests, Canada
[2] Faculty of Forestry, University of British Columbia, Canada

Abstract: In North America there is a growing interest in using mixed forest plantations as a silviculture strategy for improving forest resilience. Research has demonstrated that mixed forests have been beneficial for increasing diversity and in many cases, stand productivity. With predicted global increases in frequency and intensity of drought, the availability of water resources will become increasingly limiting, intensifying the inter and intra-specific competition within forest stands. Commercial thinning is an intermediate silviculture treatment implemented to manage water limitations, while at the same time, increasing the volume of residual trees. In the Pacific Northwest of North America, higher temperature heat events, and droughts are becoming more common, exposing coastal Douglas-fir and mixed forests to increased risk of reduced productivity and mortality. The objective of this study is to assess the effects of thinning treatments, coupled with tree neighborhood metrics, on Douglas-fir growth response to drought within different compositions of mixed forests. For this, several installations from the B.C. Ministry of Forests large-scale research experiment will be selected (EP703, established 1971-75). This long-term thinning study located on Vancouver Island, is a randomized complete block experiment designed to assess growth and yield in pure and mixed stands of Douglas-fir and Western Hemlock. Three installations (pure Douglas-fir, Douglas-fir - Hemlock mix, and Douglas-fir - Western Redcedar - Hemlock mix) will be compared, each with three levels of thinning treatments (0%, 20% and 35% of basal area removed). To assess the thinning responses in pure through mixed research installations, increment cores will be extracted from each treatment level within the selected sites. A multi-proxy approach will be used to assess Douglas-fir performance and survival to drought events by estimating tree basal area increment, and water use efficiency from stable isotope analysis. The results of this study will provide valuable information regarding silviculture methods for the management of Douglas-fir ecosystems that have been experiencing drought and are at increased risk of drought, while highlighting the effects of species complementarity.

Lessons learned from three long-term field experiments: impact of silvicultural practices on forest dynamics in a changing climate

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Cosmin Filipescu[1]
Bill Beese[2], Derek Sattler[1], Jeff Sandford[3], Chao Li[4]

[3] J.S. Sandford & Associates Ltd., Nanaimo BC, Canada
[4] Canadian Wood Fibre Centre, Canadian Forest Service, Edmonton AB, Canada

Abstract: Long-term field experiments enhance our collective understanding of forest dynamics in a changing climate and lead to the successful implementation of sustainable forest management strategies. British Columbia has a long history of establishing and maintaining long-term and large-scale forest research trials. In this presentation, authors illustrate lessons learned over several decades from three long-term experiments: the Shawnigan Lake Thinning and Fertilization project, the Levels-of-Growing-Stock (LOGS) study, and the Montane Alternative Silvicultural Systems (MASS) study. These experiments were established to provide answers to a variety of research questions from several fields, including tree physiology, tree and stand development, forest regeneration, understory vegetation, silviculture, and growth and yield. More recently, these field experiments were used to address emerging research questions relevant to forest management in a changing climate and forest carbon accounting. Authors discuss their experience with maintaining and ensuring the continuity of long-term research using these field experiments. Some of the required elements include: i) dedicated forest land ownership, public or private; ii) research teams spanning multiple organizations; iii) resources for regular remeasurements and maintenance of field installations; iv) dedicated database management; v) regular field tours with research users and other interested parties; vi) educational opportunities for forestry students and the general public. Long-term experiments provide a myriad of learning opportunities, as well as baseline data to evaluate the impacts of silvicultural interventions. Current research questions on forest dynamics in a changing climate are extremely complex and require multidisciplinary research teams making full use of existing long-term experiments.

Long-term monitoring study on establishment of permanent plots for thinning effects and development of thinning models in Republic of Korea

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Yeongwan Seo[1]
Daesung Lee[2], **Heejun Jin**[3], Sanghyun Jung[3], Eunkyung Kwan[3], Jungkee Choi[3]
[1] Institute of Forest Science, Kangwon National University; Chuncheon 24341, Republic of Korea
[2] Natural Resources Institute Finland (Luke)
[3] Department of Forest Management, Kangwon National University, Chuncheon 24341, Republic of Korea

Abstract: Accumulation of long-term data on forest is essential for sustainable forest management, but insufficient of time series data on tree growth by thinning practices in Korea. It is needed to establish the data base according to thinning practices through long-term monitoring. The final goal of the study is to develop thinning models focused on major planting species which are *Pinus densiflora(Pd)*, *Pinus koraiensis(Pk)*, and *Larix kaempferi(Lk)* in the national forests of Republic of Korea. For the study permanent monitoring plots(PMP) were established in the forest satisfied the criteria as follows;1) never thinned since plantation or passed at least 7 to 8 years since last thinning, 2) free of insect, snow or wind damages, 3) one tree species to occupy more than 80%. Each PMP consistis of three squared plots, that is, non-thinning (20m x 20m), light thinning(25m x 25m) and heavy thinning(30m x 30m) plots. The thinning ratio was 0% in the control, 20% in the light and 40% in the heavy based on the basal area. The principle for selecting trees for removal was based on the assumption that the objective of the residual stand was to produce commercial sawtimber. Therefore, thinning treatment was applied primarily to small, forked, damaged, swept, or trees otherwise unsuitable for sawtimber. Also, we considered spatial relationships between individual trees. In 2012~2015 permanent monitoring plots were installed in 45 sites of *Pk*, *Pk*, and *Lk* respectively. Inventoy factors are DBH, height, dead, species, stem quality, crown width, distance between trees etc whichwere surveyed every 3 years. A variable stand density yield model that can predict the stand volume of various densities, a site index that can diagnose the productivity of a stand, and a stocking chart that can diagnose the stock of stands have been developed. For these models to be used to predict the yield of forests considering the thinning effect and the amount of wood production by stem grade or use, it is necessary to construct a database by longer term and prevent the study site from a damage, especially anthropogenic damage.

Long-term, large-scale silvicultural experiments of loblolly pine plantations: new concepts and new findings

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Dehai Zhao[1]
Bronson Bullock[1], Cristian Montes[1], Mingliang Wang[1]
[1] Plantation Management Research Cooperative, Warnell School of Forestry and Natural Resources, University of Georgia, Athens, GA 30602, USA

Abstract: Loblolly pine (*Pinus taeda* L.) is the most commercially important species in the southern US. Intensive silvicultural treatments such as site preparation, competing vegetation control and fertilizations are commonly used to enhance wood production and reduce the rotation length of loblolly pine plantations. Numerous studies have focused on young stands and reported the increased early growth through the use of intensive silvicultural practices. However, results for young plantations are not necessarily good predictors for the treatment responses at later developmental stages. Furthermore, forest landowners and managers are now shifting their interest from short-rotation production of fiber to long-rotation management for integrated objectives including high-value solid wood products, biomass for energy, and carbon sequestration. To effectively manage long-rotation plantations, it is necessary to understand the long-term effects of silvicultural treatments on forest dynamics. Based on our comprehensive analysis of nine long-term large-scale experimental studies of loblolly pine plantations across the southern US, we will discuss some new concepts and new findings. (1) There exist maximum productivity and maximum response to silvicultural practices for loblolly pine in the southern US, and the maximum response is inversely proportional to the base site quality. (2) We can define and estimate stand-level maximum BA and maximum SDI to provide a realized carrying capacity for individual stands, which is critical for developing stand-specific thinning regimes. (3) High site quality, more intensive silviculture, or high planting density generally increased stand foliage biomass and thus increased stand aboveground net primary production (ANPP) at early ages (i.e., before reaching the maximum ANPP); thereafter, ANPP could decrease from the maximum values more rapidly or slightly, or even did not have obvious declines, mainly depending on how silvicultural treatments, initial planting density and site quality affect stand biomass mortality. These findings have refreshed and expanded our knowledge about pine plantation ecosystems and provide a basis to calibrate growth and yield models and inform integrated climate-smart forest management.

Pre-commercial thinning in naturally regenerated European beech (Fagus sylvatica L.): effects of thinning and pruning on tree growth and stem quality

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Ditlev Otto Juel Reventlow[1]
Thomas Nord-Larsen[1], Jens Peter Skovsgaard[2]
[1] Department of Geosciences and Natural Resource Management, University of Copenhagen, Frederiksberg C, Denmark
[2] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Alnarp, Sweden

Abstract: Pre-commercial thinning in naturally regenerated stands of European beech is often expensive and must be justified by improved development of the remaining crop. Based on a field experiment established in two 14-year-old naturally regenerated beech stands in Denmark, we investigated some effects of pre-commercial thinning and pruning on future crop tree growth and stem quality. The treatments included (1) no thinning, (2) moderate to heavy strip thinning, with or without subsequent selective thinning, and (3) extremely heavy strip thinning in two perpendicular directions (checkerboard thinning), with or without subsequent selective thinning and with or without pruning. The resulting residual stand densities ranged from 10^5 to only 200 ha^{-1}. Treatment effects were evaluated on one potential future crop tree for every 100 m^2. Potential future crop trees were selected 32 years after germination based on spatial distribution, growth potential and stem quality. Total crop tree height was unaffected by strip thinning, but reduced by checkerboard thinning. Stem diameter at 1.30 m above ground level increased with decreasing stand density but, for checkerboard thinning, was reduced by pruning. The lower live branch was located at a lower position with heavy strip thinning and with checkerboard thinning without pruning. The frequency of crop trees with a forked stem was largest with checkerboard thinning and these forks were located at a lower position. Stem tilt and stem bend (stem straightness) were essentially unaffected by thinning practice. However, pruned trees tilted less and had straighter stems. The initial formation of epicormic branches on crop trees was unrelated to thinning and pruning practice, but crop trees that had been pruned for these were less prone to subsequently develop epicormic branches. In summary, moderate to heavy pre-commercial thinning had no effect on stem quality, while extremely heavy thinning without pruning resulted in unacceptably low stem quality. The no-thinning option resulted in acceptable growth and stem quality of the crop trees and this remains a viable management alternative for young beech.

Preserving institutional knowledge: lessons learned from a spacing experiment established in 1957 in British Columbia, Canada

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Bianca N.I. Eskelson[1]
Andréa B.M. Cameron[2]
[1] The University of British Columbia
[2] Forest Analysis and Inventory Branch, British Columbia Ministry of Forests

Abstract: Long-term silviculture experiments have been established around the world over the past century and played a vital role in advancing our understanding of forest management practices. We learned many lessons by trial and error from the first generation of field experiments and used these insights to improve the establishment and measurement protocols for many of the experiments that were established in the last part of the 20th century. Since then, funding sources to establish new experiments have become scarce in many regions. With the retirement of experienced researchers who were involved in establishing past experiments, there is a concern regarding the potential loss of invaluable institutional knowledge related to the establishment and analysis of silviculture experiments. Consequently, there is a possibility of repeating past mistakes from the earlier parts of the 20th century. To mitigate this risk, it is crucial that we take proactive measures to document the existing knowledge on successful practices and lessons learned. In this study, we draw from a spacing experiment established in British Columbia, Canada, in 1957, to highlight the challenges faced when analyzing the data collected over more than 60 years. Some of these challenges include design features of the experiment, changes in measurement protocol and measurement standards over time, as well as limited documentation regarding establishment details and procedures. It is also important to highlight the successes and positive aspects that emerged throughout the lifetime of the experiment in terms of institutional collaborations and additional measurements that were added to address emerging research questions and needs. Even though, the analysis of the experiment was limited due to some of the design and data challenges, the results of this long-term experiment contribute substantially to the collective knowledge spacing and provide input for model building and decision-making processes. Therefore, we must continue our commitment to invest in the maintenance and remeasurement of existing trials. In addition, it is important to pursue the establishment of new experiments to answer emerging research questions and to incorporate the lessons learned in order to continually enhance our understanding of silviculture impacst on forest dynamics over time.

The Scots pine and Norway spruce growing dynamic of differenet thinning regime stands

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Benas Šilinskas[1]
Marius Aleinikovas[1], Lina Beniušienė[1]
[1] Lithuania research center for agriculture and forestry. Department of forest resource, economics and policy.

Abstract: The aim of this study is to relate initial stand density and thinning intensity to tree diameter, height and volume increment, based on continuous 30 m observations in thinning experimental stands of Scots pine (*Pinus sylvestris L.*) and Norway spruce (*Picea abies L. Karst.*). The thinning experiments of Scots pine and Norway spruce were established in 1990 and 1992 and experimental scheme in each trial comprised from five density variants: control, first time reduced density up to 3.0-4.4, 2.0-2.4, 1.0-1.2 and 0.5-0.6 thousand trees per hectare. Since the establishment, only the dead trees were removed in control plots and other density variants were thinned according to predefined thinning program. Number of trees per hectare (N), stand level competition index (CI), mean diameters (Dq), mean heights (Hq), standing volume (V), gross volume yield (GY), mean annual increment in diameter (id) and mean annual volume increment (MAIv) and productivity were analysed for each thinning variant and experiment.

Our study shows that the lowest increment in diameter was in control plots and the highest in the most intensive thinning plots (9-10), which had a 1.5 higher increment in diameter than 1-2 plots. The average volume increment is 2,5 – 3,5 times higher in 9-10 plots compared with control plots. The intensification of thinning and the signs of stabilization of growth in the control stands cannot guarantee them the position of highest productivity and cumulative volume in the future. The average diameter of the trees in a stand, as well as the diameter/height ratio and the resilience of the stand, increases steadily with decreasing stand density.

Thinning increases drought resilience of oaks at the northern edge of their distribution

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Ignacio Barbeito[1]
Jorge Aldea[2, 3]

[3] Southern Swedish Forest Research Center. Swedish University of Agricultural Sciences, P.O. Box 190, 234 22 Lomma, Sweden

Abstract: Drought can impact forests directly causing a decrease of forest growth, but also increase the vulnerability of trees to secondary pests and pathogens or fire, causing an additional loss of productivity. To develop new silvicultural strategies, it is crucial to understand if thinning can promote resistance and resilience of residual trees to drought by reducing moisture stress. Given projected drier summers, the aim of the study was to determine how oak (*Quercus robur* L.) tree growth is affected by severe summer droughts under different thinning intensities. Oak is distributed across large parts of Europe. However, the relationships between stand density and tree drought susceptibility in oaks has not yet been studied in the northern edge of its distribution in Scandinavia. This is likely in part due to the scarcity of thinning experiments in oak. We used a well replicated long-term study planted in 1952 with one- and two-year old seedlings of oak in southern Sweden, where oak is an important species economically and culturally. Three different treatments were established in 1991 following a randomized block design with two blocks, each containing three residual density levels. We collected tree cores to reconstruct past tree diameter growth before and after specific droughts occurring after thinning. We observed that heavy thinning increased drought resistance and decreased recovery time from drought, especially for stands with an initial low basal area. Positive effects of thinning on resistance, recovery and resilience dissipated over time, particularly for high thinning intensities. Our results suggest that heavy and frequent thinning interventions would be an appropriate forest management pathway to alleviate drought stress in pure oak stands at the northern edge of their distribution, by reducing competition for water.

Tree growth and forest degradation over 15 years in the Baikiaea woodlands of southern Africa

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Vera De Cauwer[1]
John L. Godlee[2], **Hermane Diesse**[1], Jonathan M. Kamwi[1], Mubita Chaka[3], Kyle G. Dexter[2]
[1] Namibia University of Science and Technology
[2] University of Edinburgh
[3] Directorate of Forestry, Namibia

Abstract: The dry Baikiaea woodlands are a fragile ecosystem at the geographic and climatic edge of the forest biome in southwestern Africa. They are subject to a combination of disturbances, mainly browsing, logging, fire and drought. Variations in the frequency and intensity of these disturbances, for instance due to climate change or changing human land use practices, can lead to forest degradation and forest loss. Currently, however, there is little long-term quantitative data on forest composition and woody biomass to assess the severity of Baikiaea woodland degradation and loss. Moreover, little is known about the growth and population dynamics of the dominant tree species in the Baikaea woodlands, limiting future wood volume and biomass projections. Long-term monitoring is hampered by many logistical challenges. This study evaluates the challenges encountered and inventory data collected over 15 years in three permanent sample plots in Namibia's state forests, representative of the western Baikiaea woodlands. The objectives are to (1) detect changes in forest structure, species composition and carbon pool, (2) assess if changes can be linked to natural disturbances, (3) determine rates of tree growth, mortality and recruitment across species and demographic groups, and (4) highlight challenges for long-term monitoring of forests in an African context. Species richness and indicators are determined for upper- and understory, while diameter distributions allow for assessing forest structure. Woody biomass and carbon are estimated with pantropical and regional allometric equations. Global climate databases and MODIS data are used to identify droughts and fires. The results contribute to determining sustainable timber harvest rates, regional carbon sequestration, and are relevant to the Great Green Wall initiative recently launched by SADC. Long-term international support is however required to expand forest monitoring infrastructure and perform repeated inventories, which can be facilitated by global plot networks such as SEOSAW.

TRENDS OF INDIVIDUAL TREE CORK INDUSTRIAL QUALITY ALONG THREE SUCCESSIVE DEBARKING OPERATIONS

T1.18 Long-term experiments to study the effects of silvicultural interventions and climate change on forest dynamics

Joana Amaral Paulo[1]
Margarida Tomé[1]
[1] Centro de Estudos Florestais / Instituto Superior de Agronomia

Abstract: In 2012 the trade of raw cork accounted for 0.159 Mtons. This value was 29% of the total traded value, since the higher added value of the cork supply chain is generated from the cork stopper production. The industrial cork quality (ICQ) is determinant for the material physical properties and therefore its final usage. ICQ varies from 1 (best) to 7 (lowest quality). The perception of stakeholders is that ICQ is getting worse in the last decades. The objective of the present work was to evaluate, at the tree level, the trends of the ICQ along three consecutive cork debarking operations and the drivers of those trends. The data set used includes cork samples collected in 37 permanent plots in three consecutive debarkings between 1996 and 2010. The data set therefore includes paired data. Each sampled was classified for ICQ following the industrial procedure. The final data set included 809 pairs of observations: 417 pairs from the 1st to the 2nd debarkings, and 392 pairs from the 2nd to the 3rd debarkings. The McNemarBowker test (MBtest) allowed to test the symmetry of the contingency tables produced. Dendrometric, stand management and climate variables were tested as explanatory factors for the trends observed. Results from the MBtest for the full data set confirmed the decrease in the quality from the 1st to the 2nd debarking (p-value<0.0001), but the same was not observed from the 2nd to 3rd debarking (p-value = 0.6628). When observed at the plot level, distinct trends between plots were observed. Dendrometric and management variables showed no significant relationship with the trends observed, with the exception of a small effect of the tree diameter, suggesting larger trees to have a higher probability of decreasing cork quality between consecutive debarking. The effect of climate, assessed by indicators such as SPEI and SPI, showed an interaction with the plots effect. Tree effect, namely due to genetics, was significant. Further research is needed regarding ICQ evolution using long term permanent plot data and more samplings. On the other hand, the effect of management practices should be researched by the installation of specific controlled trials.

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

A Wildfire Resilience Decision Support Tool for Planners and Managers

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Carrie Levine[1]
David Schmidt[1], Jordan Combs[1], Teal Dimitrie[1], David Saah[1]
[1] Spatial Informatics Group

Abstract: Planscape is an open-source wildfire resilience decision support tool for planners designed to bring the best available state and federal data and science together in a user-friendly, accessible format. Currently, Planscape is being developed in partnership with the state of California to provide free, accessible planning options to various user groups throughout the state. Planscape helps regional planners prioritize landscape treatments to mitigate fire risk, maximize ecological benefits, and help California's landscapes adapt to climate change.

The state of California is committed to increasing the pace and scale of forest, shrubland, and rangeland treatments from a current average of 250,000 acres per year to 1 million acres per year starting in 2025. However, the state noted that there was little guidance on how to prioritize projects to achieve the state's goals for achieving wildfire and climate resilience. The mission of Planscape is to empower regional and forest unit planners to prioritize resilience treatments across the landscape and fund the most impactful projects.

Planscape uses a range of open-source datasets developed by the state of California as the base data for planning. A user interface allows planners to explore the data layers individually, as well as overlaying roadways, administrative boundaries, and past fire history. The modeling framework that Planscape uses to prioritize areas for treatment is derived from ForSys, a scenario planning tool developed by the US Forest Service for exploring landscape management scenarios and optimizing decisions in terms of where and how to achieve landscape restoration and fuel management goals. Planscape provides an intuitive, user-friendly interface which enables managers to harness the power of ForSys. In addition to providing treatment scenario optimization, Planscape is also able to provide cost and revenue estimates for forest health treatments and to prioritize treatments based on cost constraints.

As Planscape development progresses, we plan to include a full suite of ecosystem service estimates based on treatment type and treatment intensity. This framework will allow practioners to leverage a vast array of data and information technologies in effective and meaningful ways, and lead to well-informed, objectively-prioritized project planning activities.

Analysis of the development of new governance approaches for the provision of forest ecosystem services. Six case studies in Europe, China & Colombia

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

[2] Eberswalde University for Sustainable Development, Sustainable Forest Resource Economics, Germany
[3] National University of Colombia, Geosciences and Environment Department, Colombia
[4] tbd

Abstract: This research presents the results of applying a systems-based analysis approach to the identification of the factors that most influence governance innovations, the relationship between system dimensions and factors in order to shed light on innovation processes/patterns and compile recommendations for forest policy and. Forest systems are conceptualised as socio-ecological-technical systems that pose particular conditions for novel governance approaches in private, community owned, and state-owned forests. Accordingly, we analyse these contextual conditions in five different regions of Europe and explore how they influence the emergence and development of governance approaches. Examples include new payment schemes and compensation approaches for the cases of the Habitat Bank in Finland, Vida Manglar in Colombia and Forest Share in Germany, as well as new partnerships and actor networks for the cases of Forest and Pasture Management in Italy, Love the Forest in Sweden and a Sustainable Forest Value Chain in Austria. The results show that the governance approaches studied are closely influenced by the context conditions in which they emerge, and vice versa. While we observed common patterns in the influencing factors that seem to play a key role in all the cases analysed, we were also able to identify particular conditions for the design and work of governance. These relate to their individual historical development, disruptive events, local context, knowledge sharing, policies and incentives. The key impact lies in assisting the management of governance innovations, shedding light on their emergence and potential for future development.

(It is currently planned to apply the framework to additional 10 cases in a Horizon Europe Project in China and Europe at the second half of 2023)

Assessing Habitat Quality of West African Forests: Trade-offs and Opportunities for Sustainable Land Management in Agricultural Landscapes.

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Paule Pamela Tabi Eckebil[1]
Chima Jude Iheaturu[1], Ifejika Speranza Chinwe[1]
[1] Land Systems and Sustainable Land Management, Institute of Geography, University of Bern, Hallerstrasse 12, 3012 Bern, Switzerland

Abstract: The expansion of agriculture in West Africa drives forest fragmentation, biodiversity loss and a decline in ecosystem services. To guide effective land and natural resource management decisions in the region, it is essential to evaluate and quantify ecosystem services. This study uses quantitative and qualitative data and employs the Integrated Valuation of Ecosystem Services and Trade-offs (InVEST) model to assess the impacts of land-use change on the ecosystem services' capacity of nine forest patches in four West African countries: Togo, Benin, Nigeria, and Cameroon. The focus is on provisioning (e.g. crop production), regulating (e.g. carbon sequestration), supporting (e.g. habitat quality), and cultural ecosystem services (e.g. sacredness and spiritual contributions), which are vital to the local communities residing near the forest patches. The analysis covers a 20-year period from 2000 to 2022, revealing recent trends. The land use change analysis shows an increase in agricultural land, particularly in areas where cocoa production serves as the primary income source for communities. However, this expansion of farmland results in a decrease in carbon sequestration due to forest conversion. Additionally, some forest patches under formal and informal protection status demonstrate improved habitat quality for tree species considering their diversity and density. While provisioning services is generally very important to the local communities, cultural ecosystem services predominate for sacred forests, showing the differentiated capacities of the forest patches to supply ecosystem services in their mosaic landscapes. Given their rate of change, we explore the potential of the forests to maintain or enhance their ecosystem services over time. These preliminary findings highlight that progressing towards sustainable management of these forests requires a differentiated approach that considers the importance of their varying ecosystem services to the local communities.

[2] Nagoya University

Abstract: Managing stand density in forestry plantations is known to have positive effects on various ecosystem services. It is crucial to assess the cost-effectiveness of such management strategies, considering limitations in human and economic capital. The objective of this study is to simulate the effects of thinning on regional-level forest ecosystem services (habitat supply, water purification, climate regulation, forestry profits) over the next 10 years and estimate the associated labor and costs. We conducted simulations to predict the growth and density of each stand for each year and identified stands in Japanese cypress plantations with tree densities above a certain threshold for thinning. We then evaluated ecosystem services based on these simulated management and stand structures. Habitat supply for terrestrial organisms was assessed using understory vegetation cover, inferred from upper stand density that influences the light environment. Water purification was estimated by predicting soil erosion using the Revised Universal Soil Loss Equation (RUSLE). Climate regulation was evaluated by estimating carbon emission reduction through biomass power generation utilizing thinned wood as a substitute for petroleum fuels. Additionally, overall revenue was calcurated by deducting costs, such as labor, from the income generated through biomass sales. The results indicate that appropriate stand density management has positive impact on understory vegetation cover at the regional scale, leading to enhanced biodiversity. Moreover, this management approach was found to reduce soil erosion into rivers by over 10% and achieve a carbon emission reduction of at least four tons or more in terms of carbon dioxide equivalents. Furthermore, even when considering the costs of additional employment, the revenue generated from fuelwood sales was projected to be profitable. In conclusion, thinning practices have the potential to enhance the supply of ecosystem services at the regional level. The labor and costs required to implement these practices are within a realistic range. The findings of this study provide valuable evidence for policymakers aiming to formulate strategies that promote regional economic development and enhance ecosystem service provision.

Case study on Management option for securing multiple ecosystem services in Kalash valley dry temperate forests in Pakistan

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Faizul Bari[1]
[1] Food and Agriculture Organziation (FAO)

Abstract: Context: Kalash valley has community owned dry temperate forests with great potential to manage for multiple ecosystem services. These are high value forests having timber, non-timber forest products(NTFPs), unique wildlife, and high significance for eco-tourism. However in the last six decades, the timber based management system, these forests have been degraded, and the various related products, services and functions have been drastically reduced. In order to restore these degraded forests and bring back the ecosystem services, the GEF financed Chilgoza Project started the resources assessment with local communities. A number of nature based solutions were also implemented including assisted natural regeneration. The payment for the ecosystem services(PES) was also implemented to generate financial resources for the re-investment in these unique forest ecosystem.

Method: To assess the resource and its value both tangible and non-tangible, a "Restoration Opportunity Assessment Methodology" (ROAM) was used. This tool utilized the GIS and RS technology for the resource assessment. Local consultation and focus group discussion were also held. Based on the results of the ROAM survey a robust management plan was formulated, where the multiple ecosystem services was the top priority for the management. In addition, the project also established plots for taking the regeneration data over 3 years period.

Results: 1)Due to the grazing exclusion, the assisted natural regeneration contributed significantly to the restoration of the degraded forests

2) There was a significant increase in the non-timber forest products

3) The negative impact of the climate change and other natural disasters were reduced

4) The integrated natural resource management approach was the successful one

5) The payment for the ecosystem services was a sustainable financial tool

Conclusions: 1) The community involvement proved a successful approach for the ecosystem services restoration

2) The natural based solutions are the key for the climate resilient forests

3) Due to the increased in production, there was evidence of the empowerment of the marginalized people

4) The women got more revenue from the utilization of non-timber forest products

5) The local communities are now in the process of registering their products as Global Indication (GI)

Comprehensive evaluation of forest assets and ecological products values based on satellite-ground data integration in Ewenki Autonomous Banner

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Chao Zhang[1]
Shuirong Wu[1], Ting Gao[2], Dengju Wang[1], Bin Sun[2], Zhihai Gao[2]
[1] Research Institute of Forestry Policy and Information,Chinese Academy of Forestry
[2] Institute of Forest Resource Information Techniques,Chinese Academy of Forestry

Abstract: Forest ecosystem is the most important component of the terrestrial ecosystems, and its ecosystem service value evaluation is the key link of realization ecological products' value. However, how to establish a spatialized forest ecosystem service value evaluation model has always been a difficult point in forest resource value evaluation research. On the basis of systematically summarizing the theory and practice of natural resource value evaluation at home and abroad, this study elaborated a comprehensive system of methodology to evaluate forest resource assets and ecological products values based on satellite-ground data integration. Several data, including the basic geographic information, multi-scale remote sensing meteorological, socio-economic and ground survey data, were integrated to evaluate the forest resource assets and ecological products value and figure out its spatial distribution pattern in Ewenki Autonomous Banner in 2021. The results showed that: 1) The value of forest resources assets in Ewenki Autonomous Banner was 67.912 billion CNY, consisting of forest land assets (17.604 billion CNY), forest assets (29.954 billion CNY), and forest carbon assets (20.354 billion CNY). 2) The value of forest ecological products in Ewenki Autonomous Banner achives 42.945 billion CNY, consisting of timber/wood products (2.572 CNY) and forest ecosystem services (20.354 billion CNY). The value of each function was ranked as water conservation (17.013 billion CNY), carbon fixation and oxygen releasing (11.566 billion CNY), soil conservation (8.859 billion CNY), biodiversity protection (2.283 billion CNY), and wind erosion prevention (652 million CNY). 3) Spatially, the value of forest resource assets and ecological products in Ewenki Autonomous Banner both showed an increasing trend from northwest to southeast. The above distribution characteristics were related to local topography, climate and of vegetation distribution. The research results provided scientific basis for promoting the transformation of green water and green mountain into Jinshan Yinshan mountain, and were of great significance for promoting high-quality and sustainable development of regional forestry.

Conserving and restoring Quercus forests for spring shed management and spring revival to reduce water woes in Uttarakhand India

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Shalini Dhyani[1, 2]
Deepak Dhyani[3]
[1] CSIR National Environmental Engineering Research Institute, Nagpur, Maharashtra India
[2] IUCN Commission on Ecosystems Management, Glad Switzerland
[3] Society for Conserving Planet and Life, Dehradun Uttarakhand India

Abstract: Climate, demography and development are mega drivers resulting in loss of Himalayan forests. Different Quercus (Oak) species have been keystone for moist temperate mixed broadleaved forests in Central Himalayas. Quercus forests are home to high biodiversity, soil organic matter, and water holding capacity that supports subsistence of marginalised local communities. Historically thousands of springsheds new major water source for locals supported by healthy natural forests. Relevance of Oak forests has been highlighted in the Springshed conservation efforts by Government of India and their is focus on protecting and restoring catchment areas dominated by Oaks for reviving springs. Over the years deforestation, forest degradation in the region has also affected spring sheds. Many of these have either dried or are projected to dry worsening the water woes. Loss of forests, arrested natural regeneration and changed forest successional patterns were crucial in in loss of springs and necessary ecosystem services for well-being. Paper presents the impact of natural and human induced pressure on Banj Oak forests and how it has affected the structure and functions. Decline in regeneration of Banj Oak and relevant associated species due to human induced pressure is reported that further worsened due to impact of climate variability on the ecological niche of the species and is projected for 84-99% decline in its potential habitats by 2050 & 2070 respectively. Long term research on Oak dominated forest identifies deforestation to be more of a socio-ecological challenge that requires customised, integrated, multi-sectoral and interdisciplinary approach for protecting springsheds. Study presents a climate sensitive forest landscape restoration by involving diverse knowledge systems, community and women involvement for improve water provisioning, reducing disaster risks and interlinked women drudgery.

Designing a process framework for estimating the supply, trade-offs, and synergies of local forests' regulating ecosystem services

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Jang-Hwan Jo[1]

[1] Department of Forest Sciences and Landscape Architecture, Institute of Life Science and Natural Resources, Wonkwang University, 460 Iksan-daero, Iksan 54538, Republic of Korea

Abstract: The supply management of ecosystem services of local forests is an essential issue as it is linked to the ecological welfare of local residents. This study aims to estimate the supply, trade-offs, and synergies of local forest regulating ecosystem services using a land cover classification map (LCCM) and a forest types map (FTM). Rigorous literature reviews and Expert Delphi analysis were conducted using the detailed variables of 1:5,000 LCCM and FTM. Land-use scoring method and Getis-Ord Gi^* Analysis were utilized on detailed variables to propose a method for estimating the local forest regulating ecosystem services' supply, trade-offs, and synergies. The analysis revealed that the rank order (1st to 5th) of supply of regulating ecosystem services was Erosion prevention, Air quality regulation, Heat island mitigation, Water quality regulation, and Carbon storage. When analyzing the correlation between the city's defined services, almost all services showed a synergistic effect. However, when analyzing locally, trade-off effects (Heat island mitigation – Air quality regulation, Water quality regulation – Air quality regulation) appeared in the eastern and northwestern forest areas. This suggests the need to consider not only the synergy and trade-offs of the entire forest between specific ecosystem services but also the synergy and trade-offs of local areas in managing the regulating ecosystem services of local forests. The study result can provide primary data for the stakeholders to determine the initial conditions of the planning stage when discussing the establishment of policies related to the adjustment of the supply of regulating ecosystem services of the forests with limited access. Moreover, the study result can also help refine the estimation of the supply of the regulating ecosystem services with the availability of other forms of data.

Economic valuation of a native forest of the Humid Chaco Ecoregion in Yaguaron, Paraguay.

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Alexander Abdel Fleitas[1]
Maria Laura Quevedo Fernandez[1], Lila Mabel Gamarra Ruiz Diaz[1], Lidia Perez de Molas[1]
[1] Universidad Nacional de Asunción, Paraguay

Abstract: Native forests, through sustainable management, can generate economic income that could avoid deforestation or degradation of forest remnants and could also be attractive for income diversification for private land owners of these areas. The objective of this study was to economically value a native forest remnant located in the Guarapi Private Natural Reserve, in the district of Yaguarón, Paraguay, corresponding to the Humid Chaco ecoregion (Dinerstein et al., 1995). A permanent plot of 10,000 m² was installed where tree species with a Diameter at Breast Height (DBH) ≥ 10 cm were recorded and identified, and the following dasometrics parameters were evaluated: DBH, commercial height and total height. The direct use valuation (VUD) was performed by calculating the marketable volume of trees categorized in utilization classes according to Resolución del Servicio Forestal Nacional 04/92 (SFN, 1992) and the indirect use valuation (VUI) by calculating carbon (C) and carbon dioxide equivalent (CO_2 eq) (Sanquetta et al., 2018), via the method based on market values. The following scenarios were studied: 1) VUD considering the implementation of forest management plans (FMP), 2) VUI through the value of CO_2 eq, taking as reference the 2020 average annual price of the European Union Emission Allowances (EUA) value reflected in the Clean Development Mechanism (CDM) European CO_2 Trading System Exchange and 3) combination of scenarios 1 and 2. The total economic value of direct use assets, with a forest management plan, for case 1 was US$ 828.21, 2) US$ 54.65/ha with the EUA market value and for scenario 3) a value of US$ 882.86/ha was obtained. The forest has an estimable value in the Humid Chaco ecoregion and the data obtained could encourage private landowners to develop sustainable management plans or other economically profitable alternatives for the better use of forest resources.

Ecosystem Service Valuation in Lower Petchburi Watershed of Thailand

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Sura Pattanakiat[1]

[4] Innovation for Social and Environmental Management, Mahidol University, Amnatcharoen Campus, Amnatcharoen 37000, Thailand.

Abstract: Evaluating ecosystem services plays a vital role in the sustainable management of watersheds and natural resources. The ecosystem service valuation (ESV) in Petchburi watershed has been operated using value transfer or simple benefit transfers process. The land use patterns in 2009, 2014, and 2019 were classified using Landsat and Sentinel imageries interpretation. Then, land use change and prediction to 2029 were also classified using CA-Markov model. It was found that grassland, paddy field, and mixed deciduous forest tended to be decreased. Meanwhile, agricultural land including pine apple, rubber plantation, and orchard tended to be increased. The ESV of forest and rangeland tend to be decreased from 97.49 and 21.11 million USD per year, in 2009, to become 94.15 and 16.13 million USD per year, in 2029, respectively. Whereas, the ESV of agricultural land and water bodies tend to be increased from 146.41 and 23.91 million USD per year, in 2009, to become 150.70 and 28.47 million USD per year, in 2029, respectively. The study findings indicate a decrease in the overall ecosystem service value within the Lower Petchburi watershed, primarily due to changes in land use such as deforestation.

Keywords: land use change, land use projection, ecosystem service valuation

ECOSYSTEM SERVICES AND AGRICULTURAL DATA: TERRESTRIAL ARTHROPODS SURVEY IN A PINE FOREST MINING AREA IN THE PHILIPPINES

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Kimberly Ann S. Domingo[1]
Sheryl Yap[2], Nelson Pampolina[3], Phillip Alviola[4], Keshia Tingson[3], Juliet Anarna[5], Irene Papa[5], Bernard Peter Daipan[3, 6], Erwin Tabaco[3], Joselito Sarmiento[4], Mary Iris De Los Reyes[3]

Abstract: This study presents the methodologies, results, and conservation recommendations for a terrestrial arthropod survey conducted in Lepanto Consolidated Mining Company, Mankayan, Benguet, during the dry season in December 2021 and wet season in June 2022. Foliage-dwelling arthropods were sampled along a one-kilometer transect line, with four sampling points at 250-meter intervals. Ground-dwelling arthropods were sampled using pitfall traps, with ten traps randomly set-up in each sampling plot. Additionally, opportunistic sampling was performed by collecting visually observed arthropods within the sampling plots. Specimens were preserved in 95% ethanol and identified up to the nearest taxa possible then subjected to diversity analyses, which provided insights into the dominance of certain species, overall species diversity, species richness, and evenness within the arthropod communities. Two types of farms were compared within the sampling sites: rice farm and crucifer farm. Results showed that the rice farm has significantly higher diversity than the crucifer farm for both wet and dry seasons, and more arthropods were collected during the wet season for both farms. This survey revealed the functional guilds of arthropods present in the area, including decomposers, pollinators, seed dispersers, insect pests, and natural enemies, wherein they play vital roles in ecosystem processes such as decomposition, nutrient recycling, pollination, and biological pest control. Moreover, most of the collected species were considered agricultural pests. Their presence in agricultural areas highlighted the economic challenges faced by farmers, who heavily rely on pesticides for pest control. Conservation strategies were proposed, emphasizing the importance of ecological pest management (EPM) in agricultural areas. EPM promotes the use of diverse crops, resistant or tolerant varieties, soil health improvement, crop rotation, stress on pests, and enhancement of beneficial insect populations. These contribute to the balance of biodiversity, pest regulation, and sustainable agricultural production. Understanding the intricate relationships among biotic and abiotic components within ecosystems can provide valuable insights for conserving terrestrial arthropods and promoting sustainable land management practices. These findings contribute to the establishment of baseline data and conservation recommendations for terrestrial arthropods in Lepanto Consolidated Mining Company and similar ecosystems.

Enhancing Forest Multifunctionality: Embracing Diverse Management Alternatives to optimize for Ecosystem Services' provision

Abstract: To meet the demands for multiple ecosystem services, forest managers need to prioritize the multifunctionality of their landscapes. National sectoral policies, at the same time, drive management towards their specific objectives, which are often developed in non-coordinated processes. In this study, we used a multi-objective optimization approach to investigate the potential multifunctionality cost stemming from national sectoral policies in four European study regions. Then, in each region, we developed three different scenarios to find the optimal distribution of management practices for each sectoral policy, and we added an additional scenario that aimed to maximize multifunctionality. In this way, we analyze the spatial trade-offs between forest ecosystem services and biodiversity in each of these scenarios. All case studies showed that the highest multifunctionality, i.e. provision of multiple ecosystem services, was provided by combining integrative management regimes with a proportion of forested land allocated to specific uses. We identified trade-offs between different ecosystem services, thereby emphasizing potential bottlenecks or reinforcing effects that may either hinder or facilitate the adoption of multifunctional-oriented management strategies. Finally, we observed that sectoral policies that addressed a greater number of services were closest to the maximum level of multifunctionality. In conclusion, it is crucial for forest policies to adopt a comprehensive approach that encompasses diverse objectives to foster multifunctionality. However, it is imperative for these policies to acknowledge and tackle the conflicts and synergies among ecosystem services, aiming to optimize management efficiency. With regard to management strategies, promoting continuous cover forestry and implementing climate adaptation-focused management regimes across all studied regions is essential. Nonetheless, to

realize the full potential of multifunctionality, it is also important to incorporate elements of intensification and allocate a substantial proportion of set-asides.

Exploring the Impact of Alternative Forest Management Methods on Greenhouse Gas Fluxes from the Forest Floor

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Ulrika Ervander[1]
Tobias Rütting[1], Per Weslien[1]
[1] University of Gothenburg, department of Earth Science

Abstract: Forest and forest management strategies have a significant role to play in mitigating the effects of the ongoing climate change. The values of the ecosystem services our forests provide are of ecological, economic, and social importance. Products from forestry are a renewable but limited resource, so the management must be done efficiently. The common management method in Sweden is through clear-cut, a method that have long term impact on both the biodiversity and the carbon fluxes from the soil. We need to learn more about alternative management strategies to limit the negative impacts on biodiversity and maximize the carbon sequestration. In our study we examine how forest management methods affect fluxes of greenhouse gases from the forest floor. We compare three management methods of a mature spruce forest on mineral soil: clear-cut, continuous cover forestry and no harvest. Flux measurements of carbon dioxide and methane through chamber measurements started the year before planned harvest and continue 3 years after harvest. While previous research has focused mainly on forest management through clear-cutting and measurements during the growing season, we focus on alternative management methods and measure fluxes all year around, to get the full picture of how fluxes of greenhouse gases are affected by how the forest is managed. Our first results show changes in the biogeochemistry of the soil after harvest for both management methods. The loss of trees on the clear-cut area resulted in increased soil moisture the first winter, which led to a deep ice layer in the soil, affecting the microbial processes in the soil during winter. The gaps created in the continuous cover forest allows more light to reach the forest floor and an increase in the photosynthesis within the field layer, resulting in lower carbon dioxide flux from the soil. The long term results of these measurements will give us deeper knowledge of how to best manage a forest and keep the carbon in the soil.

Forests and Sustainable Development Goals (SDGs) – assessing their relationship through the use of Soft Operational Research

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Renata Aguayo Lopes Da Silva[1]
Thomas Purfürst[1]
[1] University of Freiburg

Abstract: Problem Structuring Methods (PSMs) are a collection of interactive and participatory modeling techniques for handling unstructured complex problems that are characterized by the presence of multiple actors with divergent viewpoints and competing interests, trying to find potential solutions in an uncertain environment. PSMs are a type of Soft Operational Research, they are fundamentally different from traditional operational research. Soft Systems Methodology (SSM), the Strategic Choice Approach (SCA), and Strategic Options Development and Analysis (SODA) are popular Soft OR methods, that have been applied in different fields. Forests and Sustainable Development Goals (SDGs) have a complex interaction, with many synergies and trade-offs. Methods that bring more dynamic and holistic approaches are better indicated to address this relation. This study proposes the use of Soft operational research, more specifically Strategic Options Development and Analysis (SODA) to investigate forests' relationship to Sustainable Development Goals (SDGs). The main goal is to find a common approach, among the multiple actors involved, to strengthen the forest sector's participation towards SDGs by 2030, and strengthen the importance and participation of the forest sector in this agenda.

Global optimisation of wood production and carbon storage

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Markku Larjavaara[1]
Xia Chen[2], Xiancheng Lu[2]
[1] Department of Forest Sciences, University of Helsinki, Finland
[2] Institute of Ecology and Key Laboratory for Earth Surface Processes of the Ministry of Education, College of Urban and Environmental Sciences, Peking University, China

Abstract: Climate change mitigation and wood production are considered perhaps the most important ecosystem services from forests of world. Maximal biomasses and growth rates vary depending on climate. Despite of this, global optimisation of carbon storage and wood production is rarely discussed. The objective of this research is to optimise land use globally to mitigate climate change and produce wood. To reach this objective, a new physiology-based mechanistic stand development model is developed. The methodology is based on an energetic approach to forest biomass accumulation. The focus is on lowland humid forests of the world, and gross primary productivity is assumed to be influenced only by air temperature and sun elevation after canopy closure. The maintenance cost, which includes maintenance respiration and growth needed to sustain a given biomass, is assumed to be related to both temperature and biomass. The difference between gross primary productivity and maintenance cost is available for growth and growth-related respiration. The proposed research is based on published datasets. It is likely that wood production could be increased tremendously without impact on carbon storage if production were concentrated in regions with high growth to maximal biomass ratio (tropics) and carbon storage to regions with low growth to maximal biomass ratio (maritime temperate and boreal biomes).

Green Infrastructure for Forests and Trees: Policy Perspective for Multifunctional Green Infrastructure in Changing Climate

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Tjaša Baloh[1]
Boris Rantaša[1], Helena Cvenkel[2]
[1] Slovenian Forestry Institute
[2] BSC, Business support centre L.t.d., Kranj

Abstract: The Green Infrastructure for Forests and Trees (GIFT) project focuses on green infrastructure, emphasizing the importance of forests and trees. Green infrastructure can provide many ecosystem services related to biodiversity, climate, water, erosion, landscape, human well-being, etc. The aim of the project is to develop an innovative cross-sectoral approach to the design of green infrastructure of trees and forests and to promote their connectivity in different landscape types by introducing them into policy documents of different sectors and achieving an integrated cross-sectoral approach to policy planning. This requires knowledge of green infrastructure, biodiversity, ecosystem services and climate change among policy makers and professionals.

The innovative approach of the GIFT project aims to improve European regional policies by raising awareness that sufficient tree and forest cover is the first requirement to stop biodiversity loss and mitigate climate change. The communication strategy focuses on disseminating new management models for the multifunctionality of green infrastructure. The project builds on the multi-stakeholder partnership approach and involve policy makers in regional stakeholder groups.

In Slovenia, the project focuses on Gorenjska, a very forested region with inhabitants that traditionally recognise the importance of trees and hedges. Nevertheless, there are only isolated and small remnants of forests in the lowlands, which limit their function as ecological corridors. Pressure on the existing green infrastructure in the lowlands is increasing. Urban forests or larger forested landscapes are rare in suburban/urban areas, as well as smaller green spaces with shrubs and smaller tree species. Green infrastructure, especially forests and trees, is not sufficiently strategically embedded in policy, which is important for climate change mitigation and adaptation.

In our presentation, we will outline the project’s approach for creating systemic solutions for integrated management of green infrastructure not yet developed and established. With appropriate policies to support green infrastructure development and a broader range of interventions, the intensity and management of urban/suburban green spaces and agricultural lands could be adjusted to achieve better green infrastructure connectivity.

10 partner institutions from 9 European countries are cooperating in the GIFT project, which is funded by the Interreg Europe financial mechanism of the European union.

Installation of cocoa agroforests in the forest landscape of DR Congo: Implications for biodiversity conservation and climate change mitigation

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Germain BATSI[1]
Denis Jean Sonwa[2], Lisette Mangaza[3], Jean-Paul Kibambe[4], Corneille Ewango[1]

[3] University of Goma (UNIGOM)
[4] Wildlife Conservation Society (WCS), DRC

Abstract: Biodiversity decline in the tropics requires the implementation of comprehensive landscape management where agricultural systems are an integral element of biodiversity conservation. Benefits carried out within agroforestry systems have played a significant role, especially for tropical crops such as cocoa. Cocoa agroforests (C-AFS) can help developing sustainable land use since they are able to support a large array of ecosystem services while theoretically providing rural households with income and contribute to food security. This study describes the typologies, woody biodiversity, structure and carbon stock of cocoa agroforests in the main cocoa producing landscape of DRC. That landscape is located tropical rainforest of northeast, in provinces of Tshopo and Ituri. A botanical inventory is carried out in 120 plots (50 x 50 m) of C-AFS of different ages, installed in homogenous units of C-AFS. Additional information as C-AFS's size, previous ecosystem and quantity (kg) of cocoa beans harvested per year are obtained from C-AFS owners. Diameter and height of cocoa associated identified plants from 5cm of diameter and cocoa trees are measured. Using surveys and bibliography cocoa associated plants' succession guild, leaf-life span, farmer's use and IUCN status are documented. Aboveground biomass of trees are estimated using the pantropical allometric equation of Chave et al. (2014) and specific equations are used for other plants. Taxonomic diversity of plants in C-AFS is estimated at plot level (alpha diversity) and at landscape level (beta diversity) using various diversity indices, while functional diversity is estimated by farmers' assigned uses and some functional traits. The key results of this study are: Carbon stock , diversity , factors determining diversity and above-ground carbon stock, structure and composition of C-AFS in forest landscapes of northeastern DRC; diversity and carbon stock of different C-AFS typologies; main species that store more carbon and their use by farmers. These results allow us to determine the ecosystemic and socio-economic value of each C-AFS typology, and can be used as a tool for developing a sustainable C-AFS and are crucial for integrating cocoa into REDD+ process and the biodiversity conservation agenda in DRC.

[6] Department of Biology, Lund University, Sweden

Abstract: Forests provide ecological, economic and social values. These values are, however, not always compatible, resulting in conflicts over forest use and management. The increasing impact of ongoing climate change has accentuated these conflicts, both by increasing the need for forest-related ecosystem services like climate regulation and biomass for bioenergy, and by posing direct threats to the functioning of forest ecosystems through changing temperatures and precipitation patterns. One approach to address these conflicts is to strive for multifunctional forests, where trade-offs are minimized by optimizing the spatial arrangement of different forest managements and compromises are achieved that maximize the overall utility of the multiple ecosystem services supported by forests. However, the concept of forest multifunctionality is highly debated, primarily due to conflicting objectives of maximizing private goods (e.g., fiber and energy production) versus preserving public goods (e.g., regulating and cultural ecosystem services), where solutions that maximize total utility may lead to costs or missed opportunities for landowners.

In this study, we have gathered an interdisciplinary team to enhance our understanding and provide a conceptual framework for multifunctionality, focusing on areas with a high proportion of private landowners in Northern European forests. We have focused on four values: biodiversity, forest production, climate change mitigation, and support of perceived quality of life. A critical aspect of our analysis has been the consideration of these values in the decision-making process, aiming at finding ways to minimize trade-offs between them. Our framework links biodiversity, forest production, climate change mitigation, and perceived quality of life aspects to the forest structures influenced by forest management practices. We reason around how trade-offs can be adjusted and currently little prioritized benefits can be improved through spatial planning of management. We present drivers and barriers to management changes to achieve multiple goals from the landowners point of view, and discuss existing and potential policy instruments to overcome barriers, while considering legislative obstacles and incentives for landscape-scale planning. Finally, we identify areas where further research is required.

Integrating trees for sustainable coffee production in the Andean zone of Colombia: a model for climate change mitigation and rural development

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Luisa Fernanda Macias Moreno[1]
Jorge Andres Ramirez Correa[1]
[1] Universidad del Cauca

Abstract: Proper land management and the implementation of nature-based solutions can contribute to mitigate the effects of climate change. In the Andean zone of Colombia, coffee production is an important economic sector that has traditionally been grown under open solar exposure to maximize yields. However, recognizing the need for sustainable practices, over the past decade, coffee organizations in the department of Cauca have initiated to promote the planting of trees as shade for coffee crops. By mid-2023, approximately 3,200 coffee-growing families have adopted these practices, resulting in the establishment of nearly 1,250 hectares of coffee plantations that include 380,000 trees comprising 40 different species, implemented through different planting models such as of agroforestry systems, tree planting, and live fences. The project engages rural development promoters who register the beneficiaries, provide continuous technical assistance, and monitor and systematize the survival and growth of the trees over time. The main objective of the project is to contribute to the sequestration of up to 9 million tons of CO_2e over a 40-year period, thereby mitigating the impacts of global climate change. It also aims to restore degraded areas, conserve natural forests, protect water sources, enhance the diversity of native species, and improve habitat connectivity throughout the coffee-growing landscape. These efforts are especially beneficial to small-scale coffee-growing families, the majority of which have farms of less than two hectares. Consequently, this project serves as an adaptive strategy to climate change while generating new sources of income for coffee-growing communities. The outcomes of this project, which integrates agroforestry systems and sustainable practices, are expected to serve as a replicable model for other coffee-growing regions in Colombia.

Landscape-level forest ecosystem service outcomes of uneven-aged forest management

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate
Adam Daigneault

Erin Simons-Legaard[1], **Christy Carovillano**[1], Sabrina Morano[1], Aaron Weiskittel[1]
[1] University of Maine

Abstract: Most forest ecosystem services research is conducted at scales that are either highly localized or national in scope. This makes it difficult to compare across studies and identify broad forest management strategies to support operational decision-making at the landscape level. There is also a need for tools to help decision-makers identify, value, and compare cost-effective ways to enhance a range of forest ecosystem services within a given region. To address this, we develop an integrated assessment methodology that links a forest landscape model with economic and policy data and assumptions within an optimization framework. The model is applied to 3 million hectares of primarily uneven-aged, naturally regenerated commercial forests in Maine, USA, and includes nearly a dozen silvicultural treatments. We conduct 30 scenarios to evaluate the impacts of varying ecosystem service policy objectives and forest management on economic returns, carbon sequestration, timber supply, and several biodiversity indicators from 2020-2100. Results show a consistent tradeoff between increasing forest carbon sequestration and timber supply, but these impacts diminish when management can shift towards a land sparing approach largely comprised of permanent set asides and intensive plantations. However, our scenario analysis found it was not possible to simultaneously enhance all biodiversity indicators, as each depended on conditions created by often competing silvicultural treatments. Our study can help decision-makers achieve a subset of ecosystem service-related objectives, provided landowners have clear policy, social, and economic signals that enable them to vary their management strategies.

Multi-criteria decision analysis as a pathway to sustainable forest management: A Swedish case study

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Karin Öhman[1]
Eva-Maria Nordström[1], Johanna Lundström[1], Adam Felton[1], Johanna Johansson[2], Daniel Mensah[1]
[1] Swedish University of Agricultural Sciences
[2] Södertörns University

Abstract: The sustainable management of forest landscapes is a challenge, especially when faced with conflicting objectives and stakeholder interests. Today, forests are expected to provide favorable conditions for biodiversity, timber production, recreation, and other important ecosystem services while simultaneously contributing to climate change mitigation through the substitution of fossil fuels and carbon sequestration. Consequently, forest owners and other decision-makers face complex circumstances when choosing between alternative pathways for forest landscapes. These circumstances can necessitate the adoption of robust decision-making tools. One such tool is multi-criteria decision analysis (MCDA), which provides a systematic framework for evaluating and prioritizing alternative management scenarios based on multiple criteria and stakeholder perspectives. By integrating scientific knowledge and stakeholder preferences, MCDA facilitates a comprehensive assessment of the ecological, social, and economic dimensions of the forest landscape.

In this study, conducted within the SPARC project, we evaluate the effectiveness of MCDA in developing stakeholder and science-based solutions for reconciling conflicting demands placed on the forest landscape. To do so, we conducted a case study using a municipality-owned forest property located in southern Sweden. Stakeholders with diverse interests evaluated different management scenarios that were developed using Heureka, a decision support system for multi-functional forestry. We found that MCDA has great potential for promoting sustainable forest management, by enabling decision-makers to better consider trade-offs and synergies. This will result in more informed and balanced choices that better align with ecological conservation objectives and societal needs. Furthermore, the participatory nature of MCDA fosters collaboration and trust among stakeholders and thereby offers a valuable toolset for forest owners and decision-makers. While challenges exist, careful consideration of stakeholder engagement and other factors can address these challenges, and MCDA can contribute to a more effective and inclusive planning processes aimed at achieving consensus-based and sustainable forest management.

Optimal multi-criteria land-use scenarios in an Ecuadorian mountain forest landscape: a spatial explicit approach

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Karla Estefanía Pintado Chicaíza[1]
Thomas Knoke[1]
[1] Technical University of Munich

Abstract: Designing landscapes that can meet the needs of human populations while enhancing their capacity to provide valuable ecosystem services might be crucial for managing land resources in the face of ongoing environmental change. Over the past few decades, optimization models have emerged as a promising tool for assisting in decision-making related to land-use allocation problems, which often involve multiple conflicting objectives crucial for satisfying the complex population's demands. In Ecuador, Knoke *et al*. (2020) applied a robust optimization approach, considering various ecological and socio-economic indicators to determine the optimal land-use allocations that satisfy all objectives while accounting for uncertainty. The findings of this study offer valuable insights into the prospective landscape composition required to achieve multifunctionality, as well as potential trends of forest development. However, the model does not explicitly determine the landscape configuration. In other words, it does not provide the precise locations for implementing these land-use changes nor the anticipated forest conversion. Thus, the present study builds upon the study developed by Knoke *et al.* 2020 to generate optimized spatial scenarios of forest development at a landscape scale. This model upscaling will be attained by coupling the robust optimization approach with heuristic techniques to simulate land-use change by integrating real-world constraints. To this aim, probabilistic deforestation models have been constructed considering the diverse factors influencing forest conversion such as the steepness of the terrain, and the distance to roads or economic centers, among others. The machine learning tool, Random Forest, was used to build the deforestation model as a first step to determine the potential change in forest coverage. Results from this model will be implemented as input in the heuristic technique, along with spatial transition rules and constraints to develop scenarios of forest development. These scenarios will offer an overview of possible directions of landscape configuration, which may serve as a planning tool for policy and decision-makers to find compromise solutions to efficiently allocate land resources and design effective mitigation/adaptation responses.

Knoke *et al.* 2020. Accounting for Multiple Ecosystem Services in a Simulation of Land-Use Decisions: Does It Reduce Tropical Deforestation? *Global Change Biology* 26: 2403–20

Quantifying the impacts of forest management strategies on ecosystem services under climate change: A country-scale modeling approach

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Jonas Kerber[1]
Johannes Mohr[1], Marc Grünig[1], Rupert Seidl[1, 2], Werner Rammer[1]
[1] TUM School of Life Sciences, Ecosystem Dynamics and Forest Management Group, Technical University of Munich, Germany
[2] Berchtesgaden Nationalpark, Berchtesgaden, Germany

Abstract: Forest stewardship in the face of climate change presents significant uncertainties for forest managers, who are increasingly challenged to adapt conventional management strategies. To aid this transformation, decision support tools that integrate quantitative data on forest development under different treatments and climate scenarios are crucial. However, generating consistent and locally accurate model simulations required by such tools at a national scale is a challenging task.

This study proposes a comprehensive forest modeling approach using the process-based forest landscape model iLand to simulate forest trajectories and a range of ecosystem service indicators for Germany. The initial step involves replicating the forests of Germany through multiple representative landscapes that encompass the country's soil and climate conditions, as well as tree species and age class distributions. While being generated, each landscape encapsulates forest and environmental conditions for a given eco-region. Subsequently, diverse management strategies are compiled for each major forest type based on publicly available recommendations and are subsequently implemented in iLand. These strategies encompass the selection of climate-resilient tree species, as well as varying levels of forest adaptation intensity and speed.

By simulating all possible combinations of climate and management scenarios, accounting for abiotic and biotic forest disturbances until the end of the century, a comprehensive database of potential forest trajectories and ecosystem service indicators for timber, carbon storage, and biodiversity is generated. This database can then be incorporated into decision support systems to quantify the consequences of forest management decisions on the provisioning of ecosystem services.

In this contribution, we introduce the data assimilation approach employed to construct current forest conditions for the simulations. Additionally, we outline the process of synthesizing forest management alternatives at a national scale. Furthermore, we discuss the results of the simulations at both the country and regional levels, emphasizing the effectiveness of forest management in mitigating the impacts of climate change on ecosystem service provisioning in Germany's forests.

Recovery of coastal dunes in an area affected by invasive species in Playa Guanal, Isla de la Juventud, Cuba

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Maday Abad Rodríguez[1]
Francisco Gamboa Martínez[1]
[1] Territorial Delegation of Agriculture Isla de la Juventud

Abstract: Our work refers to the elimination of invasive species in a sector of Playa Guanal, located in the Protected Area of Managed Resources South of the Isla de la Juventud (RAMSAR Site), administered by the Company for the Protection of Flora and Fauna Silvestre of the Isla de la Juventud, with the aim of recovering the dune invaded by the invasive species *Casuarina Sp*, by incorporating characteristic species of the place, using the Assisted Natural Regeneration method, relying on the Ramal 595 Standard, the Methodology for the restoration of the coastal dunes and Decree Law 358. The method of elimination of the coastal casuarina was established and as a result, stability has been restored to this ecosystem through the restitution of the vegetation cover, and the capacity to withstand the inevitable changes has increased environmental conditions that occur in the coastal zone, associated with the elevation of the average sea level, the increase in the frequency of tropical storms and their ability to self-recover due to the effects of climate change in 9 kilometers of beach, being increasingly resilient marine-coastal ecosystem.

Sustainability indicators for forest management under climate change: what do we need and what can we do?

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Daniel Martey Junior Mensah[1]
Eva-Maria Nordström[1], Karin Öhman[1]
[1] Swedish University of Agricultural Science (SLU), Forest Resource Management, Sweden

Abstract: World-wide changes in conditions (e.g., global warming) and in societal expectations on forests have led decision-makers to rethink both purpose of and feasible system(s) for forest management. Forests in Sweden already play several vital functions for people such as environmental protection, provision of goods, services, and other societal structures. Climate change mitigation is on top of these multifunctional expectations on forests in Sweden, based on future projections of increased global temperatures, rising of natural hazard events, and prioritization of the nation to become a bio-based society by 2050. Stakeholders' perspectives on sustainable forest management (SFM) can be critical to change future forests management systems for the country. To evaluate different forest management strategies, however, decision-makers require adequate information about upcoming effects in relation to sustainability indicators. As part of the SPARC project, aiming at finding SFM solutions at the landscape level, this study presents an overview and evaluation of a) SFM indicators used in different research studies, and b) the type of SFM and climate-smart forestry indicators that can be modelled with a forest decision support system (DSS) as well as become useful for stakeholders' involvement in the planning process. To achieve those targets, an examination of previous literature review of indicators for SFM and climate-smart forestry was conducted to identify patterns/differences among the parameters used within different publications. Additionally, the application of the Swedish system Heureka as a standard for long-term planning and analysis allowed us to assess the potential for indicators to be quantified and forecasted with a DSS. Preliminary results suggest that a broad range of indicators are needed; however, social aspects may be challenging to model. The oral presentation will also include a summary of findings and concluding remarks about stakeholders' thoughts on sustainability indicators.

The Predictive Role of Species Diversity on Above-ground Carbon through Functional Diversity and Functional Dominance, Southwest Ethiopia

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Ferede Abuye Jeldu[1]
Motuma Tolera[1], Teshale Woldeamanuel[1]
[1] Hawassa University, Wondo Genet College of Forestry and NRs, Wondo Genet, Ethiopia

Abstract: *As both biodiversity and carbon storage are threatened by deforestation and climate change, it is imperative to understand the relationships between species diversity and carbon storage in tropical forest ecosystems of Yayu Coffee Forest Biosphere Reserve, Southwest Ethiopia (herein after referred to as the "YCFBR"), which helps to inform conservation policies intended to mitigate greenhouse gases emissions. Therefore, evaluating the response of above-ground carbon (herein after referred to as the "AGC") to effects of species diversity, functional diversity, as well as its direct and indirect effects interact to maintain AGC in the YCFBR, were the designed objectives of this study. Plot size of 20 m × 20 m was used to collect vegetation data from core and buffer zone, while 30 m x 30 m plot size was designed for transitional zone based on expected density of woody species in each zonation. Different, but proportionally 90 plots were systematically distributed for core, buffer and transitional zones as 40, 25, and 25 plots, respectively. For functional trait diversity estimation, traits relevant to plant-life strategy, competition ability, response to disturbances and climate change were selected; these were wood density, specific leaf area and tree maximum height. Structural Equation Models (herein after referred to as the "SEM"), was performed to evaluate the direct and indirect effects of species diversity, functional diversity and their interaction effects on AGC using R software. Overall results of this findings showed functional diversity and functional dominance were significant predictors of the AGC (21 %) in the YCFBR. Results from structural equation model indicated full mediation model and partial mediation models showed the effects of species richness on AGC are mediated through functional diversity and functional dominance and best predictor for AGC. Collectively, from a practical point of view, this findings suggests conserving species diversity would be the alternative choices for maintaining higher AGC in tropical moist Afromontane forests of YCFBR, Southwest Ethiopia. Further studies should focus to show the extent to which weighting variable for functional diversity and functional dominance contributions for AGC of forest ecosystem functions for climate mitigation measures.*

Use and Stakeholders' Perception of Value of Temple Forests in South Korea

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

[4] Department of Biological and Environmental Science, Dongguk University, Gyeonggi-do 10326, Republic of Korea

Abstract: As the society becomes more industrialized and urbanized, the demand for ecosystem services provided by forests changes. Temple forests in Korea, of which the origin dates to the 7th century, have been used by the Buddhist communities. Main functions of temple forests are two-folds; supply of timber for building and renovations of temple and fuelwoods and provides esthetical environment for Buddhist monks to practice Buddhism there.

The public visits temple forests which provide recreational services. With this new demand could temples to generate revenue by charging fees to ecotourists who visit temple forests. The government of South Korea made a commitment of reducing the country's greenhouse gases emissions by 40% by 2030 compared to the emission level in 2018. The forest sequestration is included in the accounting of greenhouse gases emissions as an offset. The carbon sequestration of temple forests can be considered as an investment option for ESG projects of corporations. In 2022, the Government introduced a direct payment scheme for forest owners to promote their income and enhance ecosystem services resulting by forest management. Managing forests for more ecosystem services beyond the traditional uses, including carbon sequestration, is a new option of temple forest management.

The objectives of study are: 1) to find out under how the temple forests have been used by temples and the public and 2) to identify the perspectives of temple stakeholders including monks, Buddhism believers and the public. We interviewed 40 stakeholders living in the temple and supporting temples and conducted a survey of temple forest's main function with a sample of 200 visitors to the Jirisan National Park where a few of temples are situated.

The main findings include:

The main functions perceived by Buddhist monks and believers are different from that of the public.

Buddhist monks and believers consider temple forests as a place where they can practice their religious activities.

The main functions of temple forests perceived by the public are ecological, educational, and recreational.

The public prefers temple forests to be managed for biodiversity and recreational services rather than supple of economic goods.

Variation in orchid species diversity across forest disturbance gradient in West Mau Forest, Kenya

ABSTRACT

The family Orchidaceae is the most diverse, widespread, and second largest among flowering plants. Despite having diverse socio-economic and ecological value, its spatial distribution across forest disturbance gradients is not well understood, particularly in tropical montane forests. We assessed the influence of forest degradation on orchid species richness and abundance in West Mau Forest, Kenya. Stratified systematic sampling was adopted across three different forest disturbance regimes, i.e., relatively intact forest, moderately disturbed forest, and highly degraded forest. Data collection entailed recording habitat types, morphological features of orchid species and host tree species. A total of five orchid species were recorded from nine host-tree species. The intact forest had seven host tree species with five orchid species. The moderately degraded forest had four host-tree species with two orchid species, while the highly degraded forest had no orchid species. The results suggest a strong negative correlation between orchid species richness and forest degradation status. The degradation of montane tropical forests appears to destroy orchid habitats leading to the decline in orchid species richness and diversity. Findings of this study suggest that resource offtake levels in these forests should be managed in order to secure orchid species populations.

Keywords: Orchid species; montane forests; habitat degradation

Vegetation healthy under high demand of mulch in context agroecology practices in south Togo

T1.19 Managing Forests for of Multiple Ecosystem Services under Changing Climate

Folega Fousseni[1]

[1] Geomatic and Ecosystem Modeling, Laboratoire de Botanique et Ecologie Végétale Faculté Des Sciences / Université de Lomé (Togo)

Abstract: The need for stakeholders to contribute to SDG2 achievement is no longer in question in the context of climate change, especially in sub-Saharan Africa. This study conducted in southeastern Togo, more precisely in the landscape located within a 10 km radius around the Donomade model farm, aims to assess the health status of the vegetation of ecosystems and agrosystems, including their capacity to produce biomass for agroecological practices. Thus, sentinel-2 sensor data of 2015, 2017, 2020, and 2022 years following were preprocessed and submitted to the normalized index of the ratio of vegetation fires (NBR), of the severity of vegetation fires (dNBR), and the CASA-SEBAL model computation. From these different analyses, it is found that whatever the year of the time series, vegetation stress level increases across the landscape. The highly stressed land areas are estimated to be 9952.215 ha, 10397.43 ha, and 9854.90 ha, respectively 2015, 2017, and 2020 years. The analysis of the level of interannual severity reveals the availability of areas with a high photosynthetic proportion having undergone stress. These areas, which are likely subjected to agricultural practices, are estimated at 8704.871 ha (dNBR2017-2015), 8253.17 ha (dNBR2020-2017), and 7513.93 ha (dNBR2022-2020). The total available biomass estimated by remote sensing for 2022 years is equivalent to 3741715 ±119.26 kgC/ha/y for an annual average of 3401.55 ±119.26 kgC/ha/y. On the other hand, the fraction of healthy vegetation is estimated to be 4594.43 ha, 4301.30 ha, and 4320.85 ha for the years 2015, 2017, and 2022. The correlation coefficient R2 is evaluated at 0.96, thus raising the acceptability threshold of the study area's net primary productivity (NPP) to 96%. The Skewness coefficient (0.81±0.073) indicates a mosaic landscape comprising productive and functional ecosystem components but very dispersed. Given the results, there is a strong opportunity to popularize agroecological practices. Mulching, by considering the reconversion of plant biomass consumed by accidental vegetation fires or slash-burn agricultural practices, may be an excellent alternative to enhance whole ecosystems services as target SDGs.

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

A concerted effort to understand and manage emerging needle diseases of loblolly pine in the southeastern United States

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Colton Meinecke[1]

[2] Department of Plant Biology, University of Georgia, Athens, GA, 30602, USA

Abstract: For nearly a decade, public and private land managers in the Southeast United States have reported stark increases in the frequency and severity of fungal needle disease outbreaks in loblolly pine (*Pinus taeda*) forests. Prior to the recent outbreaks, needle diseases were not considered a major threat to the health and productivity of these loblolly pine stands, which represent the region's primary timber resource. However, these diseases now affect large tracts of land, and the combination of high infection rates, and mortality of mature trees in extreme cases, has prompted calls for research to identify management solutions. In collaboration with academic, industry, state, and federal partners, we have initiated research on the issue considering multiple angles: identifying the fungal causal agents, developing inoculation procedures for a wide array of needle pathogens, optimizing resistance screening protocols, evaluating long-term impacts of biotic defoliation on tree survival and stand productivity, and prospecting for the use of phenotypic and genetic markers to aid resistance selection to needle diseases in widely deployed loblolly pine families. We utilized molecular methods to identify fungi associated with needle disease symptoms, coupled with the isolation of potential pathogens and validation of their ability to cause disease. *Lecanosticta acicola*, the causal agent of Brown Spot Needle Blight (BSNB), and other potential pathogens were identified on trees from outbreak sites throughout the region. Inoculation techniques are currently being optimized to test the pathogenicity of these species and develop an operational protocol to be implemented at the USDA Forest Service Resistance Screening Center. We are also screening improved loblolly pine families for chemical and genetic markers of resistance to BSNB using near-infrared spectroscopy and sequencing of disease-resistance genes. Finally, we are assessing the loss of leaf area index due to the presence of needle pathogens and modeling the resulting change in stand productivity. This endeavor represents a unified effort across sectors to protect Southeastern forests against emerging needle diseases.

Analyses of the Swiss Forest Protection data reveal interesting emergence patterns for pine foliage diseases

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Valentin Queloz[1]
Vivanne Dubach[1], Sophie Stroheker[1]
[1] Swiss Federal Institute for Forest, Snow and Landscape Research WSL

Abstract: Swiss Forest Protection was created 1983 to diagnose, record and address forest health problems in the context of the so called forest dieback ('Waldsterben'). Over the years, Swiss Forest Protection has collected a huge dataset of geographically referenced occurrences of pests and diseases affecting trees. Although the service first focused only on forested areas, it quickly expanded to include urban greens. Here we provide an overview of the most commonly diagnosed pests and diseases, focusing on temporal and geographical aspects of pine diseases. Pine trees are distributed worldwide and represent important ecological as well as economical players in forests. However, pine trees suffer from numerous pathogens that reduce their growth rates or even threatens their survival. Some of these pathogens have a quarantine status in Europe like for example the pine pith canker caused by *Giberella circinata* or the pinewood nematode (*Bursaphelenchus xylophilus*). Some others are not under quarantine but can be quite aggressive under climate change conditions like for example the *Diplodia* tip blight (*Diplodia pinea*) leading to huge losses in *Pinus nigra* stands in combination with severe drought. A huge data collection of tree disease diagnostics in Switzerland enables an overview of the dynamics of pine diseases over time. Out of more than 1000 records, first occurrence and abundance evolution of different pine pathogens is addressed in this study. Further, we will retrace the emergence/introduction of *Diplodia* tip blight of pines (*Diplodia sapinea*), as well as of the regulated pine diseases *Dothistroma* and *Lecanosticta* needle blight in Switzerland. These examples confirm the importance of urban areas as hotspots for introduction and emergence of pests and diseases to forest trees.

Can the phenological traits of a Norway spruce genotype predict its risk of needle pathogen infection?

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Abstract: A taxonomically diverse community of phyllosphere fungi inhabit leaves of plants, and the assembly of these communities are governed by different ecological and physiological processes. Although the assembled needle mycobiome in Norway spruce (*Picea abies*) tend to vary across environments, recent work indicates that Norway spruce genotypes harbors different mycobiomes derived from the local air spore communities. Norway spruce genotypes with higher genetic similarity had a more similar mycobiome. Previous studies has also shown that the presence of pathogenic fungi in the mycobiome can be associated to genetic variation in the host tree. In short, not all trees are equally likely to become infected by pathogens present in the local air spore communities. These observations may be driven by phenological variation between the tree genotypes among other traits encoded in the host genome. In this study, we aim to investigate the relationship between the trees phenological traits and colonization by phyllosphere pathogens present in the local air spore community hypothesizing that the timing of budflush will protect trees from pathogens with a short period of spore dispersal but not from pathogens who has a continuous presence in the local air spore community. To test this we set up a study that will run over multiple seasons focussing on the timing of budflush and the assembly of the phyllosphere mycobiome with special focus on needle pathogens. The timing of budflush at tree level is determined using manual observation in combination with remote sensing data collected with UAVs. The local air spore community is collected on weekly intervals with spore traps and shoot samples are collected from Norway spruce clones at defined stages of budflush and shoot development. The needle samples from the Norway spruce clones (needle community) and spore traps (air mycobiome communities) are characterized by high-throughput sequencing of the ITS2 region. The results from the first season of sampling will be shown, and discussed in the context of risk for infection of needle pathogens in Norway spruce.

Climate and pathogen-pathogen interactions in native pine forests

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

[2] JRU CTFC - Agrotecnio

Abstract: Climate change is favoring the upraise of different diseases in pine stands. However, we lack insights into how different diseases may cause compound impacts. Pathogens may compete because they occupy the same niche, but may also facilitate each other as they weaken the host. In native forests, diseases may simultaneously affect adult and regenerating trees of the same species, and may indirectly favor other non-susceptible tree species. In Southern Europe, *Pinus nigra* is simultaneously affected by a needle disease caused by *Dothistroma pini* and a shoot disease caused by *Diplodia sapinea*. It represents an interesting case to study how two diseases interact with each other, as these two pathogens affect canopy trees and recruits differently, and have different climatic and microsite constraints. In general, it looks as if both diseases could cause additive impacts on the canopy while competition tended to be more present in the recruits. No signs of facilitation were observed. *Dothistroma pini* was causing defoliation all over the studied area, both in cold mountainous areas and in the warmest areas down the valleys. Climate restricted *D. sapinea* to the warmest pine forests where it also contributed to defoliation. Pathogen spill-over from the canopy to recruit trees occurred all over the studied area. However, *D. sapinea* shoot blight dominated on the recruits of the warmest areas while *D. pini* needle blight tended to prevail on the recruits on the coldest sites. The combined effects of both diseases were affecting tree growth increasing crown transparency and killing conspecific regeneration. Alarmingly, diseased forests tended to show higher bush growth in the understory and therefore a more fire-prone stand structure than healthy forests.

Comparative genomics reveal species-specific variation in the mitochondrial genomes of Dothistroma septosporum and Dothistroma pini

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Abstract: Mitochondrial genomes have been used in phylogenetic studies, population genetics, and tracing the relatedness of populations. *Dothistroma pini* and *D. septosporum* are the two pathogens that cause Dothistroma needle blight (DNB): a disease that affects pine species and which is globally distributed. The pathogens cause the same symptoms and are morphologically very similar yet genetically they can be distinguished based on several nuclear gene regions and differences in the mating type genes. This study aimed to determine if there were any species-specific variations in the mitochondrial genomes of the DNB pathogens that could, in future, be used for population and evolution based studies. The two isolates from each species included in the study were selected based on differences in mating types and geographic origin. Illumina sequencing was used to obtain short-read genome sequences for isolates of *D. septosporum* from Canada and South Africa, and for *D. pini* isolates from North Dakota and Hungary. PacBio sequencing of the *D. pini* Hungary isolate and *D. septosporum* South African isolate was used to obtain long-read sequences. Contigs were assembled from the reads to form single chromosomes and the mitochondrial genes on these contigs were identified using various bioinformatic tools. The assembled *D. pini* mitochondrial genomes were 34.7 Mb and those of *D. septosporum* 33.4 Mb. The increased genome size of *D. pini* was due to large intergenic regions (over 8.2 kb) with the addition of three homing endonuclease genes of type GIY, that were lacking in *D. septosporum*. All the genomes had the 14 protein-coding genes that are typically harboured on fungal mitochondrial genomes. An exception was observed in the *D. septosporum* isolates in which the *nad3* gene was duplicated. Analysis of the duplicated genes revealed that one of the copies was a pseudogene. There was also re-arrangement of *cox1* and *atp9* genes across the species. The large amount of species-specific variation observed in the mitochondrial genomes would need to be validated in populations, but could be useful in future population studies to determine the evolutionary history of these, and other closely related species.

Comparison of Illumina vs Nanopore sequencing technologies for detecting pine needle pathogens from native and exotic Pinus sp.

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Ida Nordström[1]
Patrick Sherwood[1], Michelle Cleary[1]
[1] Swedish University of Agricultural Sciences, Sweden

Abstract: In Sweden, the vital forestry species Scots pine (*Pinus sylvestris*) is severely threatened by new and emerging foliar pathogens that are often manifested as needle cast diseases, many of which exhibit highly similar symptoms making it difficult to determine the causal agent without involving expert plant disease diagnosticians. Current detection methods that combine culture-based and molecular diagnostics have proven insufficient, costly and involve complex steps towards accurate diagnostics. Better tools that are more efficient both in terms of capacity and rapidity for disease diagnostics, are needed to be able to quickly deploy measures for disease control. Nanopore sequencing technology has several useful advantages over present 2nd generation sequencing methods like Illumina, and it has tremendous potential applicability to plant health protection especially if it can be utilized for on-site detection in nurseries, ports-of-entry and remote forest sites; essentially bringing the lab to the field. In this study, we compared the widely used Illumina platform with the nanopore sequencing platform to ascertain its feasibility for wider adoption in practice. DNA from samples of symptomatic and healthy pine needles collected from a variety of locations (forests, nurseries, ornamental plantings) across Sweden were sequenced using the MinION and Illumina sequencing platforms in parallel to examine: 1) differences in fungal community diversity and richness, 2) resolution for assigning taxonomic identification at the species level, 3) an optimal workflow for nanopore sequencing in terms of cost, time and simplicity, and 4) its feasibility for detecting potentially harmful fungi in eDNA tissue even on asymptomatic tissue. This work underscores the importance of evaluating different perspectives of cutting-edge molecular methods available for identification of plant pathogens, which focus on high-throughput identification at the species level for improving routine diagnostics.

Development, comparison, and validation of qPCR and LAMP assays as an early-warning tool for detection of conifer plant pathogens

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Iryna Matsiakh[1]
Francesco Pecori[2], Nicola Luchi[2], Alberto Santini[2], Michelle Cleary[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences
[2] Institute for Sustainable Plant Protection-National Research Council

Abstract: In Sweden, Scots pine is one of the most important commercial species: it has an annual net export value in forest products that exceeds more than 100 billion SEK, represents about 10% of total Swedish exports, and accounts for about 3% of the national GDP. Today, Scots pine has several damaging pathogens present in Sweden and more are spreading from other parts of Europe. There has already been considerable damage to some pine forests due to a wide variety of fungal pathogens that differentially affect the needles, branches, trunk or roots. For example, pine needle pathogens like species of *Gremmeniella abietina* (economic loss of more than one billion SEK), *Rhizosphaera kalkhoffii* (Christmas market losses), *Neocatenulostroma germanicum* (a new invasive pine blight pathogen in Sweden), *Lophodermium spp.*, *Dothistroma* spp. and *Diplodia* pine pathogens are becoming more and more problematic, probably as a result of changing climate which makes conditions more favourable for pathogen development.

Early detection tools that can quickly identify new and emerging threats can significantly reduce the window of time between when a pathogen can be identified and response to implement mitigation measures that can reduce losses. The aim of the project was to develop three different loop mediated isothermal amplification (LAMP) and qPCR assays for the rapid and early detection of three pine pathogens (*G. abietina, R. kalkhoffii, N. germanicum*) both in DNA extracted from axenic culture and in infected plant tissues. The LAMP assay was conducted using genomic DNA from pure cultures and tissue samples. Primers were designed using LAMP Designer software (OptiGene Limited, Horsham, UK) on the basis of the ribosomal RNA gene (ITS1-5.8 S-ITS2), available sequences of the elongation factor (EF1- α) and beta-tubulin (β-tub2) genes belonging to targeted species in Genbank, and considering other closely related species. This work presented that LAMP assays as diagnostic tool can provide a simple and portable solution and the utility of this for forest managers and advisors for quickly detecting disease agents at even remote forest locations.

Does invasive pathogen Lecanosticta acicola affect the fungal diversity on needles of Pinus species?

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Rein Drenkhan[1]
Kalev Adamson[1], Marili Vester[1], Ahto Agan[1]
[1] Institute of Forestry and Engineering, Estonian University of Life Sciences, 51006 Tartu, Estonia

Abstract: The relationship between the ecological success of needle pathogens of forest trees and species richness of co-inhabiting endophytic fungi is poorly understood. One of the invasive and dangerous foliar pathogens of pine is *Lecanosticta acicola*, which is a quite recently spread to northern Europe. We sampled two *Pinus sylvestris* and *Pinus mugo* sites in Estonia in order to analyse the relations between the abundance of *L. acicola* and overall fungal richness, specific fungal species composition, time of season and needle age. For identification of fungi, the rDNA gene region ITS1-5.8S-ITS2 was amplified using the PacBio third-generation sequencing platform.

The overall species richness of fungi was highest in autumn, showing a trend of increase with needle age. The overall species richness was higher on the second-year needles when compared to young first year needles of *Pinus*, and the trend was also visible in different birth years of needles. The fungal species richness in *P. sylvestris* and *P. mugo* needles was largely affected by actual presence of *L. acicola* on the needles.

Dothistroma pini in Slovenia – a ten-year update

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Tine Hauptman[1]
Matija Kadunc[1, 2], Zina Devetak[1], Barbara Piškur[1]
[1] Slovenian Forestry Institute, Department of Forest Protection, Slovenia
[2] University of Ljubljana, Biotechnical faculty, Department of Forestry and Renewable Forest Resources, Slovenia

Abstract: Dothistroma needle blight (DNB) has been known in Slovenia since 1971. In the last two decades, the occurrence of disease symptoms has intensified, and the DNB is now believed to be widespread in Slovenia. In the years 2011 and 2012, the DNB in Slovenia was found to be tied to both phytopathogenic *Dothistroma* species: *D. pini* and *D. septosporum*. At the time, both mating types were found for *D. septosporum*, while for *D. pini* only MAT2 was reported. After 2012, the DNB survey continued with varying intensity, and samples from new locations were obtained and analyzed. DNA extractions from conidiomata or necrotic bands directly from infected needles were performed, with presence of *Dothistroma* species and mating type determination done through PCR-based analyses. The obtained data shows broader distribution of *D. pini* in Slovenia, with both mating types present. To determine the impact of the pathogen on its hosts, crown damage assessments are currently underway at those locations where *D. pini* was initially confirmed a decade ago.

Dothistroma septosporum - three decades of research, from toxins to cross-kingdom effectors

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Rosie E. Bradshaw[1]
Mariana Tarallo[1], Rebecca L. McDougal[2], Carl H. Mesarich[3]
[1] BioProtection Aotearoa, Massey University, School of Natural Sciences, Palmerston North, New Zealand
[2] Scion, Rotorua, New Zealand
[3] BioProtection Aotearoa, Massey University, School of Agriculture and Environment, Palmerston North, New Zealand

Abstract: Dothistroma needle blight is a global problem in both natural and planted forests worldwide. One of the main causal agents,*Dothistroma septosporum*, has been studied in New Zealand for several decades, despite being a clonal population in that country. An overview of key aspects of this research will be presented, ranging from progress in understanding the role of dothistromin, a polyketide toxin produced by *D. septosporum*, to discoveries made through analysis of genomic and transcriptomic data. Recent work focusing on secreted effector proteins, some of which are potential virulence factors and some of which elicit plant defence responses, will be described. Some effectors are highly conserved and we identified two sets of effector proteins common to three pine pathogens - the fungi *Dothistroma septosporum* and *Cyclaneusma minus* and the oomycete *Phytophthora pluvialis* - that could potentially be used to screen for broad-spectrum resistance. Comparisons of the predicted tertiary structures showed a remarkable level of structure conservation among the three pathogens for each of the two sets of cross-kingdom effectors. Both sets are also highly conserved across fungal and oomycete species, including other pine pathogens. The ability of these effectors to elicit defence responses was then determined by infiltration into the pine host and *Nicotiana* spp.. model plants. One set induced up-regulation of PAMP-triggered immunity which is considered the first line of defence in plants. The second set of effectors elicited cell death in both pine and *Nicotiana* spp. and induced expressed of hypersensitive response, defence signalling and PTI marker genes in the model plant. Using CRISPR-Cas9, the*D. septosporum* orthologues of these genes were disrupted and their virulence to *P. radiata* assessed.There was tentative evidence for a role of these genes in virulence on pine. The identification of pine host targets of highly conserved cross-kingdom pathogen effectors that can elicit strong defence responses could ultimately assist in screening for increased broad-spectrum disease resistance.

Effects of Lecanosticta acicola infection and spread on the growth of Pinus taeda L. (loblolly pine)

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Jaden King[1]
Heather Alexander[1], Jonathan Cale[2], Lori Eckhardt[1]
[1] College of Forestry, Wildlife and Environment, Auburn University, Auburn, AL, 36849, USA
[2] University of Northern British Columbia, Prince George, BC V2N 4Z9, Canada

Abstract: Loblolly pine (*Pinus taeda* L.) is vital for economic stability in the southeastern United States and is the most abundant tree within Alabama, USA. Recently, loblolly pine has been threatened by rapid defoliation due to the pathogen *Lecanosticta acicola*, the causal agent of brown spot needle blight. The study objective was to determine tree response to the disease by assessing tree vigor, plot characteristics, and climate conditions using 16 forest health plots established in loblolly pine plantations around the state of Alabama. Preliminary results show that trees with more severe disease had shorter shoot lengths, shorter needles, and more oleoresin production than trees with less severe disease. Since the installation of plots, tree crowns have become more chlorotic and defoliated with each month of infection. In addition, other foliar pathogens (*Sydowia polyspora*, *Rhizosphaera kalkhoffii, and Lophodermium spp*.) have been recovered in stands with severe symptoms. The knowledge produced by this project will be used to develop best management practices for areas affected by needle blight. It shall also help direct future research actions, especially when little is known regarding the impact of the pests/pathogens associated with loblolly pine in the southeastern United States.

Emerging diseases in forest tree seedling production

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Emil Bengtsson[1]
Audrius Menkis[1], Malin Elfstrand[1], Åke Olson[1]
[1] Department of Forest Mycology and Plant Pathology, Swedish University of Agricultural Sciences, Box 7026, 75007 Uppsala, Sweden

Abstract: More than 400 million tree seedlings are produced in Sweden annually to replant harvested forest areas. These seedlings are cultivated in a highly industrialized manner, in which large monocultures of densely grown seedlings are subjected to intensive cultivation practices. Heavy fertilization and irrigation do create optimal conditions for their growth, but these practices may also stress seedlings and create conditions for the development of fungal pathogens. The use of chemical pesticides can also cause further plant stress making them even more susceptible to fungal infections.

The availability of effective fungicides in the European Union have been steadily shrinking during the last decades, thereby challenging the production of forest tree seedlings. Recently, there have been an emergence of previously neglectable diseases in Swedish forest nurseries, most notably the species from the genera *Phoma* and *Cladosporium*.

Currently, there is a lack of knowledge regarding both their infection biology and the possible reasons of their outbreaks. Changed cultivation practises, a warmer climate or new adaptations by these pathogens could all be possible explanations to the increased disease pressure. Other unknown factors should not be excluded as well. The objective of this research was to gain a better understanding of the species complex, population structure and infection biology of *Phoma* and *Cladosporium* to develop solutions for their control in forest nurseries.

Facilitating the selection of brown spot needle blight resistance in loblolly pine through the development of a high-throughput screening protocol

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Rhys Eshleman[1]

[2] Warnell School of Forestry and Natural Resources, University of Georgia
[3] Resistance Screening Center, USDA Forest Service

Abstract: Brown spot needle blight (BSNB), caused by the fungal agent Lecanosticta acicola, is a severe needle disease of pine affecting plantations in Asia, North America, Europe, and parts of Central America and Africa. Over the past few decades, both the geographical and host range of BSNB has been expanding continuously and rapidly. In the United States, an increase in disease incidence and severity on loblolly pine (Pinus taeda) has been reported by foresters. Given that loblolly pine is the main commercial timber species in the Southeastern United States, and that it has not historically been impacted by BSNB, the forestry industry and government agencies have made it a priority to manage both BSNB and other needle diseases. Prior assessments of outbreaks have suggested that loblolly pine families vary in their susceptibility to BSNB; however, these observations are still only preliminary and there have been no attempts at formal screenings of families. The US Forest Service Resistance Screening Center (RSC) has functioning protocols to screen pine families for resistance against pitch canker (Fusarium circinatum) and fusiform rust (Cronartium quercuum f. sp. fusiforme) and is therefore an optimal site for creating and deploying a high-throughput screening protocol for BSNB resistance. As a first step for protocol development, we isolated L. acicola from three sites in the region, which will be utilized for inoculation trials at the RSC. During the first inoculation trials in the summer of 2023, we aimed to test the impact of seedling age, incubation conditions and duration, and inoculum concentration on BSNB disease development. Subsequent trials will develop and refine parameters for evaluating disease incidence and severity on seedlings. The completed protocol will be scaled up for the high-throughput screening of 120 seedlings per family, the results of which will be compared with prior field assessments. These results will also be utilized in the assessment of host defense mechanisms against BSNB. This project, along with further genetic and molecular characterization of the families, strives to advance the formation of a breeding program for BSNB-resistant loblolly pine.

First report of current season needle necrosis (CSNN) caused by Sydowia polyspora on Abies grandis in Sweden

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

[3] Faculty of Forestry, Çankırı Karatekin University, 18200 Çankırı, Türkiye

Abstract: Current season needle necrosis (CSNN) is a foliar disease, infecting manly firs and pines, but is also reported in several other conifer genera. The disease is in particular a problem for Christmas tree plantations, as it causes necrosis and premature foliage shedding, resulting in significant economic and esthetic devaluation. The disease has notably been a problem of fir plantations in the Pacific Northwest of the USA but has also been present in some Nordic and Central European countries. Certain species associated with this disease are also capable of infecting tip branches, needles, cause injury-related sapstain, and reduce seedling emergence. In September 2022, CSNN symptoms were detected on 10-year-old *Abies grandis* trees on a plantation located in Southern Sweden. To identify the causal agent of the needle necrosis, symptomatic and healthy needles were collected from several trees approximately 100 meters apart. After surface sterilization of necrotic needles, fungal culturing, microscopy, and molecular diagnostics, one of the potential causal agents was identified as *Sydowia polyspora* – a saprophyte, endophyte, and opportunistic pathogen. To test this hypothesis, Koch´s postulates were applied to prove microbial causality, and field surveys were conducted to ascertain the extent of disease severity at the stand level. Fifty *A. grandis* seedlings were inoculated with *S. polyspora* conidial suspension and incubated in conditions of high relative air humidity and temperature. After 2 weeks and the initial CSNN symptoms were observed, *S. polyspora* was successfully re-isolated from the surface-sterilized necrotic needles. Damage assessment of the infected *A. grandis* stand showed that most trees had up to 25% infected crown (upper and lower) and that similar symptoms are also present in a nearby grand fir stand. This is the first time *S. polyspora*-related CSNN disease has been reported on *A. grandis* in Sweden. The reason for the surge in disease symptoms caused by *S. polyspora* and possible management implications will be discussed.

Keywords: *Sydowia polyspora*, *Abies grandis*, needle necrosis, CSNN.

Foliar fungal communities in native and exotic pine from arboreta and botanical gardens: implications for invasive species introductions.

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

MIchelle Cleary[1]
[1] Swedish University of Agricultural Sciences, Sweden

Abstract: The genus *Pinus* includes some of the most ecologically and economically significant forest tree species in Northern Hemisphere, and is also commonly planted in the southern hemisphere in industrial plantations. Because of this importance, pines are the focus of considerable research including mycological work to determine fungi associated with all parts of the trees, including mutualists, pathogens and endophytes. In recent years, several pine pathogens have increased in importance, including needle diseases such as Dothistroma needle blight or Brown spot needle blight, and *Diplodia sapinea* causing tip blight of pines. Knowledge of the diversity and biogeographic distributions of needle inhabiting fungi, as well as the role of these organisms and factors shaping foliar fungal communities remain limited. While arboreta and botanical gardens play crucial roles in preserving and showcasing plant diversity and providing educational opportunities for the study and conservation of plants, these sites also serve as potential pathways for the introduction and spread of invasive tree pathogens, which can have devastating impacts on both cultivated and natural ecosystems. In this talk, I report on different collaborative investigations in arboreta and botanical gardens in North America, Europe and Western Asia to define the fungal species diversity and richness associated with healthy, symptomatic and killed needles of native and exotic pine, and to ascertain possible novel host-pathogen associations. Methods deployed include both classical and eDNA analysis to acertain fungal taxa associated with needles and address determinants of fungal diversity and biogeographic patterns. These smaller investigations reveal a relatively large number of pathogenic fungi causing disease on exotic plantings of pine, several of which are new first reports. The findings underscore the significance of arboreta and botanical gardens as a significant pathway for the introduction of invasive tree pathogens and also highlights the need for increased awareness, improved biosecurity measures, and collaborative initiatives to minimize the risks associated with invasive tree pathogens.

Metabolic processes occurring and secondary metabolites present during infection of conifer Lophodermella needle diseases

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Jane Stewart[1]
Jessa Ata[1, 2], Jorge Ibarra Caballero[1]
[1] Department of Agricultural Biology, Colorado State University, Fort Collins, CO 80523, USA
[2] Department of Forest Biological Sciences, University of the Philippines Los Baños, College, Laguna 4031, Philippines

Abstract: Despite increasing incidence and severity due to climate change, conifer needle pathosystems are understudied which also limits our ability to design efficient management strategies and to grasp their potential as threats in forest ecosystems. Characterizing these complex host tree-microbe interactions in changing environments is important for deciphering mechanisms to improve tree resilience and to develop sustainable strategies for forest disease management. To add to our understanding of tree-microbe interactions among emerging needle diseases, we examined (1) gene expression profiles of the host and the microbiota (bacteria and fungi) within the Lophodermella needle cast pathosystem to determine the variation in metabolic processes and secondary metabolites during colonization on Lodgepole pine needles by two species of *Lophodermella*. Obtained data showed an over-expression of pathogenicity-related genes in symptomatic needles suggesting metabolic activities driven by *Lophodermella* pathogens as they dominate the mycobiota and colonize the needle tissue. Our results also suggest that members of the bacterial community are also associated with disease development and associated metabolic activities. Results from this study provide valuable insights into the pathogenicity mechanisms of *Lophodermella* pathogens and associated microbes present in this needle cast pathosystem.

Population genomic analyses to reveal the evolutionary history of the pine pathogen, Dothistroma pini

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Abstract: *Dothistroma pini*, one of the causal agents of Dothistroma needle blight, is an important foliar pathogen of *Pinus* spp. in the Northern Hemisphere. *Dothistroma pini* has a more limited distribution compared to its sister species, *Dothistroma septosporum,* and has been documented on both native and non-native pines in Europe, central and eastern North America and western Russia. Population studies conducted on *D. pini* from Europe and Russia showed evidence of human mediated movement of the pathogen across the continent and populations that were both well established and newly emerged. Comparative studies on populations from North America are lacking. The aim of this study was to investigate the population genetics of *D. pini* in the entire Northern Hemisphere and to determine the historical migration pathways of the pathogen. Isolates of *D. pini* from most of the countries where the pathogen has been recorded were selected for whole genome sequencing. Selection was based on microsatellite haplotypes, mating types and different hosts in these countries. Single Nucleotide Polymorphisms (SNPs) were determined for 91 *D. pini* genomes, and these were used for downstream population genetic analyses. Preliminary results indicated three genetic clusters. The first cluster contained isolates from central and eastern United States, Canada and all the isolates from Europe. The second and third clusters were very distinct, only containing isolates from North Dakota in North-central USA and isolates from Arkansas in South-central USA, respectively. These clusters will be used to model historical migration scenarios of *D. pini* by conducting an Approximate Bayesian Computation (ABC) analysis. This is the first study to consider the population structure and diversity of *D. pini* and determine the migration patterns in the Northern Hemisphere using genomic data. These findings will highlight possible areas of risks for future introductions of the pathogen into areas where it does not yet occur, especially in the Southern Hemisphere where its distinct absence remains an enigma.

Susceptibility of South African pine material to infection by Dothistroma septosporum in Colombia

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Ginna Marcela Granados Benavides[1]
Carlos A. Rodas[1], Michael J. Wingfield[1], Irene Barnes[1]
[1] Department of Biochemistry, Genetics and Microbiology, Forestry and Agricultural Biotechnology Institute (FABI), University of Pretoria (UP), Pretoria 0002, South Africa

Abstract: Dothistroma needle blight (DNB) is one of the most important pine needle diseases in the Southern Hemisphere. In Colombia, outbreaks of DNB have been observed on Mesoamerican pine species including *Pinus patula*, *P. tecunumanii*, *P. maximinoi* and *P. oocarpa*. Two distinct clonal populations of *D. septosporum* have been identified, of which one appears to be highly aggressive. In South Africa, the same Mesoamerican *Pinus* spp. are increasingly being planted. The aim of this study was to evaluate the possible threat that Colombian *D. septosporum* strains could pose to the South African pine planting stock. This was achieved by assessing the natural tolerance to *D. septosporum* of five South African *Pinus* species and two hybrids under field conditions and where disease severity was measured over a two year period. In addition, the genetic diversity of the *D. septosporum* population isolated from the newly infected trees was investigated using microsatellite markers. The trial was conducted on a forestry farm having high levels of *D. septosporum* inoculum on surrounding trees. The first signs of infection were observed on six-month-old trees. The hybrid *P. patula* x *P. tecunumanii* (Low Elevation population) as well as pure *P. tecunumanii* LE, *P. patula* and *P. maximinoi* exhibited high levels of tolerance to infection, while *P. oocarpa* was highly susceptible. Microsatellite data showed unexpectedly high levels of genetic diversity in the *D. septosporum* population including unique alleles and haplotypes not previously found in Colombia. The results suggest that there have been new introductions of the pathogen into Colombia. These continued introductions and emergence of new haplotypes that are able to infect Mesoamerican pine species highlight a potential risk to the South African forestry industry, and other countries, planting these pine species. Broadly, the study emphasizes the risks associated with global pathogen movement and the need for continual pathogen screening in pine breeding programs that should incorporate field as well as molecular data.

Swiss needle cast in coastal Oregon and SW Washington, USA: variation in aerial detection, foliage retention, and disease severity

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Adam R. Carson[1]

Abstract: Swiss needle cast (SNC) is widely regarded as the most important foliage disease of Douglas-fir (*Pseudotsuga menziesii*) and is caused by the fungal pathogen *Nothophaeocryptopus gaeumannii*. The distribution and disease severity of SNC were evaluated using a regional network of 106 plots located within an area that extends beyond the range of susceptible coastal forests in Oregon and Washington. Plots were measured at the time of establishment in 2013-2015 and remeasured five years later in 2018-2020. Foliage retention was found to be negatively correlated with disease severity and positively correlated with tree growth. At individual sites, needle retention and disease severity has varied between sampling periods. Aerial detection surveys have been flown since 1996, and most recently in 2022 and 2024 following north-south lines separated by 2 miles to identify geographic areas symptomatic for SNC within the coastal forests of Oregon. The 2022 survey showed the highest total area of symptomatic Douglas-fir forest recorded to date at 266,030 ha. The SNC outbreak has remained within a well-defined geographic area, yet within this area, there has been significant variation in disease impacts.

The population structure and diversity of Dothistroma septosporum in Cantabria and Valencia indicates several introductions of the pathogen into Spain

[4] Department of Vegetal Production and Forest Resources, University of Valladolid, Avenida de Madrid 44, 34004 Palencia, Spain

Abstract: *Dothistroma septosporum* and *D. pini*, the causal agents of Dothistroma Needle Blight (DNB), are important fungal pathogens of *Pinus* species. DNB was first reported in Spain in 1933 but severe disease outbreaks have only occurred in the Spanish Atlantic region in the past decade. In 2015, a needle blight disease was observed in Cantabria in stands of *P. nigra* subsp. *nigra* and *P. nigra* subsp. *salzmanii* planted alongside each other, and a third site of *Pinus nigra* subsp. *corsicana* planted seventeen kilometres from the others. In 2016, a needle blight disease was also observed in Fredes and Boixar in Valencia on *Pinus* species. The aim of this study was to identify the pathogen/s present on the affected trees, and to determine the population diversity and structure of a collection of isolates from three planted stands in Cantabria and two locations in Valencia using 12 microsatellites and species-specific mating type markers. In total, 150 isolates, all representing *D. septosporum* were obtained. The consensus between the DAPC and STRUCTURE analyses, as well as pairwise genetic differentiation, showed that there are two genetic clusters in Cantabria of which one cluster is also present in Fredes in Valencia. Furthermore, a unique cluster is present in Boixar in Valencia suggesting an introduction from an unsampled source. Although both mating types were detected among the isolates, sexual recombination was not statistically supported in any of the sites. The high genetic diversity observed in Cantabria suggests that the pathogen is not recently introduced into the region as is the case in Valencia where the population is clonal.

Validation of a universal pathogen identification tool to diagnose needle pathogens of Pinus taeda in the southeast United States

T1.20 Needle diseases of conifers: a globally rising threat to natural and planted forests

Colton Meinecke[1]

[2] Department of Plant Pathology, University of Florida, Gainesville, Florida, United States

Abstract: Little is known about the fungi causing needle diseases on *Pinus taeda*, loblolly pine, which is the primary timber species in the southeast United States. Foliar diseases have traditionally been regarded as secondary problems leading to defoliation and reduced growth, but seldom tree death. However, current reports from industry and government forest managers indicate a recent and stark increase in the incidence and severity of needle diseases in commercially managed pine forests throughout the region. This calls attention to an emerging problem for which the causal agents are poorly understood. Preliminary work has identified several fungal pathogens infecting symptomatic needles sampled throughout the region, including *Lecanosticta acicola*, the causal agent of brown spot needle blight. While *L. acicola* is likely the major pathogen responsible for outbreaks in the western part of the region, no single organism has been identified as the sole causal agent in the eastern states. Previous investigations suggest that multiple organisms result in symptom development and have highlighted the importance of identifying the pathogens in this system. Traditional diagnostic approaches such as isolations failed to identify all fungi, and metabarcoding did not provide species-level identification at an effective cost for use in routine diagnostics. For this reason, our goal is to establish a metagenomics platform to rapidly screen the microbial communities associated with diseased needles and precisely identify fungal pathogens associated with the outbreaks. To meet this goal, we have adapted a Nanopore-based platform that uses the enrichment of fungal DNA to greatly enhance sensitivity and generality with the sequencing of entire diagnostic genes. By this method, DNA samples are first barcoded followed by enrichment achieved through hybridization-based capture of multiple complete diagnostic loci, which are then amplified and sequenced in parallel using third-generation technology. The platform is being optimized using samples from diseased forests, generating species-level fungal community profiles associated with symptomatic *P. taeda* needle samples, thus providing information on the occurrence and proportion of pathogens across affected sites that may be used to develop disease management prescriptions.

Abstract: Ash dieback (ADB) has been threatening the European ash population for almost three decades, which already resulted in a dramatic loss of ecosystem, species-, and genetic diversity across the continent. Although recently much knowledge has been gathered and permitted us to better understand various aspects of the disease, a pan-European vision for actively safeguarding vital genetic diversity in the European ash population is at present non-existent. However, given that the ash dieback crisis in Europe will certainly be exacerbated in the very near future due to westward expansion of the emerald ash borer as well as to future climate change impacts, developing a cross-border perspective is urgent and vitally important. During this presentation, we suggest a proposal for a European initiative aiming to safeguard genetic diversity in European ash species by combining several approaches in concert. We discuss classical and novel opportunities for resistance breeding and genetic conservation, thereby saving time and costs mediated by knowledge transfer and joint conservation infrastructures. To avoid errors from the past, we compare the current crisis to the Dutch elm disease (DED), where the lack of resources and collaboration led to a steady and non-reversible decline in elm populations. By analyzing data from systematic long-term forest monitoring and mortality observation networks (> 400 observation plots from the ICP level I crown defoliation dataset), we estimate the time remaining to put such a European conservation initiative into action. Our conclusion is that joint European efforts can still make a difference to the level of genetic diversity loss in ash species due to ADB, provided resources are made available in the very near future.

Bark-beetle infestation patterns after storm and drought-induced outbreaks

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Simon Kärvemo[1, 2]

[3] Department of Forest Resource Management

Abstract: In the recent decades, Norway spruce forests (*Picea abies*) in Europe have been subject to large-scale tree mortality caused by the spruce bark beetle (*Ips typographus*). The outbreaks were induced by storm-felling events and periods of drought, which are becoming increasingly frequent due to climate change. Because storms and droughts spatially affect forests differently, the infestation patterns and configuration of the bark beetles might differ between storms and drought. In this study, we examined local and landscape factors associated with bark beetle-caused tree mortality after one storm (2005) and one drought event (2018) in southern Sweden. The following infestations were compared regarding differences in infestation occurrence and size and associated forest structures and climate. Based on our findings, we discovered that the allocation of infestation patch sizes for the two outbreaks were quite similar with a large proportion of small groups (≤ 10 trees) greater than 0.6. However, the outcomes from this study demonstrate that the drivers behind the spatial configuration of bark beetle infestations can differ considerably between outbreaks triggered by storms and droughts, and the main cause seems to be linked to the spatial distribution of susceptible trees. The most consistent differences for both occurrence and infestation size were that storm-induced infestations increased more with spruce volumes and area of nature reserves in the landscape; whereas for the drought-induced infestations, occurrence and size increased more with clear-cuts in the landscape and spruce heights across spatial scales. Soil moisture and mean drought index were important for both outbreaks but were more important for the infestation sizes after droughts than after storms and may involve a time-lagged effect.

The reasoning behind the differences between storms and droughts may be that during storm-induced outbreaks, when the wind-felled trees are removed or not suitable anymore, bark beetles needs to find specific susceptible standing trees, while after droughts all trees are more or less stressed, which results in a selection of large trees in dry and warm landscapes. Finally, we show that locally the previous infestation size influenced the later infestation size negatively and this seems to be related to host-tree depletions.

Early response of the undergrowth to mass spruce dieback after bark beetle outbreak in the Białowieża forest

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

[2] Institute of Geography and Spatial Organization, Polish Academy of Sciences
[3] Institute of Forest Sciences, Warsaw University of Life Sciences

Abstract: Spruce-dominated forests are commonly exposed to disturbances associated with mass occurrences of the European spruce bark beetle (*Ips typographus*). Canopy reduction triggers a number of physical and chemical processes in the ecosystem resulting in rapid changes in the vegetation of the lower forest layers.
Our aim was to determine the response of understory vegetation to the dieback of Norway spruce (*Picea abies*) in the first years after disturbance. Our study area was the Białowieża Biosphere Reserve covering the Polish part of the Białowieża Forest, in total 597 km^2. The main data source was 650 phytosociological relevés obtained from the Natural and Cultural Inventory of the Białowieża Forest conducted in 2016–2018 – the peak years of bark beetle gradation.
Shade-tolerant forest species, e.g. *Dryopteris filix-mas, Carex sylvatica, Lathyrus vernus,* and *Anemone nemoros*a, as well as some forest-edge species, showed a decrease in the frequency of occurrence or cover in the plots with dead spruce stands. While the retraction of the former seems understandable - it was probably due to the increased access to light, the reaction of the latter is not clear.
In turn, the presence of light-demanding species associated with non-forest semi-natural communities (meadows, grasslands, swamps) and species characteristic of the class *Epilobietea angustifolii* has also increased. Interestingly, some typically forest species, such as *Stellaria holostea, Galeobdolon luteum, and Milium effusum* were also more abundant after disturbance. Particularly interesting is the reaction of *Oxalis acetosella* - the most common undergrowth species in the Białowieża Forest. Its cover increased dramatically right after spruce dieback, and in the following 3-4 years gradually decreased to the pre-dieback level. A similar course of change, although to a lesser extent, was also observed in the case of *Calamagrostis arundinacea* and *Impatiens parviflora*.
We showed that early response of the undergrowth to pest-related forest disturbance selectively affects individual elements of the phytocoenosis, and it is usually extended over time, unlike, for example, fire-related disturbance. The response of individual species can be divided into directional reactions (positive and negative trends) and non-directional reactions, i.e. fluctuations. We also demonstrated that mass spruce dieback temporarily increases plant biodiversity (α-diversity).

Emerging new diseases in the Cryphonectriaceae: hidden pathogens and unexpected host jumps

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Michael Wingfield[1]

[2] Nigata Agro-Food University, Nigata, Japan
[3] Sappi Forests, Tweedie, KwaZulu-Natal, South Africa

Abstract: The Cryphonectriaceae is best-known for the *Cryphonectria parasitica* and chestnut blight that has devastated native *Castanea* populations in Europe and North America. These fungi are less well known in other parts of the world. For example, *Cryphonectria* (now *Chrysoporthe*) *cubensis*, an aggressive canker pathogen of trees in the Myrtaceae with a biology very similar to *C. parasitica,* is relatively poorly understood in terms of its global relevance. This is firstly because the canker disease caused by *Chr. cubensis* and its congeners including *Chr. deuterocubensis* and *Chr. doradensis,* have affected mainly *Eucalyptus* plantation forestry and are not yet known to cause serious disease problems in natural forest ecosystems. Research spanning approximately four decades and more recently capitalizing on DNA-based techniques has shown that the Cryphonectriaceae includes many aggressive tree pathogens of mainly, but not exclusively the Myrtales. Other than those in *Chrysoporthe*, species of these pathogens reside in genera including *Auropex*, *Celoporthe*, *Immersiporthe*, *Myrtoporthe* and others. Some of these fungi have undergone host-jumps from native Myrtales to infect plantation-grown Eucalypts and surveys both in plantations and natural ecosystems are revealing new examples. As these pathogens expand their host range, in some cases utilizing plantation-grown trees as bridgeheads in their pathways of movement, the likelihood that the could cause of new and serious disease pandemics in natural woody ecosystems will increase. Every effort should be made to prevent their movement, particularly across continents of the tropics and southern hemisphere.

Exploring the Growth-Differentiation Balance Hypothesis (GDBH) in trees. Evidence from Dutch elm disease.

Abstract: Trees are long-lived organisms suffering attacks from many pathogens during their lifetime. Disease results from timely combination of a susceptible state of the tree, the presence of a virulent pathogen and favourable environment over a sufficient time period. Under adaptive equilibrium, it is environmental changes favouring the pathogen that lead to disease. Conversely, when an alien pathogen is introduced, disease may occur under optimal conditions for the tree. This is the case with European and American elms, which are devastated by a virulent and invasive fungus, which causes Dutch elm Disease (DED). Nevertheless the trees show a strong and surprising seasonal variation in susceptibility against DED, demonstrating an inherent ability to resist infection. The period in which elms can become diseased is generally restricted to a few weeks in spring. DED occurs because during this time the vector beetles emerge and inoculate the pathogen. The reason for this window of susceptibility is not well understood, but sporadic studies indicate a link to tree growth rate and morphogenesis.

To investigate how these relationships may determine the expression of a susceptibility response, an in-depth study of the time course of primary and secondary growth including meristem reactivation, leaf area and wood development, was run in combination to assessment of susceptibility through repeated artificial inoculations from late winter to summer in a reference elm clone.

The study revealed that three growth patterns, predetermined, free and by successive flows, coexist in the elm. Each of the growth types had a specific temporal and spatial distribution in the architecture of the plant, which corresponded to different wood anatomy patterns and responses to DED inoculation. Maximum susceptibility coincided with an initial growth phase, during which expanding leaves were net carbon sinks, and spring wood was formed. The first reduction in susceptibility occurred with transition to a later growth phase when intense photosynthesis was ensured by an increasing number of mature leaves as energy sources. The results are in agreement with the GDBH, which predicts that any slowdown in growth rate that does not reduce the rate of photosynthesis can increase the resources available for defence.

How soon before we know the worst?

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Joan Webber[1]
Clive Brasier[1]
[1] Forest Research, Alice Holt Lodge, Farnham, Surrey, GU10 4LH, UK

Abstract: Examples of accidental introductions of pest and pathogens are well documented, with some proving to be highly invasive and damaging. Opportunities for such introductions have grown hugely in recent decades because of the vast increase in global trade, particularly trade in living plants and timber products, as well as more frequent international travel by individuals. Although most introduced organisms are unlikely to establish when transferred to new regions, the potential for damage is large if they do and their impact on habitats and ecosystems is long-term and usually irreversible especially if long-lived woody perennials such as trees are affected. To counter introductions, plant health measures tend to rely on prior identification of high risk organisms combined with inspection to intercept them and surveillance to ensure their continued absence. Drawbacks to this approach are that in their native range, pests and pathogens associated with co-evolved hosts may be cryptic or, if they are known, they are not recognised to pose a risk elsewhere. In addition, surveillance may fail to discover high risk pests sometimes for decades after their arrival, due to the difficulties of detection in heterogeneous natural environments, or because of the novel host/pest/pathogen combinations that some introductions make. Drawing on examples, we will explore how long the lag phase is between arrival and detection can be, what influences this and whether plant health measures can meet these challenges.

Lessons learned from the white pine blister rust and Dutch elm disease outbreaks

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Richard Hamelin[1]
[1] Faculty of Forestry, Department of Forest & Conservation Sciences, The University of British Columbia, Vancouver, Canada

Abstract: White pine blister rust, caused by the fungal pathogen *Cronartium ribicola* J.C.Fisch. (Basidiomycota), and Dutch elm disease, caused *Ophiostoma novo-ulmi* Brasier and *O. ulmi* (Buisman) Melin & Nannf. (Ascomycota), have caused two of the deadliest forest disease outbreaks in the world. In planted and regenerated white pine stands of North America, mortality can reach nearly 100%. The Dutch elm disease has killed billions of elm trees in North America and Europe. These diseases have not only caused vast economic losses but also irreversible changes to forest ecosystems. The pathogens that cause these diseases are biologically very different, yet they have in common that they are caused by alien pathogens that were introduced accidentally to Europe and North America. They also have in common that the hosts that they attack in their introduced range have very little natural resistance due to the absence of coevolution. Much has been learned about these diseases since their introductions over a century ago. Recent exploration of the genomes of these pathogens has opened a new window into their biology, epidemiology, adaptation and reproduction. The introduction, colonization and dissemination of these pathogens have left a signature in their genomes that can now be deciphered. Our understanding of the routes and pathways of introduction and spread has improved with population genetics and genomics studies. Anthropogenic transport is evident and there is support for multiple or repeated introduction events of both pathogens. Hybridization and introgression appear to play a role in the success of the Dutch elm disease pathogens. Hybridization between the white pine blister rust and a native pine rust is on-going, yet with unpredictable outcomes. We are also discovering genomic signatures of adaptation to temperature of host defense compounds that could provide some clues about invasion success and ability to overcome host defenses. The development of genomics biosurveillance systems promises to change the way we conduct monitoring by identifying variants and hybrids and assign intercepted samples to putative sources. Although such tools and analyses may not be helpful to resolve past pandemics, they can improve our ability to identify patterns and prevent future outbreaks.

Population Genetics and Structure Analysis of Cronartium pini in Northern Sweden

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Ke Zhang
Berit Samils[1]
[1] Department of Forest Mycology and Plant Pathology, Swedish University of Agricultural Sciences

Abstract: The young Scots pine forests in Fennoscandia are increasingly facing numerous abiotic and biotic challenges, with Scots pine blister rust being one of the most devastating fungal diseases. This pathogen, caused by the rust *fungus Cronartium pini*, significantly reduces the value of timber due to decreased radial stem increment, deformed branches, and excessive resin, and can even lead to the death of entire trees. Surveys conducted in 2021 and 2022 revealed the widespread presence of Scots pine blister rust, affecting 80% to 90% of forest stands in Northern Sweden.

In this study, we utilized microsatellite markers developed from the *C. pini* genome to investigate the genetic diversity and population structure of *C. pini* samples collected from northern Sweden. Our comprehensive analysis unveiled significant genetic variation within and among *C. pini* populations, indicating the existence of diverse genotypes and multiple genetic clusters. Moreover, we examined the genetic variations and structures between the heteroecious form, *C. flaccidum* and the autoecious form, *P. pini,* shedding light on their distribution patterns and disease severity.

Notably, our findings identified three distinct multilocus genotypes (MLGs) associated with *C. pini* in multiple counties, suggesting the establishment of MLGs and their corresponding clusters as potential contributors to the ongoing Scots pine blister rust epidemic in northern Sweden. These insights into the population genetics of *C. pini* provide a foundation for evidence-based management strategies, including targeted breeding programs and disease surveillance, aimed at mitigating the impact of pine blister rust on vulnerable pine ecosystems.

By enhancing our understanding of population genetics dynamics in forest pathogens, our study contributes to the development of sustainable strategies for forest conservation and ecosystem resilience in the face of emerging threats. The knowledge gained from this research is vital for implementing effective forest management practices that safeguard the health and productivity of Scots pine forests in northern Sweden.

Resilience of conifer trees to environmental stressors

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Fred Asiegbu[1]
[1] Faculty of Agriculture and Forestry, University of Helsinki, Finland

Abstract: Forest trees play crucial roles not only for mitigating effects of the climate change but also for their considerable economic and ecological value. Forest trees are equally vital as an alternative bioenergy source and play important roles in pollution abatement and the maintenance of biodiversity. Timber and its associated products from forest trees contribute substantially to the revenue generation of many countries of the world. The demand for wood and forest products is expected to continue to increase for the foreseeable future. However, major threats to the sustainable supply of forest tree products are adverse climate, insect pests and diseases. Although many microbes associated with forest trees play fundamental roles in the health of trees, influencing their vitality and productivity, others cause severe diseases. In the last century, some notable pathogenic infections of trees have been recorded and forest pathologists have contributed to tackling several of such severe diseases including chestnut blight, Dutch elm disease (DED), sudden oak death (SOD), *Heterobasidion* root rot and recently ash dieback etc. Despite all the efforts undertaken to control the spread of tree diseases, emerging and invasive pathogens still pose a threat to sustainable supply of forest tree products. Economic losses caused by phytopathogenic fungi every year are estimated at several billion US dollars. Today, the need to increase and safeguard those resources of renewable materials and bioenergy as well as to sustain timber quality together with the demand for novel wood bioproducts present major challenges for forest and tree health biotechnology programs. In this presentation, I will highlight the important components of resistance strategy of forest trees against pathogens using *Heterobasidion*- conifer pathosystem as a case study. I will show the application of genomic tools for identification of other vital traits including microbiomes in disease resistance, which are not usually included in tree resistance breeding programs. I will also discuss novel conifer wood property traits and metabolic pathways which we identified and considered important for resistance against necrotrophic pathogens such as *Heterobasidion* spp. I will outline and discuss the intractable challenges to unravelling resistance mechanisms in conifer tree pathosystems.

The Global Forest Health Crisis: A Public-Good Social Dilemma in Need of International Collective Action

Abstract: Society is confronted by interconnected threats to ecological sustainability. Among these is the devastation of forests by destructive non-native pathogens and insects introduced through global trade, leading to the loss of critical ecosystem services and a global forest health crisis. We argue that the forest health crisis is a public-good social dilemma and propose a response framework that incorporates principles of collective action. This framework will enable scientists to better engage policymakers and empower the public to advocate for proactive biosecurity and forest health management. Collective action in forest health features broadly inclusive stakeholder engagement to build trust and set goals; accountability for destructive pest introductions; pooled support for weakest-link partners; and inclusion of intrinsic and nonmarket values of forest ecosystems in risk assessment. We provide short-term and longer-term measures that incorporate the above principles to shift the societal and ecological forest health paradigm to a more resilient state.

Uromycladium falcatarium, the Falcataria mollucana rust fungus – potential bio security threat for some leguminosae in the Pacific Islands

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Sri Rahayu[1]
Tracy Johnson[2], Kenneth Puliafico[2]
[1] Faculty of Forestry Universitas Gadjah Mada, Indonesia
[2] USDA Forest Service, Institute of Pasific Islands Foresty, 60 Nowelo St, Hilo HI, 96720 USA

Abstract: *Uromycladium falcatarium* is an rust fungus caused extremely damaging disease on sengon (*Falcataria moluccana*) in Indonesia. The rust gall fungus has spread across the commercial sengon plantations of Indonesia, Malaysia and the Philippines causing economically significant damage to timber production. The fungus causes growing tissues of sengon trees to form large twisted knots and gall on the leaf, stem, branch, canopy, and which can lead to the death of young trees and damaging of all ages. The fungus spore are able to infect the seeds, survive inside the embryo or in the taste, become seed borne or seed transmitted pathogen. In the other hands *F. mollucana* were to be extremelly invasive weed on the entire Pacific Islands and need to be supress or control intensively in order to prevent the ecosystem changing. The research were conducted a series of experiments with this fungus on a suite of Fabaceae species from Hawaii, i.e. *Acacia chinensis, A. koa, A. koai, A. contorta, A. lebbeck, Leucaena leucochepala*. Plants were exposed to fungal spores under laboratory, greenhouse and natural field conditions. Although several non-target test plants showed signs of initial infection in the laboratory there was no disease progression in any plants other than the target *F. moluccana*. Galls and spores were only formed on the target plants in deliberately inoculated pathogen greenhouse conditions. Field tests have not shown any signs of non-target impact. The results of these experiments suggest that this or other strain of *U. falcatarium* may be suitable candidates for further research as potential biological control agents. We also discuss how our study can help address concerns about the biosecurity threats posed by *Uromycladium* species. The lesson learned and anticipated the gall rust diseases outbreak from the past for the future.

What do we want and where do we want it? Social acceptability of 'lost' tree species restoration in Great Britain

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Fritha West[1, 2, 3]
[1] Mariella Marzano
[2] Rehema White
[3] Althea Davies

Abstract: Resilience is recognised as a priority for 21st century forestry. Tree health is an essential component of resilient treescapes, as demonstrated by continuing crises such as *Ophiostoma novo-ulmi* and *Hymenoscyphus fraxineus*. We argue that resilience should be social and personal as well as ecological.

There are many different management methods with potential to restore resilient tree species, yet social acceptability in this context is poorly understood. The importance of social acceptability in land management is widely accepted, but tree health presents unique barriers to stakeholder engagement. Recent outbreaks have brought tree health into the headlines, but understanding is still limited. This project sought to harness recent interest in tree health and species loss by engaging stakeholders with opportunities for resilient treescapes. The aim was to explore 'lost' species restoration by focusing on elm in Great Britain, which is now largely absent in its original form but holds strong potential for restoration.

We examined the feasibility of elm restoration by assessing the cultural significance of once widespread species, *Ulmus glabra* and *Ulmus minor;* exploring current values, attitudes and experiences related to elm loss; and identifying stakeholder expectations for elm restoration, including testing the social acceptability of different management scenarios.

We determined that environmental, industrial, and personal perspectives have changed since the outbreak of *Ophiostoma novo-ulmi*, largely due to the decline in availability of elm resources, the loss of large trees, and influential memories held by older individuals. Interviews with stakeholders identified different concepts of restoration and management options with varying philosophical, practical and policy approaches. Recent publicity around tree health crises may provide an opportunity to harness wider public support for resilient treescapes, but effective management requires careful consideration of local contexts, regional differences, and sensitivities, with generational divides and misaligned organisational priorities identified as major constraints. Questions over biosecurity and ecological integrity, combined with concerns for nature equity and cultural identity, encourage us to conclude that the road to restoration may rely on emotional connection alongside environmental and policy decisions. These results have implications for how we engage the public and other stakeholders around current and future tree health issues.

When and where to take action against new invaders of forests.

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Jan Stenlid[1]

[1] Department of Forest Mycology and Plant Pathology, Swedish University of Agricultural Sciences, Box 7026, 75007 Uppsala, Sweden

Abstract: At the very early stages of an invasion by a pest or a pathogen the eradication of an potential invader should be relatively cheap; limited distribution and small units to destroy. The challenge is to detect the invader when it is present in low incidence. This reqires high alert systems that come with a high cost. At later stages erradication is often not possible and the golden rule is to work towards containment in restricted areas. If containment fails a massive and potentially devastating attack to one or several host species could be the result. At the later stages of tan invasion process, the detction of an invader is normally straight forward but the costs for controlling the attacks are multiplied. The trade off between detection and control has a pivotal point somewhere in the invasion process. When considering the optimal effort one should also include the stakes that are involved, this include economical losses as well as loss of habitat for biodiversity that is dependent on the threathened host(s). Examples will be discussed where early detection and late stage management have been successfully deployed.

Winner and loser of spruce budworm outbreak: Pine stands as a study case

T1.21 Never waste pandemics: lessons learned from past forest disease outbreaks

Abstract: In Canada, red and white pine stands are drastically declining due to forest harvesting during the last 3 centuries. Their conservation is essential to provide socio-economic, cultural and spiritual benefits. In this context, sustainable forestry practices have been developed in order to restore their natural dynamics by emulating the effects of natural disturbances. In pine stand, secondary disturbances such as spruce budworm outbreaks (SBW) are rarely consider while most of these practices focused on emulating surface fires due to its importance in pine establishment. Without fire, balsam fir colonizes the understory which prevent pine establishment and increase the probability of a SBW outbreak. SBW is the main defoliator of conifer trees in North American boreal forest and affected mainly balsam fir and spruces. This disturbance has major impact on forest dynamic in term of productivity and affected area. Given that the frequency and intensity of these outbreak tend to increase with climate change, it is vital to learn more about the effects of this insect on the dynamics of pine regeneration in order to maximize the management strategies. We aim to evaluate the role SBW outbreak in the natural dynamic of red and white pine. Specifically, we evaluate the impact of this insect on natural regeneration on seedlings.

An experimental design was established in twelve pines stands in Temiscamingue (Québec, Canada), where six stands were affected by SBW and six stands were not affected. Within each stand, we establish 28 4 m^2-plot where each pine and balsam fir seedling have been recorded and their height have been measured. Balsam fir defoliation have also been estimated. Pine seedling establishment varied between undefoliated stands and defoliated stands. Our results showed that pine establishment and growth increased during a SBW outbreak. Natural regeneration is a key component of forest management, given its major role in persistence and resilience of forest ecosystems. This study demonstrates the importance of SBW outbreaks in pine forest dynamic, providing insights for forest management.

T1.22 New challenges for forest soil resources in the face of growing global demands for forest products and the need to limit global temperature increase.

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Are the critical limits for N in soil solution of European forests still exceeded?

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Abstract: The anthropogenic emissions of nitrogen dioxides and ammonia resulted in elevated nitrogen inputs into large parts of European forests. Based on empirical evidence, critical limits for total inorganic nitrogen (nitrate and ammonium) concentrations in soil solution have been defined regarding adverse effects on ground vegetation, fungal communities, trees nutrient balance and effects of elevated nitrate leaching.

Concentrations of major nutrients in soil solution have been continuously monitored on the ICP Forests Level II intensive monitoring plot network since the late 1990s. Evaluations of the data of the first years showed that critical limits had been temporally or permanently exceeded at about one third of the plots, typically at forests exposed to high atmospheric deposition of nitrogen. Since, measures taken to reduce air pollution in Europe and elsewhere started to show an effect and atmospheric deposition of nitrogen decreased by about 30%.

In this study, we investigate the temporal evolution of the exceedance of critical limits for nitrogen in soil solution of European forests between 2000 and 2020 based on measurements on approximately two hundred Level II plots across Europe. Preliminary results show that the share of samples with exceedance of critical limits of nitrogen in soil solution has decreased in all soil depths, however not on all plots. We will present results on geographical patterns and trends and potential factors affecting these patterns and trends.

ATMOSPHERIC NITROGEN DEPOSITION IN BROADLEAF EVERGREEN MEDITERRANEAN FORESTS: UPTAKE, CANOPY PROCESSES AND CYCLING

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

[4] CREAF, Campus Universitat Autónoma de Barcelona, Cerdanyola del Vallés, Spain

Abstract: The implementation of emission reduction policies in Europe has led to a significant decrease in air pollutant emissions in many countries. In the case of Spain, a reduction in NO_x emissions has been observed; while NH_3 levels have remained relatively stable. However, evidence of nitrogen (N) enrichment and exceeding of N empirical critical loads has been reported in certain Spanish ecosystems, such as *Quercus ilex* (holm oak) forest. Holm oak is a broadleaf evergreen sclerophyllous species present over a wide range of environments and representative of the Mediterranean region.

To comprehend the effects of N deposition, it is important to understand and complete the N cycle in the ecosystem, including the input of wet and dry N deposition, the retention and transformations that occurs within the canopy, plant absorption and remobilization, and losses as soil gases emissions or leaching. To assess whether these ecosystems exceed critical loads and to check whether there has been a reduction in N deposition over the last decade, intensive monitoring has been carried out in three peri-urban *Q. ilex* forests located near major cities: Barcelona, Madrid, and Navarra. These sites represent forests with different climatic conditions and sources of pollutant emissions. Air pollutant gases and particle concentration, wet and dry deposition, meteorology, soil humidity and temperature, have been measured in 2011-2013 and 2020-2021. Dry deposition was quantified combining the empirical inferential method for surface deposition of NO_3^- and NH_4^+ with modelled stomatal uptake of NH_3, HNO_3 and NO_2. Also, the biological transformations occurring at the canopy level during the last period have been measured.

Throughfall results show the existence of seasonal biological processes at the canopy level such as N uptake and/or biological transformation. Holm oak leaves were able to absorb both oxidised and reduced N compounds, with higher rates of NH_4 absorption. Dry deposition represents a significant proportion of the total N deposition in these ecosystems. There is a seasonal variation an asynchrony between inputs of N and biological demand, leading to leaching pulses. Soil N_2O fluxes were detected under the canopy and in open areas and with no clear seasonal pattern.

Biomarkers of nitrogen availability in tree species from a Brazilian Atlantic Forest fragment

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Letícia Yuraki Seki[1], Heloísa Gonçalves Bergoc[1], Emily Cristina dos Santos[1], Gabriela Marins Correa de Oliveira[1], José Marcelo Domingues Torezan[1], Renata Stolf-Moreira[1], Edmilson Bianchini[1], José Antonio Pimenta[1], **Halley Caixeta Oliveira**[1]
[1] Department of Animal and Plant Biology, State University of Londrina, Londrina, Brazil

Abstract: Nitrogen (N) is an essential nutrient, but it can be harmful to plants and biodiversity as a whole when in excess. N deposition in forests can be caused by several factors, including the input N through the addition of chemical fertilizers in surrounding croplands. Nowadays, most of the Brazilian Atlantic Forest is composed of forest fragments surrounded by crop fields. This study aimed at evaluating changes in the N metabolism of tree species native to the Atlantic Forest in areas exposed to the application of nitrogen fertilizers. The following species were sampled: *Croton floribundus* Spreng., *Heliocarpus popayanensis* Kunth., *Astronium graveolens* Jacq., *Cabralea canjerana* (Vell.) Mart., *Aspidosperma polyneuron* Müll.Arg., and *Guarea kunthiana* A.Juss. We collected leaves and xylem sap of trees close to agricultural cultivation (considered the border adjacent to agriculture – BAC) and individuals close to a reforestation site (considered the reforestation adjacent border – BAR). The following parameters related to N metabolism were analyzed: nitrate, ammonium and amino acid levels in the xylem sap and leaves, the activity of the enzyme nitrate reductase (NR) in the leaves, and leaf protein content. For most tree species, the results indicated alterations in the N metabolism of individuals in the BAC that suggest greater N availability compared to the BAR, such as higher NR activity, higher nitrate transport in the xylem sap, higher nitrate and protein accumulation in the leaves. Furthermore, in another monitoring of N compounds in leaves of trees along a transect in a forest fragment near a maize field, we saw an increase in the content of nitrate in *G. kunthiana* located near the BAC (at up to 50 m of distance from the BAC). The leaves of *G. kunthiana* trees more distant to the BAC, from 50 to 250 m, showed a lower content of that N compound. Overall, these data suggest that N-metabolism traits from trees could be used as biomarkers for monitoring N deposition in forests, in addition to the widely used leaf total N content.

Abstract: Forests remove about 30% of the human-induced increase in atmospheric CO_2,thus playing a crucial role as a nature-based solution to mitigate climate change. However, the persistence of forest carbon sink capacity depends on how well they cope and adapt to more frequent climate extreme events and concomitant changes in the atmospheric chemistry, e.g., increasing atmospheric CO_2 and nitrogen and sulphur deposition. Recent pan-tropical and global analyses showed that the CO_2 fertilization effects on physiological and productivity metrics, such as water-use efficiency (the ratio between photosynthesis and transpiration, WUE), tree growth and forest carbon uptake have slowed down (or even decreased) over the recent decades due to increasing moisture or nutrient limitations and/or to increases in tree mortality. Moreover, earlier studies conducted in the 1980s identified acid deposition as the main driver of increasing tree mortality in Central Europe. The legacy of sulphur deposition, albeit the latter significantly decreased since the 1980s, could still affect soil processes (e.g., soil acidification, soil inorganic C loss and cation leaching) and the trade-off between carbon uptake and water loss through transpiration (WUE). Despite the long history of assessing air pollution and drought effects on forests, we still lack a unifying framework to assess the interactions between extreme climate events and atmospheric deposition. We will present results from literature review and meta-analyses we are conducting within the WG2 of the COST Action CA21138 CLEANFOREST CLEANFOREST- Joint effects of CLimate Extremes and Atmospheric depositioN on European FORESTs. Specifically, we will assess how climate extremes and atmospheric nitrogen and sulphur deposition interact and affect the ecophysiological responses (in terms of WUE and growth) of European forests to increasing atmospheric CO_2. Moreover, we will address to what extent atmospheric deposition mediates sensitivity to drought events and which mechanisms are involved. Lastly, we will discuss how processes at the different scales (leaf, tree, ecosystem) are linked and integrated both at temporal (e.g., in terms of magnitude of changes) and spatial (at the European) scales.

Community stability and airborne pollutants effects in European forest understorey vegetation

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

James Weldon[1]
Hannah Fried-Petersen[2], Ulf Grandin[1]
[1] Swedish University of Agricultural Sciences
[2] Norwegian University of Science and Technology

Abstract: While the deposition of atmospheric pollutants is widely recognised as a disturbance factor for forest understorey vegetation communities, it can be challenging to quantify and track the impact of disturbances on community stability over time. Community stability and resilience are often conceptualised using the idea of a ball rolling in a well of attraction, but while intuitive, this does not (in itself) give quantitative results. Ordination methods, on the other hand, are often used to visualise community composition and changes, giving quantitative results, but are not directly linked to the insights of resilience theory. We used data from long term monitoring sites that are part of the ICP Integrated Monitoring network to first summarise community composition using ordination methods, and then track the movement of plots in ordination space as a measure of community stability, linking the patterns that emerged to concepts in resilience theory. We further used stability as the response variable in statistical models, to investigate the influence of factors including the deposition of atmospheric pollutants (with a focus on oxidised and reduced nitrogen). Disturbances, particularly those concentrated in relatively short periods of time such as storm damage (so-called pulse disturbances) could clearly be seen in strong directional movement in ordination space (i.e., reduced stability), while the impact of atmospheric pollutants was more subtle.

Contribution of rime to nitrogen deposition in middle elevated mountains in Central Europe

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Iva Hůnová[1]
Martin Novák[2], Pavel Kurfürst[1], Hana Škáchová[1], Markéta Štěpánová[2], Eva Přechová[2], František Veselovský[2], Jan Čuřík[2], Leona Bohdálková[2], Arnošt Komárek[3]

[2] Czech Geological Survey, Geologicka 6, 152 00 Prague 5, Czech Republic
[3] Faculty of Mathematics and Physics, Charles University, Sokolovská 83, 186 75 Prague 8, Czech Republic

Abstract: Nitrogen (N) deposition, an important process of atmospheric self-cleaning, represents an important pathway for nutrients and pollutants to ecosystems. Enhanced N deposition flux contributes to acidification, eutrophication and loss of biodiversity. Hence, the correct and reliable quantification of N deposition is of the utmost importance for forest management.

Rime is an under-researched pathway of the atmospheric deposition of ecological and environmental relevance, in particular in mountain regions. Rime alongside with snow were sampled and assessed for $N\text{-}NO_3^-$ at ten border mountaintop sites across the Czech Republic (CR) in the three consecutive winters of 2009–2011. Our observations indicated significantly higher nitrogen (N) contents in rime as compared to snow at all sites. The highest N contamination was found unexpectedly in the relatively unpolluted Southern portion of the CR. The measurements were put in context with data driven geo-spatial modelling results of annual wet vertical (rain and snow) and occult (fog and rime) deposition. We have found, that despite relatively low hydrological input of rime, it contributed significantly to annual atmospheric deposition. Modelled results showed that mean winter rime deposition corresponded to about 6–25%, and mean winter snow deposition made up 25–72.5% of mean annual $N\text{-}NO_3^-$ wet-only deposition. Model $N\text{-}NO_3^-$ occult deposition estimated from throughfall and total (wet and dry) deposition is highly uncertain, however: N throughfall is not a relevant proxy for estimation of realistic total N deposition due to N exchange between the tree canopy and atmosphere. Considering the fact that wet-only deposition is a year-long phenomenon, whereas rime forms under the climatological conditions of the Czech middle elevated mountains during only a few (2–3) months a year, we can conclude that the rime deposition pathway should not be neglected in quantifying the real atmospheric deposition flux in mountain regions as it might contribute to the real deposition flux substantially even in mountains of medium elevation, as was observed in the CR.

Cool to be poor? How to preserve oligotrophic forest legacies in affluent industrial societies

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Jörg Ewald[1]
[1] Institute for Ecology and Landscape, Weihenstephan-Triesdorf University of Applied Sciences

Abstract: Intersection of lists of forest species, Ellenberg indicator values for nutrients and red lists of vascular plants highlights eutrophication as one of the chief threats to woodland biodiversity in Central Europe. A review of temporal and spatial patterns in the loss of oligotrophic forest habitats suggests that it is not solely a result of nitrogen-immissions from agriculture and combustion, but equally one of self-melioration in the course of primary and secondary succession. Acknowledging the importance of historical legacies (the "ghost of degradation past") has crucial implications on the preservation, restoration and management of forest ecosystems and their functions.
I suggest a baseline model of N-supply and soil acidification during postglacial vegetation history, whose epochs have each added characteristic legacies to the species pool, which call for complementary management paradigms in the face of eutrophication. I review effectiveness and feasibility of primary succession (postglacial), no-intervention reserves (prehistorical), conservation of species and habitats (preindustrial) and function-oriented silviculture (industrial reference period) for the conservation management of oligotrophic forest sites and their biotic communities.
In the face of continuing high N-immissions from agriculture and combustion, measures to reduce deposition and increase uptake and storage in forests must be supplemented by local conservation-oriented N-extraction through biomass (coppicing, wood pasture and litter removal) and topsoil as already practiced in grassland management and restoration.

Effect of Nitrogen deposition on plant physiology, nutrient uptake and antioxidant enzyme activities in subtropical species

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Matoor Mohsin Gilani[1, 2]
Xiangqing Ma[1], Bo Liu[3]

Abstract: With the rapid economic development and the frequent human activities in recent decades, there are induced climate and environmental changes globally, such as the elevated atmospheric nitrogen (N) deposition, which are expanding problems that affect tree growth and development in forest ecosystems. Thus, a single type of N addition may not accurately reflect their ecological effects on tree seedling growth and forest ecosystem development.

We selected species of a typical subtropical area:*Cunninghamia lanceolata, Liquidambar formosana, Pinus massoniana, Phoebe zhennan,* and *Schima superba* as the research object. Seedlings were exposed to different doses of N deposition. Two-level were used, one control and the other with N supplementation 60 kg N hm^{-2} a^{-2}. Ammonium sulfate $(NH_4)_2SO_4$, ammonium nitrate (NH_4NO_3), and potassium nitrate (KNO_3) were used as N sources. The objective of this research was to investigate the possibility that these effects might be related to the difference in seedlings physiology, antioxidative defense, sensitivity and to check if these treatments could enhance seedling performance that would be useful for the protection of these species. Nutrient contents, antioxidant enzyme activity and malondialdehyde (MDA) content varied among treatments. Excessive N deposition decreased the content of MDA, and the activities of antioxidant enzymes. Height and diameter increased among all treatment under low N deposition; however it decreased under high deposition. As N deposition increased, the activity of SOD, CAT, and POD, increased, and it decreased with low level of N deposition. The MDA content decreased first and then increased as N deposition increased.

The results indicated that high N deposition would be harmful to the growth and development of seedlings because the cell in leaves would experience peroxidation that damages the structure and function of plants. Therefore, moderate deposition increased the development of seedlings. In our experiment, all species behave noticeably in response to increased deposition. In combination with the increased leaf area, the transpiration demands were increased between all species.

The outcomes here will enhance our knowledge of the physiological and antioxidant response mechanisms of the effect of N deposition with some practical implications on the protection of the forest ecosystem.

Effects of N deposition and climate on the foliar nutrition of European tree species

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Inken Krüger[1]
Lena Wohlgemuth[1], Andreas Schmitz[2], Tanja Sanders[1]
[1] Thünen Institute of Forest Ecosystems
[2] Landesamt für Natur, Umwelt und Verbraucherschutz NRW (LANUV)

Abstract: Foliar nutrient concentrations and contents are important indicators of forest trees' nutritional status. Foliar nutrients depend on nutrient availability and uptake capacity of the respective tree, which at a longer time scale is influenced by soil properties and deposition, and, at shorter time scale by temperature and precipitation. Taking climate conditions into consideration is thus important when interpreting data on foliar nutrition.

To investigate the temporal climate impact on foliar chemistry, we statistically model the effect of average temperature and precipitation sum integrated over moving time-windows on foliar nutrients. The data included in these models involve foliar nutrients (N, P, K, Ca, Mg) of temperate tree species (beech, oak, spruce, and pine) from around 300 European ICP Forests monitoring plots. We further analyze whether climatic effects on foliar nutrients are impacted by deposition rates and available water capacity.

For German Level II plots, significant effects of current or lagged climate conditions occur among nutrient concentrations and contents in all investigated tree species. In general, N, P, and K are found to be less sensitive to climate variations than Mg and Ca. For the other tree species, we find significant climate effects on both nutrient ratios and nutrient concentrations. Nutrient ratios and concentrations are generally less sensitive to climate conditions than nutrient contents and foliar mass. When a climate condition influences a nutrient concentration and foliar mass in opposing directions, the effects via foliar mass tend to dominate the resulting responses of nutrient content. Our preliminary results suggest that climate conditions should be considered for the interpretation of foliar nutrition data for specific strata of tree species and climate aspects.

Effects of nitrogen deposition on tree water-use efficiency and ecosystem nitrogen dynamics: insights from a novel manipulation experiment in Italy

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Rossella Guerrieri[1]
Alessandra Teglia[1], Dario Ravaioli[1], Enrico Muzzi[1], Federico Magnani[1]
[1] Dept. Agricultural and Food Sciences, Alma Mater Studiorum, University of Bologna, via Fanin 46, I-40127 Bologna, Italy

Abstract: The ability of forests to continue absorbing atmospheric CO_2, and hence mitigating climate change, is constrained by global change drivers, such as increasing nitrogen (N) deposition induced by anthropogenic activities. N input from atmospheric deposition can positively affect forest productivity in N-limited forests. However, under N excess conditions (e.g., above the N critical loads), a cascade of negative effects is expected, leading to tree growth decline, increase in soil acidification and N loss pathways. Experimental simulations of increasing N deposition have been extensively used to directly determine whether atmospheric N input contributes to alleviating N limitation and to understand ecosystem responses. However, most of these experiments have considered soil N applications, often applying N doses several order magnitudes higher than ambient deposition, thus not mimicking realistic changes in N deposition. Moreover, they excluded *a priori* atmosphere-canopy exchange processes, including canopy N uptake and microbial transformations. In this context, the experiment established in a mature and eutrophic *Fagus sylvatica* L. forest in Italy represents a unique resource for advancing understanding on forest responses to global change. At this site, four treatments have been carried out since 2015: control, canopy (30 kg ha^{-1} yr^{-1}) and soil (30 and 60 kg ha^{-1} yr^{-1}) N applications. Our main questions are: do the two experimental approaches (canopy vs. soil applications) lead to different responses in terms of *i)* tree growth and intrinsic water-use efficiency and *ii)* ecosystem nitrogen processes? Moreover, can we detect symptoms of ecosystem N saturation and tree growth in the case of soil N fertilization? To answer these questions, we combined dendroecological analyses (ring widths and stable carbon isotope composition, $\delta^{13}C$) with the measure of stable N isotope composition ($\delta^{15}N$) in different forest samples, including foliar, litter, soil, main root and ectomycorrhizal root tips. On-going $\delta^{13}C$ analyses in tree rings will provide insight into physiological mechanisms underpinning growth changes in relation to different treatments. Whereas, $\delta^{15}N$ in different forest samples will help to elucidate differences in ecosystem N processes between the two approaches, i.e., N retention within the system or increasing N loss pathways and other nutrient limitations due to N saturation.

From Top to Bottom: Using Pedotransfer Functions to Predict Subsoil Organic Carbon and Nitrogen Contents

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

David Keßler[1]
Tobias Huber[2], Josef Gadermaier[1], Stefan Forstner[1], Klaus Klebinder[2], Michael Englisch[1]
[1] Department of Forest Ecology & Soil, Austrian Research Centre for Forests, Natural Hazards and Landscape (BFW), Vienna, Austria
[2] Department of Natural Hazards, Austrian Research Centre for Forests, Natural Hazards and Landscape (BFW), Innsbruck, Austria

Abstract: Most monitoring systems on soil organic carbon (C) and total nitrogen (N) sequestration are restricted to the top soil, primarily caused by ressource restrictions. Accurate estimations of C and N contents at subsurface depths are challenging due to limited data availability and the high cost and time required for direct measurements.

Therefore, pedotransfer functions (PTFs) have gained prominence in soil science as a reliable tool for estimating soil properties, including the prediction of C and N concentration and stocks at various locations and depths, as a cost-effective and practical solution.

C and N concentrations and stocks play a crucial role in understanding soil health and its potential as a C and N sink. This abstract focuses on the development and application of PTFs to predict C and N concentrations and stocks in the depth range of 50 to 80 cm based on topsoil C and N analyses and soil assessments from more than 800 soil profiles in Austria.

This study employs a dataset encompassing soil samples of forests from diverse geographic regions in Austria, with measured topsoil organic C and N, and corresponding C and N content data obtained from 50 to 80 cm depths. Various soil properties from soil assessments, such as soil texture, bulk density or root density, geological and topographic indices, tree species composition and climate data are considered as potential predictors in the PTF development.

The PTFs were developed using statistical modeling techniques, including multiple linear regression, general additive models and machine learning algorithms, such as random forests or artificial neural networks. Models were assessed by cross-validation to ensure robustness and generalizability and associated quality measures such as root mean square error and coefficient of determination.

The resulting PTFs exhibit significant predictive capabilities, enabling accurate estimations of C and N concentrations and stocks at 50 to 80 cm depths based on C and N measurements at the topsoil. Therefore, they can help in identifying forest areas with high C and N stocks at 50 to 80 cm depths, estimating C and N sequestration potentials and optimizing forestry practices to enhance soil fertility, C and N storage.

Increased export of nitrate and base cations in runoff from a final cut harvested Norway spruce forest in southwest Sweden

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Sofie Hellsten[1]
Per Erik Karlsson[1], Cecilia Akselsson[2], Veronika Kronnäs[1], Gunilla Pihl Karlsson[1]
[1] IVL Swedish Environmental Research Institute, P.O. Box 53021, SE-40014 Gothenburg, Sweden
[2] Lund University, Department of Physical Geography and Ecosystems Science, Sölvegatan 12, SE-223 62 Lund, Sweden

Abstract: Deposition, soil- and groundwater as well as runoff chemistry were sampled during six years, 2014-2020, in a 7 ha Norway spruce forest catchment, “Storskogen”, in southwest Sweden. In June 2018, approximately 75% of the forest in the Storskogen catchment was clear-cut harvested. The logging was made according to normal practices, but with a large degree of environmental protection measures.

The concentration of nitrate (NO_3-N) increased considerably after the harvest at all the different sampling sites, from very low values before harvest, to high concentrations especially in the soil water and the ground water in the mineral soil and in the runoff stream water. The changes in a central wetland were smaller.

The export of total nitrogen with the run-off out from the catchment increased substantially, from approximately 2 kg N ha^{-1} yr^{-1} before harvest, to 12 kg N ha^{-1} yr^{-1} the second year after the harvest. The nitrogen export after the harvest had not culminated the second year after harvest.

Compared to before the harvest, the pH and the acid neutralizing capacity (ANC) increased in the run-off from Storskogen after the harvest. The export of base cations with the run-off almost doubled after harvest.

Long-term depositon load and forest state monitoring in the former heavy polluted area of the Ore Mts. (Czech Republic)

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Radek Novotný[1]
Věra Fadrhonsová[1], Vít Šrámek[1]
[1] Forestry and Game Management Research Institute

Abstract: Ore Mountains is one of heavy polluted areas in Europe during the second half of 20th century. Combustion plants for heat and power generation and chemical industry which used brown coal were the main sources of air pollution. Since desulfurization of main pollution sources during 1990´s, air quality improved very quickly. Soil condition, however, was affected strongly and there is no clear improvement in the soil chemistry even after thirty years. Long-term monitoring of forest health state, growth, and soil and needle chemistry could help to answer what is happening in forest ecosystem and how forest reacts on changes in air pollution and deposition load.

Research plots were installed in the young Norway spruce (*Picea abies* [L.] Karst) stands. All stands were up to 30 years old. In 1996, the monitoring system was completed. Crown condition, height increment assessment, foliage and soil sampling and analyses as well as deposition load are the main parameters evaluated within this transect.

Defoliation of tree crowns decreased from more than 40% in the 1990´s to about 20% in the last decade. We have observed slight decrease of K, Ca, P, Zn, S concentration and slight increase of N and Mg concentration in spruce needles. It results to the imbalance between N/P and N/K ratio.

Soil reaction is strongly to moderate acid, nitrogen content in humus layer and in mineral soil is sufficient, on some plot can be evaluated as increased. Main base cation (Ca and Mg) content is influenced by liming, but on the plots without this treatment it is very low, Worse situation is in case of available phosphorus - its content in both evaluated soil layers is very low even on limed plots and is still decreasing during period evaluated.

In the end of 1970´s deposition of S reached in spruce stand 100-150 $kg.ha^{-1}.year^{-1}$ and 25 $kg.ha^{-1}.year^{-1}$ in the open field, in 2022 it was only 3,1 $kg.ha^{-1}.year^{-1}$ (throughfall) and 2,6 $kg.ha^{-1}.year^{-1}$ (bulk). Nitrogen deposition decreased from about 15-25 $kg.ha^{-1}.year^{-1}$ in the 1980´s to 5-6 $kg.ha^{-1}.year^{-1}$ in 2022. pH values of precipitation are increasing during the measuring period.

Long-term effects of clear-cut harvesting on forest soil water nitrogen in Sweden

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

[2] Department of Physical Geography and Ecosystem Science, Lund University, Sweden

Abstract: In Sweden's forests, almost all inorganic nitrogen is usually taken up by trees, ground vegetation and soil microorganisms, with very low leaching from the root zone soil water. However, disturbances in the forest, such as clearcutting, storm damage and bark beetle attacks, result in transiently elevated levels of nitrate in the soil water. These increased levels of nitrate contribute to soil acidification and can also be transported to groundwater and surface waters, contributing to increased nitrate levels in the groundwater and thereby impaired drinking water quality, as well as eutrophication of surface waters.

In this study, we show how nitrate concentrations in soil water are affected by disturbances, mainly in the form of clearcutting, at about 10 different forest sites in a nitrogen deposition gradient across Sweden. The results show that the nitrate levels increased shortly after clearcutting, even in low deposition areas, and that these elevated levels in the soil water continued for some years after clearcutting. Storm damage and bark beetle attacks contributed similarly to elevated levels of nitrate in soil water. This study shows that nitrogen concentrations in soil water increased also in low deposition areas. The time after the clear cut to the peak nitrogen concentration did not depend on where in the climate and deposition gradient the site was situated.

Nitrogen deposition affects forest health and stability in Switzerland

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Sabine Braun[1]
Simon Tresch[1], Sven Eric Hopf[1], Beat Rihm[2], Christian Schindler[3]
[1] Institute for Applied Plant Biology Witterswil
[2] Meteotest, Berne
[3] Swiss Tropical and Public Health Institute, Basel University

Abstract: Forests in Switzerland are subjected to high nitrogen deposition loads. There are various mechanisms of action of its effect on forest health and stability. The data presented here base on 174 plots of the Swiss Intercantonal Forest Monitoring during 40 years. Increased N deposition is both accelerating soil acidification and causing eutrophication. The progress of soil acidification as a consequence of high N input and subsequent nitrate and cation leaching can be shown in a subset of 43 monitoring plots with soil solution samplers. Nutritional element losses represent a risk for growth and vitality of forests and therefore for the sustainable forest management.

During the last 40 years the importance of climate change was getting obvious, and thus also interactions between N deposition and drought became more and more prominent. In forest ecosystems, ectomycorrhizal fungi play an essential role in the uptake of water and nutrients, and they are responding very sensitively to increased N deposition. This suggests increased risks of combination effects of drought and N deposition on forest vitality. In European beech forests, the combination of high N deposition and drought lead to low volume increment of trees and an increased risk for uprooting in storm events. In Norway spruce, the same combination resulted in a strongly increased mortality rate by bark beetle attack. Stem breakage was also increased on sites with high N deposition.

The combination of reduced growth, increased mortality and increased wind damages results in a strong reduction of carbon sequestration and counterbalances the initial growth stimulations reported in the 1980's as a result of increased N deposition.

Nitrogen leaching from afforested soils in Denmark over 30 years

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Jesper Christiansen[1]
Lars Vesterdal[1], Morten Alban[1], Morten Ingerslev[1], Per Gundersen[1]
[1] Department of Geoscience and Natural Resource Management, University of Copenhagen, Denmark

Abstract: Clean water production from planted forests on former cropland soils is crucial for aquatic biodiversity and human freshwater consumption. Concerns arise regarding the export of inorganic nitrogen, particularly nitrate (NO_3^-), due to its adverse effects on surface water quality and human health. However, there are limited long-term studies spanning decades on nitrogen and nutrient leaching from afforested soils.

In this study, we combined long-term data (1986 - 2019) of NO_3^-, ammonium (NH_4^+), chloride (Cl^-), and sulfate (SO_4^{2-}) concentrations in throughfall and soil water with water balance modeling for three ICP Forests Level II monitoring plots in Denmark. Our aim was to estimate the net leaching of these elements and investigate how atmospheric deposition, tree species, climate variability, and management actions interact to shape nitrogen leaching losses from the forest ecosystem.

Two of the forests, located in eastern Denmark on glacial till soils, consist of monoculture stands of pedunculated oak (Vestskoven – since 1998) and European beech (Stenholtsvang – since 1986). A mixed deciduous unmanaged and seminatural forest (Suserup – since 2002) on similar soil type was included to assess the potential trajectory of forest development for new forests.

We hypothesize that NO_3^--export through leaching on N rich post agricultural soils will be controlled plant N demand, with an initially decrease after afforestation to near-zero levels during the early N demanding growth stages, a gradually increase after canopy closure, reaching a constant elevated level, if atmospheric inputs are in excess of N accumulation in woody biomass.

With our findings we will demonstrate the pivotal role of climatic drivers in moderating water fluxes within the forest ecosystem, influencing the level of NO_3^-leaching and obscuring the direct impacts of management practices like thinning. Additionally, using the decadal time series of NO3 and element export, we aim to explore how nitrogen and other deposited elements, along with management, soil type, and forest age, drive trends in NO_3^--leaching over decades.

This comprehensive time series provides unique insights into the complex interplay between the atmospheric deposition, hydrology, forest management, and soil types, enabling the development of more robust estimates of ecosystem services related to water quality in future forests.

Nitrogen leaching to stream water from forest ecosystems under changing atmospheric environment in East Asia

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Hiroyuki Sase[1]
Masayuki Morohashi[1], Hiroki Yotsuyanagi[1], Naoyuki Yamashita[2], Urumu Tsunogai[3], Masamichi Takahashi[2]
[1] Asia Center for Air Pollution Research, Japan
[2] Forestry and Forest Products Research Institute, Japan
[3] Nagoya University, Japan

Abstract: Excess nitrogen deposition may disturb nutrient cycles in forest ecosystems. Nitrogen leaching into stream water as NO_3^- has been considered an indicator of nitrogen saturation in ecosystems. However, it has been observed that NO_3^- concentrations in stream water did not necessarily respond to changing nitrogen deposition as expected. Atmospheric environment in East Asia has been changing largely and nitrogen deposition has gradually decreased. Responses of forest ecosystems to the changing atmospheric environment have not been enough studied, yet, in terms of recovery process. In this study, long-term changes on nitrogen deposition and NO_3^- concentration in stream water in two forest catchments in central Japan are assessed based on our previous publications and the latest datasets. In the forest catchment of Lake Ijira (IJR) on the Pacific side, the EANET regular monitoring site, NO_3^- concentration has decreased with nitrogen deposition over the past few decades, suggesting recovery from nitrogen saturation in the 1990s. On the other hand, in the forest catchment of Kajikawa (KJK) on the Sea of Japan side, the EANET research project site, NO_3^- concentration has been increasing. In the case of KJK, ecosystem nitrogen demand appered to decrease with forest maturation. However, nitrogen deposition in both sites is still enough high, ≥ 10 kg N ha^{-1} $year^{-1}$. In fact, ^{17}O excess analysis of NO_3^- suggested that biologically unprocessed atmospheric NO_3^- leached into stream water larger in KJK than in IJR. In the presentation, effects of changing climate and meterological conditions will also be discussed. Other monitoring data from forest lakes in Japan and EANET sites in neighboring countries will also be referenced for discussion.

Responses of forest ecosystems to nitrogen deposition in the United Kingdom

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Elena Vanguelova[1]
Rona Pitman[1], Sue Benham[1]
[1] Forest Research, Alice Holt, Farnham, Surrey, GU10 4LH, UK

Abstract: Most of UK's woodland exceeds the critical nitrogen (N) loads. We reviewed current evidence from forest monitoring and experimental research on the measured impacts of N deposition on UK's forests. Forest monitoring (>20 years) suggest a significant decline in nitrate deposition in some lowland areas and in both ammonium and nitrate deposition in upland forests but no change in areas with high N deposition and near N pollution sources. Some ground flora response to decline or enrichment of N deposition has been identified, but forest age, canopy management, previous land use and edge effect need to be considered. Soil surveys suggest that UK's forest soils have accumulated N under conifers which may be released during forestry operations and pose a risk to water's quality and GHG emissions. Tree species and soil type play a vital role in the response of the forest to N inputs. Forest edge effect introduce both high spatial variability in N inputs and forest ecosystem responses to N deposition. Strong relationships between tree N uptake, litterfall, growth and insect damage have been related to N deposition. The generation of N through insect infestations of the forest canopy have been quantified and canopy N transformations demonstrated through stable isotopes studies. Dry and wet N deposition was found to be a significant predisposition factor for Acute Oak Decline. Clear thresholds of N deposition for ectomycorrhizal community's changes have been determined. Nitrogen input needs to be included in predictive modelling of biodiversity and tree health in forest ecosystems.

RISK ASSESMENT OF NITROGEN DEPOSITION IN SPAIN: TRENDS AND PERSPECTIVES USING EMPIRICAL CRITICAL LOADS.

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

[1] Ecotoxicology of Air Pollution, CIEMAT, Madrid, Spain
[2] Atmospheric Modelling Unit, CIEMAT, Madrid, Spain

Abstract: Human activities such as intensive agriculture and farming, fossil fuel burning and industry have significantly increased reactive nitrogen (N) emissions to the atmosphere. The subsequent deposition of this N onto natural ecosystems can alter the structure and biodiversity of ecosystems through eutrophication, acidification and disturbances of nutrient cycling. The risk assessment methodology based on critical loads (amount of atmospheric deposition of a pollutant above which negative effects on sensitive receptors of particular habitats are expected) allows the identification of the habitats threatened by a potential excess of N deposition. This methodology, developed in the framework of the Air Convention (CLRTAP/UNECE), may be used by air quality policy makers to establish emission thresholds that guarantee habitats conservation and may also be used to report the conservation status and perspective for protected habitats.
In a previous study in Spain, this methodology was applied to assess eutrophication risks by N deposition in habitats of Community interest included in the Spanish Natura 2000 network. Natural grasslands and some forests in northern mountain areas showed the highest risk, proving that biodiversity conservation in these protected areas could be endangered by N deposition.
Our objective is to expand this first risk assessment by using the recently revised empirical critical loads and atmospheric chemical transport modelling. We will use two different scenarios of pollutant emissions, in a context of climate change and taking into account the temporal evolution (between 1996 and 2055) of eutrophying nitrogen exceedances in Spain. For this purpose, a map of receptors has been constructed by combining the National Forest Inventory and the National Biodiversity Inventory cartography, and using floristic composition (dominant and diagnostic species) to codify the habitats according to the EUNIS classification as a previous step to produce a Spanish map of critical loads. Results will be presented and trends and perspectives will be discussed, with a focus on forest habitats.

[3] Dept. of Environmental Science, Stockholm University
[4] Swedish Water Authority of the South Baltic Sea District
[5] Dept. of Soil and Environment, Swedish University of Agricultural Sciences

Abstract: There is a new combination of environmental change over Europe during the last decade - nitrogen (N) deposition declines whilst air temperature is increasing. Soil microbes and their enzyme activities are sensitive to these environmental factors, and their responses may have implications for ecosystem C sequestration and nutrients availability.

The aim of this soil transplant experiment is to assess the responses of soil microbial functional groups and activity to i) change in climate, ii) change in N availability and iii) the combined change of both climate and N availability.

The soil transplant experiment was carried out in three Norway spruce field sites; Stråsan (central Sweden), Skogaby (SW-Sweden), and Čertovo (Czech Republic) on Podzolic soils. The mean annual temperature is 3, 8 and 5 °C and the current N deposition is 3, 15 and 15 kg N/ha.year in Stråsan, Skogaby and Čertovo respectively. In addition, there were N fertilization treatments at both Swedish sites. Intact soil cores were sampled (length 35 cm) and installed in soil at their host site in coarse mesh bags so that fine roots and fungi's mycelia could grow in. Cores were exchanged between each site and treatment (n =4) plus two internal controls and recollected after four years. Various soil microbial variables were measured: biomass C and N, enzymatic activities, and Phospholipid Fatty Acids (PLFA), including metabolic stress defined as the ratio between cyclopropyl and precursor PLFA. The microbial variables of the soil cores before and after transplantation were statistically analyzed.

We found significant differences in metabolic stress, PLFA and proportion of different microbial functional groups, especially in response to N availability. Highest metabolic stress was measured in the cores that remained in the N rich Čertovo, while it was lower in the Čertovo soil cores transplanted to warmer, but less N rich Skogaby-Control as well as in the Stråsan cores transplanted to N rich Čertovo. We will further disentangle the impact of climate, N availability and how these two drivers together affect soil microbes. We will also discuss possible implications of the microbial responses for ecosystem C sequestration and nutrient availability.

Spatial and temporal patterns of carbon stocks and nutrient availability in European forest soils under continued N inputs

Abstract: Forest soils play a key role in a range of ecosystem services, including climate control, biodiversity and water quality, and are a primary driver of forest productivity. However, insight in their response to ongoing environmental changes, such as nitrogen (N) deposition, relies on the availability of harmonised, spatially and temporally representative data.

Since the early 1990s, the ICP Forests Programme runs a harmonised forest soil monitoring survey across Europe, including large-scale monitoring on a systematic 16 x 16-km grid (Level I: approximately 5000 plots) and intensive monitoring with a time interval of roughly 10 years (Level II: 250 plots). Two surveys have been completed so far on both levels, while a third survey (2020-2025) is ongoing in most countries. A wide range of soil chemical (carbon (C), nitrogen, plant-available and semi-total elements, pH) and physical soil properties (soil texture, bulk density) have been analysed by national forest soil laboratories according to standardised protocols. All data are centralised in the database managed by the Programme Coordinating Centre of ICP Forests.

In this study, we present spatial and temporal patterns in (i) calculated stocks of soil organic C and macronutrients (N, phosphorus (P) and sulphur (S)); (ii) total and exchangeable pools of base cations (potassium, calcium, magnesium and sodium); (iii) the stoichiometry of C:N:P:S; (iv) indicators for nutrient availability; and (v) their spatial autocorrelation with N deposition levels; in both forest floors and mineral forest soils across Europe.

Observed differences between the soil surveys before and after the year 2000 are highlighted and

stratified by biogeographical region, forest and soil type. Finally, the consequences of changes in stocks and pools of plant-available nutrients are discussed against the background of the provisioning of forest ecosystem services, such as carbon sequestration in soils and aboveground biomass production.

Status and trends of nitrogen deposition in European forests

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Abstract: The input of nitrogen (N) into forests through atmospheric deposition has been determined for the main forest types within the ICP Forests Level II monitoring network since the 1990s from measured concentrations in continuously collected precipitation (bulk deposition) and throughfall (below tree canopy) samples. Over the past five years, a full deposition data set was elaborated, in which various technical issues were solved, inconsistencies were corrected, some data missing in the central database were added from national sources, and further completion was accomplished through gap-filling. Total deposition was calculated from bulk deposition and throughfall accounting for canopy exchange at annual and monthly scales. Here, we present the current status and the long-term trends (1996-2020) for throughfall and total deposition of dissolved inorganic nitrogen (DIN) compounds, including ammonium (NH_4^+-N), nitrate (NO_3^--N), and the NH_4^+-N:NO_3^--N ratio, for more than 300 Level II forest plots. Depositions of NH_4^+-N and NO_3^--N generally decreased over the studied period, and the decrease was also statistically significant on many of the plots. For NH_4^+-N, the decrease was the highest during the first decade, while its deposition has been stagnating afterwards. Furthermore, spatial patterns of trends in N depositions across biogeographic regions will be presented and discussed.

Twenty years of dry and wet deposition of nitrogen to Norway spruce forests Sweden

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Veronika Kronnäs[1]
Per Erik Karlsson[1], Cecilia Akselsson[2], Sofie Hellsten[1], Gunilla Pihl Karlsson[1]
[1] IVL Swedish Environmental Research Institute, P.O. Box 53021, SE-40014 Gothenburg, Sweden
[2] Lund University, Department of Physical Geography and Ecosystems Science, Sölvegatan 12, SE-223 62 Lund, Sweden

Abstract: The yearly dry and wet deposition of inorganic nitrogen (inorg-N) to Norway spruce forests was estimated with a full spatial coverage over Sweden for a twenty-year period, 2001–2020, based on combined measurements with Teflon string samplers, throughfall deposition and bulk deposition to the open field. It was shown that Norway spruce forests in south Sweden receive more N from deposition than has been previously estimated, based on modelling. Clear time trends were demonstrated for decreased deposition of inorg-N to Norway spruce forests in all parts of Sweden. The decreases were somewhat larger than what could be expected from the decrease in the reported emissions of inorg-N from Europe. The results emphasize that estimates of the total deposition are necessary in order to map levels and follow the development of N deposition in forests.

Uncertainty of critical load assessment of eutrophication in the tropical forests of Southeast Asia

T1.23 Nitrogen Depositions in a changing climate: Trends and Implications on Forest Ecosystem Services

Naoyuki Yamashita[1]
Hiroyuki Sase[2], Junichi Kurokawa[2]
[1] Forestry and Forest Products Research Institute
[2] Asia Center for Air Polution Research

Abstract: Spatiotemporal patterns of N deposition in Southeast Asia have changed significantly in recent years. More needs to be reported on the broad-scale effects on the ecosystems of tropical forests and the inland aquatic environment in this region. In a previous study targeting East and Southeast Asia, we assessed the risk of nutrient imbalances in the forest as elevated nitrate in surface water using a critical load of eutrophication. The exceedance map of critical load found that the risk may be higher in metropolitan areas such as Manila and Bangkok and in forested areas distributed near satellite cities and suburbs. Moreover, significant increases in nitrate were observed in the inland water aquatic environment of the EANET monitoring sites located in high-risk areas of our assessment. Meanwhile, the magnitude and flux of the nitrogen cycle in tropical forest ecosystems are significantly larger than those in subarctic and temperate forests. This indicates that applying a steady-state model, such as the critical load model, to this region has significant uncertainty derived from the temporal change of the fluxes. Moreover, the contribution of N fixation by the leguminous tree distributed in tropical regions should be considered. Many tropical forests are N-saturated originally; new criteria detecting further nitrogen leaching by N deposition should be established based on the current status of nitrate leaching. Because the denitrification process in the vadose zone is also significant, different criteria may be set for the leaching from the soil layer and to surface water. In this study, we optimized the critical load parameters for tropical areas by considering the regional parameter of plant traits and the spatial information available. We also set the plausible range of each parameter and evaluated the uncertainty of the critical load in this region. This approach could be realistic for assessing the risk of elevated nitrate concentrations in leaching, especially from suburban forests in Southeast Asia, where N deposition is increasing.

T1.24 Old-growth forest ecology and management

A Method to Assess the Level of 'Old-Growthness' in European Beech Forests : Results from a Network of World Heritage Beech Forests.

Abstract: Beech (*Fagus sylvatica*) is the natural dominant tree species in large parts of temperate Europe. Also, many of the remaining primary and old-growth forests in temperate Europe comprise of pure and mixed beech forests. Although there are several successful examples of strictly protected beech old-growth forest reserves, many old-growth forests are still not identified and protected and can be legally logged before their identification . The EU Biodiversity Strategy aims to map and strictly protect all remaining old-growth forests in Europe.

When assessing and mapping the remaining old-growth in European beech forests, it is essential to apply clear criteria and thresholds in a context that is complex due to a multitude of indicators and wide variety in the levels of 'old-growthness'. In order to delineate threshold values, reference values and ranges are needed.

The UNESCO World Heritage site "Ancient and Primeval Beech Forests of the Carpathians and Other Regions of Europe" is a so-called 'serial transnational site': it's a network of component parts comprising some of the best examples of primary and old-growth beech forest in Europe.

Within the LIFE-PROGNOSES project, we sampled a wide range of stand parameters that are related to characteristics of 'old-growthness' (diversity and amounts of living and dead biomass, presence of tree-related microhabitats,...) in a subset of the World Heritage site components and their buffer zones, in order to cover both the most 'natural' beech forests, but also a wide range of levels of old-growthness, as the network includes formerly managed forests that were set-aside in

recent and remote past.

Here, we will present the results of our analysis, determining a wide range of indicators and their reference values, and how to condense them to quantitative parameters (so-called Old Growth Indicators – OGI) and combine the results to produce a synthetic measure of old-growthness for European beech forests. This tool can help to organise a scientifically substantiated debate on threshold values and support the objective mapping of old-growth forests in Europe.

Aboveground Carbon Stock Mapping of a Sub-Tropical Natural Forest with Sentinel 2 Satellite Imagery: A Multi-Product Analysis Approach

T1.24 Old-growth forest ecology and management

Michael Gebreslasie[1]
Enoch Gyamfi-Ampadu[1], Alma Mendoza-Ponce[2]
[1] School of Agricultural, Earth and Environmental Sciences, University of KwaZulu-Natal, Westville Campus, Private Bag X54001, Durban 4000, South Africa
[2] Centro de Ciencias de la Atmósfera, Universidad Nacional Autónoma de México, Mexico City, Mexico

Abstract: Abstract

Accurate aboveground carbon (AGC) stock estimates are important for climate change policies and forest carbon management. However, such information is lacking in most Sub-Saharan African countries. Therefore, our study utilized Sentinel 2 imagery and an integrated Random Forest and Repeated K-fold Cross Validation [RKF-CV] (RF-RKF-CV) regression algorithm to predict and map the AGC of the Nkandla forest in KwaZulu-Natal province, South Africa. We compared the performance of four stand-alone RF-RKF-CV models. The models were composed of specific stand-alone Sentinel 2 spectral products which are Near Infrared based vegetation indices (NVI) only, Red-edge based vegetation indices (RVI) only, Spectral Bands (SB) and Combine Variables (CBV) derived from the first three products. The NVI model was more accurate (R^2 =0.680, RMSE = 144.52 Mg/ha), which could be attributed to the sensitivity of the NIR region to vegetation. The CBV model was the second most accurate while the RVI and SB models followed as the third and least accurate respectively. These other three lagged in accuracy as compared to the NVI model possibly due to noisy variables and a dip in the performance of the three Sentinel 2 Red-edge bands. It was also found that the number of variables used in each of the models did not have a significant influence on the accuracy. The Difference Vegetation Index, Enhanced Vegetation Index and NIR emerged as significant variables in the prediction of AGC. Since the NVI model was the most accurate, it was used to produce a map showing the distribution of the AGC across the Nkandla forest reserve. The produced AGC map will be useful for spatiotemporal analysis and validation of future AGC quantification. Our study outcomes will be of importance to forest carbon management. The study demonstrates the capabilities of the freely available fine-scale Sentinel 2 imagery products and integrated RF-RKF-CV algorithm for AGC prediction and mapping.

Best-in-Class Policy Provisions to Define and Protect Old-Growth Forests

T1.24 Old-growth forest ecology and management

Peter Duinker[1]
Peter Bush[2]
[1] School for Resource and Environmental Studies, Dalhousie University, Canada
[2] Nova Scotia Department of Natural Resources and Renewables, Canada

Abstract: Forests in Canada are governed largely by the provinces and territories. Thus, each sub-national jurisdiction has its own approach to the conservation of old-growth forests. The Province of Nova Scotia on Canada's east coast recently revised its policy on old-growth forests. Such forests are acknowledged to be rare relative to their abundance prior to European settlement. Because old growth delivers unique ecosystem services in terms of conservation of biodiversity, carbon, water, and soil as well as recreational, educational, and psycho-social benefits, the Government of Nova Scotia has declared old-growth forests to be of sufficient importance to warrant aggressive conservation and protection measures. An interim policy was implemented in 1999 and updated in 2012. A substantially strengthened policy was put in place in 2022. This presentation highlights the features of the 2022 policy that make it one of the most progressive policies on old-growth conservation in North America. Those features include more ecologically robust definitions of old growth, confirmed protection of old growth as well as old-growth restoration opportunity areas, strong replacement provisions should areas of public land supporting old growth be needed for provincially significant infrastructure, clarified roles for specific officials in the provincial administration, a commitment to work with privateland owners to find ways to conserve their old-growth forests, and strengthened assessment and monitoring protocols. The policy is scheduled for assessment and potential revision no later than August 2027.

Carbon accumulation, tree microhabitats, structural complexity according to naturalness and site features in old-growth beech forests in Italy

Abstract: Old-growth forests provide a unique contribution to both biodiversity conservation and climate mitigation. However, stand structural dynamics and the associated ecological processes may change significantly along environmental gradients, so features associated with increased naturalness may differ even within the same forest type.

We used a network of 200+ circular sampling plots (20-m radius) established within the Italian Components of the UNESCO Site 1133 "*Ancient and Primeval Beech Forests of the Carpathians and Other Regions of Europe"* to evaluate the relationships among forest carbon density, stand structural complexity, tree microhabitat concentration and tree ring-inferred community dynamics (recruitment, disturbance and growth trajectory history) along stand development and across a thermal gradient.

Within our study forests, tree communities with different management histories (early or advanced old-growth forests, mature or recently managed forests) were used to assess how naturalness increases determine changes in carbon stock, structural complexity and biodiversity. Tree-ring metrics were used to build a naturalness score that reflected parallel increases in the complexity of tree communities and the ecological processes that shaped them.

We found neat differences in forest structure and composition, and overall carbon density, between warm and cold beech forests. The established network allowed us to determine how the role of large trees and old-growth forest attributes change during stand development under different environmental conditions.

Classifying Mature Federal Forests in the United States: The Forest Inventory Growth Stage System

T1.24 Old-growth forest ecology and management
Christopher Woodall[1]
aaron Kamoske[1], Gregory Hayward[1], Thomas Schuler[1], Christopher Hiemstra[1], Marin Palmer[1], Andrew Gray[1], **Lara T. Murray**[1]
[1] US Department of Agriculture, Forest Service

Abstract: President Biden's executive order, 'Strengthening the Nation's Forests, Communities, and Local Economies,' (EO#14072, April 22, 2022) acknowledges the interest in mature and old-growth (MOG) forests by directing U.S. Federal agencies to define and inventory these resources on United States Forest Service (USFS) and Bureau of Land Management (BLM) lands. We propose that using an effective and enduring mature forest classification system could be adaptable to social paradigms, monitoring data streams, scientific information, and global change factors. We accommodate these design aspects by defining mature forests as a growth stage prior to the onset of old-growth attributes within a proposed Forest Inventory Growth Stage System (FIGSS). FIGSS uses the long-established USFS old-growth assessments often conducted in concert with public dialogues to identify key structural indicators of older forests. The system informs inverse modeling of the prior "mature" stage's structural thresholds enabling initial population estimates of mature forest extent using the USFS' nationally consistent Forest Inventory and Analysis (FIA) program data. With this approach, we estimate that approximately 44.8 percent of all USFS/BLM forest is mature. The FIGGS system is based on a variety of components that could be used to account for cultural values ascribed to forest conditions which could be refined across future versions such as assumptions about the relative length of growth stages, incorporating data from emerging monitoring technologies along with old-growth/mature field sampling campaigns, accommodating spectrums of site-limited and/or disturbance-driven stand development, refined variable selection processes such as machine-learning, and consideration of traditional ecological knowledge.

Dynamics of old-growth forests in Belize, Central America

T1.24 Old-growth forest ecology and management

Nicholas Brokaw[1]
Sheila Ward[2]
[1] University of Puerto Rico-Rio Piedras
[2] Independent

Abstract: To conserve old-growth forests we must understand their long-term dynamics. We studied dynamics over 24 years in four 1-hectare plots in old-growth forests (hundreds of yrs old) in Belize, Central America. The 1-hectare plots were near each other, but each was in a different forest type: hill, moist upland, riparian, and palm. In each plot we counted and identified all trees ≥10 cm DBH. Twenty-four years later we re-inventoried the plots. Among plots, the number of trees ranged from 374 to 700 ha^{-1} in the first inventory, and the number of species from 46 to 59. During the 24 years tree number declined in the hill forest but was stable in the others. Mortality (% death of trees in first inventory) among the plots ranged from 1.1-2% yr^{-1}. Recruitment (% trees newly recorded in second inventory) ranged from 0.5-2% yr^{-1}. Species totals remained stable in all plots, but a significant number of species were eliminated from and added to each plot during the 24 years. The hill forest plot was in a wind-exposed setting; the decline of tree number in it perhaps reflected the death of long-lived pioneer trees that colonized the plot after wind disturbance 40 years before the first inventory. The riparian forest plot is subject to flooding, making trees unstable and leading to many treefalls, high mortality, and high recruitment in gaps. Thus dynamics differed among the plots according to topography, and these topographically-determined forest types may be differentially susceptible to a changing climate of wind and flooding. Most important, because the dynamics of old-growth forest differed among forest types we need forest type-specific, long-term data to distinguish baseline dynamics from novel dynamics caused by climate change or human disturbance.

Exploitative or healthy coexistence: Is the practice of sacred forest system in Nigeria mutually beneficial to the ecosystem and indigenous people?

T1.24 Old-growth forest ecology and management

Jonathan Onyekwelu[1]
Nicholas Brokaw[2]
[1] Department of Forestry and Wood Technology, Federal University of Technology, P.M.B. 704, Akure, Nigeria
[2] University of Puerto Rico-Rio Piedras

Abstract: The sacred forest (SF) system, an ancient tradition, is an indigenous community-based traditional forest conservation method. It evolved through interactions between indigenous people and their environments and act as connecting link between man, nature, cultural heritage and religious beliefs. Protection is secured by indigenous people through access restriction, rules, taboos, dedication to and fear of deity(ies). Sacred forests provide ecosystem goods and services of importance to livelihoods of indigenous people. The question is whether this synergy between SFs and indigenous people is exploitative or mutually beneficial? Three prominent SFs in southwestern Nigeria were used as case study to examine the extent to which socio-economic and religio-cultural benefits derived by indigenous people from SFs contribute to biodiversity conservation. Inventory data were collected from three SFs for biodiversity assessment. Mixed-methods approach that combined semi-structured questionnaire surveys, interviews and focus group discussions were used to collect data for ecosystems services and livelihood support investigations. Results revealed that the three SFs were relatively intact with minimal anthropogenic disturbances. The high biodiversity indices (species richness: 76–106; Shannon-Wiener diversity index: 3.47–3.86; density: 1,597–2545 trees ha^{-1}) are evidence that SF is effective traditional biodiversity conservation method. This is attributed to protection by indigenous people through fear of deities, respect for taboos, access restriction/prohibition, etc. Tourism, NTFPs collection, income generation and employment were some socio-economic gains by indigenous people that drive biodiversity conservation. Important religio-cultural benefits contributing to biodiversity conservation were: use SFs for traditional festivals, places of worship and kingmaking rituals. Institutional involvement had positive effect on biodiversity conservation and ecosystem services provision from SFs. E.g., the designation of Osun-Osogbo SF as Nigerian national monument and UNESCO World Heritage site enhanced its biodiversity conservation potential, increased tourism, socio-economic gains and preserved religio-cultural values. Thus, there exist synergy between SFs and indigenous people, long-term preservation of SFs and their biodiversity depends on protection by communities while the livelihoods of indigenous people is enhanced by the socio-economic and religio-cultural benefits derived from SFs. Thus, coexistence of SFs and indigenous people is healthy and mutually beneficial.

Keywords: Biodiversity conservation, sacred forest, indigenous people, synergy, socio-economic benefits, ecosystem service

Exploring Age structure of Birch Forests in Norway: Insights from Tree Ring Data from National Forest Inventory

T1.24 Old-growth forest ecology and management

Marta Vergarechea[1]
Clara Antón-Fernández[1], Rasmus Astrup[1]
[1] Division of Forest and Forest Resources, NIBIO (Norwegian Institute for Bioeconomy Research), Høgskoleveien 8, 1433 Ås, Norway.

Abstract: The age structure of forests offers valuable insights into carbon stock potential and serves as an indicator for assessing the degree of biodiversity conservation or the risk of disturbances. Additionally, age-class structure stands as a key indicator of both economic and ecological sustainability in forest management. Tree age can be affected by various factors, including disturbances, seed presence, and tree species composition. Indeed, tradeoffs between longevity and growth rates have long been noted across tree species, as they result from the complex interplay between growth dynamics and the potential costs associated with an extended lifespan. In this study, tree ring width data from the National Forest Inventory was used to analyze the age distribution of birch forests as well as growth rates across different age classes. Then, we used a generalized linear mixed-effects model to quantify the effect of different predictor variables on birch age. We found that the middle age group (50-100) dominates most regions of the country. Moreover, we observed a prevailing age cohort within most of these regions, suggesting a significant disturbance event approximately 80 years ago. We noted that the youngest forests exhibit a notable association with a high site index, particularly in the oceanic west coast areas, while as forests age, this correlation decreases. The model showed an inverse relationship between growth rate and increasing age class, i.e., fast early growth is associated with decreased longevity. Thus, fast growth in locations with high site indices would result in a shorter tree life expectancy. The findings emphasize the importance of considering biological, ecological, and historical factors for a comprehensive understanding of tree age structures in diverse forest landscapes.

New Zealand’s indigenous forests – how much of eight million hectares is Old-growth forest?

T1.24 Old-growth forest ecology and management

Thomas Paul[1]

[1] Scion (NZ Forest Research Institute), Rotorua, New Zealand

Abstract: Indigenous forests cover around eight million hectares of New Zealand’s total landmass of 27 million hectares. A large part of these forests is under protection and valued for its biodiversity, recreational and non-timber related ecosystem services. While mostly undisturbed from direct human influence, indirect impacts such as pest introductions, weeds and climate-change-induced stressors (e.g. drought) are understood to be threats to the natural dynamics of these forests. Since 2002 New Zealand has been monitoring the large extend of indigenous forests via a plot-based forest inventory to understand their dynamics better, particular in regards to their carbon stocks and carbon stock changes as a whole. While the forest inventory is now only in its third measurement it provides insights in how these forests are structured and which tree species playing a mayor role as a significant carbon store. In light of the question “what defines Old Growth Forest in New Zealand” we present the methods and resulting data from our national forest inventory to develop and discuss a possible working definition based on stand structure and the relationship between live and dead biomass in New Zealands indignous forests.

Under the Paris Agreement, New Zealand forests will fall under the managed forest category. Changes in carbon stocks need to be accounted for if these are above or below the natural variation and can be attributed to human management. We will present estimates of current carbon stocks and carbon stock changes in forests that can be categorised as Old Growth forests and discuss the difficulties of disaggregating natural fluctuations and human induced changes through previous and current management.

Old-growth Araucaria-Nothofagus forests in Northwest Patagonia: fire, management, and conservation

T1.24 Old-growth forest ecology and management

Mauro Gonzalez[1, 2]
Ariel Muñoz[2, 3]
[1] Universidad Austral de Chile, Faculty of Forest Sciences and Natural Resources, Valdivia, Chile
[2] Center for Climate and Resilience Research (CR2), Santiago, Chile; Center for Fire and Socioecosystem Resilience (FireSES), Valdivia, Chile,
[3] Pontificia Universidad Católica de Chile, Instituto de Geografía, Valparaíso, Chile

Abstract: Fire is a major disturbance process affecting the Andean Araucaria forest landscape in north-west Patagonia. Both surface and stand-replacing fires are known to shape the structure and composition of these forests. Fire history and age structures indicate that variability in fire frequency and severity are key to explaining the mosaic of forest patches across the Araucaria–*Nothofagus* landscape. Large Araucaria trees are highly resistant to fire, and this species typically survives moderate- to high-severity fires either as dispersed individuals or as small groups of multi-aged trees. Overall, stand development patterns of subalpine *Araucaria–Nothofagus* forests are largely controlled by moderate- to high-severity fires, and therefore tree regeneration dynamics is strongly dominated by a catastrophic regeneration mode. In the context of climate change, recent widespread wildfires affecting old-growth Araucaria forests appear to be novel and an early indication of a climate change driven shift in fire regimes in north-west Patagonia. Extreme wildfire events and reburns after short intervals globally have been attributed to climate trends and land-use practices. Understanding how wildfire alters the potential for subsequent wildfire and favours transition to more fire-prone landscapes through fire-driven positive feedback are key research topics for the management and conservation of old-growth Araucaria forests in northwest Patagonia.

Old-growth forests, biocultural diversity and monks in the northern Italian Apennines

T1.24 Old-growth forest ecology and management

Renzo Motta[1]
Matteo Garbarino[1], Roberta Berretti[1], Alessia Bono[1], Milić Ćurović[2], Vojislav Dukic[3], Paola Nola[4]
[1] University of Turin, Italy
[2] University of Montenegro, Montenegro
[3] University of Banja-Luka, Bosnia-Herzegovina
[4] University of Pavia, Italy

Abstract: The silver fir (*Abies alba*) forests of the northern Apennines (Italy) have been strongly affected by past human land-use. The conservation of the silver fir in this region was mainly related to religious orders (e.g., Camaldolese, Vallombrosian, Franciscan). The monks preserved and even planted silver fir for its greater sense of spirituality and mysticism and economic value. Inspired by spiritual principles and applying traditional ecological knowledge, monastic communities developed distinctive natural resource management models, resulting in peculiar landscapes rich in both biodiversity and bio-cultural diversity. Some of these forests represent the best-preserved silver fir forests in the northern Apennines. Their presence was the main reason of the establishment of Casentino Forests, Monte Falterona and Campigna National Park. In the last decades, the management approach in these forests has shifted from traditional use to strict conservation. The current policies don't consider the peculiar "cultural" landscape created by centuries of land use and the fact that these forest stands are currently deeply different from reference old-growth stands of the same forest type still present in the Dinaric Alps. Besides, the establishment of the National Park has provoked the exponential increment of autochthonous and introduced ungulates, making it impossible for the silver fir the natural regeneration. To prevent the loss of bio-cultural diversity and landscape and, at the same time, to leave room for natural processes like spontaneous forest regeneration, both forest and natural resources management have to be re-evaluated and regularly monitored.

Old-growthness level assessed by structural heterogeneity indices in two rare Mediterranean Quercus pubescens forests

T1.24 Old-growth forest ecology and management

Emilio Badalamenti[1]
Donato Salvatore La Mela Veca[1], Massimiliano Costa[2], Giovanni Giardina[1], Tommaso La Mantia[1], Andrea Laschi[1], Federico Guglielmo Maetzke[1], Serena Petroncini[3], Giovanna Sala[1], Rafael Silveira Bueno[4]

[3] Ente di Gestione Parchi e Biodiversità – Romagna, Riolo Terme (RA)
[4] Department of Biological, Chemical and Pharmaceutical Sciences and Technologies (STEBICEF), University of Palermo, Italy

Abstract: Old-growth forests are unique ecosystems for biodiversity conservation, climate change mitigation and slope protection, as well as being a benchmark for the implementation of sustainable forest management. Although studies on old-growth forests have significantly increased in the last decades, still limited is knowledge on Mediterranean ecosystems. Particularly, no field research has been carried out hitherto in old-growth forests dominated by tree thermophilous oak species belonging to *Quercus pubescens*. To fill this knowledge gap, we characterized two *Quercus pubescens* forests (Fanuso and Gurgo) possessing old-growth traits and localized in Sicily (Mediterranean Italy). We assessed the old-growthness level by applying two structural heterogeneity indices (SHIs) specifically developed for old-growth forests, also assessing whether parameter choice can influence the SHI score. Structural attributes of living biomass and deadwood were used to calculate the indices. Both forests were found to hold some old-growth traits, while lacking other ones, with differences between sites. Fanuso proved to be closer to naturally aged forest stands, although SHI was not statistically different compared to Gurgo. Fanuso hosted a notably higher deadwood amount than Gurgo, reaching a high value (≈ 52 m^3 ha^{-1}) in the context of Mediterranean forests. Also, in this forest, the ratio dead/living wood volume exceeded the 10% threshold considered in the literature. Both forests hosted at least 100 trees ha^{-1} with a DBH > 40 cm, which accounted for about 70% of living biomass. However, both forests are characterized by a limited overall contribution of standing dead trees, as well as of large dead elements. Our study also highlights the need to standardize the parameters used to characterize the old-growthness level of Mediterranean old-growth forests in order to allow more reliable comparisons. We deem that both forests deserve primary attention also taking into account the rarity of *Quercus pubescens* forests possessing old-growth traits throughout its distribution range. Furthermore, under tailored management measures and proper silvicultural options, these stands are expected to evolve towards the old-growth stage under a medium to long-term perspective. In this regard, it is highly hoped for their inclusion in the National Network of old-growth forests as recently established in Italy.

Population Structure and Distribution of Adansonia digitata

[3] Tree Crops Limited

Abstract: Non-timber forest products (NTFPs) contribute to livelihood security of people especially those in the rural areas. There is however a growing concern that NTFP-providing trees are declining due to land-use change, use intensification and over-harvesting and therefore an urgent need for their sustainable use. This study was conducted in districts with the baobab resource in Malawi, namely; Mangochi, Salima, Mwanza, Neno, Chikwawa and Nsanje to understand the population dynamics of the species which would inform sustainable management of the species. The assessments were done on 1,223 trees in baobab clusters overlaid with systematic grids with a 500m spacing interval between individual plots. Baobab in Malawi is limited to a few areas where the environment is highly conducive for its growth with Neno and Mangochi as high potential sites and overall mean stocking ranging between 3 and 8 stems^{-ha}. Diameters for the resource ranged between 230 and 305 cm, translating to yield estimates between 520 and 1,084 fruits per tree for the districts. The resource was most prevalent in settlements and farmlands and least likely in grasslands. Population structures showed that the resource is unstable in replenishment with limited saplings and juveniles. Generally, the baobab population seemed less affected by disease or pest infection as no more than 3% of the assessed population was infested. Deliberate efforts should be made to promote the raising of baobab trees either through nurturing of existing few seedlings and saplings or up-scaled integration of the resource on farmlands.

Priority actions for the conservation of primary and old-growth forests in Europe

T1.24 Old-growth forest ecology and management

Lyla O'Brien[1]
Marcus Lindner[1]
[1] European Forest Institute, Bonn Germany

Abstract: Primary and old-growth forests are extremely important for biodiversity and the provision of many other ecosystem services such as carbon storage. Yet, in Europe, most forests are currently managed and have been for centuries. As a result, primary and old-growth forests have become extremely rare. To address this, the EU Biodiversity Strategy for 2030 sets the target to strictly protect all remaining primary and old-growth forests as part of a wider ambition to strictly protect 10% of EU land-area. However, despite this target, the area of primary and old-growth forests in Europe continues to rapidly decline. In response to this, we outline four priority actions urgently needed for the conservation of primary and old-growth forests in Europe: (1) Identify and strictly protect all primary and old-growth forests; (2) Effectively protect all primary and old-growth forests; (3) Establish effective buffer areas around primary and old-growth forests; (4) Improve connectivity between primary and old-growth forests. In this study, we provide the evidence and rationale behind the need for these four priorities through a review of the literature, as well as identify key issues that should be overcome so that they can be implemented successfully.

The importance, the current state and the future of old-growth forests in Poland

T1.24 Old-growth forest ecology and management

Barbara Bożętka[1]

[1] Nicolaus Copernicus University, Torun, Poland

Abstract: Both ecology and management of old-growth forests are of great importance for Poland, because the last remnants of ancient European forests, including those featured by high degree of naturalness and still preserving primeval character, occur in the territory of this country.

The presented work has been subordinated to the two following tasks: 1. examination of the state and status of old-growth forest formations in Poland, incorporating the issue of threats for the ecosystems, 2. investigation into the definition of the old-growth forest, its changes and application. The study focuses on contemporary times, *i.e.* on the period after the World War II, however, it must have been expanded with an insight into the history of silviculture and forest protection. The research methods involved an analysis of the relevant state forest policy (from 1950s to 2020s); examination of evolution of the old-growth forest' definition, since the policy and applied definition directly impacts the management; an analysis of main directions of use of old forest ecosystems in Poland.

The research emphasizes the human-induced changes affecting old-growth forests and alterations of their definition, which as the results of the work demonstrate, continuously take place. Moreover, the work shows that old-growth forest ecosystems have been threatened by intensive use, even in the areas having high conservation status. Regrettably, the old-growth forests in Poland have become younger…

In consequence, the author reflects upon understanding of values of old-growth forests by decision making bodies and by the society.

A key part of the study is devoted to the future of an analysed forest type in Poland. A need to properly manage the old-growth forests, with protection being treated as a priority, has been highlighted. Furthermore, this is stressed that adequate policy strengthening the position of old-growth forests should be formulated and implemented. It involves not only local level, but also a state level of forest policy and management.

T1.25 Optimizing Agroforestry carbon stocks estimates

Above ground biomass variability related to stand structure heterogeneity in agroforestry systems in Portugal

T1.25 Optimizing Agroforestry carbon stocks estimates

Ana Cristina Gonçalves[1]

[1] MED – Mediterranean Institute for Agriculture, Environment and Development & CHANGE – Global Change and Sustainability Institute, Departamento de Engenharia Rural, Escola de Ciências e Tecnologia, Universidade de Évora, Pólo da Mitra, Ap. 94, 7002-554 Évora, Portugal.

Abstract: Thee forest species, cork oak (*Quercus suber*), holm oak (*Quercus rotundifolia*) and umbrella pine (for *Pinus pinea*), are the most representative species of the agroforestry systems in Portugal. These forest systems are characterised by low densities, large spatial variability, and have as main productions are bark and fruit for cork oak and fruit for holm oak and umbrella pine. The stand structure is diverse with pure, mixed, even aged and uneven aged stands, which in turn is also reflected in the above ground biomass. To tackle the variability in these stands, stand structure was analysed with absolute stand density measures and structure and diversity measures and indices for the number of trees and basal and above ground biomass. The results highlighted the differences between the different stand structures. Moreover, the analysis of variance revealed significant differences between the structure and diversity indices calculated with the number of trees or basal area and aboveground biomass. This could be related to above ground biomass incorporating both diameter at breast height and total height, thus integrating the horizontal and the vertical distribution, conversely to the number of trees and basal area that evaluate only the horizontal distribution. Overall, the evaluation of stand structure with above ground biomass can give further insights the variability of stand structure, including diversity, in a three dimensional frame, which can also encompass above ground biomass partitioning per component.

Funding: This work is funded by National Funds through FCT - Foundation for Science and Technology under the Project UIDP/05183/2020.

Allometric Equation for Estimating Aboveground Biomass in Fruit Trees: Implication for Climate Change Mitigation in Croplands

T1.25 Optimizing Agroforestry carbon stocks estimates

Myeongja Kwak[1]
Jongkyu Lee[1], Suyoung Woo[1]
[1] University of Seoul

Abstract: Estimates of carbon stock changes in croplands are an important issue for agricultural management systems and climate change mitigation. Above-ground biomass (AGB) prediction for fruit trees is an important indicator for monitoring the carbon (C) sequestration potential of orchards. According to recent studies, the Agriculture, Forestry and Other Land Use (AFOLU) sector is a major contributor to global carbon emissions and hence simultaneously holds great potential to remove atmospheric carbon, which represents negative feedback to climate change. In particular, fruit trees in orchards contribute to carbon sequestration and can play an important role in the C cycling of terrestrial ecosystems. Allometric equations are not only a basic mathematical tool for quantitatively evaluating C sequestration but also enable non-destructive testing estimation of biomass. On the other hand, a clear need to incorporate carbon flux associated with vegetation dynamics in croplands is urgent, and the importance of improving estimates of biomass and carbon storage of fruit trees has been steadily raised in several studies. For forest and plantation vegetation, destructive methods have been used to obtain vegetation dry weight and infer biomass carbon stocks (~47.4% of dry biomass). These disruptive measures are essential, but costly in terms of time and resources. Therefore, the development of relative growth equations that relate non-destructive or semi-destructive measures of vegetation structural characteristics to above-ground biomass stocks is very important. Therefore, through this review, we would like to introduce several studies related to the development of fruit tree biomass relative growth methods. (This work was carried out with the support of "Cooperative Research Program for Agriculture Science and Technology Development (Project No. RS-2023-00220456)" Rural Development Administration, Republic of Korea.)

Carbon Stocks and Economic Contributions of Smallholder Agroforestry in Northeast India: Implications for Sustainable Landscape Management

T1.25 Optimizing Agroforestry carbon stocks estimates

Ishita Mathur[1]
Prodyut Bhattacharya[1]
[1] Guru Gobind Singh Indraprastha University

Abstract: Smallholder agroforestry, a land-use system that integrates trees with agricultural crops or livestock, offers great potential for addressing climate and biodiversity goals, as well as provide economic resilience. This can prove to be significant alternative for the erstwhile indigenous shifting cultivators of Northeast India, who are undergoing an agroecological transformation. While the practice of shifting cultivation has become ecologically and nutritionally unsustainable, the tribal communities of Tripura, comprising one-third of the state's population, are now adopting agroforestry alternatives for social, economic and ecological resilience. This study aimed to estimate the aboveground biomass (AGB) and belowground biomass (BGB) carbon stocks of diverse smallholder agroforestry plots. A total of 70 plots were sampled across the two districts of Tripura, which included homegardens and plantations, for estimation of AGB and BGB using allometric equations specific to the region. The results revealed significant variations in carbon stocks among the different agroforestry systems. The average AGB carbon stock ranged from 20 to 165 Mg/ha, based on the agroforestry category. A correlation between the age of the crop stands and carbon stock was also observed. Additionally, these agroforestry plots contributed to about 23 to 78% of their annual household income. Assessing the carbon storage potential of agroforestry practices will provide valuable data for sustainable land management and policy development in this area of continuous forest landscape transformation, especially when compared with the practice of shifting cultivation. The findings of this study will contribute to the development of effective strategies and policies aimed at promoting social and economic resilience, as well as ensuring food security among indigenous communities, by utilizing forests and trees to achieve climate and biodiversity objectives.

Combining 2D and 3D methods to monitor carbon in agroforestry systems

T1.25 Optimizing Agroforestry carbon stocks estimates
Daniel Ortiz-Gonzalo[1]
[1] University of Copenhagen

Abstract: Agroforestry, the practice of integrating trees into farming landscapes, offers substantial potential in climate change mitigation and adaptation, as well as livelihood improvement. However, these contributions are often overlooked in Measurement, Reporting, and Verification (MRV) systems, which are pivotal for countries to achieve their climate objectives under the Paris Agreement. In tropical regions, among other reasons, agroforestry accounting is constrained by uncertainties tied to data scarcity.

Here we aim to assess cost-effective methods to identify agroforestry systems and non-destructively quantify above ground biomass at the individual tree level. To accomplish this, we implemented a multi-scale approach that integrates remote sensing and deep learning with field data gathered using images (processed by photogrammetry and neural networks) and smartphone LiDAR. We linked 2D data (crown segmentations derived from satellite imagery) to 3D data (tree functional traits derived from point clouds) to monitor the biomass and carbon across a range of agroforestry systems in Peru.

This combination of technologies successfully served to monitor biomass and carbon in scattered-trees in silvopastures, hedgerows, and shaded systems. Challenges, however, arose when dealing with complex, closely-canopied systems such as multistrata and old fallows. Our findings contribute to strengthening the inclusion of agroforestry in MRV systems.

Mapping Sustainability: Agroforestry's Extent and Carbon-Sequestration Potential in Kangra District of North-western Himalayas

T1.25 Optimizing Agroforestry carbon stocks estimates

Prashant Sharma[1]
Daulat Ram Bhardwaj[1], Garima Gupta[2]
[1] Dr YS Parmar University of Horticulture and Forestry, Solan, India 173230
[2] Rani Lakshmi Bai Central Agricultural University, Jhansi, India 284003

Abstract: Implementing agroforestry can substantially contribute to attaining the United Nations' most formidable sustainable development goals (SDGs). Regrettably, a widely held fallacy persists regarding the insignificance of agroforestry, leading to its frequent neglect by decision-makers and policymakers in matters pertaining to land use and environmental issues. The lack of information regarding the regional extent of agroforestry practices and their carbon (C)-sequestration potential is the primary cause of this disregard. Several techniques are available for quantifying the C-sequestration capacity at the field level. However, the compilation of such information becomes progressively complex when evaluating it at the district level. Thus, the present investigation centres on the Kangra district in the Western Himalayas to tackle the aforementioned concern. The study employs remote sensing and Geographic Information System (GIS) methodologies to demarcate the region encompassing agroforestry and evaluate its corresponding capacity for C-sequestration. Using eleven bands of Sentinel-2 imagery (10 m resolution) and three biophysical parameters, the random forest method was used to estimate the extent of agroforestry areas, while the CO2Fix model was used to estimate the potential for C-sequestration. The results indicated that agroforestry covered about 32.43% of the district, followed by agriculture (20.78%), forest (19.41%), grassland (8.01%), water (4.7%), desolate land (3.5%), snow cover (3.4%), and built-up areas (2.75%) with an overall accuracy of 79.77% and kappa coefficient of 0.743. In addition, 28 species (61.08 tree ha^{-1}) were identified and classified into three groups: slow-growing (3 species), medium-growing (15 species), and fast-growing (10 species), having average age of 60, 18 and 5.5 years, respectively. Over a 25-year simulation period, agroforestry systems in the district would sequester 76.29 Mg C ha^{-1}, resulting in an annual C-sequestration rate of 3.05 Mg C ha^{-1} $year^{-1}$. In addition, it was anticipated that the district's agroforestry systems would have an annual CO_2 abatement capacity of 2.07 million t CO_2 equivalent. These preliminary estimates provide valuable insight into the scope of agroforestry and its C-sequestration potential, which are important indicators for the contribution of agroforestry to a country's climate change objectives or INDCs under UNFCCC.

Possibilities of Quantifying Mitigation Capacity in Agroforestry Systems

T1.25 Optimizing Agroforestry carbon stocks estimates

Orsolya Szabó[1]
Tamás Molnár[1], Éva Ilona Király[1], Zsolt Keserű[2]
[1] University of Sopron, Forest Research Institute, Department of Ecology and Silviculture
[2] University of Sopron, Forest Research Institute, Department of Plantation Forestry

Abstract: Nowadays, mitigation is playing an important role in the light of the Paris Agreement and the European Climate Regulation. In 2022, the report of the Intergovernmental Panel on Climate Change (IPCC) classified agroforestry as one of the three most important mitigation alternatives within the land use sector.

The methods used to estimate carbon sequestration are very diverse. We have large- and smaller-scale global models based on extrapolation of field measurements from sample areas, which are used in forestry for carbon sequestration estimates, and are therefore likely to result in severe under- or overestimation of the total carbon stock. A model examining agroforestry systems adapted to the Hungarian conditions has not been prepared yet.

Using cloud-based systems (e.g. Google Earth Engine or Global Forest Watch) we can create maps and graphs displaying biomass, soil carbon content, carbon absorption and greenhouse gas emissions. Their advantage is large spatial coverage, but their disadvantage is medium spatial resolution, so systems with small areas cannot be examined by them.

In case of shelterbelt systems, we can perform a more accurate carbon stock calculation based on the data of the National Forest Stock Database, which is based on field measurements and estimated data. Unfortunately, this method cannot be used in all types of systems.

In case of field measurements, we examine the amount of carbon stored in the above- and belowground biomass, as well as in the soil. In two sample areas in Hungary (alley cropping and shelterbelt systems) we use the traditional method for measuring above-ground biomass is to cut down individual trees and plants, and then measure their carbon content in laboratory. The carbon content of the soil sample is determined according to a methodology, and the root-to-shoot ratio is used to express the belowground biomass. In our research work, we want to assess the mitigation potential of Hungarian agroforestry systems, comparing the accuracy of the mentioned methods.

Soil carbon accounting in agroforestry systems – a review and standardized guideline

T1.25 Optimizing Agroforestry carbon stocks estimates

[3] German Agroforestry Association (DeFAF), Germany
[4] Chair of Soil Protection and Recultivation, Brandenburg Universtiy of Technology Cottbus, Germany
[5] Soil Science and Plant Nutrition, Faculty of Life Sciences, Rhine-Waal University of Applied Sciences, Germany

Abstract: Agroforestry systems have great potential to sequester carbon in soil and to mitigate the impacts of climate change. Key factors herefore are predominantly the presence of perennial woody plants and the absence of soil tillage in the tree strip zone. However, obtaining reliable and comparable data from different agroforestry systems poses a challenge due to their diverse designs, management practices, and environmental conditions. This complexity makes it difficult to estimate the overall impact of agroforestry on soil carbon sequestration and other soil indicators. Many researchers have highlighted this challenge.

One promising approach to estimate carbon stocks is the use of transect sampling in alley cropping systems. By systematically sampling along transects within tree strips and adjacent arable or grassland strips, the internal heterogeneity of an alley cropping system can be addressed. However, transect sampling methodologies differ widely and may result in biases of over- or underestimation of the tree influence of the system as a whole.

We will present a review of transect sampling methodologies based on studies used in a meta-analysis on soil organic carbon sequestration in alley cropping systems and discuss six common biases with regard to sampling locations and overall system analysis. Furthermore, we propose a guideline for transect soil sampling to overcome these biases, and to contribute to improved field study design and description, comparable and robust data collection – overall improving agroforestry estimates across systems. Practical examples of the implementation of the proposed guideline will be shown from Gladbacherhof, the research farm of the Justus-Liebig-University Giessen, and practical farms involved in a citizen science agroforestry monitoring project of the University of Münster.

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Bridging the Gap: Insights from Practitioners on Applied Forest Restoration across Europe

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Abstract: In the face of global change, the biodiversity loss and degradation in forest ecosystems have highlighted the urgent need for ecological restoration for forest conservation. In Europe, conservation has a long tradition, being particularly complex due to diverse ecological, political, social and economic conditions. Successful restoration requires a comprehensive understanding of the interactions between climate, ecosystems (including their biodiversity), and society.

The SUPERB project aims to consolidate and share the extensive knowledge on forest restoration across the various situations in the European Union, providing evidence-based practical insights. This is being achieved by: 1) collecting site-level restoration activities through European workshops with different stakeholders, 2) analysing reforestation or restoration projects and questionnaires, and 3) developing national-level restoration narratives based on national expert assessments.

This study presents a comprehensive characterization of the diverse forest restoration activities in European regions, facilitating the extraction of valuable lessons when combined with scientific information. By bridging the gap between practitioners and scientific research, this research aims to enhance the effectiveness of applied forest restoration efforts across Europe.

Carbon2Mine, a second chance for the industrial reconversion of mining areas in northern Spain. Management models and carbon cycle

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Tamara Martínez-Martínez[1]
Rubén Forján[1], Alís Novo-Fernández[1], Pilar Garcia-Manteca[1], Sven Mutke[2], Paula Soares[3], Asun Camara-Obregon[1]
[1] SMartForest research group & INDUROT, University of Oviedo. C/ Gonzalo Gutiérrez de Quirós s/n,33600 Mieres, Spain
[2] Instituto de Ciencias Forestales (ICIFOR-INIA), CSIC CONSEJO SUPERIOR DE INVESTIGACIONES CIENTÍFICAS Carretera de La Coruña, km 7,5 · 28040 Madrid, Spain
[3] Instituto Superior de Agronomia, Universidade de Lisboa. CEF - Centro de Estudos Florestais. Tapada da Ajuda, 1349-017 Lisboa, Portugal

Abstract: The Carbon2Mine project is a Reverse Mining initiative funded by the European Union through the LIFE program. Focusing on the Asturian Mining Basins, an area deeply affected by the consequences of deindustrialization in Europe, the project aims to address the economic and sociodemographic imbalances resulting from this process. Furthermore, it recognizes the enduring impact of mining activities on the landscapes and ecosystems of the region.

One of the project's key objectives is to develop new forest management models that contribute to carbon sequestration and fixation while minimizing the carbon footprint associated with current management practices in the study area. These models also ensure compliance with legal conservation restrictions and regulations.

To achieve this, various models based on field data have been adjusted and extended to cover other mining areas. The project involves the characterization and interpretation of available databases, validated through aerial photography, to differentiate between degraded and natural soils in mining waste dump areas. Furthermore, a network of 150 experimental plots has been established to characterize vegetation systems.

To validate the models against real-world conditions, a grid of sampling points has been established throughout the area using a systematic statistical sampling method. At these points, data on carbon content and other soil variables have been collected, enabling the assessment of different terrain types within the project's scope.

The collected data aims to facilitate the development of sustainable forest and grassland management models for mitigating climate change. The project's specific objectives include: i) reducing the carbon footprint of forestry activities by 55%, ii) increasing vegetation presence in degraded and natural soils by 50-75%, iii) maximizing CO2 fixation in soils and vegetation through increased soil carbon sequestration, and iv) developing an assessment tool for tracking carbon capture in terrestrial ecosystems at the regional level, among other goals

Considerations of the voluntary carbon market parties to invest in prestoration actions.

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Arnout Asjes[1]
Josephine Haas[1]
[1] Land Life Company

Abstract: This presentation addresses the topic posed for this prestoration session:

".. the finance sector is more than ever ready to invest into nature and green solutions, however there is large uncertainty about the quality and long–term benefits of investment opportunities, how to credit these, and how to effectively bring the large demand for investment opportunities and the widespread but dispersed need for locally-adapted prestoration (restoration combined with adaptation) actions together."

Land Life, as only private partner in SUPERB, is largely funded by the voluntary carbon market to finance its nature-based reforestation activities of degraded lands. In this presentation we will inform the audience on:

- What makes a high-quality carbon credit?
- How can benefits be shared with local communities?
- How does the voluntary carbon market support nature-based solutions?

We will address the following topics:

- Market Growth: The voluntary carbon market is projected to experience significant growth in the coming years. Increasing awareness and concern about climate change, coupled with corporate sustainability commitments, are driving the demand.
- Standardization and Transparency: Standardization and transparency are critical factors for the future success of the voluntary carbon market.
- Technology and Innovation: Advancements in technology are expected to drive innovation within the voluntary carbon market.
- Pricing and Market Mechanisms: As the demand increases, the pricing of carbon credits may become more dynamic.

The voluntary carbon market is subject to various factors and issues, including evolving global climate policies, market dynamics, and stakeholder engagement. Ongoing monitoring and adaptation to emerging trends and challenges will be key to realizing the full potential of the voluntary carbon market in addressing climate change.

Coping with tree plantation failure under extreme drought events in France: The role for insurance in the forest owner-forest company relationship

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Sandrine Brèteau-Amores[1]
Marielle Brunette[2], Julien Jacob[2]
[1] APESA, Bordeaux, France - Associate researcher at Université de Lorraine, Université de Strasbourg, AgroParisTech, CNRS, INRAE, BETA, Nancy, France
[2] Université de Lorraine, Université de Strasbourg, AgroParisTech, CNRS, INRAE, BETA, Nancy, France

Abstract: In France, in the case of plantation failure, the forestry company provides a replacement for dead plants if the mortality exceeds a certain percentage of the plantation. Mortality not covered by the insurance remains the forest owner's liability. However, the insurance can be waived if the mortality of the plants is unrelated to the quality of the forestry company's service, for example, in periods of excessive drought or damage caused by animals. Nevertheless, due to the lack of a clear definition of drought, this insurance clause is rarely applied, and plantation failure is more often than not the forestry company's liability, greatly increasing its costs. In this context, our study aims to address the following questions. In the case of plantation failure, is it less costly for the forest owner to replant, not replant, or restart the whole plantation? What is the impact of changing the liability scheme between the company and the forest owner in terms of replantation costs and risk sharing? What is the optimal scheme in terms of risk sharing between the stakeholders (forest owners, forest companies, insurance companies)? First, we performed a cost assessment of different itineraries of plantations as a function of different mortality rates. The breakdown of the replantation costs between the company and the forest owner was also investigated. Second, we developed a theoretical model in order to define the optimal risk distribution between the stakeholders. First results show that no replanting is the least expensive option for the forest owner, followed by replanting and then by starting the whole plantation anew. Reducing the company's liability is an interesting option to reduce its exposure to risk. Modifications of the company's liability allows for the inclusion of private insurance contracts against plantation failure.

Disinformation, idealistic visions and Santa's home: Public and political discourses surrounding the proposed EU Nature Restoration Law

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Simon Fleckenstein[1]
Simon Schaub[2], Metodi Sotirov1[1]
[1] Chair of Forest and Environmental Policy, Institute of Environmental Social Sciences and Geography, University of Freiburg, Germany
[2] Institute of Political Science, Heidelberg University, Germany

Abstract: The necessity of restoring degraded natural ecosystems, including forests, has gained strong political momentum worldwide. In the European Union, a legally binding instrument was proposed by the European Commission in June 2022 to implement Europe's domestic and international commitments under the Biodiversity Strategy for 2030 and the Convention on Biological Diversity (CBD). However, the legal proposal of the so-called Nature Restoration Law (NRL) triggered highly controversial debates among stakeholder groups and political institutions. It faced fierce opposition throughout the ordinary legislative procedure, particularly from forest and agricultural landowner associations, as well as conservative and right-wing political parties. The law only survived the political negotiations by undergoing far-reaching amendments.

This study applies Discourse Network Analysis (DNA) to i) identify supporting and opposing discourse coalitions that developed during the formulation and negotiation process of the NRL, ii) unravel the justifications and claims these discourse coalitions utilized to influence the negotiation process, and iii) analyze how different discourse coalitions influenced the negotiation process and the final outcome of the EU NRL. The analysis builds on process-tracing using qualitative content analysis of key policy outputs, starting from the legislative proposal to the final negotiated text. Perceptions and positions of public stakeholders are analyzed using data from a public consultation, while the discourses among EU parliamentary groups are derived from parliamentary debates and position papers.

In times of intensifying climate change and rapid biodiversity decline, coupled with simultaneous setbacks in environmental policy development in the European Union due to political tensions and economic crises, this study provides crucial insights into ongoing environmental political developments in the EU, where the "EU Green Deal" stands at a crossroads.

Forest recovery after fire: forest restoration in the Spanish Demo under SUPERB

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Javier de Dios García[1]
Javier Dedios[1], Rocío Gallego[1], Iñigo Oleagordia[2], Rafael García[2], María Gómez[2]
[1] Forest Management and Natural Resource Department, CESEFOR, Spain
[2] General Directorate for Natural Heritage and Forestry Policy, Junta de Castilla y León, Spain

Abstract: The SUPERB project aims to develop systemic solutions for upscaling urgent ecosystem restoration for forest-related biodiversity and ecosystem services through 12 demonstration sites in Europe. One of its demos is located in Castilla y León, Spain, where the rural abandonment and the lack of forest management accentuates the processes of scrubbing of the landscape and homogenisation of the territory. This leads to an increment in forest fuel resulting in large forest fires. Moreover, large forest fires are a major impediment to the recovery of the Cantabrian brown bear (*Ursus arctos*), one of the most endangered mammals in Europe. The recovery of the Cantabrian brown bear is tightly linked to the improvement of its habitat and increasing forest resilience necessarily involves improving forest management to change the fuel model. We have therefore three main issues to resolve that are connected: tackling rural abandonment, changing the forest fuel model and to improving the habitat of the brown bear.

Within the SUPERB project we are going to carry out ecosystem restoration in the forests of El Bierzo with a socio-ecological and upscaling vision, involving stakeholders and considering restoration beyond SUPERB. We will carry out enrichment plantings with fruit broadleaves trees to improve brown bear habitat, silviculture activities to reduce forest fuel, as well as chestnut plantations near rural villages for chestnut production to help boost rural development. This will be done by involving local and regional decision-makers through stakeholder engagement workshops, which so far have already shown good involvement. We are currently implementing the whole restoration process, as the SUPERB project lasts until 2025, with some lessons learned so far.

In order to evaluate the recovery of ecosystem services of Mediterranean forests in El Bierzo after forest fires, thirty-six stands with a gradient of degradation caused by fire have been established. In these stands, samples of different indicators of ecosystem services and biodiversity are being collected. This sampling process will be carried out during three consecutive years (2022, 2023 and 2024), which will allow us to obtain preliminary results in mid-2024.

Forest reproductive material production and legal framework – how does it meet the requirements of forest regeneration and prerestoration?

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Martina Đodan[1]

[5] University of Novi Sad, Institute of Lowland Forestry and Environment
[6] Federal Forest Office, Vienna, Austria
[7] Department of Forest Growth, Silviculture and Genetics, Austrian Research Centre for Forests BFW

Abstract: Forest Reproductive Material (FRM) is crucial for forest restoration, artificial regeneration and nowadays much needed forest prestoration. Availability of adequate and adapted forest seedlings/cuttings are especially important after forest decline and in cases when site degradation must be prevented by fast and efficient silvicultural interventions. The complexity of FRM production grows increasingly as well as the need for adapted FRM. Thus, procurement of quality seed, as well as nursery production harmonized with needs in practical forestry could be seen as a backbone of current prestoration efforts. When production in forest nurseries is regarded, this stage in FRM procurement is even more complex and expensive then the collection of forest seeds since it lies not only on the seed production but numerous other circumstances and activities as well. But, there is a growing problem with procurement of adequate FRM in recent years, forcing forest practitioners in seedling/sapling production to face harsh challenges and production risks. This reached its peak in 2022 when pedunculate oak, one of the commercially most important tree species missed seed crop for several years in the row. The research addresses the issues of FRM production (especially nursery production), legislative framework, the needs of practical forestry in respect to FRM together with specific constraints and challenges in different countries of Central (Austria, Slovenia), Southeast (Croatia, Serbia, Bosnia and Herzegovina) and East Europe (Romania). Research includes analysis of seed stands and nursery production data with overview of legislative framework. It shows differences in approaches in European regions and countries, but underlines joint issues and challenges in facing increased challenges and meeting increased needs which arise mainly out of efforts on forest restoration/prestoration, conservation and enhancement of biodiversity and ecosystem services. Best nursery practices and the need for adequate planning are underlined so the research presents the good background for learning and improvement of FRM planning and production between countries and regions.

Keywords: Nursery production; Challenges; Constraints; Sustainable Forest Management; Tree species; nursery ownership, FRM types.

Learning from the past to face future challenges: gathering expert knowledge on the evolution of forest restoration in Europe

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Abstract: The growing recognition that healthy forests are key to tackle many of the challenges humanity faces (e.g., biodiversity, water and climatic crises) is resulting in a historical momentum encouraging forest restoration at the global, national and regional scales. This momentum is accompanied by multiple initiatives and policies that call, for example, for the restoration of at least 30% of the degraded ecosystems by 2030. However, the translation of these ambitious goals into reality is still a major challenge due to multiple limitations and uncertainties. One such challenge is that the success and failure of past restoration efforts remain poorly documented and disseminated. Thus, there is a clear need to capitalize on past experiences in forest restoration to minimize mistakes and maximize the efficient use of resources in the future. We address this challenge by collating information on the major practices and historical evolution of forest restoration in Europe. We aim to 1) examine the ecological, social, political and economic characteristics of the main forest restoration and adaptation initiatives across Europe, 2) understand how the nature of these initiatives has evolved over time and what the main drivers of change have been, and 3) synthesize the lessons learned from past and present restoration practices to facilitate success in future efforts. This is being achieved by analyzing and synthesizing the detailed information provided by 31 national experts from 20 European countries in the form of narratives and 38 indicators. As a result, the role of shifting political, ecological, social and economic conditions and decisions in shaping forest restoration in Europe over the last two centuries will be described and recommendations will be made.

Perceptions of Forest Ecosystem Benefits and Forest Restoration Across Europe: Insights from Key Informant Interviews

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Moses Kazungu[1]
Marcel Hunziker[1]
[1] Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Research Unit Economics and Social Sciences, CH-8903 Birmensdorf, Switzerland

Abstract: Forests provide various ecosystem benefits across geographies and landscapes. The specific benefits people in a locality perceive are influenced by their social, economic, and landscape features. In Europe, forests are managed for multiple purposes, including outdoor recreation and creating habitats for biodiversity. However, perceptions of forest ecosystem benefits have been suggested to vary across landscapes and social structures. Studies investigating people's perceptions of forests and forest restoration across various population structures and geographical locations in Europe are limited. Our study aims to explore people's perceptions of forests and forest restoration across population structures and geographical areas in Europe. Understanding the societal perceptions of forests, ecosystem benefits, and their link to forest restoration across diverse landscapes is vital for informing policies seeking to improve ecosystem functions. We employed a multi-layered approach to design the interview procedure and snowball techniques to identify 20 key informants in selected European countries, including Sweden, Germany, Scotland, Spain, and Croatia/Serbia.

Preliminary results reveal that perception of forests varied within population structures but not across study regions. We found two distinct perceptions of forests among the study respondents. On the one hand, forests are perceived as everything – -respondents with this view derived part of their livelihoods from forests but infrequently visited the forests. On the other hand, forests were perceived as unique places. People who held this view did not directly work in forests or forest-related activities; however, they recognised the roles of forests in society and nature and frequently visited the forests (many times a week). Furthermore, we found that forest restoration was perceived to be associated with improved ecosystem benefits. However, the degree of importance attached to each ecosystem benefit varied among the population and across the study regions.

Our results highlight variations in perceptions across population structures but not across the study locations. The findings are essential for survey designs, highlighting the necessity for future research on people and forests. The results suggest that future research should expand the scope of forest studies by encompassing diverse perspectives and simultaneously enhance efforts to promote forest values among various population groups.

Prestoration of Riparian Area Shaped by Human Activities and Climate Changes – Replacement of Alochthonous Poplar Plantations with Oak Forests

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Martina Đodan[1]
Ivan Balenović[1], Jasnica Medak[1], Darjan Prugovečki[1], Sanja Perić[1]
[1] Croatian Forest Research Institute

Abstract: High productive poplar plantations have significant role in securing fast wood production, especially if selected non-native poplar clones are regarded. The beneficial influence of such plantations can also be seen in preparing bare land for forest communities with higher structural and composition complexity, which often provide higher biodiversity and ecosystem services. They are a part of a tradition of European forestry and the most western part of Pannonia plane is no exception. The studied area is placed in the most western part of Pannonia plain covering Northeast part of Croatia. The study represents an example of prestoration of areas covered by non-native poplar plantations through planting of oak forests, which is interesting for several reasons. Even though local society broadly respects sustainability and biodiversity through long lasting tradition of forestry, the pressure for intensive wood production, poor management due to civil war, impoverishment and depopulation of the area backed up with negative impacts of climate changes (higher severity and prolonged duration of droughts and absence of flooding) create high need for restorations. This should be tackled carefully, with high sense of environmental, societal and financial aspects. The area has significant portions covered by poplar plantations in different conditions, ages and even restoration examples, but mostly with lower productive ability and resilience capacity, low tree diversity and lower value of ecosystem services. It all leaves a significant space for increase of ecosystem services, biodiversity and adaptation capacity. The research presents activities initiated in the scope of H2020 SUPERB, which include monitoring of restoration activities conducted during the last three decades in the studied area and initiation of prestoration activities on 50 ha. Furthermore, the paper will tackle the problem of restoration with narrow-leaved ash, currently the most discussed tree species for restoration activities in lowland area of Croatia. The research clearly shows complexity of prestoration from Croatian aspect of one of the 12 adaptive restoration actions covered by SUPERB project including stressors, restoration necessary and initiated prestoration activities altogether placed in the interesting socio-economic circumstances of this poor and depopulated area of Croatia.

Restoration of forests partially affected by past human activities in the south-eastern Făgăraș Mountains within the S.U.P.E.R.B. Project.

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

[1] Forest engineer, Conservation Director, Fundatia Conservation Carpathia, Brasov Romania
[2] Conferentiar doctor engineer Forestry Faculty Transilvania University, Brasov Romania
[3] Forest engineer, Conservation Carpathia Foundation, Brasov Romania

Abstract: In the demo study area, located in the South East of the Fagaras Mountains, Romania, the mosaic of forest landscapes includes:

Remnants of virgin and quasi-virgin forests, mostly at altitudes above 1400 m and up to the timber line, a number of forests which still have natural structures and compositions, little affected by logging;

Relatively large areas where natural beech-fir-spruce mixt forests were cut 70-90 years ago and replaced by artificial spruce plantations,
Areas where forests have been mostly ilegal felled and then abandoned;

Areas of sub-alpine secondary pastures where historically did exist scientifically important spruce-arolla pine stands and higher up dwarf pine and juniper scrubs;

Riparian alder galleries have been affected in the past by road construction, wild logging on the slopes, wood deposits and are also invaded by spruce saplings from seeds provided by existing neighbouring monocultures;

The main objectives of the reconstruction activities are:

- to achieve the ecological connectivity of the remaining quasi-virgin and natural forests still existing in the area by supporting and speeding up natural processes,

- achieving the full functionality of the upper Dâmbovița forest ecosystem (an important watershed for the Romanian Capital Bucharest) on the long term, which can evolve undisturbed by human activities as nonintervention zone in the future Făgăraș Mountains National Park.

The reconstruction activities consist mainly of:

-Initiating the return of natural forest types in spruce monocultures through careful and repeated interventions, i.e. reducing the density in spruce monocultures and saving the beech, fir trees still existing there, planting the missing species under the massif. In more difficult to access areas, the spruce trees removed are peeled and left in place;

-In areas affected by past non-compliant felling, based on analyses of historical forest planning data,

the planting composition aims at restoring forests similar to natural ones, but taking into account climate change as much as possible;

-Restoration of riparian habitats is initiated by removing spruce from the alder galleries and planting alder saplings.

-In areas above de forest line, in the continuation of the forest, attempts to recreate dwarf pines and junipers scrubs will be initiated through plantations.

Unlocking the Potential: Systemic Approaches to Scale Up Urgent Ecosystem Restoration for Forest Biodiversity and Ecosystem Services

T1.26 Prestoration – combining restoration and adaptation – of European forests for people and planet

Abstract: The "SUPERB - Systemic solutions for upscaling of urgent ecosystem restoration for forest related biodiversity and ecosystem services" project, funded by the European Commission from 2021 to 2025 as part of the Horizon 2020 Green Deal initiative, provides robust scientific evidence in support of the proposed Nature restoration law, thereby addressing the pressing need for substantiated data in forest restoration field.

The primary objective of the SUPERB project is to create favorable conditions for large-scale restoration of forests and forest landscapes throughout Europe. This is achieved through twelve extensive demonstrations conducted in collaboration with local stakeholders. Additionally, the project focuses on generating practical knowledge based on evidence, pertaining to the sustainable management, governance, and financing of restoration efforts, by learning from previous and ongoing projects in Europe and other regions. Another important goal is to enhance societal support for restoration and its associated benefits. To accomplish this, SUPERB establishes a strong network and movement involving multiple stakeholders, promoting the development, adoption, and expansion of transformative approaches and actions for forest restoration. During this session, SUPERB work packages leaders will share key findings and results, engaging in discussions with researchers in the field. The concept of *prestoration* combining restoration and adaptation will be discussed along with approaches and benefits for biodiversity, ecosystem services and carbon storage in a European context. We will also discuss the need and options to create an enabling environment for large-scale future-oriented forest restoration and transition to integrative forest management (integrating biodiversity conservation into sustainable forest management at different scales) that receives broad-scale acceptance and support by relevant stakeholders and society at large.

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Balancing stress and acclimation – physiological responses of boreal plants to long-term whole ecosystem warming and elevated CO2

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Abstract: Global climate change is disproportionality increasing temperature in the high latitudes, including the vast, carbon rich boreal forests. Plant biochemical or hydraulic sensitivity to warmer, drier air could lead to reduced carbon uptake if species are not able to adapt or acclimate to the novel conditions. To test boreal species response to warming, a boreal black spruce bog ecosystem is being exposed to long-term temperature (0 to +9 °C) and elevated CO_2 treatments (ambient or + 500 ppm), http://mnspruce.ornl.gov. Conifer tree (*Picea mariana* and *Larix laricina*) and ericaceous shrub ecophysiology has been monitored over time revealing species-specific and seasonal differences in morphology, phenology, photosynthesis, respiration, water potential, sap flow and hydraulic stress. The warming treatments have led to a longer active season (4-5 days per °C) based on measurements of tree transpiration and phenology. Warming led to an increase in the thermal optima of photosynthesis in both tree species, but this acclimation did not keep pace with the rate of warming. In addition, since there was little evidence for acclimation of respiration, net photosynthesis declined with warming. Nighttime transpiration was evident during periods of high vapor pressure deficit in both black spruce and larch trees. Warmer plots experienced greater twig water potential stress (especially *Larix*), leading to loss of foliage and branch tip dieback. Water stress was likely due to hydraulic limitations to atmospheric water demand or, during drought, lack of root water availability due to a drop in the water table beyond the shallowly rooted plants. Late season shrub foliar losses in warmer plots were exacerbated by moth herbivory. Treatment impacts were confounded due to periodic early spring freeze events, summer heat waves and drought. Drone and ground-based measurements indicate canopy temperatures could periodically be much higher than air temperatures, even exceeding 50 °C. The dynamic and species-specific responses of vegetation to climate change treatments and extreme events highlight the complexity of modeling future responses in this ecosystem. Results are being applied to ELM-SPRUCE, a version of the E3SM land model that can be used to scale up to the landscape.

Canopy coverage in experimental plots for forest landscape restoration

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

[1] Universidad Nacional de Asunción, Paraguay
[2] Itaipu Binacional

Abstract: Canopy coverage plays a crucial role as bigger coverage aims to reduce the incidence of grasses, due to competition with trees for light. Canopy coverage is important for the implementation of Forest Restoration projects as grass management incurs high costs. The objective of this study was to evaluate the initial canopy coverage in different planted species. The study was conducted in an experimental trial for forest landscape restoration in the district of Hernandarias, Alto Parana department, Paraguay, which is part of the Itaipu Biosphere Reserve. Eight treatments were installed in strip patterns for utilization and conservation. Canopy coverage measurements were taken 12 months after plot installation (2021) by making two perpendicular measurements of coverage, and after that the canopy coverage area was calculated. A graphical comparison was performed, revealing that ***Mimosa bimucronata*** (DC.) Kuntze (jukeri'i) had the highest coverage with an average value of 8,33 m^2, while ***Ilex paraguayensis*** A. St.-Hil. (yerba mate) had the lowest coverage with an average value of 0,01 m^2. Among the 30 selected species, ***Mimosa bimucronata*** (DC.) Kuntze (jukeri'i) demonstrated the highest coverage. Therefore, selecting this species for future projects would be of interest, as it could have a greater impact on grass competition by reducing maintenance costs.

Canopy Nitrogen Uptake – Biogeochemically Relevant or Ecological Novelty?

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Richard Nair[1]

[1] School of Natural Sciences, Trinity College Dublin

Abstract: Atmospheric transport of nitrogen (N) pollution has been an important environmental issue for more than half a century. Nitrogen is a crucial nutrient for plant growth, but N has both eutrophic and phytotoxic effects at high concentrations. Hence potential nitrogen deposition effects on forest health and productivity are a balance between release from N limitations and induced phytotoxic effects under high deposition.

Interaction between changing nitrogen loading and forest health and nutrition has direct biogeochemical implications via control of the carbon cycle, and cascading implications via forest growth or decline. Traditionally it has been assumed that most nitrogen uptake by plants is through roots. Hence a logistical shortcut in many experiments which simulate nitrogen deposition in forests is applying nitrogen to the forest floor, which is reasonable if roots are the only major route of N uptake but implicitly omits canopy interactions with nitrogen deposition.

Nitrogen passing through forest canopies may be processed or taken up by epiphytic microbes and by plants themselves. How much nitrogen contributes to forest function, and the mechanisms behind this uptake, are difficult to generalize. At the plant level, canopy nitrogen uptake may contribute to plant nitrogen nutrition, and canopy interactions remove, slow, and alter nitrogen fluxes reaching the soil, affecting wider plant community properties and processes such as leaching. Canopy uptake may be a strategy for some species in particular ecological niche but not for others. However, all canopy interactions are difficult to simulate, and a large variety of different experimental methods, and study systems have been used over the past decades. This is against a background of changing deposition environment of multiple elements, as emissions controls have been implemented in some regions, while emissions have increased elsewhere.

Here I will synthesise recent evidence from experiments and observational networks for canopy uptake of nitrogen deposition as an important and biogeochemically relevant flux in the Anthropocene with a focus on why both observational and experimental studies in past conditions may have failed to detect a substantial effect of this flux, and why recent studies may do so now.

Carbon and nutrient cycling in warmer soil: Conclusions after 18 years of artificial soil warming in a temperate mountain forest

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

[8] University of Natural Resources and Life Sciences (BOKU)

Abstract: Soil warming likely alters biogeochemical cycling processes in forest soils, but the longer-term warming effects on soil organic carbon (C) storage and nutrient pools remain elusive. In 2005 we initiated a soil warming experiment in a spruce dominated mature forest near Achenkirch, Austria which commences until today. Patches of shallow, though high organic C containing calcareous forest soil are warmed by +4°C during the snow-free seasons. Soil warming increased the soil CO_2 efflux by ~ 40% and, against all expectations, this stimulation effect remained more or less constant throughout the past 18 years of soil warming. Accordingly, soil C stocks should have significantly declined over time, but until 2019, no such significant change in topsoil C stocks could be detected (subsoil C content was lower in warmed soil). Increased C inputs from higher fine root biomass, turnover and exudation counterbalanced the respiratory C losses, although not completely. Periodic analyses of microbial community structure and physiology suggest that it took more than a decade until first sights of adaptations in microbial element cycling were realized. Nitrogen availability remained overall unaffected by warming whereas microbial phosphorous availability decreased. We will provide detailed C and nutrient budgets at the conference and discuss how meaningful such only-soil-warming studies are when considering potential warming effects on the whole forest ecosystem.

Climate change-mediated diet shifts for outbreaking forest defoliators: examining direct effects and interactions with insect disease

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Leah Flaherty[1]
[1] Department of Biological Sciences, MacEwan University, Edmonton, Canada

Abstract: The developmental phenology of forest defoliators and their host trees is expected to advance with climate change, which can alter the phenological match between these species, and ultimately, forest defoliator diet. For example, spring egg hatch dates for forest tent caterpillar (FTC) (*Malacosoma disstria* Hübner) is expected to advance less significantly with warming than budbreak of its primary host, trembling aspen (*Populus tremuloides* Michx). This change in food resources can have direct effects on FTC but may also interact with natural enemies, including pathogens. We conducted two laboratory and one field experiment to examine interactions among FTC, climate warming-associated diet shifts, and two entomopathogens: microsporidia (*Nosema disstriae* (Microsporida: Nosematidae)) and *Bacillus thuringiensis* var *Kurstaki* (Bacillales: Bacillaceae) (Btk). FTC with known microsporidia spore loads were fed one of three diets of aspen foliage simulating either current developmental synchrony, or scenarios associated with increasing climate warming. We assessed impacts on fecundity, egg hatch, stage-specific survival, and adult traits. We also subjected FTC fed different diets to an assay where larvae were droplet-fed either a control solution or a solution with added Btk, i.e., ForayÒ 76B. We assessed mortality after 5 d and reared surviving larvae to assess larval, pupal, and total survival, as well as adult traits. Results suggest that neither microsporidia infection nor the diet alterations tested here impacted the susceptibility of 4th instar FTC larvae to Btk at a concentration of 2 IU Btk/larva. Climate-induced diet alterations did however reduce neonate survival but was associated with improved performance of surviving neonates. Results also suggest that microsporidia infection may reduce rates of successful egg hatch and the survival of older FTC larvae. This work examines the impacts of changes in host quality associated with climate change on forest insect populations, and agents that cause disease in forest pest insects. We anticipate our results can be applied to predict how climate change will impact forest pests, which is crucial for both forest and pest management planning.

Climatic gradients and Microclimatic variations of temperate forests in northern Patagonia, Argentina

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Alois SIMON[1, 2]
Ernesto J. REITER[3], Jonas FIERKE[4], Helge WALENTOWSKI[1]
[1] HAWK University of Applied Sciences and Arts, Faculty of Resource Management, Göttingen, Germany
[2] University of Natural Resources and Life Sciences Vienna, Institute of Forest Ecology, Department of Forest and Soil Sciences, Austria
[3] University of Goettingen, Plant Ecology and Ecosystems Research, Germany
[4] University of Goettingen, Institute of Geography, Department of Catrography, GIS and Remote Sensing, Germany

Abstract: Understanding the two-dimensional mesoclimatic zonation and microclimatic variations within mountain forest ecosystems is crucial for understanding regional species turnover and effects of climate change on these systems. The temperate mountain forests in the Andean region of South America are among the largest old-growth deciduous forest areas in the world. Due to their pronounced disturbance regime and different successional stages, a climatic zonation combined with the characterisation of climatic niches is important to identify thresholds and tipping points of species occurrences.

We used micro-loggers to measure air temperature and relative humidity for one year at 40 measurement points along steep moisture gradients, as well as elevation gradients in mountain forests in northern Patagonia, Argentina. Climatic gradients from wet forests in the west to dry forests in the east and lowland forests to high-altitude forests are covered. Our results unveil mesoclimatic patterns within these forests characterised by variations in temperature and vapour pressure deficit along the altitudinal gradient in general, but also at different times of the year. Additionally, microclimatic variations were detected within the forests at the local scale, indicating the influence of disturbances, topography and forest successional stage. For example, *Austrocedrus chilensis* and *Nothofagus dombeyi* differed mainly by the temperature of the warmest days. Temperature differences between forest stands and gaps were more pronounced in the warmest month of the year and at lower elevations, with up to 2.5 K higher values in the second half of the day in gaps. Such microclimatic variations have a major influence on tree species turnover and ecological processes within these forest ecosystems.

The findings contribute to our understanding of the complex interplay between topography, climate, and vegetation in shaping the spatial patterns of species occurrences, which is essential for informed forest management and conservation strategies in this ecologically significant region.

Decline in ectomycorrhizae due to experimental drought in Sub-mediterranean Quercus pubescens stands

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Tanja Mrak[1]
Tina Unuk Nahberger[1], Mitja Ferlan[1]
[1] Slovenian Forestry Institute, Večna pot 2, 1000 Ljubljana, Slovenia

Abstract: Secondary *Quercus pubescens* Willd. stands in karst Sub-mediterranean of Slovenia play an important ecological role in the protection of shallow soils from erosion. The frequency and duration of droughts in this area is expected to rise in the future due to global changes and this may add to the already harsh and highly variable growth conditions there. To be able to predict the outcome for *Q. pubescens* in the increasingly drought conditions, we have set up the rain exclusion experiment in Slovenian Sub-mediterranean, which included the study of ectomycorrhizal fungi actively associated with its fine roots.

The experimental setup consisted of two plots of approx. 100 m^2 covered by translucent roof and two control plots of the same size. Sampling of ectomycorrhizal community was performed before the start of the experiment and after one year on all plots. Ectomycorrhizae were sorted based on their morphological characteristics into morphotypes and Sanger sequencing was performed for representative morphotypes. Vital and old/dead ectomycorrhizae were quantified. Diversity indices of ectomycorrhizae were calculated, and community compositions compared by “vegan” package in R.

The vitality of ectomycorrhizae significantly decreased after one year at rain exclusion plots compared to controls. Species richness and Shannon diversity index were reduced as well. Community composition of ectomycorrhizae in controls and rain-exclusion plots were significantly different after one year of experiment and the number of unique taxa decreased. The ectomycorrhizal community reduced to a subset of taxa, that were mainly present before the start of the experiment and belonged to the most frequent taxa of the site. The loss of biodiversity of active ectomycorrhizal fungi could have functional consequences for the uptake of nutrients and water in the future drought impacted *Q. pubescens* forests that need to be considered.

Deep soil organic matter response to warming

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Michael Schmidt[1]
[1] University of Zurich, Department of Geography

Abstract: In an increasingly warmer world, soil will warm in near synchrony with air temperatures. Consequently, heterotrophic respiration accelerates, but is unclear how this will affect soil organic matter (SOM) stocks, the Earth's largest terrestrial stock of reactive carbon. And half of that SOM stock resides in deep soil (below 30 cm). Meta-analyses of how SOM responds to warming exist, but so far did not cover the deep SOM. Despite their large stock size, subsoils remain largely underrepresented in warming studies. But what becomes increasingly clear, is that deep SOM can respond very differently to warming than surface soils, and may show even stronger response than surface soil to changing environmental conditions.

Sources of uncertainty in predictions of how global SOM will respond to a warmer world is the lack of (1) process understanding of deep SOM dynamics, and (2) the lack of multitemporal, especially decadal, observations. (3) We still cannot synthesize and analyze data stemming from the increasing number of field experiments, because experiments were made using different methodologies, or results are reported in different units.

The aim of this presentation is to summarize the latest research insights on belowground carbon cycling, and ultimately to contribute to the answer the question: What will be the role of deep soil organic matter in terrestrial carbon cycle feedback to warming over the next century?

Diversity Patterns and the Factors: Response of Soil Microorganisms and Nematodes to Elevation Gradients in a Temperate Forest of South Korea

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Abstract: Elevational gradients provide natural experimental conditions for studying the effects of climate change on forest biodiversity. Ecologists have shown that elevational gradients are associated with changes in temperature, precipitation, plant compositions, and other biotic and environmental factors, which in turn affects the communities of soil microorganisms and nematodes. Nevertheless, the diversity of soil microorganisms and nematodes and the factors along the elevation gradient are still debated. Additionally, it is unclear how their diversity simultaneously change along the elevation gradient. Here, we examined the diversity patterns of soil microorganisms and nematodes and subsequently investigated the relative importance of tree-related factors, such as tree diversity, identity and quantity, and environmental factors including climatic and edaphic factors. For this, we analyzed data from 27 plots located at different elevational bands in the temperate forest of Mt. Gariwang, South Korea. Through multimodel inference tests and variance partitioning, we identified the key factors driving each group's diversity and compared the relative contribution of tree-related and environmental effects. Our findings indicate that the bacterial and fungal diversity decreased with increasing the elevation. However, the nematode diversity did not show significant changes, which suggests that site-specific conditions have a greater influence than the elevation itself. Furthermore, the bacterial diversity was modified by factors such as soil pH and functional dispersion of leaf size, while the fungal diversity was only governed by the pH. The nematode diversity was driven by aboveground biomass, ammonium-nitrogen levels, and tree size inequality. Overall, environmental factors had a stronger impact on soil microbial diversity, whereas tree-related factors mainly regulated the nematode diversity. Our results demonstrate that the diversity patterns and the factors of soil microorganisms and nematodes vary among different organismic groups within the micro-food web. These findings provide new insights into the factors shaping soil microorganisms and nematode diversity in temperate forests and enhance the understanding of soil organismic groups' responses to the elevational gradient. Beyond ecological understanding, this knowledge can support efforts to mainstream soil biodiversity for sustainable development agenda, the post-2020 biodiversity framework, and initiatives focused on soil restoration and health management in forest ecosystems.

Effects of disrupted forest continuity on tree growth rate and environmental sensitivity

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Andreas Lundgren[1]
Joachim Strengbom[1], Gustaf Granath[2], Björn Lindahl[1], Karina Clemmensen[1], Tamlyn Gangiah[1]
[1] Swedish University of Agricultural Sciences
[2] Uppsala University

Abstract: In light of global warming and the expected alterations to local climate, forest resilience to environmental changes is of importance for many ecosystem functions in the boreal forest. However, in the Fennoscandian boreal region, forests are subjected to intensive forestry management with little empirical knowledge on how this may affect long term productivity and sensitivity to altered growing conditions. Here, we present long term effects of disrupted forest continuity on tree growth rate and sensitivity (inter-annual growth variation) by comparing forests of long continuity (only subjected to selective logging) to those that were regrown after deforestation (clear-felling) ~60 years ago in northern Sweden. Using tree cores and dendrochronological methods, as well as measurements of microclimatic conditions and soil properties, we compare the forests' growth patterns and environmental sensitivity. In general, we found connections between early benefits to growth rates following a disruption event and increased growth sensitivity as well as dependency on precipitation. Furthermore, the growth benefits experienced by disrupted forests are exclusive to early establishing trees, whereas trees established later show growth patterns similar to those in forests with long continuity. The early establishing trees also present some indication that the rapid growth rates in early life is connected to a decreased growth potential in the long term. Thus, although continued intensive harvesting that disrupt forest continuity may initially result in highly productive forests, it may come at the expense of long-term productivity as well as increased sensitivity to environmental changes.

Effects of warming, reduced precipitation and snow changes on growth and physiology of two co-existing seedlings in a temperate secondary forest

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

[2] Qingyuan Forest CERN, National Observation and Research Station, Liaoning Province, Shenyang 110016, China

Abstract: Seedling establishment of dominant tree species can determine the regeneration direction, and seedling stage is the most sensitive to environmental conditions (e.g., temperature and water) in the plant life cycle.

Warming and precipitation reduction in the growing season have been concurrent throughout this century in most temperate regions (e.g., Northeast China) and have increased drought risk to the growth, migration, or mortality of tree seedlings. On the other hand, there is usually a greater warming regime in the non-growing season of temperate regions, and this warming can induce the changes in snow (e.g., changes in depth of snow, leading to more frequent rain-on-snow events and freeze-thaw cycles causing snow compaction and formation of ice layers in the snowpack) and consequently influence the seedling establishment in the subsequent growing season.

Coexisting tree species with different functional traits in temperate forests may have inconsistent responses to both warming and decreased precipitation, and both warming and changes in snow, which could result in a species distribution shift and change in community dynamics. Unfortunately, little is known about the growth and physiological responses of coexisting species to the changes in these meteorological elements.

Thus, we selected seedlings of two coexisting species in a temperate secondary forest of Northeast China (water conservation forest): *Quercus mongolica* (drought-tolerant species) and *Fraxinus mandschurica* (drought-intolerant species) to analyze the growth and physiology of seedlings under three experiments: 1) constantly elevated 2 °C in the surface soil above control plots at Qingyuan Forest CERN; 2) under strictly controlled conditions simulating the predicted warming (+2 °C, +4 °C) and precipitation reduction (-30%) compared with current conditions; and 3) simulating six conditions of snow changes under warming (normal snow depth, twice snow depth, no snow cover; control, snow compaction, formation of ice layers in the snowpack).

Our results can fully understand the responses of two co-existing seedlings to warming and changes in precipitation, and predict the development direction of temperate secondary forest under the background of global changes.

Elemental Dynamics and Limitations of Quercus petraea L. Under Experimental Canopy Nitrogen Deposition

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Daniel Minikaev[1]
Camilla Wellstein[1]
[1] Faculty of Agricultural, Environmental and Food Sciences, Free University of Bozen-Bolzano, Italy

Abstract: In the light of rising global air pollution levels, we have been engaged in better understanding the effects of increased Nitrogen (N) deposition rates on Carbon (C) sequestration in forest ecosystems.

While most experimental studies investigating N deposition have been using ground fertilization methods, those might not proveto be the most representative of the actual deposition pathway. Thus, in our research we have adopted an improved approach of above canopy N application, with a conservative rate of 20 kg N ha^{-1} yr^{-1}, which may better simulate true deposition and feasable future scenarios.

The experimental site is located in South-Tyrol, Italy, where natural mature Sessile Oak (*Quercus petraea L.*) stands have been treated since 2015 with N fertilizer applied to either above the canopy, or to the forest floor directly (for comparison), alongside unfertilized control plots.

To this day, no major shifts were detected in tree productivity, water use efficiency, leaf development, and C & N contents, nor clear treatment impact on radial tree growth.

Hence, we set an objective to explore whether potential overlooked productivity inhibitions might exist in the system. Nutrient imbalances, Phosphorus (P) in particular, may have a key role when attempting to monitor the effects of N deposition in forests. These imbalances are often induced by increased N deposition, and may shift ecosystems from N to P limitation.

We provide a deeper examination of the the state and availability of nutrients in the system, with an emphasis on P, and will report measures of total and available soil elemental fractions, foliar concentraions and ratios, and soil enzymatic activities, throughought the years of the experiment. Thus far, sub-optimal ambient P concentrations were found in the tree foliage, with a general increase in N:P ratios in the recent years, further agreveated in the N treated plots, with a slight edge towards the above canopy fertilization.

We will therefore have the opportunity to emphasize the importance of describing a wider elemental profile when undertaking forest research and management, while presenting missing regional ecosystem health data, and at the same time distinguishing between the different N application approaches.

Foliar optical signals to investigate shoot biogenic volatile organic compound emissions from Scots pine and English oak saplings under warming

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Abstract: Accurate quantification of long-term emissions of biogenic volatile organic compounds (BVOCs) is essential for understanding biosphere-atmosphere feedbacks due to their key roles in atmospheric chemistry. However, proper tools for observing BVOC emissions at large scales are still missing. Remote sensing of optical signals such as photochemical reflectance index (PRI) are promising solutions to fill the spatial knowledge gap, based on the linkages of carotenoids with both BVOC biosynthesis and PRI.

We conducted the experiment in the growth chamber in summer 2022. We wanted to investigate how the relationships between foliar PRI and shoot BVOC emissions change in response to mild (35 °C) or extreme (40 °C) heat stress during the peak of growing season in Scots pine and English oak. Our research questions were: (1) do photoprotective mechanisms such as foliar carotenoid pigment contents or non-photochemical quenching dynamics mediate the relationships between PRI and BVOC emissions in response to warming? (2) do these controlling factors differ between tree species / BVOC emission types (e.g., isoprene and monoterpene emitters)? and (3) can PRI capture the changes in BVOC emissions in response to warming?

For English oak, we found a significantly increasing **isoprene** emission rate in response to mild heat stress (35 °C), but a lower **isoprene** emission rate in extreme relative to in mild heat stress in English oak. On the contrary, in Scots pine the isoprene emission rate was only slightly higher in extreme stress compared to room temperature and mild heat stress. Some main monoterpenes, including **α-pinene, camphene**, **β-pinene** and **limonene,** had clear increasing emission rates from room temperature to extreme heat stress, in both species.

In this communication, we will evaluate and examine how these BVOC dynamic patterns related to biochemical and photoprotective dynamics can be detected in terms of foliar pigment contents,

PAM fluorescence measurements and eventually, leaf spectral reflectance measurements. The expected outcomes will give new insights into leaf-level mechanistic links between PRI and BVOC emissions for plants in response to climate warming.

Genetic variation of Russula ochroleuca, a mycorrhizal generalist, along an altitudinal gradient in a German low mountain range

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Angela Siemonsmeier[1]
Markus Blaschke[2], Ralph Kühn[3]
[1] University of Applied Forest Sciences Rottenburg, Professorship Forest Protection and Risk Management, Germany
[2] Bavarian State Institute of Forestry, Department Biodiversity and Conservation, Germany
[3] Technical University of Munich, School of Life Sciences, Chair of Zoology, Germany

Abstract: Context

Climate change puts forest ecosystems under high pressure, especially in mountains, where rising temperatures force species to adapt or to migrate uphill following their moving temperature optima. Since phenotypic plasticity is limited, genetic adaptation in response to the changing climate is expected. The mycorrhizal community has to deal not only with rising temperatures, but also with changing plant communities and increased occurrence of drought events with an impact on mycelia in the topsoil. Mountain ranges and their climatic conditions changing with altitude offer the possibility to study genetic adaptation to a changing climate over short distances. We used microsatellite markers to investigate the genetic structure and potential adaptation of *Russula ochroleuca* populations along an altitudinal gradient in a German low mountain range.

Methods

Along an altitudinal gradient in the Bavarian Forest in southeast Germany, spanning a range from 300 to 1400 m a.s.l., 149 fruit bodies of *Russula ochroleuca*, a mycorrhizal generalist, were collected on 69 sample plots in managed forests and unmanaged strict forest reserves in autumn 2019. Inner tissue from the stipe was sampled and microsatellite analyses using seven markers developed in this study were performed on an ABI Prism™ 377 Sequencer.

Results

The microsatellite analyses showed a low level of inbreeding and a high genetic variation within populations along the altitudinal gradient. For three sample plots, locations of sampled fruit bodies were mapped to investigate if underground mycelia produced several contiguous fruit bodies with identical genetic profile and if it was possible to determine the area occupied by a genetic individual. However in most cases, even fruit bodies located in close proximity of a few centimeters showed different microsatellite marker profiles. A genetic structure related to altitude, management type or leading tree species was not found due to the high intra population variation.

Conclusions

The mycorrhizal generalist *Russula ochroleuca* showed an almost panmictic genetic structure along the investigated altitudinal gradient as well as across management types and forest ecotypes. With

regard to the observed high genetic variability, *R. ochroleuca* appears to be well prepared for the challenges of a changing environment due to global climate change.

Growth and phenology of Norway spruce in a future wetter climate: the FAHM study

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Abstract: Global climate change alters regional precipitation patterns and causes precipitation increase in Northern Europe. More frequent rain events extend periods with high relative air humidity in forest canopies. Norway spruce (*Picea abies* [L.] H. Karst.) is a widespread, economically important conifer, which is currently facing a decline in several parts of its range due to the massive bark beetle outbreaks as well as its high susceptibility to drought, wind, and root rot damage. In spring of 2020, monospecific and mixed (50:50 with *Betula pendula*) spruce stands were planted at the Free Air Humidity Manipulation (FAHM) experimental site in hemiboreal Estonia, where 9 study plots (⌀ 14 m) include 3 controls, 3 plots with elevated air humidity (by 5-7%), and 3 plots with elevated soil moisture (by 15%). The treatments were designed following the regional climate change projections by 2100 (IPCC). Our aim was to compare basic tree growth traits, spring phenology and occurrence of lammas growth (second flush of shoots in late summer) between the treatments. After three growing seasons, the height of spruces remained 22% lower and stem diameter 15% smaller in the air humidification treatment compared to soil irrigation and control. In mixed plots, spruces growth was slower, especially in the soil irrigation treatment, than in monospecific plots. The negative effect of air humidification was, however, also smaller in mixed plots. Annual height increment of spruce was greater in trees with earlier budburst, irrespective of treatment. The lammas shoots were more frequent in soil irrigation (26%) and control plots (22%) than in air humidification (3%). Hence, spruce growth can be reduced by increasing air humidity and at wetter soil, the growth rate did not benefit from mixing with fast-growing light-demanding *B. pendula*. Higher incidence of lammas shoots on wetter soil could indicate to higher risk of frost damage but lower incidence under more humid air can counterbalance this. Although growth rate of spruce was inferior in mixed stands, smaller growth differences among treatments and lower incidence of lammas shoots still suggest that spruces may better acclimate with future more humid climate in mixed forests.

Growth and physiological acclimation patterns of Scots pine after long-term irrigation

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Abstract: Scots pine (Pinus sylvestris L.) is a prevalent tree species in Europe, and understanding its acclimation potential is crucial for predicting its growth and vitality under future climatic conditions. To investigate long-term acclimation patterns to changes in soil water availability, a 17-year-long irrigation experiment was conducted in an inner-Alpine valley of Switzerland (Pfynwald). This experiment employed two treatments: i) continuous irrigation for 17 years during the vegetative season and ii) interruption of irrigation after 11 years ("stop" treatment).

Our dendrochronological investigation of the long-term effects of increased water availability revealed three stages of growth acclimation. Initially, we observed a significant increase in growth (overyielding) during the first four years. This was followed by a continuous but declining overyielding trend over the subsequent eight years. Finally, after 12 years of irrigation, the growth rates of the irrigated trees regressed to pre-irrigation levels. The "stop" treatment, which discontinued irrigation in the 12th year, showed a continued reduction in growth. However, we found that tree vitality, determined by canopy transparency, had a greater influence on growth and physiological adaptation compared to the impact of increased water availability.

In this third acclimation phase, we explored the treatments' structural and physiological differences by comparing isotope ratios recorded by stem and needle non-structural carbohydrates (NSC), xylogenesis and quantitative wood anatomical variables. Irrigated trees showed consistently longer growing periods, lower tree-ring $\delta^{13}C$ reflecting lower stomata restrictions, and higher hydraulic conductivity compared to control trees. However, the similar relationship between tree-rings $\delta^{18}O$ and $\delta^{2}H$ (O-H relationship) of irrigated and control trees indicate a similar "physiological balance" between autotrophic and heterotrophic processes. On the contrary, the stop treatment showed the lowest growth rates, highly conservative wood anatomical traits, and an ongoing "stress reactivity" and acclimation to the removal of irrigation, as indicated by the weak O-H relationship and high $\delta^{2}H$ values.

We conclude that after 17 years of treatment, i) irrigated trees have reached an acclimation balance although maintaining higher overall biomass and higher stomatal conductance and photosynthetic rates, ii) the stop trees have not yet acclimated to the non-irrigated conditions, and iii) canopy vitality strongly influences acclimation responses.

Height increment of Scots pine shows complex responses to weather conditions in the north-eastern Baltic region

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

[2] Institute of Forestry and Engineering, Estonian University of Life Sciences, Kreutzwaldi 5, 51006 Tartu, Estonia

Abstract: Weather growth relationships, which are crucial for the accuracy of local and regional tree growth/distribution predictions are largely acquired based on the variation deconstruction of radial increment. However, the radial increment is strongly affected by local conditions, which can have nonstationary effects, thus adding noise and uncertainty regarding the long-and medium-term weather/climate-growth relationships. In this regard, the primary, i.e., height increment, which is less affected by local and microsite, hence is a more straightforward proxy for productivity, has received considerably less attention, particularly due to laborious gathering of data. Furthermore, under accelerating environmental changes, local relationships, which are usually estimated as a linear response, are getting outdated, hence assessment of their plasticity and stationarity across the regional spatiotemporal gradient is paramount for reliability of predictions. In this study, the published long-term time series of height increment of Scots pine from the north-eastern Baltic region (Latvia, Estonia and Finland) were revisited and regional weather drivers were distilled using variance deconstruction and generalized additive modelling techniques. At the sub-regional scale, height increment was affected by a complex of meteorological conditions, which had carryover effects. Height increment was prevailingly sensitive to thermal conditions in preceding year indicating influence on the formation of growth initials rather than their elongation, with precipitation showing only marginal effect. Even though sub-regional climatic gradient was represented by the dataset, the most of the regional weather effect on height increment were linear or near-linear implying that from the perspective of local population, the analysed part of the gradient has been narrow. This also indicates high ecological plasticity of height increment of the studied population, hence ability to cope with the anticipated environmental changes.

Keywords: relative annual additional increment; Pinus sylvestris; sub-regional climatic gradient; plasticity of response; adaptability.

How canopy gaps mediate the impact of decreasing snow on tree seedlings in boreal forests?

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Yihan Cai[1]
Makoto Kobayashi[1]
[1] Hokkaido University

Abstract: Forest ecosystems generally have highly heterogeneous canopies, usually recognized as canopy gap structures. While the roles of canopy gaps in the forest succession are well known, the role of gaps has not yet been fully considered in the context of climate change, especially under changing snow regimes. We therefore conducted a field manipulation experiment in a boreal forest in Hokkaido, northern Japan, to assess how gap structures mediate the impact of decreasing snow on the survival and growth of tree seedlings. Additionally, by measuring biotic and abiotic factors such as feeding damages rate, light availability, and other microclimate factors, we would elucidate the factors that possibly limit plant survival and response.

The experiment was conducted in 40 years old *Picea glehnii* forest located in the Teshio Experimental Forest. Five 10 m × 20 m canopy gap plots were created in July 2022 by cutting down all the trees in those areas. Also, five 10 m × 20 m plots were set up in the forest interior as canopy plots. Snow manipulation block and control block were then set up in each plot (5 m × 5 m each; totally 20 blocks). 20 seedlings for each 4 species (2 deciduous species and 2 coniferous species) were planted within each plot in October 2022 (totally 1,600 seedlings). Snow manipulation was conducted in the beginning and end of winter by shoveling to reduce snow cover days following RCP 4.5 scenarios (2.5 - 3°C temperature rising) from 2022 to 2024. Plant survival rate and relative growth rate were measured in late June and September along with feeding damages. Light availability and other microclimatic factors were kept measuring since October 2022. Here, we would like to provide some results from our first-year manipulation experiment.

How to predict the interacting effects of climate, water, and soil nutrient availability on forest productivity

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Abstract: Contrary to earlier expectations of increased forest growth under rising temperature and atmospheric CO2 in boreal forests, growth in many Nordic forests has declined in recent years. Due to the potentially vast negative consequences for both the economy, ecology, and carbon sequestration, a better understanding of the reasons for this decline is urgently needed. Several environmental factors limit tree growth, including temperature, CO2, soil moisture, humidity of the air, and soil nutrient availability. But although the separate effects of water limitation and soil nitrogen availability are well known, it remains a challenge to predict how trees manage their combined effects under novel conditions. To address this question we introduce a new physiological model based on optimality principles which accounts for plasticity in stomatal conductance and leaf nitrogen concentration. This allows the model not only to capture gross primary productivity (GPP) and transpiration in response to weather conditions but also effects of soil moisture and nitrogen availability. We demonstrate the accuracy of the model compared to GPP estimates from eddy flux measurements and canopy transpiration in fertilized and unfertilized pine forest in northern Sweden. We also show that the response to increased soil nitrogen availability can be captured by a reduced carbon cost of N uptake and an increased leaf area per sapwood area. The results imply that the interactive effects of water and N limitation on GPP and water use in boreal pine forest can be explained by the trees striving for an optimal balance of maximizing growth while limiting hydraulic risk. This model provides a fundamental tool for analyzing the expected future growth of Nordic forests and potential management strategies.

Impact of Drought and Rewetting Cycles on Soil Greenhouse Gas Fluxes across an N Deposition Gradient in Austrian Forests

Abstract: Climate change has increased the frequency and intensity of extreme weather events such as drought periods and heavy rainfall in large areas of the world, including Central Europe. Despite decreasing nitrogen deposition rates in this region, forests are still subjected to high N deposition rates from agricultural and industrial sources. These disturbances affect fundamental biogeochemical processes and likely alter greenhouse gas fluxes in forest soils. However, the full impact of N deposition on the response of forest soils to increasing extreme weather events is still unknown.

In this project, our approach combines the use of active manipulation simulating drying-rewetting (DRW) cycles on a natural gradient over three representative Austrian broadleaf-forest sites with detailed field GHG observations, microbial laboratory analyses and process-based modelling. The DRW plots received the long-term averaged rainfall concentrated in three single extreme precipitation events and were excluded from rain the rest of the vegetation period. N-addition plots received extra N at a rate of 50 kg N ha^{-1} y^{-1}. Soil GHG fluxes were measured with automated chambers at a high temporal resolution on all plots. Soil samples were taken before and after each irrigation event to measure microbial responses to drying and rewetting and the abundance of methanotrophic bacteria. Measurements were conducted in 2021 and 2022.

Results show reduced soil CO_2 fluxes, extremely reduced N_2O fluxes, and increased CH_4 uptake under DRW treatments compared to natural environmental conditions. Natural drought conditions led to a convergence of N_2O emission levels in the DRW and control plots. N addition only had modest effects on GHG fluxes The significance of the interplay between a higher frequency and intensity of DRW cycles and N deposition rates for the soil GHG budget and the feedback between forests and climate change will be presented and discussed.

Longer-term soil respiration responses to experimental warming in subtropical and temperate forests relate to soil organic matter composition and fine root biomass

Abstract: It is still uncertain how global warming will affect soil CO_2 fluxes and which carbon (C) cycling processes in forests soils are going to be most affected in the long-term. Here, we experimentally warmed the surface soil of a subtropical and a warm temperate forest by ~ 1.5°C from 2012 to 2022 and compared the short-term (2-3 years) with longer-term (10 years) warming effects on soil CO_2 fluxes, fine root biomass, soil organic matter (SOM) chemistry and microbial community composition. Soil warming did not affect soil CO_2 fluxes in the short term, but decreased them in the longer term (-10.3%, heterotrophic and autotrophic respiration similarly affected) in the subtropical forest. In the warm temperate forest, soil warming increased soil CO_2 fluxes by 35.3% in the short term and by 29.8% in the longer term (heterotrophic and autotrophic respiration similarly affected). Soil warming significantly increased fine root biomass in the temperate forest, whereas finer root biomass was slightly decreased in warmed soil of the subtropical forest. In the subtropical forest, soil warming significantly altered soil organic matter (SOM) properties towards increased aliphaticity and decreased O-alkyl C content. This was likely linked to the significant long-term decline in heterotrophic soil respiration at this forest site. Microbial biomass and both, bacterial and fungal diversity were not affected by long-term soil warming at either site. Albeit the distinctive soil respiration responses, soil organic carbon contents remained unaffected after 10 years of soil warming at both sites. A decrease in SOC content was only detectable in warmed-trenched plots in the warm temperate forest, suggesting that also in this forest, increased root C inputs had compensated the respiratory C losses under natural (un-trenched) conditions. Overall, our results suggests that SOM chemical composition and fine root biomass are key determinants in the long-term response of soil respiration to warming, which may vary considerably among different forest ecosystems.

Key words: soil respiration; climate change; SOM chemical composition; ^{13}C NMR spectroscopy; long-term soil warming; subtropical forest, temperate forest, fine root biomass, microbial diversity

Minerals control soil organic carbon stability predominantly via enzymes and nutrients in red soil hilly Critical Zone

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Xiaoqin Dai[1]
[1] Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Sciences, Beijing 100101, China

Abstract: Mineral protection is a widely accepted important mechanism regulating soil organic carbon (SOC) preservation and loss. However, how minerals affect SOC dynamics, especially through the intrinsic enzyme- and nutrient-mediated processes, is not fully understood. Here, we measured specific carbon mineralization rate (C_{min}/SOC), the contents of SOC, particulate organic carbon (POC), mineral-associated organic carbon (MOC), and mineral contents (Fe/Al oxides), enzyme activities, and nutrient contents (NH_4^+-N, NO_3^--N, total N, available phosphorus) along the soil profiles of different forest types in the red soil hilly Critical Zone. We found that poorly crystalline Fe/Al oxides (Fe_o and Al_o), and complexed Fe/Al oxides (Fe_p and Al_p) were closely negatively associated with C_{min}/SOC, and positively correlated to SOC, POC, and MOC. Notably, the variations in C_{min}/SOC and SOC explained by the mineral itself were less than by its interactions with enzymes and nutrients, highlighing that minerals control SOC stability predominantly through enzyme- and nutrient-mediated processes. The key controls of minerals on POC and MOC were divergent, in which POC was indirectly influenced through the enzyme- and nutrient-mediated pathways, but MOC was directly associated with minerals and its interplay with nutrients. More importantly, minerals explained more variations in POC and MOC contents at subsoil and parent material, reflecting a depth-dependent effect. Overall, our results highlight an intrinsic enzyme- and nutrient-dependent mechanisms of mineral protection for SOC stabilization, which provides new insights into in-deep understanding of SOC dynamics.

N and P interactions in an old-growth temperate woodland subjected to long-term free CO2 enrichment

[5] University of Bangor

Abstract: Understanding the impacts of increasing atmospheric CO_2 concentration on nutrient availability and tree photosynthesis is essential to predict ecosystem carbon stocks. This is particularly important for temperate forests which are one of the largest CO_2 sinks in the world. Higher atmospheric CO_2 concentrations are expected to stimulate photosynthesis, but the potential for an increase in tree biomass in these forests strongly depends on nutrient availability. Increases in biomass production will require that trees take up greater amounts of nutrients from soils under elevated CO_2 (eCO_2) and/or increase nutrient-use efficiency, for instance, enhancing foliar nutrient resorption efficiency.

Very few Free Air CO_2 Enrichment (FACE) experiments have been carried out in old-growth forests. Most long-term eCO_2 studies have been conducted in younger stands that were N limited. However, P may also play a very important role in moderating productivity in temperate forests. In this study we use a whole-ecosystem FACE experiment established in an oak dominated, 175 years old temperate forest (BIFoR-FACE) to determine the stoichiometry characteristics of carbon, nitrogen and phosphorus of trees and soils in the ecosystem and reveal the carbon-nutrient interactions of the forest after 7 years of CO_2 enrichment. To do so we assess the nutrient content dynamics in green leaves, leaf litter, wood, roots and soil from 2018 to 2022.

Focused on year 2021, we show that enriching the atmosphere with 150 ppm CO_2 has stimulated nutrient resorption efficiency and net photosynthesis by 37%, while the growth of the dominant tree species (*Quercus robur*) has only slightly been increased in some of these years. Stoichiometrically, we found P-limitation as an important factor affecting productivity and higher N resorption efficiency under eCO_2. We consider the implications of the findings and explore paths of C allocation in this mature temperate oak.

Overstory-Understory relationship variation in Miombo Woodland along a rainfall and fire gradient

Abstract: Miombo woodland is a forest ecosystem that covers a large part of eastern and southern Africa including the southeast of the Democratic Republic of Congo (DRC), Angola, Malawi, Botswana, Zambia, South Africa, Namibia, Zimbabwe, Tanzania, and Mozambique. Across this wide geographic coverage, rainfall and fire have been identified among the main environmental drivers that influence the distribution, composition, and vertical structure of Miombo woodland. Like other forest ecosystems, Miombo woodland's vertical structure is composed of different strata but mainly consists of understory and overstory.

However, the forest overstory-understory relationship has been scarcely explored. Little is known about the influence of overstory conditions (diversity, canopy coverage, tree density) on understory vegetation and the mechanism involved. Most forest models in Miombo woodland have focused on the overstory woody vegetation neglecting the understory vegetation despite its importance in ecosystem functioning. Studies on the understory of Miombo have been conducted on a local scale but focused on the vegetation description, neglecting the effects that rainfall and fire can have on this relationship at different scales of impact (localized impact to regional impact).

This research uses field data collected in 12 vegetation monitoring plots of 0.5 ha to 1 ha located in Namibia and the DRC and aims: (i) to explore the variation of overstory and understory vegetation along a fire and rainfall gradient in terms of composition and structure; and (ii) to analyze the influence of overstory conditions on understory vegetation along the fire and rainfall gradient.

In the context of global change that faces Miombo woodland, a good knowledge of the relationship between environmental drivers and forest parameters will contribute to improving natural resource management and support international policy initiatives such as REDD +.

Photosynthetic thermal acclimation of clonal Norway spruce trees along a broad latitudinal gradient

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

[4] Department of Forest Ecology and Management, Swedish University of Agricultural Sciences, Sweden

Abstract: The ability to acclimate to increasing growth temperature is a key determinant of how long-lived plants such as trees will respond to climate change. Most field-based studies on thermal acclimation to date have utilized trees from geographically separate populations that have adapted to different growing environments over generations. Here, we have excluded the potential confounding effect of local adaptation by investigating clonal Norway spruce (*Picea abies*) seedlings planted in 2013 at four sites along a latitude gradient from mid-Sweden (Uppsala) to south-western France (Bordeaux) with a 6.4 ˚C annual mean temperature range. The experimental design included 3-4 individuals of close to 300 Swedish, eastern European and mixed genotypes at each site.

The first study on photosynthetic thermal acclimation potential focused on three closely related Swedish genotypes. We found that light-saturated net photosynthesis and the maximum rate of carboxylation (V_{cmax}) at a constant reference temperature of one-year-old needles increased with increasing growth temperature, while the maximum rate of electron transport (J_{max}) did not. Both rates exhibited seasonal acclimation with lower values during the spring than during the late-summer. In addition, the J_{max} to V_{cmax} ratio at 25 ˚C was highest during the spring and decreased along the latitude gradient with increasing growth temperature driven by the increasing V_{cmax}. In a second study, the thermal acclimation of photosynthesis of selected Swedish and eastern European genotypes (two each) was compared to investigate how long-term adaptation to climatic conditions at the area of a genotypes' origin affects the ability for photosynthetic thermal acclimation. These results will be discussed regarding the potential of genotype selection to improve the photosynthetic performance of Norway spruce in a warmer climate.

Site-Specific Response of Norway Spruce to Drought Conditions in the Italian Alps

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Luca Da Ros[1]
Enrico Tomelleri[1]
[1] Free Univeristy of Bozen/Bolzano

Abstract: The Italian Alps are experiencing a rapidly shifting hydrological cycle due to climate change. With the rising occurrence and extended duration of summer droughts, significant obstacles are anticipated to emerge, impacting the resilience and productivity of forest ecosystems. In light of this, our study focuses on the Norway spruce (*Picea abies*), a species of relevant value for ecological and economic reasons within the alpine region. In 2020, we established two contrasting experimental forest sites in South Tyrol (Eastern Italian Alps) - Carezza, a humid and fresh location, and Ultimo, a comparatively warmer and drier site. At each site, twenty trees are equipped with a novel IoT device (TreeTalker), capturing hourly data on several tree physiological parameters (Flux density, Stem Water Content, Radial Growth) and environmental parameters (Temperature, Relative Humidity, Radiation). Such data are accompanied by additional stand-level parameters (soil moisture and temperature, Precipitation). The primary objective of our study was to enhance our comprehension of the ecological dynamics that drive patterns of forest resilience amidst a changing climate. Our study centered around two primary research questions. Firstly, how do spruce trees growing in contrasting microclimatic conditions respond to periods of drought? Secondly, can we discern a divergence in physiological responses that suggests site-specific adaptation of these trees? Thus, by combining physiological and environmental variables, we could characterize the physiological response of trees quantitatively. Our findings revealed a divergent response between the two sites, which can be attributed to the long-term adaptation of trees growing on drier slopes. Additionally, the insights gained from our research will be instrumental in devising adaptive forest management strategies, crucial for safeguarding the future of Norway spruce forests in the Alpine region.

Survival and growth of the same Picea abies genotypes along a transect through Europe

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Curt Almqvist[1]
Göran Wallin[2], Lasse Tarvainen[2]
[1] Skogforsk (The Forestry Research Institute of Sweden)
[2] Department of Biological and Environmental Sciences, University of Gothenburg, Sweden

Abstract: Field measurements have been made on a large set of clonal Norway spruce trees planted at four sites along a latitude transect from south-west France (Bordeaux) to mid-Sweden (Uppsala). The sites were established in spring 2013. Three-year annual mean temperature has a range of 6.4 °C over the transect, which is similar to the maximum range of warming predictions for the coming century (IPCC 2013). In addition, two of the four sites are drier and two wetter allowing for studying the impact of water availability on temperature acclimation among the provenances and genotypes. The experiment is designed to have the same genetic material at all field site (~300 clones of east European and Swedish provenance, replicated 3-5 times at each site. This material gives us a unique ability to assess the relationships among tree provenance, traits, and temperature acclimation potential over a vast natural climate gradient. Results from field measurements from 2013 – 2022, covering the severe heat and drought year 2018 is included. The growth and survival responses of the genotypes were highly variable between sites indicate different sensitivities to heat and drought.

Swedish forestry in the future - the competitive effects of future tree species in mixed forestry under climate warming

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Clydecia Spitzer[1]
Michael Gundale[1], Stefan Hupperts[1], Sandra Jämtgård[1]
[1] Swedish University of Agricultural Sciences

Abstract: Mixed species forestry may become important for Swedish forestry in the future as a means to adapt to global change. In Sweden, average temperature is expected to increase by 3.2℃ by the end of the century. Therefore, research related to the productivity and competition of tree species in mixtures under climate warming is necessary. In addition, investigating the responses of other potential commercial tree species besides *Picea abies* and *Pinus sylvestris* to climate warming and their interactions with current commercial tree species in mixtures will be important for informing future management decisions. Several trial sites have been established in Sweden more than thirty years ago to understand the productivity of twelve tree species (i.e., both native and exotic). These sites provide useful information based on current climate and resulted in the identification of *Larix sibirica* as a potential commercial tree species in Swedish forestry. However, these ongoing research efforts will not be able to shed light on the question: how will this species respond to a warmer climate in Sweden and to what extent will this influence their interactions in species mixtures? Here, we will present results from a growth chamber experiment consisting of four commercial tree species (*Larix sibirica, Betula pendula, Pinus sylvestris and Picea abies*) in single species, two species, three species and four species mixtures under ambient and elevated temperatures (3°C). We will focus on how increased air temperature affects forest tree species productivity, their interactions with other commercial tree species in mixtures and their interactions with mycorrhizal partners. We particularly discuss shifts in the colonization of ectomycorrhizal fungi with various mixtures, as well as above- and belowground species complementarity and their responses to increased temperature.

The response of combined drought and heat stress on plant growth and carbon flow in a greenhouse study

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Byung Bae Park[1]
Woobin Youn[1], Ji Young An[1, 2]
[1] Department of Environment and Forest Resources, College of Agriculture and Life Science, Chungnam National University, Republic of Korea
[2] Institute of Agricultural Science, Chungnam National University, Republic of Korea

Abstract: Anthropogenically-driven surges in abiotic stress frequency and intensity are among the major drivers of global shift in plant environment. Impaired plant growth often stems from the confluence of various stressors whose individual effects are difficult to ascertain. However, the accelerating impacts of climate change necessitate the understanding of plant growth in response to various stress factors. The purpose of this study is to investigate changes in the growth and carbon distribution patterns following the introduction of drought and heat stress in plants. To distinguish individual and combined stress impacts, treatments applied using discrete and combinative approaches. Height, root collar diameter, and biomass will be measured for plant growth, while carbon flow and distribution will be determined via stable isotope tracing. We will analyze which secondary metabolites the plants produce. We hypothesized that combined stress would produce new secondary metabolites, with more negative effects on growth and carbon distribution than individual stress. This study will contribute to the understanding of plant response mechanisms and survival strategies under stress in the future.

The SPRUCE Experiment: Cutting Edge Climate Change Research on Northern Forested Peatlands

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Randy Kolka[1]
[1] USDA Forest Service Northern Research Station

Abstract: The Spruce and Peatlands Responses Under Changing Environments (SPRUCE) experiment is an ambitious ecosystem-level experiment that is testing the response of high-carbon northern peatland ecosystems to increased temperatures and elevated carbon dioxide. The experiment is being conducted in a black spruce peatland in northern Minnesota at the USDA Forest Service's Marcell Experimental Forest (MEF). SPRUCE is supported by the US Department of Energy and is a collaboration between Oak Ridge National Lab, the USDA Forest Service and 100's of other scientists from across the globe. Northern peatlands are an ecosystem considered especially vulnerable to climate change and responses to warming and interactions with increased atmospheric CO_2 concentration are anticipated to have important feedbacks on global climate. SPRUCE is evaluating the response of the existing plant and soil communities to a range of warming levels from ambient to +9°C, with and without elevated CO_2, provided via large, open-top chambers. Belowground heating began in 2014, aboveground heating in 2015, and elevated CO_2 treatments commenced in June 2016. We anticipate running the experiment for 10 years. I will present an overview and some of the results of SPRUCE, including treatment effects on greenhouse gas production, soil processes, and the plant communities.

Tree drought and heat tolerance traits for climate resilient forests

T1.27 Response of forest ecosystems to global change: Learning from experimental manipulations and natural gradient studies

Leonie Schönbeck[1, 2]
Magnus Löf[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences
[2] University of California, Riverside, USA

Abstract: Increasing frequency and intensity of droughts and heatwaves worldwide cause reductions in forest productivity, threatening the ecosystem services that forests provide and their carbon sequestration potential. As an example, in central and northern Europe, the summer of 2018 has exposed certain tree species to temperatures close to their thermal tolerance limits, in addition to severe drought stress. The exact individual role of drought, rising temperatures and vapor pressure deficit (VPD) in driving forest growth reductions are unknown, neither are the physiological consequences of heat and drought, but as trees need water for leaf temperature control, drought and heat tolerance might be strongly coupled. We study the interaction between drought and heat stress on trees and plants. We hypothesize that heat and drought tolerance are coupled i) on a global climatic scale as species-specific trait and ii) physiologically during acclimation to drought and heat. Two case studies will elaborate on these hypotheses. In the Mediterranean ecosystem of southern California, six plant species responded in different magnitudes to heat and drought stress. Drought tolerance increased with increasing temperatures, even in absence of soil water deficit, suggesting a physiological coupling between drought and heat tolerance. In a climate chamber experiment in southern Sweden, four important European tree species – *Pinus sylvestris, Picea abies, Betula pendula* and *Quercus robur* – were planted in pots and exposed to two different temperature and three different drought treatments. After acclimation of eight weeks, the trees were exposed to two consecutive heat waves with a two-week recovery period. Before and after acclimation and heatwaves, drought and heat tolerance indicators were measured, such as turgor loss point, photosynthetic thermal optimum and thermal tolerance. The results reveal the acclimation potential of plants and trees worldwide, and lead towards predicting acclimation potential and risks to future hot droughts. The study outlines the importance of considering the combined effects of drought, heat and accompanying VPD in assessing and predicting tree productivity, health and mortality during extreme environmental events.

VPDrought – a novel approach to disentangle atmospheric and soil drought in a natural Scots pine forest

Abstract: The intensification of droughts through rising evaporative demand (i.e., vapor pressure deficit or VPD) is a considerable concern for governments and societies because of their disastrous impacts on natural systems. For forests, ecosystem services such as wood provisioning and carbon sequestration are severely jeopardized by these changes, leading to significant uncertainties regarding climate regulation. Climate-vegetation models are not only in need of data on atmospheric and soil drought sensing mechanisms but are also critically challenged by insufficient understanding of the processes driving forest vulnerability to climate change. Only by deciphering the single vs. combined VPD and soil moisture effects will we be able to improve global predictions.

We apply a scale spanning approach to disentangle the processes affected by atmospheric (i.e., VPD) and soil droughts from the tissue to the tree and the ecosystem level. We set up the first atmospheric humidity and soil moisture manipulative experiment in a mature natural forest. We combine air humidity (and thus VPD) manipulation using a humidification system in the canopy of adult trees exposed naturally to high summer VPD and a below canopy through-fall exclusion system. The system is installed at the long-term Pfynwald irrigation experiment, which is since 2003 a pivotal WSL monitoring and experimental site anticipated to be near its tipping point with respect to climate change.

This experiment helps us understand how the soil moisture responses of trees, shrubs, and microbial communities are altered by atmospheric dryness from the tissue- to the ecosystem-level. This novel manipulative VPD and soil moisture experiment provides a critical empirical test platform to address the most critical questions in the context of climate impacts in temperate forests. The data will ultimately allow the development of novel predictive methods to assess climate change impacts on

forests. Preliminary data will show the effects of altered atmospheric and soil drought on adult Sots pine trees.

T1.28 Restoring degraded riparian ecosystems: Context matters

Assessing Tropical Riparian Zones Conditions By Blue Target Protocol

T1.28 Restoring degraded riparian ecosystems: Context matters

Gabriel Oliveira Ferraz[1]

[4] Swedish Angling and Fisheries Conservation Association, West region, Sweden

Abstract: Environmental assessment protocols have demonstrated a good ability to assist in the management of actions aimed at preserving, conserving and recovering ecosystems. However, most existing protocols focus either on the terrestrial structure or on the aquatic landscape, not directly addressing the riparian zones, important areas for the stability of processes related to the hydrological cycle, contributing to the availability and quality of water from streams. The Blue Targeting Tool (BTT) - designed by Water Management in Baltic Forests (WAMBAF) project in Swedish forest areas - is a document with a binary structure and simple language that seeks to enable and promote the participation of many stakeholders of society in assessing the integrity of riparian areas through 4 evaluative sections: Conservation, Impact, Sensitivity and Additional Values. Given the success of this protocol in Swedish forest management areas, this project was structured with the aim of designing a tropical version with a focus on high gradient regions in the Atlantic Forest biome. The adapted version was applied in the state of São Paulo (Brazil), in 15 reaches of headwater streams belonging to the Corumbataí river basin. In addition to the protocols, 3 environmental parameters were collected to provide data on stream water, riparian forest and landscape conditions. With the objective of evaluating the consistency of the assessments, the participants in the application of the protocol were classified as specialists (ESP) and non-specialists (NES), totaling 254 evaluations (ESP=60 and NES=164). The scores obtained by applying the protocol showed consistent results between groups; where most topics showed similar choice percentages between ESP and NES (response difference ≤ 25%). The protocol showed a good ability to indirectly measure the structure of the riparian forest present based on calculated basal area values, grouping the study areas into classes with significant difference (p(median) < 5%) between them. The results obtained demonstrate the potential of this protocol in promoting integration between different stakeholders for the joint construction of a database for monitoring riparian areas. However, it is still necessary to engage more stakeholders and validate the protocol with scientific data.

Evaluation of ecological restoration efforts on riparian ecosystems in neotropical region: effects on water quality

T1.28 Restoring degraded riparian ecosystems: Context matters

Matheus Ogasawara[1]
Ricardo Taniwaki[2], Silvio Ferraz[1]
[1] University of São Paulo, Department of Forest Sciences, “Luiz de Queiroz” College of Agriculture, Brazil.
[2] Federal University of ABC, Engineering, Modelling and Applied Social Sciences Center, Brazil.

Abstract: The riparian forest is considered an important component for maintaining the dynamics and functionality of streams. Restoration of tropical riparian forests can have an equally significant effect on tropical streams and, consequently, is a promising tool for the restoration of tropical aquatic ecosystems and the maintenance of their ecosystem services. In neotropical regions, restoration of streams is carried out indirectly through forest restoration of riparian vegetation, without direct intervention in the channel. Likewise, knowledge about the impacts of stream restoration measures implemented at the channel scale is little known in these regions. This study aims to evaluate the effects of ecological restoration efforts on water quality riparian ecosystems in 15 catchments along a gradient of restored forests of different ages in southeastern Brazil. The basal area of the riparian forest was measured, using transect plots (25m x 10m) installed across the stream in each of the 15 catchments. In-situ measurements of water temperature and electrical conductivity were performed using the YSI ProODO optical dissolved oxygen and the YSI 85 conductivity. Laboratory analysis was conducted on water samples collected during the dry and wet seasons of 2022 to determine the concentrations of total dissolved carbon, dissolved organic carbon, dissolved inorganic carbon, total nitrogen, and orthophosphate (P). The results demonstrate that basal area was higher in older restored riparian areas compared to younger riparian areas. The older areas showed lower electrical conductivity values, with a median of 18.8 µS/cm, it also showed the lowest values of total dissolved carbon and dissolved inorganic carbon, both in the dry season and in the rainy season, with values of 4.14 mg/L and 6.39 mg/L, and 1.60 mg/L and 1.97 mg/L, respectively. For the dissolved organic carbon and orthophosphate (P) there was no statistical difference between the values of among the ages of the forests. We concluded that age of restored riparian forest was strongly linked to the riparian forest structure demonstrating that older restored areas was responsible to improve the water quality, showing the importance of restoration of degraded riparian ecosystems for the water quality in neotropical streams.

Improving forested riparian zones with green and blue infrastructure measures along small watercourse in Latvia

T1.28 Restoring degraded riparian ecosystems: Context matters

Toms Štāls[1]
Līga Pentjuša[1], Zane Lībiete[1], Ilze Kukāre[2]
[1] Department of Forest regeneration and establishment of tree plantings, Latvian State Forest Research Institute “Silava”
[2] Latvia’s State Forests

Abstract: Forested riparian zones along small watercourses are vital for ecosystem health. These zones act as buffers, protecting and filtering water, stabilizing banks and reducing erosion. They support habitats for diverse species and facilitate species movement. Riparian zones regulate the hydrological cycle, controlling water flow and preventing floods, and contribute to groundwater recharge. They also provide recreational opportunities and enhance the aesthetic appeal of landscapes. Preserving these areas is essential for ecosystem sustainability and the well-being of communities.

The study area focuses on a 1.4 km section of the Tora River that runs through forest land in the north-central part of Latvia. The average width of the river in the study area is 2-4 meters, with a 50-meter wide riparian protection zone. The forest along the river has previously been managed without considering water quality, resulting in even-aged and over-dense spruce stands in close proximity to the water. However, the riparian zone also includes valuable habitats and structures that are important for biodiversity, such as standing and fallen deadwood and old oak trees from previous generations, which harbor several rare species.

To improve water quality in the stream, safeguard existing natural values, enhance environmental accessibility, and educate the public, green and blue infrastructure measures will be implemented in the area during the summer and autumn months of 2023. These measures will involve diversifying the riparian zone, thinning dense spruce stands, promoting the growth of broadleaved tree species, constructing a peak flow control structure in the ditch before it discharges into the Tora River, and creating a nature trail with informative exhibits about the processes occurring in the riparian zone.

Environmental monitoring has been conducted in the study area for the past two years in preparation for the planned green and blue infrastructure measures, and it will continue for several more years. This monitoring includes tracking various parameters across the entire territory, such as physical and chemical indicators of ground, precipitation, and river water. It also involves monitoring groundwater levels and air temperature on the riverbank (to assess shading) and analyzing the volume and composition of litter.

Restoring degraded riparian areas in Ghana: Key lessons for up scaling

T1.28 Restoring degraded riparian ecosystems: Context matters

Shalom Addo-Danso[1]
[1] Forests and Climate Change Division, CSIR-Forestry Research Institute of Ghana

Abstract: Riparian ecosystems are critical for the provision of ecosystem services such as clean water, and are integral to the hydrological cycle. However, riparian areas in most developing countries including Ghana have been degraded by human-activities such as excessive water abstraction, unsustainable farming practices, excessive tree cutting, and uncontrolled sand mining. There have been efforts to restore degraded riparian ecosystems in Ghana, and there is the need to evaluate their progress to identify factors that contribute to their success or otherwise. The objective of this study was to provide new insights into field implementation of riparian restoration projects by compiling information and data from secondary sources in a database from 2010 to 2022 to identify key interventions, constraints and important lessons that could inform up scaling in the country and across the sub-region. In the last decade, riparian restoration projects have focused on both micro-watersheds and corridors that cover large geographic areas. Key interventions that have been implemented include natural regeneration, assisted natural regeneration, planting of indigenous tree species and agroforestry practices. It is noteworthy that most initiatives adopted participatory approaches involving non-governmental organisations, local communities and public sector agencies. Overall, the projects have contributed to improving the integrity of riparian areas, but constraints such as inadequate funding, inadequate knowledge on the choice of suitable species, destruction from animal browsing and seasonal bushfires, inadequate effective monitoring and evaluation, and the exclusion of groups including pastoralists remain. Some of the important lessons include the need for a strong collaboration and continuous engagement among key stakeholders, especially the traditional authorities and land users. Furthermore, local people should be empowered through training and capacity building activities, and incorporate local indigenous knowledge to guarantee local ownership. Promoting community water infrastructure and technologies to increase access to safe water, designing inclusive monitoring and evaluation frameworks, and dealing with threats from bushfires and animal browsing and applying decision-support tools for restoration are important lessons to implement riparian restoration projects on the ground.

Restoring Degraded Riparian Ecosystems in Sub-Saharan Africa: A Multi-Disciplinary Approach and Methodological Framework

T1.28 Restoring degraded riparian ecosystems: Context matters

Anthony Aidoo[1]
SAMUEL FOSU[1], Naana Mintaah Akufo[1]
[1] Communities Forestry And Social Development International-COFOSODE, Ghana

Abstract: Riparian habitats, usually found where land and water meet, are essential for the provision of water and for maintaining other ecosystem services including biodiversity. However, these ecosystems have been severely degraded by human activities including urbanization, deforestation, mining, and agriculture, particularly in sub-Saharan Africa. Using case studies from Ghana, where mining is a common activity in riparian forest areas, this paper analyzes the present level of knowledge regarding restoration techniques for damaged riparian ecosystems. The paper argues that successful riparian ecosystem restoration requires a multi-disciplinary approach, involving close collaboration between ecologists, hydrologists, social scientists, and other stakeholders.

The methodology for restoring degraded riparian ecosystems involves a multi-phase approach that includes initial assessment, planning, implementation, and monitoring. The assessment phase involves gathering baseline data on the extent and nature of the degradation, as well as identifying key ecological, social, and economic values associated with the ecosystem. The planning phase involves developing a restoration strategy tailored to the specific needs and goals of the ecosystem. The restoration strategy may include various techniques such as erosion control, riparian re-vegetation, and invasive species removal. The implementation phase involves carrying out the restoration actions identified in the planning phase, which can range from interventions such as habitat restoration, streambank stabilization, water flow management, and community engagement initiatives to larger and more complex projects. This phase requires close collaboration between various stakeholders, including landowners, government agencies, and community groups. The last phase involves monitoring to evaluate the success of the restoration activities, and using adaptive management principles to improve or revise activities where necessary. Monitoring may involve the use of various indicators, such as ecological health, flood control, and water quality. To conclude, restoring degraded riparian ecosystems is a complex process, and it should be implemented using collaborative and adaptive approaches that recognize the complexity of riparian ecosystems and the socio-ecological systems in which they are embedded.

Restoring Degraded Riparian Ecosystems: Case study Ondiri Wetland in Kenya

T1.28 Restoring degraded riparian ecosystems: Context matters

MARY GATHARA[1]
Riziki Mwadalu[1], Mohamed Elema[1]
[1] Kenya Forestry Research Institute

Abstract: Ondiri wetland which forms the headwaters of River Nairobi; is a quaking bog undergoing degradation mostly due to anthropogenic activities thus reducing its ecological functions such as providing habitat for flora and fauna. The main objective of the study was to assess the levels and causes of degradation and undertake rehabilitation activities to restore its functions. The study was undertaken from 2018 to 2022. The specific objectives of the study were: to determine the impacts of land-use activities on the ecological and socio-economic functions of the wetland; to assess the pollution and degradation of water quality in the wetland; and to undertake rehabilitation activities using ecologically appropriate tree species and grasses. The survey purposively targeted the households bordering the wetland while for quantitative data, water samples were collected to monitor concentration of heavy metals and Total Dissolved Solids (TDS). Rehabilitation of the degraded sections of the wetland was undertaken using bamboo and indigenous tree species which were planted in three layers within the riparian zone. Planting layout along the riparian zone was as follows: layer 1: bamboo species adjacent to the water body and sedges, layer 2: assorted indigenous trees next to farmlands, layer 3: fruit trees adjacent to farmlands. Approximately 2.0 km of riparian land has been rehabilitated. The results of this study show that negative land-use systems such as intensive agricultural activities, unsustainable abstraction of water and poor sewage systems have affected water quality, quantity and reduced biodiversity. Results of three years' annual trend of cadmium, lead and chromium after rehabilitation technology intervention in the wetland revealed that cadmium level in year 1 was 11.12mg/l, year 2, 8.96mg/l and year 3, 2.9.mg/l. Lead levels decreased from 2.74mg/l to 2.68mg/l and 2.20mg/l, respectively whereas chromium levels remained constant at 1mg/l. All these levels of heavy metals are beyond allowable limits by World Health Organization (WHO). TDS remained at 900mg/l for the 3 years which is above WHO limits. The study recommends complete rehabilitation of the 3.3km perimeter using suitable grass and tree species. Urgent gazettement and protection of the wetland using multi-agency approach is also recommended.

Small waterways are neglected in production forestry operations across northern, high-latitude forests

T1.28 Restoring degraded riparian ecosystems: Context matters

William Lidberg[1]
Eliza Hasselquist[1], Lovisa Lind[2], Jussi Jyväsjärvi[3], Antti Leinonen[4, 5], Erik Emilson[6], Brian Kielstra[6], Lenka Kuglerová[1]
[1] Swedish University of Agricultural Sciences
[2] The Land and Environmental Court of Östersund
[3] Metsähallitus
[4] University of Eastern Finland
[5] Ministry of Agriculture and Forestry
[6] Natural Resources Canada

Abstract: High-latitude forests are home to vast freshwater resources and are among Earth's most intensively managed forests. An implication of this intensive management is the widespread yet undetected loss of intact headwater stream length and ecological function. Headwaters can represent 70-80% of the total stream length in forested watersheds and are essential for downstream water quality, water security, and biodiversity. Riparian buffers are the primary prescribed tool used in forestry as protection. Here we evaluated the loss of intact headwater riparian zones using national and regional-scale LiDAR scans of three of the top five wood-producing regions, along with records of every harvest in the five years before the scan. Our findings indicate that New Brunswick, Canada, and the country of Finland had more intact riparian zones following harvesting than the country of Sweden, with an average reduction in the tree cover of 9%, 24%, and 40%, respectively, when comparing unharvested and harvested riparian zones. This suggests that forestry operations in Finland and Sweden could better prioritise protecting small waterways. However, it is important to note that stream density in New Brunswick is 1.3 km/km^2 compared to 0.2 km/km^2 in Finland and 1 km/km^2 in Sweden, partly due to differences in climate, but also political decisions about what is worth protecting. There are differences in how each country defines and includes waterways on maps, with Finland classifying waterways like straightened streams or ditches differently in their stream database. This could explain why Finland appears to have fewer waterways than Sweden, when climate and topography are similar. If we assume that Finland has a comparable number of waterways as Sweden, there is the potential that they are not protecting riparian forests along 80% of their waterways. Similarly, the lower results seen in Sweden could be due to many waterways being assumed to be ditches, where no buffer would be required - even if upstream and downstream would be considered more 'natural'. In addition to implementing clearer riparian buffer policies in Sweden, identifying and defining the extent of the headwater stream network is crucial in protecting these fragile ecosystems and their downstream users.

The Rwanda Riparian Restoration Project

T1.28 Restoring degraded riparian ecosystems: Context matters

Camille Rebelo[1]
[1] EcoPlanet Bamboo

Abstract: The small, landlocked nation of Rwanda is one of mountainous terrain, combined with intensive land use and production by the country's multitude of smallholder farmers. Steep slopes are intensively farmed, resulting in soil erosion representing a major threat to food security. Such erosion results in the siltation of rivers that interlace these mountains. Landslides, collapse of river banks and loss of adjacent farmlands is cited as a major concern for farming communities. Downstream, these rivers feed into dams which supply a significant portion of the country's energy needs through hydropower. Siltation represents cost and production issues for such hydropower production. Localized problems are also of concern in this agrarian country, with

Riparian buffer zones, representing the land adjacent to the rivers, varying in width of between 1 and 20 meters depending upon the size of the river, are classified as government lands, under the jurisdiction of the Rwanda Water Resources Board. Farming is prohibited within such lands, which are set aside for conservation and protection purposes. The cultural and socio-economic context of Rwanda results in a scenario where such delineations are respected by the surrounding farming communities.

Between 2019-2022 the Government of Rwanda, in partnership with implementing entity EcoPlanet Bamboo, undertook a pilot restoration project targeting the planting of 150km of such riparian buffer zones utilizing select species of non-invasive, densely clumping sympodial bamboo. Based on the success of this initial project and support of surrounding communities, the project is now being scaled up utilizing carbon finance across key upland watersheds, in partnership with district authorities and surrounding communities.

This presentation will discuss the approach, the multiple actors involved from government to implementation, to carbon financing, the context of this unique project and its replicability elsewhere, as well as the lessons learned to date.

T1.29 Risk-based surveillance for quarantine forest pests

A new approach for identifying future biotic threats using current pest distributions

T1.29 Risk-based surveillance for quarantine forest pests

Jon Yearsley[1]
Ultan O'Donnell[1], Richard O'Hanlon[2], Andy Bourke[2], Conor McGee[2]
[1] School of Biology and Environmental Science, University College Dublin, Ireland
[2] Plant Sciences Division, Department of Agriculture, Food and the Marine, Ireland

Abstract: Quantitative evidence plays a valuable role in helping to inform and build consensus in complex decision-making, such as the problem of ranking future biotic threats to a region. It does this by providing lines of evidence that are transparent, easily shared and repeatable. Examples of this type of quantitative evidence are the analysis of global trade pathways that may transport a pest from one region to another, or grouping regions by their communities of pests.

Here we present a new probabilistic method that uses data from the European and Mediterranean Plant Protection Organisation's global database to rank the future pest threats for a host tree species in a particular region. The method is based upon the analysis of similarities between pairs of pest distributions. The approach allows for uncertainties to be placed upon the pest threat rankings and measures of performance to be calculated using current pest distributions. The method is explained using examples of specific tree species in Europe.

Analysis of Quarantine Forest Pest Monitoring Techniques and Results in Croatia: A Five-Year Synopsis

T1.29 Risk-based surveillance for quarantine forest pests

Nikola Zoric[1]
Dinka Matosevic[1], Andrija Jukic[1], Tomislav Krcivoj[1]
[1] Croatian Forest Research Institute, Jastrebarsko, Croatia

Abstract: Preservation of forest health and reduction of harmful impacts from native and invasive alien species on ecosystems are of critical importance in Croatian forest stands. Some of the non-native insect and fungal species have been recognized as potentially dangerous forest pests that could have devastating effects of natural forest ecosystems in Croatia.

We present a five-year synopsis of quarantine forest pest monitoring in Croatia, concentrating on the employed methodologies and monitored pests. The analysis incorporates traditional approaches, such as visual inspections, trapping, morphological and molecular analyses, conforming to the European Food Safety Authority (EFSA) guidelines. New methods and technologies are also used: small aerial vehicles or drones equipped with multispectral sensors provide a better insight into forest health and damage, and pests can be monitored over larger areas.

In the last five years we have monitored a range of quarantine insect and fungal pests in various forest ecosystems and on wide diversity of host plants. The results of our study provide valuable insights into the national surveillance scheme for invasive pests and pathogens, species of surveyed pests and their potential impact on forest health. The study highlights successful application of various methods, including visual inspections, trapping used as early warning system, use of UAV, morphological and molecular analyses, in detecting and identifying alien insects and fungal pests. The results from this overview serve as a foundation for the development of targeted strategies and informed decision-making for future survey programs, enabling the prevention of introduction and spread of forest pests and continued protection of forest ecosystems in Croatia.

Bio-economic optimization of surveillance for detection of priority quarantine forest pests in Switzerland

T1.29 Risk-based surveillance for quarantine forest pests

Benno A. Augustinus[1]
Rebecca S. Epanchin-Niell[2], Heike Lischke[3], Valentin Queloz[1], Eckehard G. Brockerhoff[1]

[2] University of Maryland, College Park, Department of Agricultural and Resource Economics, United States of America
[3] Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Land Change Science, Switzerland

Abstract: When designing surveillance schemes for several forest pests simultaneously, one must address several questions: (i) What is the optimal total yearly investment? (ii) Which of the surveyed organisms should receive more resources? And (iii), at which locations should these resources be invested? To answer these questions for a monitoring program for six priority quarantine and two quarantine forest pests in Switzerland, we used a bio-economic model. The model determines optimal type, number, and location of survey locations, accounting for differences in introduction likelihood, detectability, and spread rates across different locales. It relies on fine-scale trade data, information on host tree availability in urban and forest environments, human population density, eradication costs, and specific biological information for the respective pests.

The model gave an estimate for yearly investment in monitoring, and survey recommendations varied per species and locale. For two of the eight species, *Anoplophora glabripennis* and *Anoplophora chinensis,* the model deemed surveys by means of trapping as economically unjustified. For these species, the estimated probability of background detection by the public in case of an establishment was very high and spread rates comparably low, reducing the benefits from formal surveys. Instead, relying more on citizen “scientists” would be more cost-effective.

The model suggests where in Switzerland sampling would yield the highest economic benefit – with greater effort in areas with higher introduction risk and for species with low likelihoods of detection by the public and fast spread rates. We discuss how the model suggestions differ from simpler approaches and highlight the strengths and weaknesses of our bio-economic approach for risk-based surveillance monitoring.

Characterisation of foliar fungal endophytes and pathogens in Irish forest trees

T1.29 Risk-based surveillance for quarantine forest pests

Flavio Storino[1, 2]
Richard O'Hanlon[2], Jon Yearsley[1], Neil Warnock[3], Archie Murchie[3]
[1] University College Dublin
[2] Department of Agriculture, Food and the Marine
[3] AFBI

Abstract: In the last few decades, because of changing climate and increased international and intercontinental travel, the rate of detection of novel invasive plant pests and pathogens has been steadily increasing (Ramsfield et al. 2016). This is particularly true for tree pests and pathogens on the island of Ireland, where in the last two decades many new disease-causing insects and microorganisms have made their appearance and caused damage(O'Hanlon et al., 2020). To address this issue, AdaptForRes project was established. One of the aims of this multi-stakeholder project, which includes partners in academia, governmental institutions and industry, is creating a surveillance network capable of detecting the arrival of novel pests and diseases, following the example of past projects that have shown the efficacy of said method (Bulman, 2008).

For the first time island-wide several sites will be surveyed, both in person and through the assistance of forest inspectors. These sites were chosen according to their proximity to shipping ports, cities and/or sawmills, locations that increase the chance of novel pathogens to be introduced and spread. In order to validate the surveillance network, we are evaluating the community of foliar endophytic fungi of sessile oak (*Quercus petraea*), Scots pine (*Pinus sylvestris*) and Sitka spruce (*Picea Sitchensis*), three of the most important forest tree species in the island of Ireland. Twigs and leaves will be randomly sampled in each site, then they will be plated to isolate endophytic fungi which will then be morphotyped and identified through barcoding. From the first sampling round, more than 100 morphotypes were isolated and analysed, showing the potential presence of pathogens. Moreover, foliar samples will also be stored for metabarcoding, in order to reveal the presence of slow-growing or cryptic species. The data obtained through these surveys will be analysed in combination with other datasets to generate an optimised surveillance network. This work will also generate a collection of fungal isolates, pathogenic or not, that will be used for further research on a national and international level. We might also show the presence and distribution of pathogens that have already been reported or of novel ones.

Clues for inferring invasion routes of invasive wood-boring insects

T1.29 Risk-based surveillance for quarantine forest pests

Etsuko Shoda-Kagaya[1]
Shigeaki Tamura[1]
[1] Forestry and Forest Products Research Institute

Abstract: Inferring the introduction routes of non-native species is useful not only for controlling their spread but also for preventing further invasions of other species with similar ecological characteristics. Most recent studies for estimating invasion pathways of alien species have used genetic analysis, as molecular ecology has progressed. But, much other information is available to estimate invasion routes. In this talk, we will introduce clues for inferring invasion routes and discuss their effective combinations.

In Japan, three wood-boring insect pests have recently invaded; the red-necked long-horned beetle (*Aromia bungii*), the Asian longhorned beetle (*Anoplophora grabripennis*), and the rusty-spotted long-horned beetle (*Apriona swainsoni*). These species have severely damaged and killed many broadleaf trees. Their original distributions are in continental East Asia. Although larvae of these species bore living host trees, they can become adults even if host trees die during their development. Therefore, these pests are able to be transported across the sea via wood packaging materials as well as living trees.

We used the following clues to infer the invasion routes of these three species; morphological variation, spatio-temporal change of damaged trees, the surrounding environment around the invaded area, import records of living trees in the invaded area, and genetic population structure. Morphological variations can suggest the origin of the organisms before developing molecular markers. Genetic population structure suggests the size of introduced populations and the diversity of sources. Spatio-temporal change of damaged trees allows estimating of initially established sites. The environment around the initially invaded area and import records of living trees are useful for inferring whether the species were introduced through live trees or wood-packing materials. For example, in *A. bungii*, the genetic population structure suggested multiple introductions into six non-continual invaded regions. In addition, the initially established sites were estimated to be near or in industrial parks based on spatio-temporal change of damaged trees in most of the invaded regions. From these clues, we inferred the invasion route of *A. bungii* as follows; wood packing materials infested by their larvae were imported from its original country and they were transported into various industrial parks in Japan.

Crop-based surveillance methodology: a new multi-pest survey approach.

T1.29 Risk-based surveillance for quarantine forest pests

Abstract: The EU is continually exposed to the introduction of new pests and pathogens, increasing the need for greater phytosanitary effectiveness. EU Regulation 2016/2031 requires Member States to carry out surveys of quarantine pests in the EU and pests not yet listed. In this context, one of the main current challenges is to better organise surveillance campaigns, moving from pest-based surveillance to a crop-based surveillance strategy, i.e. monitoring several pests and pathogens at the same time, in order to reduce the survey effort while maintaining, or even increasing, the overall effectiveness of the surveillance programme. The European Commission asked EFSA to provide scientific and technical assistance in the field of plant health, including the transition to this new approach. One of the tasks of the ongoing EFSA-funded "Innovative Approaches to Survey broadleaved tree Pests and Pathogens" (IASPP) project is to support this approach by developing multiple surveys on broadleaved tree pests, identifying the best strategies that can be used across several organisms active at the same time. Based on the latest available literature, including the *ad hoc* prepared EFSA's pest survey cards (PSCs), key information on the host-parasite system was collected and pests and pathogens were grouped according to their phenological and physiological similarities.

Don’t be a Know-It-All: A Retrospective Analysis of Phylogenetic Host Range of Invasive Pathogens

T1.29 Risk-based surveillance for quarantine forest pests

Abstract: Risk uncertainty limits the effectiveness of proactive biosecurity to avoid negative impacts on all types of forest ecosystems and people who depend on them. Although most invasive forest pathogens were already described species, the risk they posed could not be assessed before they became established, and their biogeographic origins, taxonomy, and genetics continued to remain uncertain even during and after the epiphytotics they caused. To mitigate the uncertainty, “sentinel” trees are monitored outside of their native range where they might be exposed to a new pool of pathogens, leading to pre-invasion host records. North American trees have been planted abroad for forestry for over 500 years, resulting in thousands of pathogen records. In order to assess the power of the sentinel approach, a retrospective analysis of pre- and post-invasion knowledge of phylogenetic host range was conducted for the much smaller number of pathogens that are known to be invasive in North America. Biogeography and host records were reviewed for an updated, comprehensive list of established invasive forest pathogens in North America, and a chronology was built for hundreds of thousands of records of North American hosts on other continents. A phylogenetic tree of woody plants was then used to a) standardize a chronology of pre- and post-invasion changes in documented host ranges and b) predict richness of invasive pathogens based on floristic similarity of invaded to original ranges.

Forest Biosecurity in Canada – an Integrated Approach

T1.29 Risk-based surveillance for quarantine forest pests

Jeremy Allison[1]
Tod Ramsfield[2], Brad Tomm[2], Mireille Marcotte[3], Meghan Noseworthy[4]
[1] Canadian Forest Service, Great Lakes Forestry Centre
[2] Canadian Forest Service, Northern Forestry Centre
[3] Canadian Food Inspection Agency
[4] Canadian Forest Service, Pacific Forestry Centre

Abstract: Canada's forest biosecurity policy and regulatory frameworks are governed under a number of international agreements, and federal and provincial legislation. Given the breadth and diversity as well as the ecological and economic importance of Canada's forests, forest biosecurity in Canada is constantly evolving and improving. Historical and recent examples of the impacts of non-native pest introductions and approaches to addressing incursions and introductions, illustrate both the challenges and successes of past, current and potential future collaborations between different jurisdictions. As most non-native species in forest ecosystems have been introduced accidentally, invasive species management programs in Canada focus on prevention. Prevention efforts in Canada emphasize pathways and commodities with historically high propagule pressure. Our knowledge of the pathways involved in the invasion of forest ecosystems in Canada is primarily based on border interception records, risk assessments for pests and pathways, surveillance programs, and participation in international research networks (e.g., the International Forest Quarantine Research Group). This presentation will summarize forest biosecurity in Canada and present some summaries of pest interception databases that are ongoing as part of a collaboration between the CFIA and CFS.

New invasive forest pests threatening the European and Mediterranean forests: an EPPO perspective

T1.29 Risk-based surveillance for quarantine forest pests

Dmitrii Musolin[1]
[1] European and Mediterranean Plant Protection Organization (EPPO), France

Abstract:
European and Mediterranean Plant Protection Organization (EPPO) is an intergovernmental organization created in 1951 by 15 countries, which now (2023) has 52 member countries. It works for and with National Plant Protection Organizations and widely engage experts from the EPPO region and beyond in its work.

One of the EPPO's missions is a cooperation between member governments to pursue and develop protection of plants and plant products against pests and the prevention of their international spread, especially their introduction into the EPPO region.

This mission is achieved by creating and managing an early warning system (EPPO Alert List), evaluation of the risks presented by emerging pests (Pest Risk Analysis), preparation of recommendations on pests which should be regulated in the EPPO region, and preparation of associated Standards (e.g., on diagnostics, phytosanitary measures).

In the presentation, an update will be made on the EPPO Global Database (preparation of dynamic datasheets on 300+ priority pests), recent additions of forestry pests to the EPPO Alert List, A1 and A 2 Lists, Pest Risk Analyses recently performed or reviewed by EPPO, and recent development of the EPPO Network of specialists working on surveillance, monitoring, and control of the Emerald ash borer, *Agrilus planipennis* in Europe.

Plant health surveillance in Switzerland: from legislation to implementation

T1.29 Risk-based surveillance for quarantine forest pests

Aline Knoblauch[1]
Benno A. Augustinus[2], Eckehard G. Brockerhoff[2], Rebecca Epanchin-Niell[3], Valentin Queloz[4]

[2] Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Forest Health and Biotic Interactions, Switzerland
[3] University of Maryland, College Park, Department of Agricultural and Resource Economics, United States of America
[4] Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Swiss Forest Protection WSS, Switzerland

Abstract: Risk based plant health surveillance is critical for early detection of dangerous insect pests and pathogens and thus, for their successful eradication. While in agricultural systems, surveillance designs are mostly based on the well-known distribution of target crops, planning a sound protocol for forest ecosystems is more challenging. Switzerland shares a common phytosanitary area with the European Union (EU) and as such, introduced a legal obligation for plant health surveillance of so called "priority quarantine pests" which are shared with the EU. While guidelines and their integration within the legal phytosanitary framework are crucial, developing a plant health surveillance system that is scientifically sound, risk-based, optimized for costs as well as accepted by those responsible for its implementation, is vital for success. In order to achieve this, we developed a tailored approach for the specific needs of Swiss forests. The Swiss Federal Institute for Forest, Snow and Landscape Research WSL adapted a model for risk-based and cost-efficient plant health surveillance in Swiss forests, based on a model developed for the United States Department for Agriculture (USDA). Concurrently, we involved regional forest health officers in a three-year pilot programme in which we jointly developed, tested and optimized methods in the field for country-wide application.

Specifics of forest ecosystems aren't always considered in broad plant health aspects and it is thus even more important that international exchange and support in these matters is further strengthened.

The Forest Trapping Network: a new surveillance method for invasive forest pest species in the United Kingdom

T1.29 Risk-based surveillance for quarantine forest pests

Thomas Kendall[1]
Alice Walker[2], Max Blake[2]
[1] Forest Research, Northern Research Station, Scotland, United Kingdom
[2] Forest Research, Alice Holt Lodge, England, United Kingdom

Abstract: The Forest Trapping Network (FTN) is a rolling programme designed by Forest Research to survey forests across Great Britain for a broad range of invertebrate pests over a five-year cycle. The FTN aims to: efficiently trap for Coleopteran pest species identified in the new EU Exit Regulations 2020, and any further pest threats identified in the future; ease logistical issues by consolidating current trapping programmes for individual pest species into a single network; and improve current trapping methods for quarantine pests. The FTN began with a series of pilot studies between 2020-2022 and was fully launched in 2023.

In each year of the five-year cycle, we will select 25 forests across GB. At each forest, we will install a cross-vane trap baited with a broad-spectrum attractant appropriate to the tree species in five forest blocks of different species (spruce, fir, pine, oak, and other mixed broadleaf). Individuals caught from target groups (including Cerambycidae, Scolytinae and Molytinae) which contain the target pest species will be identified to species level.

Pilot data from 2021/2022 suggested that none of the pests identified in the EU Exit Regulations 2020 had become established at any forest surveyed by the FTN. However, we detected the quarantine species *Ips typographus* in one forest. 11,373 individuals from target groups were sampled in total: the majority (98%) were members of Scolytinae (34 species). The remaining 14 species belonged to a range of target groups including four species of Cerambycidae, two of Molytinae and three species of Siricidae. We found one new county record (*Xeris pallicoxae*, a nationally rare woodwasp).

The broad-spectrum trapping employed by the FTN will aid early detection of invasive forest pests across GB, which are likely to become a greater threat as climate change facilitates range expansions. There is also potential for the FTN to be adapted to cater for additional regional requirements - for example, traps for *Ips cembrae* and *Ips sexdentatus* within the existing Pest Free Area in Scotland. Finally, the FTN is likely to expand our knowledge of the life-histories and native ranges of forest-dwelling insects in Great Britain.

Trade networks and alien species: global trends of introduction risk

T1.29 Risk-based surveillance for quarantine forest pests

Davide Nardi[1]
Lorenzo Marini[1]
[1] University of Padua, DAFNAE, Italy

Abstract: In the last decades, globalization has dramatically increased the volume of transported goods and the number of commercial partners. As a result of this higher connectivity, many insect species have been unintentionally and repeatedly introduced outside their native ranges. Many of those alien species can become forest pests leading to huge economic impacts on non-native forest ecosystems worldwide. Depending on their traits, species can be moved through specific or generic pathways. While specialized insects feeding on single host plant species are often strongly associated with the flow of living plants, others are weakly associated with specific commodities, mainly depending on the total volume of trade.

International trade can be effectively represented by unipartite and bipartite networks. Networks can describe complex relationships and are constituted by nodes (i.e. countries) and links (trade routes). The complexity of international trade networks can be thus simplified using indexes, such as node-level metrics (e.g. degree centrality), network-level metrics (e.g. connectance and modularity). First, we want to investigate the role of network metrics in explaining patterns of global first findings of insects. Second, comparing imports and exports, and including temporal dimension we described current trends in trade data of high-risk pathways.

Our findings showed that, besides the total income, network metrics are a useful tool in explaining alien species introductions for single countries. Moreover, networks can describe global dynamics in international trade, such as globalization process or perturbations related to exceptional events such as wars or pandemics. The increasing connectivity of commercial route network and the opening of new markets, especially for those high-risk pathways, will lead to increase the risk of alien species introductions in the future. Given the current trends in the international trade network, more efforts will be needed to cope with alien insects in the coming years.

Using host groupings to rank future biotic threats before arrival

T1.29 Risk-based surveillance for quarantine forest pests

Ultan O'Donnell[1]
Conor F. Mc Gee[2], Andy Bourke[2], Jon M. Yearsley[1]
[1] University College Dublin, School of Biology and Environmental Science, Ireland
[2] Department of Agriculture, Pest Risk Analysis Unit, Ireland

Abstract: Invasive species are seen to be a major threat to both biodiversity and ecosystem services. Pest-risk analysis can be a key step to identify potentially invasive species for a given region, and prioritise preventative action for high risk species. Some common methodologies rely on mutual consensus among a large group of experts on a given topic, which can be logistically intensive and time consuming. Species distribution modelling is a tool that could inform the pest risk analysis process by quantifying the habitat suitability of a species in a region, and a resulting ranking of establishment likelihood of potential future biotic threats prior to arrival in a region. However, this quantitative approach is often infeasible due to the low availability of georeferenced occurrence data.

This study looks at overcoming this data availability issue by using host occurrence data to estimate the likelihood of establishment of forestry pest species. Occurrence data of a species' hosts were used with species distribution models to develop a ranked list of forestry pests that were most likely to establish in a region based on the environmental conditions where hosts are recorded. This approach is based on the hypothesis that for a pest and host to exist in unison, they must both be able to survive in similar environments.

Ireland was used as a test region for this new approach. For each pest a habitat suitability map of the pest's host group was estimated for Ireland using the SDMs. The distribution modelling was validated by using spatial cross validation, and AUC metrics were used to assess overall model performance. The produced maps were then compared to rank the risk of establishment by the relative habitat suitability between each pest's host group. Similarities to this research were found in the literature, namely used for quantifying disease risk by measuring the habitat suitability of disease vectors like mosquitoes. We discuss how quantifying the risk of establishment is important in whittling down potential biotic threat candidates for consideration when prioritising biosecurity strategies, and acknowledge how more recent advancements in computing power improve the accessibility and practicality of this comparison methodology.

T1.30 Securing multiple ecosystem services from mountain forests

Altitudinal distribution of Swiss stone pine (Pinus cembra) in the Styrian Alps as facilitator of silvicultural stability and resilience strategies

T1.30 Securing multiple ecosystem services from mountain forests

[4] 4 WLM – Wald – Landschaft- Mensch, 6020 - Innsbruck, Austria

Abstract: Alpine forest ecosystems dominated by Norway spruce (*Picea abies*) in the Austrian Alps are facing increasing threats through bark beetle (*Ips typographus*) infestations. The situation calls for immediate diversification of the tree species spectrum in order to create stable and resilient forest stands for providing multiple ecosystem services for the presence. The project Dynamic Forest Type Classification in the Austrian province of Styria created an empirical database resulting from 1800 forest site investigation plots. Analyzed data show that in the Western Styrian Alps Swiss stone pine (*Pinus cembra*) may be dominant or sub-dominant in many forest stands across six forest vegetation zones (FVZ), currently from the moderate cool mixed forest zone up to the very cold conifer forest zone. This corresponds to an altitudinal gradient of more than 1000 m, ranging from about 1300 m up to 2300 m ASL.

The actual presence of Swiss stone pine (SP) in the analyzed forest plots could at least partly have been facilitated through the occurrence of *Rhododendron* species, which co-host *Chrysomyxa rhododendri*, a fungus which infects *Picea abies* and decreases its vitality in the alpine forest ecosystems. Together with forest management this might be one of the reasons for the presence of SP in such a wide altitudinal range.

In the current situation SP turns out to be a suitable alternative for the diversification of the tree species spectrum in Styrian and Austrian alpine forest ecosystems, as it can successfully grow on most of the given forest sites within the relevant FVZ. From acidic siliceous to loamy carbonate bedrocks SP is able to establish on forest sites as dominant or subdominant tree species. Additionally, tree species suitability of SP is high in the FVZ, with increasing growth in the lower FVZ. Both the high presence and suitability on various forest sites define SP as prominent tree species in alpine forest ecosystems for increasing their stability and resilience. For a successful establishment of SP, its competition with *Picea abies, Larix decidua* and *Abies alba* has to be silviculturally regulated in order to maintain its share.

Are landscape changes due to past disturbances making mountain forests less vulnerable to future threats?

T1.30 Securing multiple ecosystem services from mountain forests

Sebastian Marzini[1, 2]
Erich Tasser[1], Camilla Wellstein[2], Rupert Seidl[3, 4, 5], Werner Rammer[3, 4], Marco Mina[1]

[5] Berchtesgaden National Park, Berchtesgaden, Germany

Abstract: Mountain forests have been highly impacted by global changes. Natural disturbances, such as windstorm and bark beetle outbreaks are expected to increase, jeopardizing ecosystem services provided by forest ecosystems. In the Eastern Italian Alps, the 2018 windstorm Vaia has caused significant damages in mountain forests, creating a heterogeneous landscape of disturbed and intact forest stands. Subsequently, it triggered bark beetles disturbances that were further exacerbated by high summer temperatures and drought events. There is a growing interest in understanding how these newly formed forest landscapes will develop in the future, and how forest management influences these dynamics. We studied the future susceptibility of forest stands towards natural disturbances and climate changes in a landscape located in the Eastern Italian Alps highly affected by the Vaia storm. Our aim was to understand whether the impact of the windstorm on current forest structure will lead to an amplification or a reduction of bark beetle-mediated disturbances and future windthrows.

Using a process-based forest landscape model (iLand), we initialized a forest landscape using pre- and a post-windstorm forest conditions. We simulated forest successional dynamics under combinations of climate change and management scenarios (Business-as-Usual vs forest diversification) for the next 200 years, investigating forest's recovery and comparing of the susceptibility to future windstorm and bark beetle disturbances for the two landscape scenarios.

Results showed an overall increase of bark beetle disturbances and windthrows events for both landscape scenarios under climate changes. Nevertheless, simulated disturbance damages were higher for the pre-storm scenario due to high structural and compositional homogeneity. Differently, in the post-windstorm landscape scenario the spatial and compositional heterogeneity caused by the storm led to a reduction of future windstorm severity and bark beetles disturbances, especially when forest diversity was further promoted by alternative management. Our findings show that forest stands after a significant disturbance impact are more likely to resemble a more stable and resistant system, especially when applying forest interventions that improve both composition and structural heterogeneity. In the absence of significant disturbance events, present stands are highly vulnerable and current management practices are not capable to ensure resistant ecosystems.

Assessing recreational value of mountain forest: the case of Tržič municipality, Slovenia

T1.30 Securing multiple ecosystem services from mountain forests

Irena Mrak[1, 2]
Matjaž Guček[1], Tina Simončič[1], Živa Bončina[1], Aleš Poljanec[1]
[1] Slovenia Forest Service
[2] Faculty of Environmental Protection

Abstract: Recreation is an important forest ecosystem service in mountain areas contributing to the well-being of individuals and communities. Assessing the recreational value of forests in terms of recreational use includes the assessment of the various factors such as accessibility, amenities, visitor preferences, as well as the impact of the visit on forest and their long-term vital condition. This paper presents a comprehensive approach for assessing the recreational value of forests carried out as part of the project ForestEcoValue (Interreg Alpine Space). In order to conduct the assessment in an area predominantly comprising mountain forests, we use the municipality of Tržič (155 km^2 landcover: over 74% forest) as a study area and set the objectives of the assessment. We considered different user groups and conducted surveys to understand their preferences and expectations. Visitor numbers were quantified using visitor logs and monitoring methods to determine the demand for recreational activities. Accessibility and facilities, including trails and visitor facilities, were assessed for quality and capacity. In addition, the natural features and overall condition of the forest ecosystem were assessed as they enhance the recreational experience. The data analysis revealed trends and patterns that provide valuable insights into the recreational value of forests. The results show the importance for considering recreation in forest management, policy decisions and conservation efforts. Communicating the assessment outputs to stakeholders can raise awareness, support sustainable practises and facilitate decision-making processes. Overall, this summary highlights the importance of a multidimensional assessment approach for understanding and optimizing the recreational value of forests in a way that provides win-win solutions with the primary functions of the mountain forest in the area, namely timber production at lower elevations and protection against natural hazards at higher elevations.

Changes in Carbon Sequestration by Forest Biomass in Secondary Forests System based on 10 years Observation in Liaodong Mountains, China

T1.30 Securing multiple ecosystem services from mountain forests

Yirong Sun[1, 2]
Jinxing Zhang[1, 2], Lizhong Yu[1, 2]
[1] Institute of Applied Ecology, Chinese Academy of Sciences, Shenyang 110016, China
[2] Qingyuan Forest CERN, National Observation and Research Station, Liaoning Province, Shenyang 110016, China

Abstract: The aboveground biomass (AGB) in forests plays an important role in the carbon cycle and climate change, has been widely recognized as evaluating carbon sequestration and carbon balance capacity of forest ecosystems. Accurate estimation of forest AGB is particularly important for studying the carbon cycle of the terrestrial ecosystem.

To estimate the accurate AGB in the forests, we established long-term fixed plots in three forest types, including secondary forest, Korean pine plantation and larch plantation. The plots area was set as 50 m×50 m. DBH, height and the death of each tree in the plots were recorded from 2012 to 2022. And then the total AGB was calculated by the allometry models, and the carbon sequestration from forest biomass was calculated at last.

The storage of AGB in secondary forest was the highest among three forest types, which increased from 45.25 Mg/ha in 2012 to 52.24 Mg/ha in 2022. But the increasement of AGB in larch plantation was the highest from 2012 to 2022. Furthermore, the loss AGB from death of trees has 2.27% of the percentage.

These results indicated that the highest carbon sequestration from biomass was found in the larch plantation in the secondary forest systems in Liaodong Mountains, China. And the dynamics of tree mortality should also be considered in carbon cycle of the terrestrial ecosystem.

Communities' Perception of Ecosystem Services on the Forest Rehabilitation of Abandoned Mine Areas in Korea

T1.30 Securing multiple ecosystem services from mountain forests

Bohwi Lee[1]
Hakjun Rhee[2], Dawou Joung[1], Jihye Kim[3], Ju In Ko[3]
[1] Department of Environment and Forest Resources, Chungnam National University, Daejeon, Republic of Korea
[2] Department of Forest Science, Sangji University, Wonju, Republic of Korea
[3] Research Institute of Technology, Korea Mine Rehabilitation and Mineral Resources Corporation, Wonju, Republic of Korea

Abstract: Rehabilitation of mining areas can reduce various damages to ecosystems. However, the rehabilitation effects on the ecosystem services (ES) and contribution to local communities are not well known. It is important to clearly identify the ES beneficiaries affected by mining activities, to find out how the beneficiaries make a profit from surrounding areas in cooperation with local stakeholders, and to manage the rehabilitation areas for the ES that the beneficiaries want. This study chose 18 ES (4 provisioning, 7 regulating, 5 cultural, and 2 habitat services) based on TEEB (The Economics of Ecosystems and Biodiversity). Then 11-points Likert scale (0: unknowability, 1~5: negative benefit, 6~10: positive benefit), semi-structured surveys were conducted for 87 community residents (62 from Taebaek-si and 25 from Jeongseon-gun) to investigate social awareness and identify key services. The results from two local communities showed high awareness and demands mainly on cultural (mental & physical health, aesthetic appreciation, and recreation) and regulating services (local climate & air quality, and moderation of extreme events). These services were related to daily lives in local communities, provided positive benefits to them, and potentially improved future livelihoods of the residents. However, the average scores were limited to 6~7 points, indicating that the benefits to local communities were meager. The awareness of provisioning services was negative even if it provides goods and profit opportunities. This indicated a disconnection between local communities and provisioning services due to forest rehabilitation without considering local communities that traditionally relied on specific provisioning services before mining activities. Future forest rehabilitation in abandoned mine areas needs considering welfare of local communities for sustainable use of rehabilitated forest and enhancing ES. This study conducted only qualitative evaluation based on frequency analyses. Quantification and valuation of key ES are warranted in the future to promote ecosystem services from forest rehabilitation of abandoned mine areas. The perception of forestry and mining experts using Delphi method is also presented and discussed.

Ecological aspects of forest regeneration of large clear-cut areas in the mountains

T1.30 Securing multiple ecosystem services from mountain forests

Ondřej Špulák[1]
[1] Forestry and Game Management Research Institute, Czech Republic

Abstract: Changes in climate increases frequency of disturbances and severity of insect attacks also to the forests in the mountains of the Central Europe. Disintegration of the forest stands and rise in number and especially size of clear-felled areas in commercial forests in mountains bring difficulties in forest regeneration regarding harsh climate. To recover fulfilment of ecosystem services, the forests has to be renewed. Natural regeneration is often slow and in favour to limited number of species with pioneer strategy, more successively coping with the conditions. Frequently, regeneration of more diverse forests cannot be done without an artificial regeneration. To establish forest stand of more sensitive target species, two-phase forest regeneration using pioneer species as nursing (preparatory) trees is recommended. The paper will aim to highlight most important ecological aspects of (micro-) climate of forest regeneration in mountains and to formulate arising recommendations for forest praxis. Emphasis will be laid especially on temperatures (air and soil), air humidity and soil moisture. The parameters were monitored in young stands of different species (spruce, birch, dwarf pine), diverse conditions (age, plantation/forest density), positions (depth, height above ground, distance to tree, aspects). There were found differences in temperature regime, soil moisture and air humidity. For two-phase reforestation, the results e.g. show more favourable conditions for planting of target species in N, NW or W side of the crown of conifer nursing plants. The positions are less affected by temperature extremes, proximity to the plant increases air humidity. Because of the air temperature layering, injury by late frost can be reduced by planting of advanced (higher) seedlings. The synthesis of published personal data and results of new data analyses will bring more specific outcomes, which can help to secure multiple ecosystem services of renewed mountain forests successfully.

Effects of adaptive plantations on ecosystem service provision in Swiss forests

T1.30 Securing multiple ecosystem services from mountain forests

[1] Forest Resources and Management, Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Switzerland

Abstract: Climate change affects forests, and the effects are expected to increase in the coming decades. Therefore, adaptive management strategies are essential to mitigate these effects. We used MASSIMO, an empirical individual-tree management scenario simulation model, to investigate the ability of Swiss forests to adapt their tree species compositions to changing climatic conditions. Specifically, we implemented an *adaptive plantation* module that enables, in addition to natural regeneration, the planting of tree species adapted to the expected future climate conditions. The plantation module is based on observed tree species mixtures from the Swiss National Forest inventory and on expert recommendations for current and potential well-adapted future plant communities. Thereby, future plant communities have been simulated based on current plant communities, soil information and climate scenarios. These plant communities depict the idealized tree species composition (including recruitment) in natural forests in balance with the dominant current or future environmental conditions. For planting, we considered both native and non-native species, including *Pseudotsuga menziesii*, *Cedrus atlantica* and *Quercus cerris*. Forest development simulations with MASSIMO, reflecting recent management practices indicated that changes in species composition were considerably slower than required to match future climate conditions. This was observed with both natural regeneration and adaptive planting. Therefore, to effectively address future climate challenges while ensuring sustainable timber production, protective function and other ecosystem services, Swiss forests may require additional support, such as shortening of rotation periods to faster regenerate or plant climate adapted tree species.

Forest management for ecosystem services and its financial compensation: the Swiss National Forest Inventory survey among foresters

T1.30 Securing multiple ecosystem services from mountain forests

Christian Temperli[1]
Barbara Allgaier Leuch[1], Christoph Düggelin[1], Christoph Fischer[1]
[1] Swiss Federal Institute WSL, Forest Resources and Management, Zürcherstrasse 111, 8903 Birmensdorf, Switzerland

Abstract: Most central European forests simultaneously provide multiple ecosystem services. These include wood production, protection from avalanches, rockfall and landslides, carbon sequestration, recreation and the provision of drinking water and habitat for a broad range of species. Forest management is necessary to provide and sustain many of those ecosystem services. Often, the management costs are at least partly covered by the revenue of the harvested wood or through subsidies, for example in protective forests against avalanches and rockfall. However, in many cases, management for ecosystem services is not compensated for. Prominent examples are interventions to maintain the safety for recreation in (peri-) urban forest, carbon sequestration or to promote forest biodiversity. Hence, new compensation schemes such as carbon and biodiversity certificates have been developed. The extent to which management interventions are conducted for the provision of ecosystem services other than wood production, and to what degree and by whom they are financially covered is only partly known at the Swiss national scale. We included a series of questions in the forester's survey of the Swiss National Forest Inventory (NFI) covering approximately 3700 sample plots to reveal the 1) forest area, on which management interventions for ecosystem services other than wood production has been conducted, 2) the funding body and 3) to which degree management costs are covered. Ecosystem services considered are protection of drinking water supply, protection of biodiversity, recreation, education, protection against gravitational natural hazards and carbon sequestration. First results point to an almost full coverage of protective forest management through cantonal and federal contributions. Management for drinking water supply, recreation and biodiversity promotion is more prevalent in public forests and is mostly covered by the (public) forest owner. The forest area, on which certificates support management is relatively small and the largest area is for carbon sequestration. We discuss challenges related to delimitating management interventions for different ecosystem services and the potential and risks of new funding schemes. As the sample covers a systematically distributed half of the Swiss NFI, covering diverse forest types and management situations, this survey is valuable for forest policy making in Switzerland and beyond.

Identifying climate change forest refugia in the central European mountains

T1.30 Securing multiple ecosystem services from mountain forests

Sarah Le Berre[1]
Dominik Thom[2], Rupert Seidl[2], Wolfgang Buermann[1], Cécile Rémy[1]
[1] Institute of Geography, Augsburg University, Augsburg, Germany
[2] School of Life Sciences, Technical University of Munich, Freising, Germany

Abstract: Ongoing climate change is altering the geographic distributions of plant species world-wide. In a warming world, terrestrial taxa are predominantly shifting toward colder locations, corresponding to higher latitudes and higher elevations, to track their climate niches. Consequently, during the last decades, a progressive decline of cold mountain habitats and their biota has been observed. The vulnerability of mountainous ecosystems urges to adapt current management plans to climate change in order to conserve and protect areas with strong biodiversity potential. In this context, refugia of forest tree species may play a fundamental role to sustain long-term population viability, enabling vegetation communities' persistence, minimizing the potential for deleterious species interactions and avoiding regional species extinctions. Therefore, we are aiming at predicting the location of forest refugia and characterize environmental factors leading to forest refugia occurrence under future climate change in central European mountains. To achieve this, we used fine-scale spatial datasets combined with an advanced individual-based forest model, iLand, allowing us to simulate future vegetation dynamics. Our results show the relative importance of key biotic and abiotic predictors (i.e. climate conditions, current vegetation composition, topography and soil attributes) for future forest refugia occurrence in the Central European mountainous ecosystems. These research outputs will provide a ground to quantify the vulnerability of forest refugia to altered disturbances (bark beetles outbreaks and windstorms) on forest refugia and critical information for improving habitats conservation efforts in central European mountains.

Managing European Alpine forests with close-to-nature forestry under climate change: Impacts on carbon sequestration and other ecosystem services.

T1.30 Securing multiple ecosystem services from mountain forests

Simon Mutterer[1]
Clemens Blattert[1], Timothy Thrippleton[1], Jurij Diaci[2], Gal Fidej[2], Leo Bont[1], Janine Schweier[1]
[1] Forest Resources and Management, Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Zürcherstrasse 111, CH-8903 Birmensdorf
[2] Chair of Silviculture, University of Ljubljana, Jamnikarjeva 101, SI-1000 Ljubljana

Abstract: Close-to-nature forestry (CNF) has a long tradition in managing European Alpine forests and contributes to the continuous provision of key forest ecosystem services, such as protection against natural hazards. Climate change poses, however, new challenges and raises questions about the future applicability of CNF in the Alpine region: Is CNF a promising approach to adapt forests to the consequences of climate change? And can the current management practices meet the increasing societal demands towards alpine forests, including the potentials for climate change mitigation?

To answer these questions, we used the climate-sensitive forest-growth simulator ForClim to simulate forest development over 90 years for more than 11.000 ha across two case study sites representing a large biogeographic gradient (Karavanke mountains, Slovenia; inner-alpine Val Müstair, Switzerland). Simulations considered different climate scenarios and management strategies: current CNF management, CNF with increased or reduced management intensity, a strategy considering the planting of climate-adapted tree species, and two reference strategies with extremely intensive (clearcut) and no management. Impacts of management on the provision of forest ecosystem services and biodiversity were assessed by an indicator framework that also covers carbon sequestration in- and outside the forest ecosystem boundary.

Our results showed that CNF performs well in ensuring multiple forest ecosystem services and biodiversity in the long term. However, none of the strategies provides all objectives equally well; e.g., while biodiversity was increased by no management, protection and timber production jointly benefited from the adaptation strategy. The effects of climate change differed both, between and within the case study sites along environmental gradients. In the inner-alpine Val Müstair, ecosystem services were more sensitive to climate change than in the Karavanke mountains. Under the extreme climate change scenario, carbon sequestration potentials decreased at lower elevations in Val Müstair. This negative effect could be compensated to a certain degree by the strategy which fostered climate-adapted species.

To conclude, sustaining multiple ecosystem services and carbon sequestration potentials against uncertainties of climate change requires an adaptation of CNF by fostering climate-adapted tree species. Furthermore, a diversified management including protected areas is central for the conservation and enhancement of biodiversity in alpine forests.

Monitoring a forest landscape and their ecosystem functions after large fires in sub-Antarctic ecosystems

T1.30 Securing multiple ecosystem services from mountain forests

Ángela Hernández-Moreno[1]
Andrés Salazar Estay[1], Eduardo Arellano-Ogaz[2]
[1] Centro de Investigación en Ecosistemas de la Patagonia (CIEP), Coyhaique, Chile
[2] Center of Applied Ecology and Sustainability, Pontificia Universidad Católica de Chile, Santiago, Chile

Abstract: Western Patagonia is recognized as one of most isolated regions, with large proportion of intact temperate old-growth forests, but is also recognized for having suffered largest fires in modern human history (1930-60), where over 3 million hectares were burned. Although more than half a century has passed since these large-scale fires, there is still no empirical evaluation of the land cover dynamics to establish the rate of forest loss and recovery, and its effect on the structure and function of the landscape post fires. We aimed to assess forest recovery processes post-fires and ecosystem functions at the landscape level over the 1984-2018 period in western Patagonia. A landscape ecology approach was applied through analysis of land cover dynamics focused on temperate forest. A set of ecosystem functions of regulation, support and provision was mapped through quantitative data and spatial proxies. The results showed that despite past fires the Coyhaique province landscape has maintained an area of ~ 79% unchanged during the last 34 years. The old-growth forest loss ~32,600 ha, and the secondary forest has increased by over ~69,000 ha during the 1984-2018 period. An improvement in the landscape function to regulate climate was observed through the potential carbon stock proxy, which showed an increase of 3.6% as a result of secondary forest recovery. Water supply function showed greater capacity in old-growth forests of mountains, while lowest capacity in more anthropized areas. In Conclusion, the balance of loss and gains highlights the recovery of native forests, being one of few temperate forest ecosystems from the southern hemisphere showing this process. Despite this forest recovery process, ecosystem functions do not recover at the same rate, highlighting that the greatest functional capacity of the landscape is generated in forests far from anthropized areas. The implications of the results obtained stimulate a socio-ecological and technical-political discussion to harmonize a sustainable use of an ecosystem poorly studied in western Patagonia.

Role of forest cover in supporting sediment retention ecosystem service using modelling and valuation in the Himalayan watershed

T1.30 Securing multiple ecosystem services from mountain forests

Rahul Yadav[1]
Shachi Pandey[1], Tara Chand[1], Raman Nautiyal[2]
[1] Forest Ecology and Climate Change Division, Forest Research Institute, Dehradun, India
[2] Indian Council of Forestry Research and Education, Dehradun, India

Abstract: Soil erosion is one of the most implicit risks that influence the ecology as well as economy of the Himalayan watershed. Soil and water quality in a watershed are adversely affected by soil erosion due to sedimentation deposition and export. Soil erosion is accelerated due to the diverse land use and fragile ecosystems in the watershed. However, forests and its density based on canopy cover plays a major role in controlling soil erosion and supporting sediment retention services in the ecosystem. The study attempted to comprehend the role of forest density and to evaluate the cost of the service in monetary terms for the sediment retention ecosystem services. Global dataset was used to assess the contribution of forest cover density class in sediment retention ecosystem service. The sediment retention service was estimated using InVEST Sediment Delivery Ratio (SDR) model. The basin was assessed for SDR for three forest cover types *i.e.,* Very Dense, Moderately Dense and Open Forest under two scenarios *i.e.,* with (F_1) and without (F_0) forest cover. The replacement cost method was used to estimate costs of soil loss. Furthermore, to understand role of forest density, the costs of sediment retention service were valuated for all three forest cover types (very dense, moderately dense and open forest) in two scenarios *i.e,* 'F_1' & 'F_0' The results indicated that very dense forest provides more sediment retention service as compared to the moderately dense and open forest. Also, it was found that the cost of sediment retention service was higher under F_1 scenario when compared to F_0 scenario. The results indicated that the potential contribution of the forest vegetation in avoiding soil erosion in the watershed was found to be 1.4×10^8 tons. The study concluded that the forests play a key role in supporting sediment retention service in Himalayan watersheds. Results indicates that sub watersheds with greater and denser forest cover are least prone to erosion. Furthermore, valuation methods integrated with advanced system analysis are useful for sustainable management, decision making and restoration practices in the Himalayan watershed.

The impact of alternative land use scenarios in the sustainabiility of protected mountain forests

T1.30 Securing multiple ecosystem services from mountain forests

[1] Institute for Research on Natural Resources, Agroecology and Rural Development (IRNAD), UNRN-CONICET, Argentina
[2] Laboratory of Research in Ecological and Environmental Systems (LISEA),UNLP, Argentina
[3] Chair of Tropical and International Forestry, TU Dresden, Germany

Abstract: Native Forests in mountain regions are important elements for the tourism sector. Considering the ecosystem services provided, conservation in these forests is increasing popularity in the agenda of the governmental actors at different scales. In addition, combined housing crisis and tourism development impact in the real-estate market causing additional land-pressure into forestlands. In Argentina, the region of Patagonia is considered as one of the most attractive and visited tourism destinations in the country. Protected areas in this region are territories where conservation, tourism and traditional productive activities converge, increasing the pressure over the territory. In this context, our aim was to analyse the impact of different land-use future scenarios in a particular mountainous protected area in Patagonia as a case study. In order to do so, actors interests and power as well as sustainability indicators based on a pressure-state-response methodology using the SDGs targets as baselines, were used to develop a set of future scenarios based on the main land-use pressures affecting the territory: development of formal tourism, development of informal tourism, conservation intensification, forest sector growth and livestock expansion. Following a multivariate analysis we selected the main influencing indicators acting as tipping points to evaluate the level of sustainability of the hypothetic scenarios by developing land-use models. Results showed that the development of tourism can have different winners and losers depending on the formality of the activity and that the conservation scenario may not be the most sustainable if the cultural dimension of the study area is considered. Additionally, the optimal scenario for a high sustainable value may be a combination of characteristics of the different contrasting activities. Further, it is important to analyse the informal interests of actors since they may play a crucial role.

The Role of Deforestation and Forestry Interventions in Landslide Prone Areas : A Case Study of the Rift Valley Region, Kenya.

T1.30 Securing multiple ecosystem services from mountain forests

David Langat[1]
Joshua Cheboywo[1], Jesse Owino[1], **Ernest Ronoh**[1], Nereoh Leley[1], Abdalla Kisiwa[1]
[1] Kenya Forestry Research Institute, Rift Valley Eco-Region Research Programme, P. O. Box, 382-20203, Londiani, Kenya.

Abstract: Landslides pose a significant threat to Kenya's livelihoods and cause extensive social, economic, and environmental damage. The Rift Valley region has experienced numerous landslide incidents, largely attributed to deforestation. The steep terrain, vulnerable soils, heavy rainfall, and seismic activity in the Rift Valley make it highly susceptible to landslides. There is currently a lack of clear understanding regarding the role of forests in mitigating natural disasters and managing watersheds. To address this knowledge gap and develop effective interventions, a study was conducted in the landslide-prone areas of the Cherangany Escarpment in Elgeyo Marakwet County, Rift Valley. The study employed an exploratory survey design to gain familiarity and a deeper understanding of the problem. Data were collected through various methods, including Key Informant Interviews, Focus Group Discussions, rapid bio-physical assessment, and observations. Socio-economic data, both qualitative and quantitative, were obtained from the Focus Group Discussions and informal Key Informant Interviews. The collected data encompassed historical landslide occurrences, perceptions of landslides, land use and land use change, impacts of landslides, and existing and potential landslide remediation measures/policies. The results revealed an increase in landslide frequency in the Cherangany Escarpment over the past two decades, mainly attributed to intense rainfall. Although earthquakes can trigger landslides, local knowledge could not establish a direct link between earthquakes and landslide occurrences in the region. The study also found that the natural forests in the area were previously intact and biodiverse, with selective clearing and shifting cultivation practices by the local population. However, population growth led to increased encroachment on steep slopes for agricultural purposes, resulting in the loss of stabilizing trees and exacerbating landslide incidents. Fragile geology, combined with high rainfall and steep slopes, were additional factors contributing to the escalating landslide rates. To restore, rehabilitate, and conserve the ecosystem, protect human livelihoods, and preserve wildlife habitats, it is crucial to adopt and implement appropriate mitigation measures. These measures should include the restoration of the landscape with suitable tree species. By addressing deforestation, stabilizing slopes, and managing land use, the region can reduce the risk of landslides and protect the delicate balance of its natural environment.

Use of pioneer broadleaves for restoration and diversification of forests in the mountains of the former air-polluted region in Central Europe

T1.30 Securing multiple ecosystem services from mountain forests

Ivan Kunes[1]
Martin Balas[1], Vilem Podrazsky[1]
[1] Czech University of Life Sciences Prague

Abstract: The mountain forests in the border area among the Czech Republic, Germany and Poland were in the 1970s and 1980s heavily damaged by air pollutants (SO_2, NO_x, dust etc.). Although the pollution was later substantially reduced, restoration of diversified forests, able to secure multiple services, proved to be extremely difficult at the high elevations. The contribution summarizes the knowledge and experience with the use of pioneer broadleaves for forest restoration or diversification of coniferous stands. Attention is given to birch (*Betula pubescens* and *Betula pendula*), rowan (*Sorbus aucuparia*) and grey alder (*Alnus incana*). The effect of fertilizers applied to the planted trees was also assessed to provide the young stands with the initial nutritional support on acidified sites. The information provided is based on findings from plantation experiments established on degraded sites and on the experience of forest practitioners from the region. To evaluate the pioneer broadleaves, the survival rate of plantations, their height increment, radial increment and nutritional status were assessed. Soil chemistry was monitored as well. The main results are as follows: Birch seems a universal and resistant pioneer tree. However, to reforest mountain sites, it is highly important to distinguish between the tetraploid and diploid taxa. The tetraploid birches, belonging to *Betula pubescens* complex, should be preferred to the diploid *Betula pendula* to replant the harsh mountain sites in Central Europe. Rowan is more shade tolerant tree. Therefore, this species is suitable for mixtures with the target (climax) species or other pioneers. Grey alder should be used on climatically less exposed sites. On the other hand, grey alder responds well to fertilization and is beneficial on sites where the topsoil was degraded or removed by improper management or erosion. On the whole, the stands of pioneer broadleaves can provide the necessary ecological cover to stabilize the degraded habitats as well as to form an admixture to coniferous forests on exposed or degraded sites. More sensitive climax tree species can be introduced under the shelter of these nurse pioneer broadleaves. Protection of the broadleaves from the hoofed game is essential to ensure the success of the plantations.

Vegetation Density and Altitude Determine the Supply of dry Afromontane Forest Ecosystem Services: evidence from Ethiopia

T1.30 Securing multiple ecosystem services from mountain forests

Bianca W. Kassun[1]
A. Maarit I. Kallio[1], Erik Trømborg[1], Meley Mekonen Rannestad[1]
[1] Norwegian University of Life Sciences (NMBU), Faculty of Environmental Sciences and Natural Resource Management, Norway

Abstract: Mapping forest ecosystem services (ES) and identifying both natural and anthropogenic factors influencing their supply and distribution is a key step for developing a sustainable and climate-smart forest management plan. This is particularly important for the management of dry and mountain forests which are among the most threatened and neglected ecosystems globally. These forests are facing increasing demands for different land uses and ES with rising conflicts with each other.

This study identified, quantified, and mapped the spatial distribution of one supporting, three regulating, and four provisioning forest ES. Furthermore, a set of potential natural and anthropogenic factors influencing ES distribution in Desa'a forest, a dry Afromontane Forest in Tigray, Ethiopia, was assessed. The supply of some of the assessed ES depended on vegetation density, while the supply of others depended on woody species diversity, which resulted in a clustering of ES in two different geographical areas. Both natural and anthropogenic factors were important for explaining variations in the spatial distribution of ES. However, the most influential factors were vegetation density and altitude.

Our findings can contribute to the development of sustainable forest management strategies for dry and mountain forests by providing knowledge on the spatial supply of ES. The ES maps can be used as a basis for developing dedicated zoning plans for the study area which could improve forest management.

Vulnerability to climate change may affect ecosystem services in mountain ranges of Valdivian Temperate Rainforest in South-Central Chile

T1.30 Securing multiple ecosystem services from mountain forests

Joceline Rose[1]
Sabine Müller-Using[1], Yasna Rojas[1], Marjorie Martin[1]
[1] Instituto Forestal (INFOR), Chile

Abstract: Mountain forests are considered particularly vulnerable to the effects of climate change but deliver important ecosystem services. A previous study situated in Panguipulli, in the Valdivian Temperate Rainforest Ecoregion, in Chile, revealed that a high proportion of the population depends on forest ecosystem services to sustain their livelihoods. Specifically, wood, NTFPs, protection and scenic beauty are valued.

With the objective of evaluating the vulnerability of mountain forests in this territory, in 2013 22 plots have been established in an altitudinal gradient from 600 to 1250 masl. At the beginning of the study, a socio-environmental vulnerability index was generated on expert´s opinion. With the aim of validating this appreciation and being able to offer adaptation strategies, these plots have been monitored in dasometric and floristic terms, now reaching a period of 10 years.

Data has shown that the gradient covers 4 forest types, each associated with different ecosystem services and levels of vulnerability. Based on the data time series, each of them growth, mortality of trees, regeneration and indicator species of herbaceous plants were analized with the following main results:

Tree growth is highly dependent on site and exposure conditions, especially in higher altitudes. In the *Laureliopsis philippiana - Nothofagus alpina – Nothofagus dombeyi* forest type a high mortality was observed. Monitoring of herbaceous indicator species shows a slight increase of *Chusquea culeou* in all forest types, a native invasive bamboo species that is considered an indicator for forest degradation. On the other hand, an increase of *Pseudopanax valdiviensis* is observed in the two lower forest types, a climbing species typical of more mature forests in a state of growth and conservation.

Contrary to what was assumed in the initial study, the high mortality in the *Laureliopsis philippiana - Nothofagus alpina – Nothofagus dombeyi* forest type in combination with the bioclimatic stress, observed in recent years, might indicate a high vulnerability to climate change. As it is predominant in this mountain area, the consequences for the supply of ecosistem services might be important. For adaptation measurements it is necessary to understand the triggered dynamic, and continue monitoring if species move through natural regeneration.

Wild and semi-wild edible plants as coping strategies to conflict and climate-change-induced food shortages: Evidence from Tigray, Ethiopia

T1.30 Securing multiple ecosystem services from mountain forests

Selamawit Desta[1]
Sarah Tewoldeberhan[2], Tadese Beyene[1], Meley Mekonen Rannestad[3], Emiru Birhane[2], Aster Gebrekirstos[4]
[1] College of Natural and Computational Science, Mekelle University, Ethiopia
[2] College of Dryland Agricultural and Natural Resources, Mekelle University, Ethiopia
[3] Faculty of Environmental Science and Nature, Norwegian University of Life Sciences, Norway
[4] World Agroforestry Center (ICRAF), Kenya

Abstract: Introduction/Background: Global food insecurity is on the rise due to increasing conflicts combined with climate change-induced problems. Dry forests, on which millions of poor people rely, are well known for their provisioning ecosystem services like food. Hence, wild and semi-wild edible plants provide cheap, easily accessible, and readily usable food/nutrition alternatives in the fight against increasing food shortages and at times of conflict.

Objectives: The objective of the study was to identify and document wild and semi-wild edible plants that are used as coping mechanisms to conflict and climate-change-induced food shortages in Tigray, Ethiopia.

Methodology: An ethnobotanical study of wild and semi-wild edible plantswas conducted in Dess'a dry Afromontane Forest, part of the Eastern Afromontane Hotspote. Thirty key informants and 222 general informants were included in the study. Semi-structured interviews, group discussions and field observation were used to collect data. The obtained data were quantified using informant consensus, preference ranking and direct matrix ranking.

Result: A total of 68 wild and semi-wild edible plant species belonging to 55 genera and 38 families out of which forty (58.8%) wild species and 28 (41.2%) semi-wild species were collected. Fruits of *Opuntiaficus-indica* and leaves of *Amaranthusdubius* and *Capsella bursa-pastoris* were the most preferred edible plants. Age, gender, educational level, marital status, and key informant vs. general respondents were found to have significant differences in knowledge about these edible plants. Immediate consumption in the field, household consumption and supplementary food were the main uses of these plants. When other foods are ample these plants are used as snacks and as main foods during times of food shortage, famine and conflict. Drought, fuel wood collection, lack of good management, overgrazing, agricultural expansion and urbanization were the major threats to the sustainability of these plants.

Implication/conclusion: Wild edible plants are safeguards for poor communities during difficult times. The role of these plants in ensuring food and nutrition security is high, and thus better management of these valuable plants is essential. Further development of the species and these foods is also important.

Keywords: wild and semi-wild edible plants, forest management, sustainability, ethnobotany

Abstract: In Canada, clearcutting has been the dominant forest management practices, causing biodiversity loss, vulnerability of regeneration to natural disturbances and depletion of forest sources. Partial harvest is considered as a promising alternative to clearcutting system to integrate ecological, economical, and social objectives into silvicultural planning. However, partial harvest has not been widely adapted to the Canadian boreal forest yet and needs further evaluation for multidisciplinary research to adopt it to achieve sustainable management goals. The aim of this study is to evaluate the effects of partial harvests (50-75% of basal area removal) on conifer regeneration and soil microbiome in natural even-aged black spruce (Picea mariana (Mill.) B.S.P.) stands 18 years after silvicultural intervention. An experimental design with six sites (younger stands: 2,316 trees/ha, 79 years old; older stands: 1,272 trees/ha, 156 years old) and six silvicultural treatments (clearcut: 100% of basal area removal; seed-tree: 75%; close-selection, distant-selection, mini-strip: 50%; unmanaged as a control) was established by Canadian Forest Service in Monts-Valin and North Shore regions of Quebec. First, we counted and categorized all seedlings by species and height class in each micro-plot and assessed a dominant seedling for the growth features (age, height, diameter, reproduction type) and micro-environment (solar radiation, rooting substrate, soil properties). Second, we evaluated water use efficiency of two conifer seedlings (P. mariana, Abies balsamea) by analyzing stable carbon isotope ratio ($\delta^{13}C$) in one-year-old 5 cm branch cuttings. Third, the effects of the silvicultural treatments on soil microbiome (fungi and bacteria in bulk and rhizosphere soil) were studied by applying state of the DNA metabarcoding techniques and soil physiochemical analyses. This knowledge will be useful to better understand the dynamics and driving factors of regeneration of Canadian boreal forests after partial harvest to build decision making tools in order to adapt partial harvest to the sustainable forest management goals.

A Fennoscandian regional study of forest growth to answer the new climate and silvicultural challenges

T1.31 Silviculture of boreal forests in the face of climate change

[3] Norwegian Institute of Bioeconomy Research (NIBIO)

Abstract: In Fennoscandia there are several forest growth models (FGMs) used as support to research and practical management. They have been fitted mostly on stands managed with the dominant Rotation Forestry (RF) system and growing under the past & current climate.

There are two main changes in the forestry sector. First, the ongoing climate change is predicted to strongly affect Fennoscandia by increasing temperatures and changing precipitation patterns. Second, there is an increased interest in continuous cover forestry (CCF), which avoids the use of large clear-felling leading to uneven-aged stands. However, CCF data are still limited in Fennoscandia.

This will result in applying FGMs fitted on past conditions in drastically different ones, either in terms of climate or forest structures. Furthermore, models for RF usually rely on predictors that are meaningless or unknown in CCF stands, such as stand age or site index (SI, stand height at a certain age).

Our aim is to fit new FGMs that can be applied in the future climatic conditions and in all kinds of forest structures, for all Fennoscandia, by merging data from Finland, Norway, and Sweden. We will use the three National Forest Inventories (NFIs) for fitting, making the model more robust by employing a very wide range of data. We will use a hybrid modelling approach (combining empirical and process-based methods) for better climate-sensitivity. We will independently validate them on Long-Term Experiments (LTEs), collecting all the sparse data about CCF and other alternative structures together with the already abundant RF data.

We will investigate forest growth at a larger scale than it has ever been done for the region.

We will focus here on the preliminary analyses of growth dynamics in the NFI data. We will show: issues on merging data collected with the different systems; sources of additional interregional data; harmonization of the indices of forest productivity, to overcome the problems of SI for uneven-aged stands; and comparison of general forest growth dynamics across the countries and bioclimatic regions. These results alone will be extremely useful in understanding forest dynamics at the regional scale and providing a basis for future silvicultural recommendations.

Boreal silviculture in the face of climate change: A North American perspective

T1.31 Silviculture of boreal forests in the face of climate change

Brad Pinno[1]
[1] University of Alberta

Abstract: Climate change is expected to have a disproportionately large impact on boreal forests both directly, such as through weather influences on tree growth, and indirectly through increases in disturbances including fire, insects and drought. In addition, the worldwide demand for wood products in increasing meaning that silviculturists and silviculture researchers will have to balance ever more demands on our forests. In the boreal forests of western North America, a variety of new operational silviculture practices and research projects have recently been initiated related to climate change adaptation. Operationally, climate based seed zones, tree breeding for both growth and climate resilience, nursery production techniques to promote strong root systems, and partial harvesting of mixed-species stands are all being done to meet combinations of climate adaptation and productivity goals. Silviculture research ranging in scale from individual tree to stand to forest landscapes is also underway. For example, thinning and competition control has been demonstrated to increase water availability and drought resiliency at the individual tree scale in lodgepole pine and mixed conifer forests. At the stand scale, new techniques for actively growing mixed-species stands with a range of tolerances are being developed from studies such as the Judy Creek trembling aspen – white spruce trial. While at the landscape scale, timber supply modelling is being used to evaluate the impacts of different silvicultural regimes, in particular differences in management intensity, stand density, and species composition, on wood supply and future disturbance risk. However, in many ways the science and implementation of climate smart silviculture is moving faster than forest policy which will need to change if climate adaptation silviculture is to be fully operationalized.

Can resilience to climate impacts be increased by promoting historic forest composition and structure?

Abstract: Climate informed adaptive silviculture strategies will often need to consider the ecological and management legacies that have shaped our current forests. In the sub-boreal forests of western Canada the composition and structure of many stands reflects historic diameter-limit cutting entries that targeted specific species but were not designed to achieve long-term objectives. These historic entries have produced complex multi-species stands; however, the composition of the stands have been considerably altered from their historic conditions. These management legacies provide both opportunities and constraints when trying to plan for future climates. Using the JPRF Adaptive Silviculture for Climate Change (ASCC) instillation as a case study we: 1) evaluate how diameter limit-cutting influence the composition and structure of the forest stands compared to historical conditions, 2) assess the vulnerability of the forests to climate change, and 3) appraise whether management designed to restore historic forest structure decreases sensitivity to climate change. The JPRF ASCC installation is large scale (200 ha), consisting of five silviculture treatments that provide a gradient from no-intervention (no-harvest control) to clear-cut, with three intermediate harvesting treatments (resistance, resilience and transition) that represent different degrees of forest retention. The forests are representative of Sub-boreal Spruce forests that are the dry and warm type of this ecotype. Climate change is projected to make the region warmer, but there is less certainty about whether the area will become warmer and wetter, or warmer and drier. The legacy of past management is that the forest is projected to be more susceptible to future drought and wildfire risk in the near-term, with the longer-term implications for climate sensitivity dependent on the realized climate trajectory. Restoration of historic stand structures is projected to temporarily mitigate some climate impacts, but with trade-offs between some forest services.

Climate Change Impacts on Canada's Boreal Forest: Advancing Silviculture through the Silva21 Research Program

T1.31 Silviculture of boreal forests in the face of climate change

Amy Wotherspoon[1]
Ignacio Barbeito[1], Alexis Achim[2], Nicholas Coops[1]
[1] University of British Columbia
[2] Université Laval

Abstract: The circumboreal forest, the world's largest land biome, is crucial for habitat, biodiversity, and renewable resources. Climate change introduces uncertainty for future forest dynamics and productivity. Canada, with 28% of the world's boreal zone, holds 270 million hectares of boreal forests vital for the forestry economy. The Silva21 research project aims to advance silviculture practices, particularly in the changing climate of various forest types, including the boreal forest. Projections generated for Canada's boreal ecozones reveal extreme changes. The boreal cordillera in the northwest will experience an 83% gain in mean annual precipitation, while parts of the boreal plains and boreal shield west will face significant drying and warming trends with a ten-fold increase in mean annual temperature and climate moisture index falling below zero, respectively. The boreal shield east will experience warmer and wetter winters despite increased annual precipitation due to 26% less snowfall. These changes pose risks of disturbances such as drought, forest fires, and pest outbreaks, leading to a decline in aboveground biomass and a shift to younger stands dominated by early successional species. Boreal species may seek refuge in northeast Canada in regions of greater moisture availability, potentially causing the deborealization of dominant species and increased mixedwood stands. Proactive forest management and silviculture planning are crucial to anticipate these changes in climate and forest structure and maintain stand production and carbon sequestration. Employing a no-regret approach to silviculture, multiple treatments should be applied at different stages of a forest's life cycle based on regional requirements. In addition to treatments this includes 1) observing stand attributes and climatic drivers of tree growth, as well as stand development and disturbances using remote sensing, satellite imagery and continuous forest inventory framework, 2) adapt region-specific silviculture that considers local cost-benefit analyses and operational realities, and 3) adapt strategies to future forest reality to promote long-term forest resilience or transition to future climate. Lessons learned from Silva21, including long-term legacy trials, will benefit other countries with similar anticipated projects and shifts in boreal regions worldwide.

Developing models of site index and stand characteristics for silver birch plantations

T1.31 Silviculture of boreal forests in the face of climate change

Daesung Lee[1]

Abstract: Along with growing interest in biodiversity and forest health, research on the silviculture of boreal broadleaved tree species has recently taken on greater significance. The most important broadleaved tree species in Finnish forestry is silver birch (*Betula pendula* Roth). Although there are growth and yield models for naturally regenerated silver birch, models focusing on planted silver birch stands are still needed. The objectives of this research for planted silver birch were to examine the dominant height growth for site productivity and to develop the models of site index and stand characteristics in Finland. The Swedish field experiments were also examined to compare the growth and to validate the models fitted using the Finnish data. The data used for modeling included the long-term thinning experiments of silver birch plantations that were measured repeatedly over a 30-year period in most cases. Additionally, to increase regional coverage and sample size, we included field trials comprising both birch breeding materials and unimproved birches. The 43 experimental sites (354 plots in total) were located across southern and central Finland and included both former agricultural land and forest sites. The age range in the observations was 7–69 years, and the measurements were taken 1–9 times with a 5-year interval. The plots were thinned 0–4 times depending on experimental designs. The data for modeling were restricted to the stands thinned from below. The data for the Swedish thinning trial data were collected from 36 sites in southern and central Sweden. Because the dominant height differed between unimproved and improved birches, the breeding effect was included in a site index model using the Chapman-Richards function. In stand models for unimproved birches, the selected response variables were basal area-weighted mean height, basal area-weighted mean dbh, and stand basal area. The estimated site index, age, the number of trees, and thinning dummy variables were the most significant predictors when fitted using seemingly unrelated regression with mixed effects. These growth models will be implemented in simulation software, and they will provide more reliable estimates for the future development of planted silver birch stands.

Disturbance effects of alternative forest management strategies – landscape simulation modeling as a decision support tool

T1.31 Silviculture of boreal forests in the face of climate change

Katharina Albrich[1]

[2] Finnish Meteorological Institute, Helsinki, Finland

Abstract: Forest disturbances are a source of considerable uncertainty and economic loss for forest managers. Climate change is expected to intensify disturbance regimes and interactions between different disturbances, e.g. wind and bark beetle in boreal forests. A wide variety of measures to adapt to these uncertainties has been proposed, such as adapting species composition and rotation lengths or shifting to continuous-cover forestry. To understand the potential effects of these options and to guide forest managers, innovative tools are needed which consider the interactive effects of climate change and disturbances.

We used a landscape simulation approach (iLand model) to explore a wide array of alternative management scenarios for a landscape in Southern Finland. iLand is a process-based model, which includes dynamic disturbance modules and an agent-based forest management engine allowing for the implementation of detailed forest management strategies. We simulated adaptations of even-aged management (increased broadleaf shares, changed rotations lengths) as well as different spatial intermixtures of even- and uneven-aged management. We focused on the effects of wind and bark beetle disturbances, particularly the amount of wood affected by disturbance, comparing both historic climate and multiple climate change scenarios.

The simulations suggested notable differences between management scenarios, with disturbance impacts being particularly sensitive to rotation lengths and broadleaf shares. Bark beetle disturbances increased considerably under climate change. While reducing spruce shares and rotation lengths reduced these particular disturbance risks, it also reduced wood production. When intermixing even- and uneven-aged management, the spatial arrangement had an effect, with disturbance risks of a stand being affected also by the management in surrounding stands. Our results highlight the potential of using simulation modelling to explore a wide portfolio of management options and their effects on future forest disturbance risks and ecosystem services, particularly when it is necessary to consider trade-offs between multiple management objectives.

Establishing mixed conifer forests - a study testing different spatial planting designs and scarification methods

T1.31 Silviculture of boreal forests in the face of climate change

Therese Strömvall Nyberg[1]
Emma Holmström[1], Kristina Wallertz[2], Urban Nilsson[1]
[1] The Swedish University of Agricultural Sciences, the Southern Swedish Forest Research Center, Sweden
[2] Asa Research Station, Sweden

Abstract: Sweden has a rich history of forest cultivation and management. Traditionally, forestry has been focused on even-aged monocultures of either Norway spruce (*Picea abies*) or Scots pine (*Pinus sylvestris*) usually planted in a spacing of about 2 by 2 meters. However, alternative management methods are needed to increase diversity and decrease risks from abiotic and biotic threats and to improve forest growth while maintaining ecological functions. Establishment of mixed forest in boreal forest often rely on spontaneous ingrowth that complement planted seedlings but there is an increasing demand for knowledge on establishment of mixed species stands where several tree-species are planted. New research shows that seedling density, not the spatial planting design, is important for stem quality and production. In this study, we evaluate the early results from a regeneration experiment with focus on establishment of mixed forest with different spatial planting designs. Tree species treatment plots with either mixture (M) or monoculture of Norway spruce (S) and Scots pine (P) were planted in the spring of 2020 on three sites. For each M, S and P treatment, three levels of spatial design were further established, resulting in a total of nine treatments replicated on three blocks. The spatial design was created by three types of soil scarification with an excavator: Single seedlings (S1) planted in small mounds with bare mineral soil (0.5 m^2), groups with three seedlings (S3) in small inverse scarification patches (1 m^2) and groups with five seedlings (S5) in large inverse scarification patches (2.25 m^2). The hypothesis tested was inverse scarification would (i) make a smaller impact on the forest floor compared to mounding, (ii) increased seedling vitality and survival and (iii) improve seedling growth. Seedlings in the experiment were measured one-three years after planting, including height growth and eventual damages and vitality. In addition to hypothesis testing, results will be discussed in relation to eventual practical implications.

Forest management trends under climate change in Fennoscandia: potential effects on disturbance agents.

Abstract: This literature review explores the relationship between natural disturbances and the impact of management practices on the susceptibility to damage. Natural disturbances, such as wildfires, insect outbreaks, and storms, play a vital role in shaping ecosystems. However, human activities and forest management decisions can either exacerbate or mitigate the effects of these disturbances. Understanding the interplay between natural disturbances and management strategies is crucial for sustainable land management and conservation efforts. Natural disturbances are becoming increasingly severe and frequent due to factors like climate change and land use patterns. Therefore, comprehending how management practices can influence susceptibility to damage is essential for developing effective mitigation strategies. Additionally, with growing human populations and increased utilization of natural resources, it is crucial to strike a balance between resource extraction and ecosystem resilience. This literature review aims to shed light on how management choices can impact the susceptibility of ecosystems to natural disturbances. We looked at different management strategies, such as prescribed burning, few or no thinnings, mixed forest stands, shorter rotations and selective logging among others, and how they can affect forest's susceptibility to damage. Proper implementation of these practices can reduce fuel loads, enhance biodiversity, and promote forest resilience. However, inadequate or inappropriate management approaches may increase susceptibility to disturbances. The outcomes of this research could have broad implications for land managers, policymakers, and conservation practitioners. Firstly, it can inform the development of adaptive management strategies that consider the potential impacts of natural disturbances and climate change. By identifying the most effective management practices, policymakers can implement policies that promote ecosystem resilience. Secondly, this review can contribute to the development of adaptive management approaches, landscape-scale adaptation plans, and informed decision-making processes, ultimately promoting the sustainable use and conservation of natural resources.

Future challenges for the boreal forest in context of climate change

T1.31 Silviculture of boreal forests in the face of climate change

Johan Bergh[1]

[1] Linnéuniversitetet, Fakulteten för teknik (FTK), Institutionen för skog och träteknik (SOT). Linnéuniversitetet, Kunskapsmiljöer Linné, Grön hållbar utveckling.

Abstract: The boreal coniferous forest belt is a forest ecosystem (Taigan) that stretches across the globe from northern Europe, along northern Russia (Siberia) across the Bering Strait to Canada and Alaska. The boreal forest covers approximately 15% of the Earth's land mass and constitutes the world's largest land-based carbon reservoir. The boreal forests plays also a very important role for climate mitigation and the possibilities to replace fossil-based materials or other materials that are not sustainable for the environment.

Growth in most boreal forest ecosystems is limited by plant nutrients and primarily nitrogen, but of course also by the harsh winter climate. Climate change will have a very large impact on the boreal forest both regarding forest growth and increased risk of various forest damages.

An earlier start of the photosynthetically active period in the spring will most likely mean that more sunlight can be used for photosynthesis production, which can lead to increased growth. There are also other factors that can affect forest growth, such as increased concentration of CO_2, soil nutrient availability, bud-burst/leaf unfolding and changes in precipitation pattern. Native tree species can use further north and new tree species can be introduced if necessary.

The other side of the coin is the forest damage because a warmer climate can favor pests but also some harmful pathogens. In addition, new pests and pathogens can be introduced and established as the harsh boreal climate becomes milder. Other concerns are increased frequency of extremely dry summers, winter storms and other extreme weather events.

In order to create a more sustainable and resilient forestry, we should consider the way we manage the forest. An adaptation of existing forestry methods and new ways of managing the forest will be needed in the future, without jeopardize the role of the boreal forest to mitigate climate change.

How Increased Understanding of Disturbance Dynamics Can Influence Silvicultural Systems in the Southern Boreal Forest

T1.31 Silviculture of boreal forests in the face of climate change

Marcella Windmuller-Campione[1]

[2] Oregon State University
[3] U.S. Forest Service
[4] Arbor Analytics

Abstract: The boreal forest reaches its southern extent in the Great Lakes Region of the United States (Wisconsin, Minnesota, and Michigan). A major forest ecosystem within the southern boreal forest is lowland conifer or peatland forests, which are dominated by black spruce (*Picea mariana*) and eastern larch (*Larix laricina*) in the overstory. Conventionally these systems have been managed as even-age systems using a clearcut regeneration harvest, relying on a combination of natural regeneration and artificial regeneration through aerial seeding. The regeneration harvest occurs as the stands reach the stem exclusion stage of stand development. There is increasing interest in exploring alternative or disturbance-based silviculture to increase tree species diversity and structural complexity to meet goals that increase wildlife habitat and climate resilience. Our lab established hundreds of plots across black spruce and eastern larch forest communities to explore stand development and the influence of two of the major disturbance agents: eastern spruce dwarf mistletoe (*Arceuthobium pusillum*) and eastern larch beetle (*Dendroctonus simplex*). Both disturbance agents highlighted the potential for two-aged and uneven-aged management to increase diversity and complexity in these systems. For example, we found that black spruce forests have the potential to be managed using the triad approach with some areas managed using more intensive clearcut regeneration harvest, some managed more extensively using irregular shelterwood with reserve regeneration harvests, and some using active or passive reserves. Increasing the diversity of management within these systems can help adapt these forests to a changing climate and increase ecological and economic resilience.

Knowledge brokering and the historical legitimization of mechanized forestry

T1.31 Silviculture of boreal forests in the face of climate change

Jimmy Jönsson[1]
Janina Priebe[2]
[1] Lund University
[2] Umeå University

Abstract: This presentation addresses knowledge as a policy instrument in relations to engage small-scale forest owners in contributing to profound societal transitions, such as the transition to a carbon neutral society. Learning from past transitions, the presentation is based on a historical case: the transition to mechanized forestry in the boreal regions of Sweden during the 1950s and 1960s. This transition aimed to enforce Swedish forest industry and was mainly expected to be implemented through a forestry act. As such, it was supported by state authorities and joint stock companies. However, it met resistance from small-scale forest owners, a group owning about half of the Swedish forest land. Instead of industrial silviculturalists, many of them identified themselves as farmers and were less keen to invest into chainsaws and tractors. In this context, we focus on how local forest owner associations used local knowledge campaigns to engage small-scale forest owners in adapting to mechanized forestry. We employ the concept of "knowledge brokering," describing a process of "translating" knowledges and interests to "enroll" non-expert actors to a certain cause. The analysis was based on readings of historical texts. We found various effects of knowledge brokering on the Swedish small-scale forest owners. First, knowledge brokering helped building a multimedia knowledge society around forest owners, including, for instance, film screenings, forestry dictionaries, forestry journals, and machine demonstrations. Second, it provided forest owners with technical know-how through recurrent technological trials. Third, it helped building an educational structure for forest owners, most noteworthy through the means of locally arranged study circle courses. Forth, it shaped the identity of "the forest owner" as something different from "the farmer." Fifth, and finally, it contributed with critical perspectives and cautious attitudes towards new technologies. We argue that knowledge brokering, ultimately, helped legitimizing the process of mechanization and, thus, contributed to the achieving of a profound societal transition in Sweden. We also argue that the climate transition can learn from historical cases, such as the mechanization of forestry, in combining the "hard" top-down policy instruments with "soft" bottoms-up instrument of knowledge brokering.

Mean wood cell age in trees and wood assortments

T1.31 Silviculture of boreal forests in the face of climate change

Erik Wilhelmsson[1]
[1] Swedish University of Agricultural Sciences

Abstract: In Sweden and in many other countries felled trees are mainly used for timber and pulpwood. The top of the tree and the branches may be used for bioenergy, but this fraction are by some seen as unsustainable because it takes a rotation (80-120 years) to produce. Generally, the age of a tree means the years since it started to grow, but we know cells grow every year, and take up carbon. Thus a living tree has cells with age down to 0.

The topic of this study is to estimate the mean and max wood cell age per tree and per wood assortment. This question is relevant as forests are important for carbon sequestration and storage as well are as a source for bioenergy.

Growth functions in the Swedish planning system Heureka result in diameter at 1.3 m, height and tree volume. These data and taper functions are used for calculation of stem area each annual ring in at every decimeter of an average tree. Taper functions are also used for bucking in timber, pulpwood and energy wood. Then mean and max wood cell age per assortment are calculated. Also branches may be included (but are not in the following example).

Spruce (Pices abies) stand on a productive site in South of Sweden (SI Spruce 34 m at 100 years) may be clear felled at 50 years age. The volume mean tree with height 21.4 m and dbh 23.5 cm are bucked to timber to diameter 14 cm under bark at 11.0 m height, pulpwood from 11.0 to 17.3 m to diameter 5 cm ub, and then 4.1 m of energy wood. Mean age of wood cells - as well as carbon uptake - are for timber 14 years, for pulpwood 8 years and for energy wood 4 years. Corresponding max age for wood cells are 50, 25 and 11 years. Mean wood cell age for a tree are 13 years.

This results show it is important we include mean and max wood cell age as variables when describing trees and stands, specially in relation to carbon sequestration.

Mitigation and adaptation of carbon sequestration in multi objective forest management through co-creation with stakeholders (HIILIPOLKU)

T1.31 Silviculture of boreal forests in the face of climate change

Liisa Ukonmaanaho[1]
Katriina Soini[1], Heikki Tuomenvirta[2], Janne Artell[1], Liina Häyrinen[1], Soili Haikarainen[1], Esa Huhta[1], Jari Hynynen[1], Jaakko Juvonen[2], Pentti Pirinen[2], Aura Salmivaara[1], Leena Stenberg[1], Petteri Vanninen[1], Eija Pouta[1]

[2] Finnish Meteorological Institute

Abstract: Forest management can affect how much carbon is stored in forest biomass and forest soils. Understanding of how forest management practices can be optimized for either carbon sequestration, water protection, or biodiversity has become more accurate. However, reaching the carbon neutrality goals, requires practice-validated strategies for the implementation of best-suited carbon sequestration methods in multi objective forest management.

The main objective of the HIILIPOLKU (https://www.luke.fi/en/projects/hiilipolku) is to create co-creation practices in partnership with local forestry actors (e.g. landowners, forest service entrepreneurs, NGOs) that nudge carbon sequestration in forests with simultaneous support for water and biodiversity protection. Practices will be based on research information and strive for socially just and rewarding implementation. The local, voluntary-based model of carbon sequestration by individual forest owners produced in the study is conceptualized and its applicability nationally in forest counseling will be evaluated.

The HIILIPOLKU study will be carried out in the Puruvesi catchment area, South-East Finland, boreal forest. The development of carbon stock in trees and soils under different forest treatment options are calculated and their change is estimated with Motti- and SUSI-model simulations in current and future climate conditions. The preliminary simulations results have, for example, shown that there will be more carbon sequestration when longer rotation period is chosen and respectively biodiversity increase when share of broadleaves trees increase in forest. The results of the carbon balance, wood production as well as impacts on the water quality and biodiversity will be applied stand level to the forest of individual forest owners and further utilized in co-creation process. The best feasible solutions and compensation strategies for socially and economically acceptable carbon sequestration in forests will be developed, while taking water protection and biodiversity into account.

Modelling Wind Damage in Swedish Forests: Resistant Edge Management

T1.31 Silviculture of boreal forests in the face of climate change

Emily Delin[1]

[1] Swedish University of Agricultural Sciences, Southern Swedish Forest Research Centre, Sweden
[2] Norwegian University of Life Sciences, Faculty of Environmental Sciences and Natural Resource Management, Norway
[3] Swedish University of Agricultural Sciences, Tönnersjöheden Experimental Forest, Sweden

Abstract: Windstorms are predicted to increase in frequency and severity in Northern Europe as climate change develops. Critical wind conditions and their consequential damage threaten multiple services provided by forests (including monetary and biodiversity value) as well as impact human health and security (both directly and indirectly). High wind speeds can cause damage to forest stands through uprooting and snapping. The increase in damage experienced due to severe storm events over time may be due to changes in wind speed and direction, but is also likely influenced by changes in forest management. To better manage forest land to prevent losses from wind storms, we must understand what conditions make a stand susceptible to wind felling. In this paper, data from the Swedish National Forest Inventory was used to model the effects of site, stand and, more specifically, edge characteristics on wind mortality. We hypothesized that an edge's presence and edge's orientation will significantly influence the probability of wind-induced mortality within a stand. We further hypothesized that orientation toward the westerly to the southwesterly directions would lead to increased mortality. In order to test these hypotheses and analyze the influential factors on presence and quantity of wind damage in Swedish forests, generalized linear Mixed-Effects Models were created using R. A binomial model provided insights on factors that increased the probability of wind damage occurring in managed forest, with particular focus on the timing and spatial orientation of adjacent clearcuts. Additionally, a Gaussian model relating volume lost in windstorm events to spatial and temporal variables along with management activity was the basis for more in-depth investigation into the risks and expected losses under extreme wind conditions and currently common management regimes. From these results, a deeper understanding of current and future risks for mortality due to wind damage in Swedish production forests was achieved, allowing for more comprehensive management decisions for sustainable forestry practices.

Open Forest and Nature data in evaluation of the success of regeneration of pine, spruce and birch, and their mixtures

T1.31 Silviculture of boreal forests in the face of climate change

Karri Uotila[1]
Jari Miina[1], Aura Salmivaara[1], Saija Huuskonen[1]
[1] Natural Resources Institute Finland, Finland

Abstract: This study evaluates factors affecting the success of regeneration of Scots pine, Norway spruce and silver birch using open forest and nature data. Such knowledge would be used in silvicultural planning to diversify tree species usage, moving away from an overreliance on spruce, and to promote the establishment of mixed forests.

Regeneration treatments included monocultures of planted pine, spruce and silver birch and seeded pine, and their 50/50-mixtures created by planting. In addition, pine mixture was created by direct seeding and birch mixture by natural regeneration. Soil inversion was used for soil preparation in planting, whereas patch scarification was used for direct seeding. Field data was measured after the first growing season from the experiments established during 2020–2022, comprising of 284 sample plots (1000 m^2) in 18 mineral soil stands in Finland.

Several variables from open forest and nature datasets were used to predict the regeneration success at the seedling and plot level. Different terrain indices, e.g. topographic wetness (TWI), were computed from digital elevation models. Site and stand characteristics at final felling were obtained from Finnish Forest Centre datasets. Climatic and geological variables were downloaded from the datasets of the Finnish Meteorological Institute and the Geological Survey of Finland. Erosion risk and forest trafficability indices from open datasets were also incorporated.

Several variables were found to affect the regeneration success. TWI showed a positive correlation with the survival and height increment of planted spruce and silver birch. Stand volume at clearcut correlated negatively with the survival of planted pines and the number of pine seedlings in direct seeding. High potential evaporation in July decreased the number of pine seedlings regenerated in direct seeding.

Open forest and nature data could be used more efficiently at the regeneration phase. Information on site and growing stock and their variation within regeneration area would help support the selection of regeneration method and tree species at a micro-stand level by dividing a stand to smaller units based on e.g., soil properties and microtopography. These ongoing experiments will provide additional data in the future.

Red wood ant (Formica rufa group) survival in clearcuts can be increased by concentrating retention trees to an area surrounding the ant mounds

T1.31 Silviculture of boreal forests in the face of climate change

Emil Andersson[1]

[1] The Swedish University of Agricultural Sciences, SLU

Abstract: Red wood ants (RWA) of the *Formica rufa* group are keystone species in boreal forest, where they act as ecosystem engineers, building large mounds of conifer needles and other litter materials. These mounds function as hotspots for carbon and nitrogen mineralisation, as well as for many different arthropod species that utilize them for protection and resources. It is known that RWA colonies can be negatively affected by logging, and these effects are thought to be amplified by climate-change. Recently there has also been an international call for developing forest management plans that take RWA protection into consideration.

Here we look at a concrete and easily practiced measure that could be quickly implemented through policy change. In Swedish law, forest owners are obligated to save a number of retention trees at a clearcut. The trees chosen could be the ones that stand next to RWA mounds, but would such measures be sufficient to have a positive effect? To answer this, we experimentally measure the effect of saving the trees next to a RWA mound during the final harvest.

In cooperation with Swedish state owned company Sveaskog, we mapped RWA mounds in forest stands that are going to be harvested by clearcutting. When found, all trees within a 10 meter radius from the mound were measured, as well as the mounds themselves. Every second plot was used as a treatment where the trees were marked to be retention trees, while the other plots served as controls. After the stands were clearcut, and a RWA foraging season had past, we measured the effect on RWA, both as mound abandonment, and as the conditions of the mounds and of worker health. Stands that were not cut at all served as a baseline measure.

Our results so far show lower mound abandonment and higher health at treated sites where trees were kept in the 10 meter radius plot around the mound. In conclusion, our results point to recommending forest owners and managers to concentrate retention trees to the vicinity of RWA mounds to protect RWA and their mounds.

Short-term effects of thinning on above-ground biomass in Scots pine stands

T1.31 Silviculture of boreal forests in the face of climate change

Amanda de Castro Segtowich[1]
Emma Holmström[1], Ola Langvall[2]
[1] Department of Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Alnarp, Sweden
[2] Unit for Field-based Forest Research, Siljansfors Experimental Forest, Swedish University of Agricultural Sciences, Mora, Sweden

Abstract: Forests play an essential part in the mitigation of climate change consequences, since trees uptake CO_2 from the atmosphere through photosynthesis and store carbon throughout their life. Allometric functions derived from destructive sampling can be used to predict the variation in carbon storage. In addition to edaphoclimatic conditions, forest management practices, such as thinning, also have an impact on growth and biomass allocation patterns. Scots pine (*Pinus sylvestris*) is one of the most relevant tree species in Sweden and the world. Within this context, this study aimed to evaluate the short-term effects of thinning on above-ground biomass compartments (stem, needles and branches) and total biomass on Scots pine stands in Sweden. The study was conducted in Siljansfors and Jädraås, located in central Sweden. The experiment has four treatments: control (unthinned), thinning from below (25% of basal area removal), thinning from above (25% of basal area removal) and heavy thinning from below (63% of basal area removal), randomized within blocks. In total we have four blocks, two on each site. Destructive biomass sampling was performed before thinning and three growing seasons after thinning. Allometric equations were created to estimate total biomass, as well as biomass in the different above-ground compartments. Additionally, we will also showcase the seasonal variation and development of leaf area index (LAI) for the different treatments. We hypothesized that 1) individual trees in the same diameter classes in the heavy thinning treatment will have increased biomass growth, whereas 2) total stand biomass will be higher in the control treatment in comparison to the thinned ones, and 3) the reduction in LAI after thinning will still be lower in the heavy thinning compared to control after three years, but 4) in lighter thinnings LAI is again at the same level as the control.

Within-stand variation and its influence on thinning practices

Abstract

The state of within-stand variation in boreal, coniferous production forests, and how it is dealt with in thinning operations, is a scarcely researched subject area. In fall 2018, we surveyed a series of Norway spruce or Scots pine dominated production stands scheduled for first commercial thinning. Here, we evaluated how within-stand variation was handled in the thinning operations and finally how the stands and subsequent thinning practice conformed with the thinning guidelines.

Within-stand variation in the yield attributes was evaluated in various ways and it was expressed using the Q_n scale estimator. Initially, yield attributes before and after thinning were compared using paired t-tests. At last, the thinning practice was evaluated before and after thinning by modelling the agreement with the basal area target as a function of stem density and dominant height.

Thinning reduced the within-stand variation in basal area, standing volume, and stem density, however, dominant height, quadratic mean diameter and basal area weighted mean height remained unaffected. Thinning had a short-term effect on within-stand variation as it returned to the pre-thinning state 10 years after thinning. Sample plots conformed more with the basal area target in the thinning guidelines with increasing dominant height and stem density, both before and after thinning. Only stands with high stem density and at high dominant heights (>16 m) agreed with the thinning guidelines.

The reduction of within-stand variation may increase the homogeneity in tree size but the reduction itself may produce future stands which contain little biodiversity. The consequence of the poor agreement with the thinning guidelines may be postponed executions of thinning, which in turn

increase the stands' susceptibility to wind-throw. Adapted silvicultural guidelines may be needed to promote early thinning operations.

Abstract: To increase the resilience of boreal forests facing the changing climate the species selection used in artificial forest regeneration needs to be diversified. Norway maple (*Acer platanoides* L.) is one potential species for this in the Nordic countries. In Finland the species' natural distribution is limited to southernmost part of the country, but particularly in the warmer climate it can be planted further north.

The northernmost seed orchard (sv458, Turvala) of *A. platanoides* in Finland is situated in Punkaharju (61° 47' N; 29° 21' E), which is outside of the natural range of the species. In a seed harvest in 2020 X-ray radiography of intact seeds showed that some of the seeds were infested with an unidentified insect larva. The species was identified as scarce maple piercer (*Cydia inquinatana* (Hübner, 1799)) by a DNA analysis.

In September 2021 seeds were collected from 20 individual trees from the seed orchard to assess the prevalence of the insect. All seeds from three branches from each tree were collected and X-rayed to assess seed quality. Additionally fresh seeds fallen prematurely on the ground were collected from 4 circular $1m^2$ plots around each of the 20 trees and similarly assessed. The DNA of 68 insect larvae found in the seeds (half collected from the crowns and half from the ground) was extracted and sequenced.

The DNA analysis confirmed the insect species to be *C. inquinatana.* Larvae were found in 2% of the seeds collected from the crowns and an additional 9% were destroyed by them. In the seeds collected from the ground, the percentages were 11% and 30%, respectively. 74% of the seeds collected from the crowns were healthy and viable according to the radiography, whereas 39% were such on the ground. According to statistical analysis there were no differences in the proportion of larvae infested or damaged seeds among the trees.

The results show that seed specialist *C. inquinatana* – whose only known host species in Finland is *A. platanoides* – is able to cause seed damage in a seed orchard located outside of the tree species' natural distribution range.

Detecting fungal pathogens in forest nurseries: seedborne fungal communities and foliar fungal communities of nursery-grown Pinus sylvestris seedlings

T1.32 The biosecurity risks of international movement of tree seeds

Rebecca Larsson[1]
Audrius Menkis[1], Åke Olson[1]
[1] Forest Mycology and Plant Pathology, Swedish University of Agricultural Sciences, SE-75007, Uppsala, Sweden.

Abstract: Fungal infections can have high economic impact in the production of forest tree seedlings, especially in case of intensive management practises (e.g. extensive monocultures, dense cultivation systems, shortage of beneficial organisms). Fungal pathogens are often controlled with different management methods, including cultural methods and fungicidal applications. Better knowledge about local fungal communities, especially common pathogens, would improve preventative and directed control methods and ultimately reduce the use of chemical treatments. In this study, we investigated (1) fungal communities associated with seed material of *Pinus sylvestris*, *Picea abies* and *Larix sibirica* from different origins used in Swedish forest nurseries and (2) the seasonal dynamics of foliar fungal communities associated with nursery-grown *P. sylvestris*-seedlings. Additionally, four microbial treatments were tested to investigate possible effects on seedling growth and disease control. Treatments and sampling of healthy needles were done every third week during one growing season. DNA was extracted from (1) seeds and (2) needles, followed by amplification with fungal-specific primers and high-throughput sequencing of the ITS2 region. Results showed a clear separation of fungal community composition on seeds of different tree species and a gradual geographical separation of different seed origins. The fungal pathogens *Sydowia polyspora* and *Cladosporium* sp. were found on all seed samples, while *Ophiostoma* sp., *Phoma herbarum*, and *Sirococcus conigenium* were among the most abundant species. On *P. sylvestris* seedlings, the results showed large changes in foliar fungal community composition over time. *Phoma herbarum*, *Cladosporium sp*., and *S. polyspora* were among the most abundant species on seedling needles. A low number of disease incidents were reported (overall infection rate < 0.6%). However, infection of *Diplodia sapinea* were found during the study period. Microbial treatments were not found to have either a positive or negative impact on seedling growth or survival. In this study, we found the same fungal pathogens to be highly abundant on seed material as well as *P. sylvestris* seedlings. Provided information on fungal communities, especially occurrence of fungal pathogens, from both seed material and nursery-grown *P. sylvestris* seedlings is relevant to improve preventative and directed control strategies of fungal diseases in forest nurseries.

Environmentally friendly seed treatments to reduce pathogenic fungi in conifer seeds

T1.32 The biosecurity risks of international movement of tree seeds

[3] Svenska Skogsplantor, Sweden

Abstract: The absence of pathogenic fungi in seeds is critical for forest regeneration to produce healthy plants for future forests. Our previous work has shown that tree seeds contain a wide variety of fungi, including plant pathogens. One of these fungi found in Swedish seed orchards was *Diplodia sapinea* - a serious fungal pathogen of pines that causes shoot blight and crown dieback. This fungus has a very plastic lifestyle; it can exist for many months to years as an endophyte or latent pathogen, and becomes active following stress (e.g., drought) or other conditions that affect tree vigor. There is a need to better control infestations of collected and stored seed to minimize the introduction of *D. sapinea* and other pathogens during plant propagation in reforestation operations. Treatments such as heat or UV-C light are options that can be applied to seed that may reduce the incidence of *D. sapinea* and other fungi in seed, but they have not been widely tested on forest tree seed, and the effects of such treatments on tree seed fungi (including *D. sapinea*) and seed germination are unknown. In this project, we assessed germination and fungi associated with *Pinus contorta*, *Pinus sylvestris* and *Pseudotsuga menziesii* seeds, with a specific focus on *D. sapinea*, before and after the UV-C light treatments (one and three times using CleanLight machine) and heat treatment (55°C for 8 hours). Fungal populations were assessed using an RNA metabarcoding approach to identify and quantify viable fungi in seeds, as targeting only viable fungi is important to accurately assess the efficacy of treatments. Additionally, the amount of viable *D. sapinea* present in the seeds was specifically tracked in the different treatments using RT-qPCR. Ultimately, this project provides management options and allows to mitigate the risk of introduction and spread of *D. sapinea* and other fungal pathogens with seeds used in reforestation nurseries.

EUPHRESCO project COSEPATH, are seeds a potential pathway for pests and pathogens and a risk for future forestry?

Abstract: The introduction and spread of harmful organisms have important economic and ecological consequences. Traditionally, tree seed material has been considered a relatively low risk pathway for the movement of exotic pests and pathogens, although there is a growing awareness that the risks are only poorly understood. Spread through the movement of infected seed may be one of the drivers for the emergence of diseases such as pitch canker caused by *Fusarium circinatum* on pine and Douglas-fir, Neonectria canker caused by *Neonectria neomacrospora* on fir or Sirococcus blight caused by *Sirococcus* species on a wide range of conifers. The objectives of the EUPHRESCO project COSEPATH were (i) to gather current knowledge on seed borne pathogens of conifers; (ii) to generate data on the movement of conifer seed, focusing on the most traded conifer genera and/or species; (iii) to compare and run 'in parallel' testing of seed lots using the traditional and molecular methodologies by different laboratories with the aim of harmonising methodologies for the detection of pathogens. Information generated from this project provided sound scientific evidence of seed borne fungi that could be useful to professionals (nurseries, producers, foresters, importers), policy (government), scientific community (researchers) and for any interested party. At the same time, the project highlighted the gaps in knowledge that will need to be addressed in future studies to minimise risks of introducing pests and diseases through seed movement and trade.

From eco-evolutionary perspectives to pest risk assessment in seed-borne insects: a literature review

Abstract: Plant-insect interactions have provided for decades many ways to understand how some species affect the distribution, the abundance, and the evolution of others. Because they affect the number of viable seeds available for plant recruitment, seed predators have received considerable attention from ecologists for the influence they may have on plant demography, spatial distribution, diversity and evolution. Considered as the most important seed predators during the pre-dispersal phase of seed development, the success of insects in the exploitation of the pre-dispersal niche primarily rely on their flexibility in synchronizing their life-cycles with the ephemeral availability of seeds on their host plant, and on evolved strategies for coping with the highly variable and unpredictable seed resource in both space and time. Besides their ecological interest, cone- and seed-feeding insects caught the attention since the first half of the 1900s as serious pests of seed crops for afforestation after tree harvesting. Their economic impact even increased when seed orchards were established in 1950-1960, and they have remained so far a serious threat for the ever-growing need of wood for a variety of products as a cause of seed deficit in the newest seed orchards. Here, we will review the ecological and risk assessment implications of insect pre-dispersal seed predation in forested ecosystems. We will discuss how tree-insect seed predator interactions illustrate key mechanisms of animal-plant relationships and their potential consequences on invasion risk. We will also discuss seed deficiency issues for reforestation and possible management aspects for seed orchards.

Fungal pathogens in Norway spruce seed production: incidences and causation.

[2] Natural Resources Institute, Oulu, Finland.

Abstract: Swedish forestry is sustained by planting about 200 million Norway spruce (*Picea* abies) seedlings every year. Most of these seedlings come from seeds originating from seed orchards, which have been established to transfer the genetic gain in growth and yield achieved through plant breeding since the 1940s. However, today there is a deficit of seeds coming from Swedish seed orchards because of irregular flowering and cone set, but also due to pest and pathogen infections. Norway spruce buds and seeds are colonized with a wide range of fungal species. We have used high-throughput sequencing to investigate the species composition in buds and seeds from Norway spruce seed orchards. A genetic locus in Norway spruce associated with presence/absence of *Thekopsora areolata* — the causal agent of cherry spruce rust, a major pathogen of cones was identified with genome-wide association mapping. Furthermore, to investigate the reproduction mode and population structure of this pathogen, newly developed microsatellite markers and a hierarchical sampling strategy were used. From one location in Norway, one location in Finland and five locations in Sweden, one aecium per infected cone was analysed. In addition, multiple aecia per scale and cone were sampled at two locations in Sweden. The results show an overall high genotypic diversity, and at country and location levels no genetic structure was found which indicates high gene flow and random mating in *T. areolata*. However, at the cone/scale level multiple identical genotypes were found. These results suggest that *T. areolata* has long distance spore dispersal in Fennoscandia with common recombination events and clonal or vegetative spread in cones and scales. Furthermore, the genome of *T. areolata* was sequenced and assembled. Analyses of the gene expression of two spore types, urediospores and aeciospores, were performed.

Mycobiome research for safer international tree seed trade

Abstract: Tree seeds are generally regarded as a pathway with a low risk of introducing plant pathogenic fungi. Consequently, seed movement is generally not regulated from a phytosanitary perspective, despite evidence of certain harmful fungi, such as *Diplodia sapinea* or *Fusarium circinatum*, having been introduced to new areas through the importation of seeds. Additionally, recent studies have revealed significant levels of infection and diversity among fungi, including pathogens, associated with seeds and indicated that tree seeds are a pathway of introduction for potentially pathogenic fungi. Here we present the outcomes of extensive research conducted to analyze all fungi, including viable ones, associated with traded tree seeds and seeds obtained from botanic gardens. Through traditional plating as well as RNA-based and DNA-based high-throughput amplicon sequencing, we characterize the diversity of these fungi, identify the main factors influencing their species composition, and investigate the vertical transmission of tree seed-associated fungi. Our findings confirm that tree seeds harbor a wide range of fungi, some of which have the potential to harm plants. Furthermore, the composition of fungal species appears to be primarily influenced by the species of the host tree, likely due to the prevalence of vertical transmission. These results indicate a significant risk of introducing and establishing seed-borne fungi in new environments, emphasizing the importance of further studies of the spread and impact of these fungi. Moreover, enhanced risk assessment and management strategies are necessary to mitigate the phytosanitary risk of tree seed trade effectively.

Seed pathway of tree pest dissemination: gathering knowledge to improve forest health management

T1.32 The biosecurity risks of international movement of tree seeds

Nicolas Denancé[1]
[1] GEVES - National Seed Testing Station, 25 rue Georges Morel, 49071 Beaucouzé, France.

Abstract: The Earth is not only a blue planet, but also a green one, with forests covering around 38% of habitable land surface. However, like any other crops, forest health is threatened by pests whose impact varies greatly depending on the tree species, management practices, and regions of the world. In a context of global trade, the transport of infested plant materials is a major factor in the spread of organisms to new territories, which can be the source of emerging diseases. It is critical to deploy strategies to limit this from happening. All around the world, regional plant protection organizations play key roles to promote phytosanitary measures or regulation. Identifying pests and their vectors is a first step towards risk analysis, and international initiatives are bringing together research results on the role of seeds as vectors of pests. The International Seed Testing Association (ISTA) has a long history in promoting uniformity in seed quality evaluation, as illustrated by the activities of its technical committees on forest tree and shrub seed (FTS), and seed health (SHC). Among these, ISTA contributes to increase our knowledge of the diversity of seed pests and to develop suitable detection methods. One of such a tool, the ISTA Reference Pest List (ISTA-RPL) is a repertoire of seed-borne pathogenic organisms in about 70 plant species, including a dozen of forest trees. It aims to inventory, based on scientific results, if these pests can (or cannot) be transmitted vertically or transferred in the environment under natural conditions, making seeds a vector of dissemination. This literature resource may be a valuable source for risk assessors and policymakers in their goal to evaluate the need to regulate pests or not. It also opens avenues of R&D work by seed companies, academic laboratories, or industry to develop diagnostics, detection methods, or treatments.

Seed-Borne Diseases as Potential Biosecurity Risks in Agroforestry Systems: The Case of Grevillea robusta and Moringa oleifera in Kenya

T1.32 The biosecurity risks of international movement of tree seeds

Jane Njuguna[1]
Angela Muthama[1], Eston Mutitu[1], Ely Mwanza[1], Joseph Machua[1], Priscilla Kimani[1], Bernard Kamondo[1]
[1] Kenya Forestry Research Institute

Abstract: Tree seed is the most commonly used forestry propagation material globally. Most seed-borne pathogens that include fungi, bacteria and viruses are found on the seed coat, inside the seed or in debris and are undetectable through visual observation. Seed exchange also transfers seed-borne pathogens and pests and poses serious biosecurity risks since they are broad spectrum and infect many plant species, animals and sometimes humans. Seed-borne diseases and pests further cause food insecurity in developing countries by causing severe postharvest losses and seedling mortality in the nurseries and on farms. *Grevillea robusta* and *Moringa oleifera* are popular agroforestry species with multiple benefits whose seed is moved widely across the East and Central African region. This study determined important seed-borne pathogens and insect pests affecting the two tree species and developed protocols for their germplasm health testing. Standard International Seed Testing Association (ISTA) seed health testing methods were used to test seed lots of five provenances of each tree species. Three replicates of four hundred seeds from each provenance were tested using standard blotter test and agar plate methods to detect seed-borne pathogens while insect pests were detected visually and through microscopy. The most prevalent pathogenic fungi isolated were *Fusarium sp*. At 13.5% on *G. robusta* and 11.25% on *M. oleifera*. The average occurrence of other fungal genera isolated from both tree species were *Aspergillus sp*. (11.5%), *Penicillium sp.* (10.5%), *Botryosphaeria sp*. (7.5%), *Phoma sp.* (7.0%) and *Alternaria* sp. (2.5%). These pathogens are known to cause postharvest seed rots and also field losses worldwide through seedling rots, blights and deaths. *Pestalotia sp.* was only isolated from *G. robusta* seeds. Isolations from untreated seeds used as control in the laboratory analysis included two more species; *Rhizopus sp.* (4.5%) and *Cladosporium sp.* (3.75%). This study led to the development of seed pathogen detection protocols for the two trees species in Kenya. The protocols together with sensitization of stakeholders on the potential risks posed by seed-borne pathogens will be part of biosecurity and phytosanitary measures to facilitate exchange of quality and disease free tree seed for forestry and agroforestry systems to reduce associated losses.

Seed-borne fungi detected on conifer seed and the potential biosecurity risk for future forestry

T1.32 The biosecurity risks of international movement of tree seeds

Ana Maria Perez Sierra[1]
Chris Hardy[1], Ruth Chitty[1], Robert Needham[1], Sietse van der Linde[2], Shelagh McCartan[3]

[3] Maelor Forest Nurseries-SE Lab, Wales, UK

Abstract: Seed-borne pathogens of forestry species have not been well studied, despite increasing concern about global trade and biosecurity. To investigate the presence of potential pathogens on conifer seeds, unprocessed seeds of fir (*Abies fraseri, A. procera*) and spruce (*Picea sitchensis*) were sourced from UK forestry sites, and processed seeds of spruce (*P. abies, P. sitchensis*), fir (*A. alba, A. fraseri*) and cedar (*Cedrus atlantica*) were sourced from international seed suppliers. Each batch was quality assessed using ISTA protocols and seed X-rays, moisture content measurements, germination and viability tests were performed. To investigate the presence of fungi, seeds were subjected to three different surface sterilisation and culture media combinations. Pure cultures were obtained, their DNA was extracted and the ITS region of the different morphotypes was sequenced using the primers ITS1F-ITS4. The NCBI BLAST database was used to confirm the identity of the cultures. A total of 74 unique fungal species were identified from cultures across all seed batches and media types. On no single media/treatment combination all 74 fungi were detected. Seeds disinfected with sodium hypochlorite and plated on potato dextrose agar (PDA) plus streptomycin sulphate (PDA+S) media yielded both the highest total diversity of fungi, and the highest number of unique identifications. The next highest diversity was detected on seeds disinfected with H2O2 and plated on PDA+S media, but a greater number of unique identifications was found following the ISTA protocol using water agar (WA) media with H2O2 seed sterilisation. Several important plant pathogens were detected. The detection of *Sirococcus piceicola* on *P. sitchensis* seed collected from a UK forest site was the first record of this fungus in the UK. The findings of this study suggest that the global movement of tree seed could presents significant risks in terms of the introduction and spread of forest pathogens.

Sowing the safe and healthy seeds of our future forests

T1.32 The biosecurity risks of international movement of tree seeds

Abstract: Tree planting and reforestation efforts require an extensive production system of seed and seedlings with improved gains, including adaptation to future climates. Along this operational system, seedlings are attacked by seed-borne pests and pathogens which cause substantial economic losses and threaten the large investment into selecting seeds of higher performance. Filamentous fungi are the primary cause of diseases related to seed-borne pathogens. They can be pathogenic or can become pathogenic depending on environmental conditions. The presence of dormant fungi inside the seed also raises some concerns about the risk of introduction of exotic invasive pathogens via seed trade. The current knowledge on the diversity and function of conifer seed-borne fungi remains limited, and the exact cause and the risk associated with many pre-emergent seedling diseases is still poorly understood. To fill this gap, we are presently exploring the diversity of fungal communities (i.e. the "mycobiome") of seeds from four conifer species of high ecological value and significant importance for reforestation in North-America. We have identified 150 fungal species from 60 seed-lots using culture-based methods, fungal DNA-barcoding, and third-generation sequencing with a portable sequencing device (Oxford Nanopore MinION™ technology). The most frequent fungal species (about 15% of our collection) identified on the seed coat and inside the seed are presently screened for pathogenicity in an in vitro assay. We expect to rapidly leverage these resources to create innovative solutions that will improve the present capacity for identifying, detecting, and mitigating fungal diseases in early stages of the reforestation system, reduce the risk of introduction of exotic pathogen via seed trade and help to secure the renewal of tomorrow's forests.

THE EFFECT OF DIFFERENT NUTRIENT MEDIA ON THE DIVERSITY OF CULTURABLE SEED ENDOPHYTES IN EUROPEAN BEECH (FAGUS SYLVATICA L.)

T1.32 The biosecurity risks of international movement of tree seeds

Kinga Stolarek[1]
Iva Franic[1], Michelle Cleary[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Alnarp, Sweden

Abstract: The knowledge about associations between plants and fungal endophytes is limited, especially within tree seeds. Recent molecular studies show that high diversity of fungal communities inhabits tree seeds. Potential plant pathogens which may be introduced to new regions by seeds trade are part of them. However, traditional culturing, one of the most common assessing methods of fungal diversity in plant material, allows to capture only a small fraction of them. On the other hand, this method enables the detection of viable fungi and provides pure isolates for future studies. Different nutrient media have been used within this method, and more studies are needed to test the effect of nutrient media type on the captured diversity of fungi. Therefore, the impact of media and seed origins on endophyte diversity was tested. Seeds of European beech (Fagus sylvatica L.) from six locations within Europe were plated on three commonly used media types that differ in carbon sources (Malt Extract Agar, Potato Dextrose Agar and Water Agar). Moreover, the study assessed the overall diversity of endophytes within tested seeds. Almost all tested seeds of European beech yielded fungi. A high diversity of fungal endophytes was detected, including plant pathogens. Diversity and community composition captured in this study were not influenced by medium type. Obtained fungal communities among the three used media did not differ significantly, indicating similar ability in utilisation of both simple and complex carbohydrates by them, which allows for the comparison of fungal diversity assessed by those media. However, the seed origin seems to be a key driver of fungal diversity and community composition differences. It indicates the possibility of the movement of potential fungal pathogens within the seeds trade for tree regeneration purposes. The use of local seeds sources in forest regeneration could reduce this danger.

Abstract: Pine wilt disease (PWD), caused by the pinewood nematode (PWN) *Bursaphelenchus xylophilus* has been severely affecting maritime pine (*Pinus pinaster* Ait.) forests in the Iberian Peninsula. Although *P. pinaster* is highly susceptible to PWD, heritable resistance has been reported. Additionally, recent transcriptomic and biochemical analyses of *P. pinaster* trees exposed to PWN highlighted the importance of the jasmonic acid (JA) defence pathway, secondary metabolism pathways like terpene and lignin biosynthesis, oxidative stress response genes, and resistance genes in achieving resistance. In contrast, activation of the salicylic acid (SA) defence pathway has been linked with susceptibility to PWN. In this work, the main objectives were to further characterize the molecular interaction of *P. pinaster*-PWN at the post-transcriptional regulation level by microRNAs, and to identify *P. pinaster* SNPs associated to PWD resistance taking advantage of available data and resources. Small non-coding RNA sequencing of PWN artificially inoculated and control plant samples allowed to identify a set of differentially expressed (DE) microRNAs (miRNAs). The predicted target genes of miRNAs DE in inoculated *versus* control plants are involved in JA defence pathway, response to oxidative stress, and terpenoid biosynthesis, whilst miRNAs DE in resistant *versus* susceptible plants were predicted to target*RLKs* and a *GDP-L-fucose synthase*. Further studies using RT-qPCR have highlighted other possible miRNA roles in the regulation of immunity pathways, cell wall reinforcement, and oxidoreductase activity in resistant genotypes. As a complementary approach, available RNA-seq data from PWN-inoculated susceptible and resistant plants were used for SNP discovery and a customised SNP array (4TREE Axiom array) was used to genotype over 500 plants from another PWN inoculation assay. The analyses, including a multi-locus GWAS to associate 6348 genotyped SNPs with the phenotypic variability in PWN response,

identified 9 SNPs associated with the phenotypic response after PWN inoculation. Some of the identified SNPs were related to the abscisic acid pathway, linoleic acid synthesis, and signalling responses downstream of pathogen perception. Overall, the results from the molecular analyses here presented contribute to clarify the underlying mechanisms involved in PWD resistance and provides SNPs that may be useful for selection/breeding purposes.

Characterisation of cuticular compounds of alternative vectors of pinewood nematode (Bursaphelenchus xylophilus) and the threat posed to UK forestry

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Abstract: Pine wilt disease (PWD) is recognised as one of the most serious threats to conifer forestry worldwide. The disease is caused by the pinewood nematode (PWN), *Bursaphelenchus xylophilus*, which has formed novel phoretic associations with different species of cerambycid beetles, in the genus *Monochamus,* in each new country it has become established in (Japan, China, Korea, Taiwan, Portugal, Spain, and its native North America). PWD continues to spread despite extensive border surveillance and containment efforts in the affected countries, whilst climate change and global movements exacerbate the risk of spread. PWN has been intercepted on infested material coming through UK ports and processors, and is expected to arrive in the UK in the coming years. In contrast to continental Europe, the UK has no indigenous *Monochamus* species. But does the absence of *Monochamus* preclude the establishment of PWN? We will examine the potential of alternative vector species that may facilitate the spread of PWN in the UK. The UK has genera of beetles (including but not limited to: *Tomicus, Hylobius* and *Pissodes*) which like *Monochamus,* carry out maturation feeding on healthy plant tissues, and could enable infection via primary transmission of the nematode, in the absence of *Monochamus*. These genera and other cerambycids are already known to carry related *Bursaphelenchus* spp. (although not *B. xylophilus*), and, therefore may have previously been overlooked as potential transmitters of PWN, both in the UK and Europe. PWN aggregates toward their *Monochamus* vectors in the pupal stage using chemical cues (volatile organic cuticular compounds, VOCCs) from the cuticles of the beetles. This research builds on existing work characterising and comparing the specific cuticular profiles of *Monochamus galloprovincialis* to candidate vector species native to the UK and Portugal. Comparing cuticular profiles could provide insight into why *Monochamus* is favoured and may also highlight candidate species for further investigation. We will discuss the implication of our findings on the projected security of UK pine forests in the absence of PWN's preferred vector.

Comparison of tree injection effects of abamectin and emamectin benzoate single and mixed formulation products against pinewood nematode

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Sang Myeong Lee[1]

[3] Kyungpook National University

Abstract: Tree injection is the most commonly used method to prevent pine wilt disease caused by Pine Wood Nematode (PWN). In Korea, abamectin and emamectin benzoate single agents are the most commonly used agents to prevent PWN infections. These nematicide and nematicide-insecticide mixed formulations are used to inhibit the proliferation of PWN and control insect vectors. This study examined the effect of each formulation and (or) product of these pesticides by injecting the recommended doses of the formulations in live pine trees two months prior to inoculation of PWN. The effect of preventing proliferation of PWN lasted for 2 years, but the efficacy was different depending on the formulation or product. Generally, the effect of emamectin benzoate products was significantly higher than that of abamectin. Among the abamectin formulations, the effect of micro-emulsion was significantly higher than that of the emulsifiable concentrate; and in emamectin benzoate formulations, the lowest effect was recorded in treatments with micro-emulsion. In mixed formulations, all treatments showed 100% prevention in the first year, but in the second year, the effect of abamectin mixture was lower than that of emamectin benzoate mixture. Emamectin benzoate products were superior to abamectin products as tree injection nematicides for the prevention of the PWN. However, since the effect varies depending on the product, it is thought that sufficient consideration is required when selecting the formulation.

Effectiveness of a DNA detection kit based on LAMP method for rapid detection of Bursaphelenchus xylophilus in Pinus pinaster

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

María Menéndez-Gutiérrez[1]
Lucía Villar Caamaño[2], **Raquel Díaz**[1]
[1] Lourizán Forest Research Center, Silviculture and Improvement, Pontevedra (Spain)
[2] Arume Foundation, Spain

Abstract: The conventional *Bursaphelenchus xylophilus* diagnostic methods involves the nematode isolation by the Baermann funnel technique and subsequent identification via morphological identification or molecular-based techniques using PCR or real-time PCR. These are time-consuming methods and requires specialized expertise. Nevertheless, a DNA detection kit based on loop-mediated isothermal amplification (LAMP) was recently developed to be used under field conditions and without the need of specialized techniques for a rapid detection. This methodology was developed using *Pinus densiflora* and *Pinus thunbergii* as *B. xylophilus* host and a Japanese isolate of this nematode. The aim of this study is to examine if this method is able to detect *B. xylophilus* isolates from different origins using *Pinus pinaster* as the nematode host and the efficacy of this detection kit.

We conducted two experiments, in the Experiment 1, *P. pinaster* wood chips were artificially inoculated with seven *B. xylophilus* isolates of different origins and after 30 days of incubation at 25 °C, the LAMP kit was used to detect the nematode. In Experiment 2, three-year-old *P. pinaster* seedlings were artificially inoculated with a Spanish isolate of the nematode and then sampled at 3 different dates after inoculation to determine the presence of the *B. xylophilus* using the LAMP kit.

The DNA detection kit evaluated was able to detect *B. xylophilus* isolates from all of the assessed origins and we observed the sensitivity of the detection increases when the nematode densities do.

Emerging Threats to Spanish Pine Forests: Exploring the Impact of Pine Wilt Disease on the Forestry Sector in Galicia

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Juan Picos[1]
María Menéndez-Gutiérrez[2], Raquel Díaz[2]
[1] Escola de Enxeñaria Forestal. Universidade de Vigo.
[2] Lourizán Forest Research Center, Silviculture and Breeding Department, 36153, Pontevedra, Spain.

Abstract: One of the current concerns for Spanish and European pine forests lies in the pinewood nematode Bursaphelenchus xylophilus (PWN), responsible for causing pine wilt disease. This nematode has emerged as one of the most dreadful threats in those countries where it is not native, leading to substantial environmental and economic damages in stands of various pine species. Portugal, where the nematode was first detected in Europe, has been designated as a demarcated area due to the infestation severity. In Spain, bordering regions with Portugal (Extremadura, Galicia, and Castilla y León) have experienced some disease outbreaks since 2008. Anticipated models indicate a natural expansion of the disease in these areas over the next decade.

Galicia, in NW Spain, is likely the Spanish region most vulnerable to this disease and where the economic impact can be particularly unfavourable. This is due to the vast area of stands of pine species susceptible to this disease (P. pinaster, P. radiata and P. sylvestris) and the significant economic and social importance of the softwood value chain. Furthermore, there are factors that contribute to the difficulties in controlling a potential outbreak and exacerbate the impacts, not only of an actual infection but also of the perceived risk that it is possible. With 98% of the region's forests under private ownership and extensive fragmentation, the value of standing timber becomes highly vulnerable when mandatory measures are imposed. The threat of PWN intensifies the incentive to switch to Eucalyptus or even consider abandoning forestry activities altogether. Additionally, the southern parts of Galicia are recurrently plagued by forest fires, which pose a risk due to the presence of burnt wood.

Present work aims to comprehensively examine and explore the potential ramifications of the expanding pine wilt disease on the forestry sector, specifically within the pine wood value chain and associated processing industry in the northwest of the Iberian Peninsula. The analysis considers the imminent risk of disease spread and its impact. Alongside the direct mortality induced in forests, the study also delves into the effects of containment and control policies, shedding light on their efficacy and implications.

Examination of the effect of nematicide injection on pine trees in the natural occurrence of pine wilt disease

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Abstract: The effect of nematicide tree injection on Pine Wood Nematode (PWN) is normally tested by artificially inoculating PWN after tree injection with nematicides. However, in the current study, the efficacy of nematicides in preventing proliferation of the PWN and eventual tree death was examined on black pine, *Pinus thunbergii* on an island that is naturally infested by PWN. The number of dead pine trees and the number of pine trees infected with PWN were investigated for 1 to 3 years after tree injection with abamectin, emamectin benzoate, and acetamiprid and emamectin benzoate mixed formulations. The number of dead trees decreased by more than 90% in treated pine tree stands in both the 1st and 2nd year when compared to the initial tree-death rate before treatment. Among the dead pine trees, the number of trees in which PWNs were detected decreased by more than 85% in the first year, and by more than 93.8% in the second year when compared with the initial detection rate in dead tree stands sampled before treatment. On the other hand, in untreated tree stands, pine tree death increased by 46.2% and 75% after 1 and 3 years, respectively; and the number of dead trees in which PWNs were detected increased by 68% in the first year and by 4% in the second year. Our results therefore showed that when PWN outbreaks were left untreated, the occurrence of dying trees markedly increased every year. And in nematicide tree-injected treatments, the number of dead trees in the second year was lower compared to the first year, proving that the tree injection had a significant effect on suppressing the pine wilt disease.

Identification of new parasitism-related target genes in the migratory endoparasitic nematode Bursaphelenchus xylophilus.

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Abstract: The migratory plant-parasitic nematode (PPN) *Bursaphelenchus xylophilus* (pinewood nematode, PWN) is a European quarantine organism listed as a top pathogen that causes economic and ecological damage to the coniferous forestry industry. To find new solutions in sustainable agriculture and forestry systems, is essential to understand the mechanisms of parasitism. The interactions between the nematode and the host are mediated by proteins which are critical molecules during infection. Most of these proteins are (potentially) produced in the pharyngeal gland cells, considered a specialized tissue and are delivered into the host to promote the disease. Supported by genomic and transcriptomic data previously established for the PWN, a promoter DNA motif (STATAWAARS) was identified and associated in the promotor region of different secreted pharyngeal gland cells coding parasitism-related genes, allowing the identification of a large set of genes potentially involved in the infection. The analysis of the top most abundant genes revealed a repertoire of sequences that have no known annotation or similarity to other identified sequences - novel or *pioneer* genes. These genes are enriched in these tissues and are species-specific and/or genus specific. By *in situ* hybridization we validated that some of these specific proteins are expressed in the pharyngeal gland cells. Oxidative stress assays revealed that some gland cells-expressed *pioneer*genes have an up-regulation when exposed to an oxidative agent, suggesting that these proteins might have an important biochemically function in the ROS scavenging. Considering the extensive damage caused by PWN, the finding of new parasitism-related proteins represents new targets for the development of new biotechnological solutions for nematode control.

Abstract: Traditional forest-tree breeding programs provide society with improved tree growth and stem straightness. Recently, the most advanced forest breeding programs also try to meet the needs of the forestry industry by improving their breeding populations for wood quality. In addition, globalization and climate change have highlighted the importance of considering resistance to biotic and abiotic agents in these programs. The Galician genetic breeding program for Pinus pinaster began in the late 80s to supply the demand of the Galician forestry sector. The selection criteria was mainly growth and stem straightness. First-generation seed orchards were established based on these traits. The feasibility of adding wood quality traits, basic density and modulus of elasticity, as selection criteria has recently been explored. Regarding forest health, the pinewood nematode (PWN), Bursaphelenchus xylophilus, is one of the most important threats to P. pinaster. In fact, this disease has caused an enormous impact, both economically and ecologically, in some Asian and European countries, where it is not native. For this reason, the study of PWN-resistance in families of P. pinaster from the Galician breeding program has also been performed. To advance in the breeding program, we focused on traits related to growth, stem form and wood quality as well as forest health (i.e., PWN resistance). Growth traits and wood quality were studied in several half-sib progeny trials, measured at age 12. Since PWN is a quarantined organism in the European Union, PWN resistance was evaluated in two-year-old seedlings under controlled greenhouse conditions. Results proved that evaluated traits were heritable at the studied age and no significant relationship was found between the most important traits, apart from the positive one between basic density and modulus of elasticity. Finally, we have defined different breeding scenarios considering the PWN resistance to compare the genetic gain obtained for each trait in each case and we have also discussed how they would impact the Galician breeding program.

Monitoring the Threat: Surveillance of Bursaphelenchus xylophilus in Croatian Forest Stands

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Nikola Zorić[1]
Dinka Matošević[1]
[1] Croatian Forest Research Institute, Division for Forest Protection and Game Management

Abstract:
Bursaphelenchus xylophilus, the causative agent of Pine Wilt Disease (PWD), poses a significant global threat to forest ecosystems. Although currently absent in Croatia, its potential impact necessitates proactive surveillance. Hence, we have developed a comprehensive surveillance strategy adhering to EFSA guidelines, which emphasizes early detection, rapid response, and prevention of its introduction and spread.
Our surveillance program incorporates visual inspections and pheromone traps targeting the insect-vector Monochamus genus. Unmanned Aerial Vehicle (UAV) technologies are leveraged for expansive coverage, with a particular focus on high-risk areas such as ports, nurseries, and sites with imported wood products.We place a strong emphasis on regular monitoring and data collection from Croatian forests. This data, covering aspects such as the nematode's distribution, population dynamics, and potential vectors, is crucial for implementing effective control measures such as quarantine, sanitation practices, and targeted interventions.

The surveillance program's primary objectives are to detect any incursion of B. xylophilus and monitor its potential spread. The economic and social implications of these measures are profound, aiding in mitigating potential impacts on Croatian forest ecosystems. Future prospects involve exploring additional control methods such as tree eradication and breeding for resistance. Our proactive approach aims to safeguard Croatian forests' biodiversity and economic value from PWD, providing valuable insights for informed decision-making in forest management, thus aligning with global efforts to combat this disease.

Natural subsidence of pine wilt disease epidemic in a forest stand located at the northern-limit of the disease-affected area in Japan

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Katsunori Nakamura-Matori[1]
[1] Tohoku Research Center, Forestry and Forest Products Research Institute

Abstract: The temporal pattern of the extent of damage by pine wilt disease (PWD) often differs among the forest stands even when they are located close to each other. Although the epidemic finally leads to a severe decline of the pine trees in most cases, we occasionally encounter a case where the epidemic seems to subside naturally with a substantial number of pine trees remaining when the stand is situated in cool temperature conditions and thus usually at the frontline of the PWD-affected area. In fact, we traced a subsidence of PWD in a *Pinus densiflora* stand located in the northern-limit area of the PWD-affected area in Japan, by investigating the yearly change in the number of PWD-killed trees and the vector density in the stand. The long-lasting occurrence pattern of the small number of PWD-killed trees was considered to be attributed to the opportunistic exteriorization of latent infection of the pathogenic nematode, *Bursaphelenchus xylophilus*, as a residual effect of a past outbreak of the disease. No or only a small number of adults of the vector insect, *Monochamus alternatus*, had been recorded for years regardless of the occurrence of weakened pine trees by shading and wind- or snow-broken trees, indicating that the vector insects have less chance of immigration and manage to maintain their population in the stand. The cool temperature condition slows the symptom development of the diseased trees, and decreased proportion of summer-autumn dead trees militate against propagation of the insects. Consequently, PWD can subside naturally after an outbreak event when there is no continual immigration of the vector insect and under climatic conditions unfavorable for the efficient propagation of the vector.

Plant secondary metabolites for effective control of Bursaphelenchus xylophilus

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Abstract: Plant secondary metabolites (PSMs), small molecular products derived from plant secondary metabolism, are highly interesting due to their proven insecticidal, nematicidal or bactericidal activities. Considered a serious threat in Eurasian pine forests, the plant parasitic nematode *Bursaphelenchus xylophilus* is the causal agent of Pine Wilt Disease, for which conventional pest management strategies have not yet successfully accomplished eradication. In line with EU Agenda 2030 for sustainable development, most of the synthetic nematicides usually used are now banned from the list of recommended active substances and plant protection products (EC 1107/2009). Therefore, aiming the development of sustainable plant protection products, we evaluated the nematicidal activity of 35 PSMs against *B. xylophilus* in direct contact bioassays. Nematodes were exposed to 2 mg/mL of each PSMs during 24 h, after which mortality was determined. Overall, 11 PSMs were able to attain a mortality higher than 50%. Only four PSMs (benzaldehyde, carvacrol, thymol and octanol)could achieve full mortality.Additionally, comparing with the conventional nematicide emamectin benzoate, 7 PSMs showed higher nematicidal activities. Further studies will address the effect of the 4 PSMs in plant host and their impacts in other soil and pine tree organisms.

This work was funded by National Funds through FCT to PB by SFRH/BD/134201/2017, to JMSF by 2022.00359.CEECIND (NemACT) and projects NemaWars (PTDC/ASP-PLA/1108/2021) + UIDB/05183/2020 to MED, UIDP/50017/2020+UIDB/50017/2020 + LA/P/0094/2020 to CESAM.

Proteomics on host tree-pinewood nematode interactions

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Joana Cardoso[1]

[2] CNC-Center for Neuroscience and Cell Biology, University of Coimbra, Rua Larga, Polo I, 3004-504 Coimbra, Portugal

Abstract: The pinewood nematode (PWN), *Bursaphelenchus xylophilus*, is the causal agent of the pine wilt disease (PWD) and is considered one of the most severe forest pests worldwide. During the last 20 years, advances have been made for understanding the molecular bases of PWN-host tree interactions. Major advances emerged from transcriptomic and genomic studies, which revealed some unique features related to PWN pathogenicity and constituted fundamental data that allowed the development of postgenomic studies. Proteins are the final product of gene regulation and provide the final evidence of the function of a gene. Therefore, proteomic studies are fundamental to discovering what proteins are produced and clarifying which molecules are directly involved in the parasite-host interaction. From these, the PWN secreted proteins have been of particular interest as they are directly involved in this interaction. Advanced proteomics methodologies using a robust platform for differential protein profiling, namely data independent acquisition mass spectrometry methods, were explored to analyze *B. xylophilus* secretomes stimulated with aqueous extracts from pine species with contrasting susceptibilities (*Pinus pinaster* and *P. pinea*) and secretomes of PWN isolates with different virulence. Several putative *B. xylophilus* virulence biomarkers were identified, most associated with peptidase and glycoside hydrolase activities. Additionally, proteome profiles of *B. xylophilus* inoculated and non-inoculated *P. pinaster* and *P. pinea* seedlings are being obtained and analyzed. Proteomic methodologies have been useful for understanding cellular activities, protein functions, and metabolic pathways involved in host tree-PWN interactions, shedding light into the mechanisms associated with PWN pathogenicity and host trees resistance/susceptibility.

Relationship between the pinewood nematode distribution in pine stem and embolism development

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Ai Akami[1]
Kenji Fukuda[1, 2]
[1] Department of Natural Environmental Sciences, Graduate School of Frontier Sciences, The University of Tokyo, JAPAN
[2] Department of Forest Science, Graduate School of Agricultural and Life Sciences, The University of Tokyo, JAPAN

Abstract: The development of xylem embolism in Japanese black pine (*Pinus thunbergii*) seedlings after inoculating the pinewood nematode (*Bursaphelenchus xylophilus*, PWN) was monitored by compact magnetic resonance imaging (MRI). In parallel, the nematode distribution and population structure in the 1-year-old stem of the seedlings were examined by isolating the nematodes from 1-year-old stem segments cut into the length of 1 cm by the Baearmann funnel technique.

From the MRI observations, embolism development in the inoculated seedlings was categorized into five phases according to the occurrence and the length of massive embolisms. The vertical length of massive embolisms was found to correspond to the maximum relative embolized area (REA, %) in stem cross-sections of the seedling. The massive embolism initialized from any point of the stem, not restricted to the inoculation site. Nematode population burst started when the maximum REA reached ca. 50%, and then rapidly increased within a few days. The nematode population in the xylem of the whole 1-year-old stem strongly correlated with the maximum REA in the stem, while the nematode population in the 1 cm long stem segment weakly correlated with the REA. This result can be explained by longitudinal nematode movement beyond the segments. The nematode population in the whole 1-year-old stem also highly correlated with the maximum circumferential proportion of cambial death seen in the cross-sectional MR images. Moreover, the proportion of second-stage juveniles of PWN also correlated with the REA in the xylem. In contrast, the nematode population in bark tissue did not correlate with either the REA or cambial death.

These results suggest that, in pine wilt disease, nematode reproduction in the cambial zone is a key step in the development of massive embolism and tree death.

The current diagnostic methods for pine wilt disease in Korea

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Hyerim Han[1]
[1] Forest Entomology and Pathology Division, National Institute of Forest Science, Republic of Korea

Abstract: Pine wood nematode (PWN), *Bursaphelenchus xylophilus*, is the causal agent of pine wilt disease (PWD), which results in the most destructive disease to many coniferous species. South Korea is one of the most severely damaged countries and more than thirty years have passed since PWD was first found in Busan in 1988. To date, the system of PWD investigation and diagnostic techniques has been dramatically changed and developed. NFC electronic tags are in use to prevent the monitoring blind spots, and a record management system using QR code from the monitoring and diagnosis of dead pine trees to control has been established. In addition, for rapid diagnosis of PWD on-site, we developed two on-site PWN detection methods using a recombinase polymerase amplification (RPA) assay and loop-mediated isothermal amplification (LAMP) assay. For RPA assay, the primer set sequences Bx_ITS2_F1 (5′-Biotin-GCACGTTGTGACAGTCGTCTCGCATTGTTC-3′) and Bx_ITS2_R1 (5′-FAM-TCGAGCACGAAGCCCTCTCGCCCCGCACGG-3′) were designed in order to amplify a 129 bp fragment exclusively from PWN genome. RPA assay for PWN detection was optimally conducted at 37°C for 15 min using PWN gDNA, and the detection limit of our RPA assay was 1.6pg of gDNA from PWN. For LAMP assay, the primers set was designed after aligning internal transcribed spacer sequences from the genus of *Bursaphelenchus*. The LAMP primer set sequences are BX-F3(5'-GCAGAAACGCCGACTTGT-3'), BX-B3(5'-GCGCCGTTGAAACAACATC-3'), BX-FIP(5'-CCGCGTAAAACAGATGGTGCCT+AGTTTCTGCACGTTGTGACA-3'), BX-BIP (5'-TACGCACTGTTTGTCCGTGCG+ACCAAACGGTTTAGCCGC-3'), BX-LF (5'-GCGAACAATGCGAGACG-3') and BX-LB(5'-CTTCGTGCTCGATTGTCGTGC-3'). The system proposed in this study is high-performance capable of diagnosing PWN up to 1pg, detection was optimally conducted at 62°C for 15 min using PWN gDNA. The developed rapid diagnosis methods on-site protocol follows;
Collect the wood chips from dead pine trees. Add the 1ml DNA extraction buffer in a 2ml tube containing 10 pieces of wood chips and incubate at room temperature for 10 min. After incubation, add 2μl of lysate solution to the diagnosis mixture. And amplify DNA 15 min at 37°C for RPA, or 62°C for LAMP, respectively. After DNA amplification, add the SYBR green I dye and measure the absorbance value which can distinguish the negative and positive reactions.

The geo-historical process of formation, inhibition and release of the virulence of Bursaphelenchus xylophilus

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Hongyi Wang[1]
[1] Technology Center of Xiamen Customs, P.R. China

Abstract: After the invasion of pine forests in Eurasia, *Bursaphelenchus xylophilus* which was widely distributed in North America was found with virulence. In the long geo-historical evolution of *B. xylophilus* that native from the Eastern North America, its virulence produced and was later suppressed, due to the coevolution with host *Pinus* spp. and the impact of changes in pine forest environment of the North America.
According to the distribution of Pinus fossils in different geological ages and the distribution pattern of *Pinus* spp. in present, it shows that the diversity of *Pinus* spp. has increased significantly with the decrease of the average temperature of the earth since the Cretaceous; The divergence intensity of *Pinus* spp. and its evolution level in the North America is higher than that in Eurasia. Therefore, the evolution level in the *B. xylophilus* group nematodes represented by *B. xylophilus* with virulence in the North America is also higher than that represented by *B. mucronatus* in Eurasia by the high divergence intensity of *Pinus* spp. However, in the process of coevolution with host plants, the virulence of nematode eliminated the susceptible host, further promoted the evolution of pine trees, and formed new species that could inhibit the *B. xylophilus* virulence after the earth cooled since the Holence. Obviously, *Pinus* spp. in Eurasia had no experience of coevolution with *B. xylophilus*, so that *Pinus* spp. in Eurasia cannot resist the attack of *B. xylophilus* with virulence when it invaded from the North America.
Of course, the virulence release of *B. xylophilus* is also caused by vector insects with high transmission efficiency, and the higher temperature environmental conditions in the subtropical arid areas in Eurasia, but these are not the main factors. Compared with the long geo-historical process of evolution in North America for tens of millions or even hundreds of millions of years, in the short time of invasion to Eurasia for more than 100 years, how to reduce the damage of *B. xylophilus* to Eurasia pine forests under natural conditions, we may find answers in it.

The Pine Wilt Disease in the Iberian Peninsula: 25 years after the first detection of Bursaphelenchus xylophilus

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

[3] Instituto Conservação Natureza e Florestas, IP. Av. República, 16. 1050-191 Lisboa, Portugal

Abstract: Pine Wilt Disease (PWD), caused by the pinewood nematode (PWN) *Bursaphelenchus xylophilus*, is a causal agent of mortality of pines (*Pinus*) in countries where it was accidentally introduced, i.e in Japan, China, Korea, Taiwan, Portugal and Spain. International trade of infected wood is the main pathway for PWD spread. In the Iberian Peninsula, *B. xylophilus* causes mortality mainly in maritime pines (*Pinus pinaster*), although small plantations of *P. nigra* and *P. radiata* were also found affected by the nematode. Efforts implemented by the Portuguese Forest Authoritiy (ICNF) follow the guidelines of the Commission Implementing Decision 2012/535/EU. These actions involve forest surveys to detect and eliminate wilting and declining pine trees, during the autumn and winter months, placing of traps to monitor and control the insect-vector (*Monochamus galloprovincialis*) during its spring-summer flight period, regulation and inspection activities to economic operators (e.g., wood transport, wood exports), and public awareness.

In this presentation, we will give a general overview of the Portuguese national strategy against this alien pathogenic nematode, with an update on the PWD management made during the last 25 years, with the overall impact in the Portuguese pine forests and the changes and improvements made along the years on the strategies and methodologies applied. The evolution of the situation in the Spanish territory, since the first detection in October 2008, will also be presented.

Finally, on-going research will also be reported, aiming not only the improvement of remote detection of wilting pines and the insect-vector trapping but also the development of innovative survey and control methods based on Volatile Organic Compounds released by the PWN and its insect-vector, within projects such as "PURPEST-Plant pest prevention through technology-guided monitoring and sitespecific control" and "Reassessing the threat posed by the pinewood nematode (*Bursaphelenchus xylophilus*) to UK forestry: exploring alternative vectors and novel detection tools".

Key words: Pinewood nematode, *Monochamus galloprovincialis*, control, Europe.

The PineWALL project – Linking pine cell wall composition and structure to pinewood nematode resistance

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

[4] University of Porto, Faculty of Sciences, Associated Laboratory for Green Chemistry, REQUIMTE, Porto, Portugal

Abstract: The pinewood nematode (PWN), *Bursaphelenchus xylophilus*, uses its stylet to perforate cell walls (CW) while releasing CW hydrolytic enzymes. Thus, understanding CW chemistry and structure is essential to unveil how it may influence host susceptibility to PWN. To achieve this, an innovative transdisciplinary project (PineWALL – FCT-PTDC/ASPSIL/3142/2020) was established. Saplings of *Pinus* species with different susceptibilities to PWN infection (*P. pinaster*, *P. halepensis* and *P. pinea*) were inoculated with PWN and disease progression was monitored under controlled temperatures (25°C and 30°C) and different irrigation regimes. At the end of the assays, differences in nematode reproduction factors were determined. Vibrational spectroscopy techniques (FTIR and Raman) are being applied for a global CW characterisation. Preliminary data revealed that there are significantly different CW compositional properties between PWN-inoculated and non-inoculated *P. pinaster* samples. Namely, phenolic compounds are upregulated in PWN-inoculated plants, presumably as part of defence mechanisms. Chemical analytical methods will be employed to further characterise different CW fractions. We also intend to employ immunological approaches to unveil the CW glycome profile and reveal *in muro* glycan distributions. By the end of the project, all data will be integrated to identify CW biomarkers that may be applied to predict pine susceptibility/resistance to PWN infection.

Transcriptional changes in response to 3-octanol in the plant-parasitic nematode Bursaphelenchus xylophilus.

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Margarida Espada[1]
Pedro Barbosa[1], Madalena Mendonça[1], Cláudia S.L. Vicente[1]
[1] MED – Mediterranean Institute for Agriculture, Environment and Development, Instituto de Investigação e Formação Avançada, Universidade de Évora, Pólo da Mitra, 7000-083 Évora, Portugal

Abstract: The pinewood nematode, *Bursaphelenchus xylophilus*, is one of the most damaging plant parasite, causing economic and ecological losses in coniferous forestry industry. The spread of pinewood nematode (PWN) has a direct impact on natural resources and wood industry, and an indirect effect on the restrictions in the circulation of wood products from affected areas worldwide. Currently, the strategies used for PWN control are preventive. Application of chemicals to control PWN is possible but it's not a sustainable and efficient option. The search for new control strategies in line with the EU's sustainability goals highlight significant knowledge gaps.

Compounds naturally produced by plants might play an important role in nematode control. Independent experiments were conducted to evaluate the molecular response of the root-lesion nematode *Bursaphelenchus xylophilus* to 3-octanol ($C_8H_{18}O$). Nematicidal activity of the 3-octanol was accessed at a 2 mg/mL concentration for 30 minutes. Bioassays were performed following the standard direct contact methodology. Nematode transcriptomic analysis revealed that the presence of 3-octanol can have an effect (upregulation) in the expression of different genes involved in the xenobiotics biodegradation metabolic pathways and a down-regulation effect in the expression of genes related to lipid and carbohydrate metabolism pathways. This study might generate important results and understand the mode of action of these nematicidal molecules providing new targets for nematode control.

Funding: NemaWAARS project is funded by National Funds through FCT - Foundation for Science and Technology under the Project PTDC/ASP-PLA/1108/2021 and CEEC'18 for M. Espada (CEECIND/00066/2018) and C. S.L. Vicente.

Volatile organic compound (VOC) profiles as a fingerprint for pinewood nematode detection – Development of a new portable detection tool

T1.33 The Pine Wilt Disease dramatic impact on conifers forest across the world, today and in the future

Abstract: Pine wilt disease (PWD) has spread rapidly and evaded pest management strategies in many Asian countries. In Europe, the first detection of its causal agent, the pinewood nematode (PWN), occurred in Portugal, in 1999. Since then, the PWN has been detected throughout Portugal mainland, Madeira Island and in Spanish pine forests from Galicia and Estremadura provinces. In the last two decades, containment and mitigation of this priority pest has mobilized extensive investment. These efforts were partially inefficient, due also to the limited efficacy of the available detection and monitoring techniques. PURPEST (purpest.eu) proposes that volatile organic compound (VOC) profiles specific to the PWN can be used to construct a VOC-based system (Sensor System) for the detection of infected material. This system has the potential to revolutionize the current methodologies by offering an alternative to the traditional collection of wood samples and screening for PWN. To accomplish this task, VOC profiles of the PWN and infected pine material will be analysed through headspace GC-MS, and then used to fine-tune sensor components for the development of optimized sensor systems and, finally, a sensor system prototype will be validated in the field and at import control sites. Implementation of PURPEST advances pest management strategies by allowing an early detection of PWD and increasing the inspection rate in pine stands and woody material from coniferous importations with a non-invasive, reliable and high throughput methodology thus preventing entry into new forestry areas.

PURPEST is co-funded by the EU through grant agreement 101060634.

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

Continuous cover forestry for diversification of forest benefits: a case from small-scale forest farmers in Sweden

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

Nataliya Stryamets[1]
Marine Elbakidze[1], Thomas Hahn[2]
[1] Swedish University of Agricultural Sciences, Faculty of Forest Sciences, School for Forest Management, Skinnskatteberg, Sweden
[2] Stockholm Resilience Centre, Stockholm University, Stockholm, Sweden

Abstract: Politicians, decision-makers, and foresters at multiple levels highlight that climate change has become a major factor influencing forest management decisions, and there are ongoing debates concerning what type of forest management provides more opportunities for climate change mitigation and adaptation. Continuous Cover Forestry (CCF) is seen as forest management based on ecological principles with a view to avoiding degradation effects, including those triggered by climate change. However, there is a lack of studies on how to do transitioning toward CCF in countries where other forest management systems dominate.

This study aims to identify and compare the benefits attributed to continuous cover forestry (CCF) by forest farmers who are the pioneers of CCF in Sweden, and to analyze how they perceived obstacles and opportunities for transitioning towards this type of forest management. In Sweden forestry conducted by forest farmers has a long tradition; the clear-cutting model is dominating while CCF covered only less than 3%

In total, 20 qualitative, semi-structured interviews of residential forest owners were conducted during January-April 2023. The average age of interviewees was 63 years old, all with higher education. For all interviewees, except one forest owner, the income from forestry was of secondary importance. Forest owners are concerned about climate change and how to get diverse climate benefits from their forests. Our results show that forest farmers attributed multiple intangible benefits to CCF such as biodiversity, forest health, carbon storage and sequestrations, microclimate regulation and resistance to drought, aesthetical, cultural, and recreational values. Among the attributed tangible benefits were economic benefits (to reduce costs on tree planting, thinning), increased yields of berries and mushrooms, hunting, and higher timber quality. We discuss challenges (e.g., availability of small types of machinery), opportunities (e.g., ecological, aesthetical, and economic benefits), barriers (knowledge gaps, and traditions in forestry), and possibilities (e.g., subsidies and grants) for transitioning from clear-cut to CCF forest management.

Effect of Norway spruce shelter density and soil scarification method on mortality and height growth of underplanted beech, silver fir and Douglas fir

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

[3] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Sundsvägen 3

Abstract: In Europe, 6-7 million ha even-aged, pure stands of Norway spruce grown outside its natural range are prone to natural disturbances. Climate change may accelerate these problems necessitating methods for converting these plantations into more heterogeneous forest with larger resistance towards natural disturbances. Based on an experiment on former heathland, we examined mortality and height growth of European beech (*Fagus sylvatica* L.), European silver fir (*Abies alba* Mill.), and Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco) planted under shelterwood of 17-19 m tall Norway spruce (*Picea abies* (L.) Karst.) at shelter densities initially ranging by basal area from 10 to 36 m^2ha^{-1} (271-1099 stems ha^{-1}). Underplanting included plots of beech (100%) and silver fir (100%) as well as plots with two-species mixtures of silver fir/beech (66%/33% and 33%/66%) and Douglas fir/beech (66%/33%). The experiment also included two soil scarification methods (patch and strip scarification). The experiment was an unbalanced factorial split-plot design, replicated in time and space, and totaling 144 plots in four blocks. The experiment was followed for 19 years during which a gradual reduction in shelter density took place although in some plots the shelterwood was removed abruptly by e.g. windthrow. Shelter densities larger than 10 m^2ha^{-1} had a minor effect on the mortality of beech and silver fir, while shelter densities larger than 20 m^2ha^{-1} resulted in increased mortality of Douglas fir. Subsequent abrupt reduction in shelter density resulted in increased mortality. Height growth decreased with increasing shelter density, more for Douglas fir than for beech, and marginally more for beech than for silver fir. For shelter densities less than 15 m^2ha^{-1}, height growth of silver fir was unaffected. Beech grew faster when mixed with Douglas fir. The soil scarification method did not influence mortality, but strip scarification resulted in marginally larger height growth than patch scarification. The shelter effect was related mainly to competition for light, while late frost and browsing were important in open shelters (<10 m^2ha^{-1}). Based on these results, recommended initial shelter densities are ≤10 m^2ha^{-1} for the establishment of Douglas fir, approximately 15-20 m^2ha^{-1} for silver fir, and around 15 m^2ha^{-1} for beech.

The trees, the people and the marteloscope – What human tree selection behaviour can tell us about CCF training requirements

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

Arne Pommerening[1]
[1] Department of Forest Ecology and Management, Swedish University of Agricultural Sciences SLU, Sweden

Abstract: Research into human tree selection behaviour started in the 1990s and only gradually expanded in Europe and North America. The main objective of this research field is to understand how humans – professionally and unprofessionally – interact with the trees in the forest. Human-tree interaction can be best measured when test persons are asked to select trees for various purposes, e.g. for commercial forestry scenarios, for conservation or recreation. A specialised research plot, the marteloscope, has been proposed for hands-on training but also for designing research experiments. Research results particularly of the last two decades have taught us valuable lessons about how humans with different backgrounds respond to training and to tree selection tasks. We also understand much better the subtleties of the ways how trees influence human decisions. In addition, marteloscope experiments leave a time-stamped snap shot of the current skill set of forestry staff in a given region and their agenda towards forest management. This offers strategic information for designing regional and national training programmes for fostering the uptake of new types of forest management such as CCF or conservation but can also be employed for establishing a system of quality assurance ensuring that training programmes are effective and adapt. National and international projects in Europe annually collect hundreds of data records on human tree-selection behaviour that are not properly analysed with a view to deepen our understanding of human tree-selection behaviour. Low-cost citizen-science approaches and strategic partnerships between such projects and universities could fundamentally help improve the scientific basis of training.

Transforming Sitka spruce monocultures to continuous cover forestry in Ireland

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

Grace Jones[1]
Ian Short[1], Áine Ní Dhubháin[2], Edward Wilson[1, 2]
[1] Teagasc, Forestry Development Department, Ireland
[2] University College Dublin, School of Agriculture and Food Science, Ireland

Abstract: Clearfell forestry continues to be widely practiced, both in Ireland and internationally, partially due to a lack of growth and development data from alternative forest management options. However, it is increasingly important to maintain some forest cover since forests are often expected to provide continuous multiple benefits, such as: timber production, habitat, soil cover and recreation. Here, data is presented from two Sitka spruce continuous cover forestry (CCF) trial sites in Ireland. These sites are some of the oldest ongoing CCF trials and the results include information on stand development and potential timber assortments under transformation to CCF.

In 2010 two stands of Sitka spruce, both ready for their first thinning, were selected to investigate different approaches to transformation for CCF. The three treatments applied to three plots in each stand were: low thinning, crown thinning, and graduated density thinning. Low thinning represents an industry standard where the smallest and worst trees are removed, whereas graduated density thinning removed more stems nearer to the extraction rows (racks) and fewer stems further from the racks. The graduated density thinning racks were shifted during the second thinning. Subsequent graduated density thinnings were the same as a crown thinning; quality trees were selected and favoured.

This presentation reports on the stand development, including stem diameter distribution and tree volumes (from Ireland's Tree Volume and Carbon calculator), from 2010 to 2023. The log grades and volumes removed during the four thinnings are reported by treatment and site. Low thinning had the narrowest diameter distribution and removed the lowest volume of sawlog during the 2023 thinning for both sites. Graduated density thinning had the lowest standing volume, likely due to this treatment including heavy first and second thinnings. The results from these experimental trials will give insight into how the stand condition changes over time during the transformation process.

Transitioning southern pine plantations to continuous cover forests: Lessons from long-term stand conversion experiments in slash and longleaf pine

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

Ajay Sharma[1]
[1] Auburn University, College of Forestry, Wildlife and Environment, USA

Abstract: Continuous cover forestry (CCF) is not common in the southern United States, the region known for its highly productive and intensively managed pine plantations. However, increasingly, many private landowners and governmental land management agencies, who value naturally regenerating, resilient, diverse forest stands with timber production as only one among many management objectives, are seeking alternative management options that maintain continuous forest cover, such as uneven-aged forest management. Even though most silvicultural research has been focused on intensive management of plantations in the region over the past 70 years, several experiments have been conducted in the past two decades to identify techniques for effectively transitioning plantations to continuous cover. Data from the ongoing long-term, replicated, operational-scale silvicultural trials in longleaf (*Pinus palustris*) and slash pines (*P. elliottii*) at multiple sites in Florida and Alabama in the southern United States suggest that these pine stands can be effectively transitioned to continuous cover, uneven-aged stands, and that the transition can be economically as well as ecologically competitive alternative to existing even-aged management options. The transition silviculture harvest methods (e.g., group opening and single tree harvests) implemented in these experiments have been found satisfactory at naturally regenerating southern pines and maintaining stand and fuel conditions conducive to frequent fire regimes. While even-aged (clearcut-plant-clearcut) plantations may produce higher total merchantable timber in southern pines, naturally regenerating uneven-aged, continuous cover stands are efficient at producing saw timber and have been found to be more resistant and resilient to damages caused by climatic or natural disturbances, such as hurricanes in 2004 and 2018. The stands in transition have higher structural diversity and they maintain consistent pool of stand carbon. Based on data collected over two decades, this presentation will provide the current state of knowledge and the prospects of managing southern pines using CCF.

Transitioning to multifunctional landscapes in Sweden?- a place-based longitudinal case study covering five decades

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

Per Angelstam[1, 2]
Lucas Dawson[2]
[1] Inland Norway of Applied Sciences
[2] Swedish University of Agricultural Sciences

Abstract: Context: Public choice and complex global dynamics, including climate change, are driving desires for the growing suite of goods, services and values that society expects from forest landscapes. This is particularly true where intensive forestry practices have negative impacts on natural and cultural values, and on value chains dependent on multifunctional forest landscapes.

Aim: Focusing on the Swedish Tiveden forest massif as a hotspot for developing diverse forest-based value chains, this study has two aims: (1) To analyse five decades of projects and processes to support rural development through landscape planning, and alternatives to rotation forestry based on clearcutting. (2) To analyse the cross-sectoral “Collaboration Tiveden” platform for knowledge production and learning to identify barriers and bridges supporting the emergence of landscape planning and forest management systems contributing to multifunctional forest landscapes.

Methods: (1) Using grey literature, expert interviews and participatory observations we mapped efforts 1974-2022 to develop integrated landscape planning and forest management approaches to support multi-functional forest landscapes. (2) Based on focus groups with stakeholders, subsequent causal loop modelling with key stakeholders, and validation using independent data, we identify barriers and bridges supporting a transition away from industrial forestry towards multifunctional forest landscapes.

Results: Over five decades, a total of 11 projects aimed at sustaining multiple landscape values advocated comprehensive spatial planning to accommodate those. However, these ambitions failed to materialise. Systems analyses of driving forces supporting multifunctional landscapes, and independent monitoring data, clearly demonstrate negative effects of intensified forestry on natural and cultural values, on rural development, and on nature-based tourism. As a remedy attempt, a social platform for stakeholder collaboration demonstrates trials of “clear-cut-free” forest management. Nevertheless, the polarisation of forest landscapes increases, which stresses the need for both protecting high conservation value forests, and nature restoration.

Conclusions: Transitions to multifunctional landscapes require several forest management systems, and integrated spatial planning. Social learning through ongoing evaluation of place-based initiatives attempting this is crucial. Evidence-based mapping of the distribution and abundance of both material and immaterial landscape values is a prerequisite that needs to be satisfied

Variable-density thinning designs for harvester-based operations in northern Europe

T1.34 Transitioning to Continuous Cover Forestry in Times of Climate Change and Energy Crisis

Andreas Brunner[1]

[1] Norwegian University of Life Sciences

Abstract: Conversion to continuous-cover forestry (CCF) will be a major task for forest managers during the next decades. In the boreal forests of northern Europe, little experience with CCF exists and concepts for conversion to CCF are only starting to be developed and tested now. In contrast to forest management in central Europe, tree marking is uncommon in northern Europe and decisions about tree removal during thinning are made by harvesting machine operators.

Inspired by concepts for variable-density thinning (VDT) developed in Washington and Oregon 30 years ago, I developed a concept for conversion towards selection system structures. A main assumption of this concept is the creation of horizontal variation in tree sizes in young stands, where vertical tree size variation would be difficult to maintain due to the fast growth of young trees. The concept modifies the VDT concept of thinnings with skips and gaps in a way that harvester operators can assign the different treatments without prior tree marking. The concept further modifies the original VDT concept by applying crown thinning to variable density in the remaining matrix. Crown thinning is best to preserve and favor existing size variation. Crown thinnings differs substantially from the current practice of thinning from below.

The presentation will describe the design of the VDT treatment and illustrate examples from a series of demonstration plots established in Norway in 2023. Challenges for machine operators in learning and applying this new concept will also be addressed.

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

Analysis of miRNAs produced by the PPC-tolerant species reveals novel target genes in F. circinatum for their successful use in SIGS technology

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

[2] Sustainable Forest Management Research Institute (iuFOR), University of Valladolid-INIA, Spain

Abstract: It is known that small RNAs can be transported between plant hosts and their fungal pathogens, inducing target gene silencing in the counterpart through a phenomenon called cross-kingdom RNA interference. This mechanism of RNA-mediated communication is currently being elucidated in detail in plant-pathogen interaction models. In order to identify new and natural target genes in the pathogen, it is necessary to determine which host plant microRNAs (miRNAs) are involved in this phenomenon. miRNAs are a class of non-coding RNAs that play an important role in the regulation of gene expression through the RNA interference mechanism. This study aims to elucidate the essential miRNAs of pines that are delivered and responsible for the tolerance to the pathogen *Fusarium circinatum*. Therefore, miRNA molecules were extracted and sequenced from *Pinus pinea* (tolerant) and *Pinus radiata* (susceptible) during their interaction with *F. circinatum*. Through comparative analysis, we identified a dozen miRNAs produced by *P. pinea* that were not produced by *P. radiata*, with high sequence homology to transcripts of *F. circinatum*, suggesting that these genes would be the natural targets that the tolerant pine host specifically uses to inhibit Pine Pitch Canker (PPC) disease caused by *F. circinatum* though RNA interference. To verify the essentiality of these genes for fungal virulence, we performed knock-out experiments in *F. circinatum*, observing a reduction of virulence. Furthermore, we successfully utilized these genes as targets in SIGS (Spray-Induced Gene Silencing) technology, in which RNAs targeting pathogen virulence-related genes are externally sprayed onto plants. These RNAs can be taken up by the pathogens to silence their genes and inhibit disease formation, in our case PPC in pines.

Metabolomics of virulence and hypovirulence: Do hypovirulent Cryphonectria parasitica strains produce different metabolites than virulent strains?

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

Farooq Ahmad[1, 2]
Nobuhiro Suzuki[3], Julio Javier Diez Casero[1, 2]
[1] Sustainable Forest Management Research Institute, Universidad de Valladolid & INIA, Avda. de Madrid, 34004, Palencia, Spain.
[2] Department of Vegetable Production and Forest Resources, University of Valladolid, Avda. de Madrid, 34004, Palencia, Spain.
[3] Institute of Plant Science and Resources, Okayama University, Kurashiki, Japan.

Abstract: *Cryphonectria parasitica* causes chestnut blight disease and was responsible for the death of around 4 billion chestnut trees in North America. The disease can be controlled by applying *C. parasitica* isolates infected with *Cryphonectria hypovirus 1* (CHV-1), which decreases the disease severity. However, the method relies on using the pathogen itself, promoting the spread and establishment of the pathogen. In addition, a high genetic diversity, especially vegetative compatibility type diversity, of the pathogen makes biocontrol unsustainable. Therefore, a more sustainable approach is needed to control the disease. In this study, we hypothesized that viral infection in the fungus produces some metabolites to decrease fungal virulence. For this purpose, we infected virus-free fungal strains with CHV-1 or *Cryphonectria hypovirus 4* (CHV-4). Untargeted high-performance liquid chromatography coupled with mass spectrometry (HPLC-MS) is being done to see if some metabolites are only present in hypovirulent (CHV-1 infected) strains and not in virulent strains (virus-free strains or CHV-4 infected strains). Metabolite annotation will be performed to identify these active biochemicals. These chemicals will be further tested on virus-free strains to test their effect. By comparing metabolite profiles, we will gain insights into the biochemical factors associated with hypovirulence. These biochemicals will be available for future studies to develop bio-fungicides and help control the disease sustainably. This study will help bypass the unsustainable biocontrol method and provide an alternative to disease management.

Organic vesicles for dsRNA delivery in the control via SIGS of forest diseases, using the Phytophthora-Quercus and Fusarium-Pinus pathosystems

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

SANDRA MOSQUERA[1]
IRENE TERESA BOCOS ASENJO[1], JULIO JAVIER DIEZ CASERO[1], JONATAN NIÑO SANCHEZ[1]
[1] Department of Plant Production and Forest Resources, University of Valladolid, Spain. iuFOR Sustainable Forest Management Research Institute, University of Valladolid–INIA, Spain

Abstract: SIGS is a plant protection strategy in which dsRNAs are externally applied to plants to induce systemic gene silencing in targeted organisms and limit disease development. Despite the multiple examples showing its effectiveness for controlling plant pathogens and pests, the instability of RNA molecules and their reduced uptake by the targeted organism are still challenges that need to be overcome before using this technology in the field. Nanocarriers, including organic vesicles, have proven effective in overcoming both challenges as they improve the pathogen uptake and protect the dsRNA from nucleases and harsh environmental conditions. We evaluated whether these organic vesicles can deliver dsRNA specific to genes relevant to the *Phytophthora cinnamomi* and *Fusarium circinatum* infection. We applied the dsRNA-loaded vesicles to the plants inoculated with the pathogen. Then, we evaluated disease progression and the expression of the targeted genes in the hosts inoculated with the pathogens. Our work shows that coupling SIGS and nanocarrier technology is a promising strategy for the environmental-friendly management of forest diseases in the XXI century.

Population dynamics of RNA viruses in declining Mediterranean forests

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

Sergio Diez-Hermano[1]
Jonatan Niño-Sanchez[1], Wilson Acosta[1], Marcos De la Peña[2], **Julio Javier Diez**[1]

[2] Institute for Plant Molecular and Cellular Biology (CSIC-UPV), Valencia, Spain

Abstract: Global change alters forestry habitats and facilitates the entry of new pathogens that don't share a co-evolution history with the forest. Due to the combination of degraded forests and urban massification, the human population is particularly exposed to new infectious diseases, such as the coronavirus pandemic. For this reason, the study of RNA viruses is essential to understand how viral flow across different hosts and forest sanitary conditions might occur, and to prevent possible outbreaks of human diseases in the future. In this work the viral diversity found in trees, insects and fungi from Spanish Mediterranean forests is described. To this extent, three habitats (*Quercus ilex, Castanea sativa* and *Pinus radiata*) showing signs of decline were sampled in two different years (2021 and 2022) and RNAseq was performed on tree tissues, insects and fungi. Viral identities were assigned by searching for matches to conserved motifs of the RNA-dependent RNA polymerase (RdRP) using Palmscan. Up to 15 viral families were identified in 2021 sampling, with Botourmiaviridae (25%) and Partitiviridae (6%) being the most abundant. Distribution of viruses across ecosystem was: *Q.ilex* (57%), *P.radiata* (27%) and *C.sativa* (16%). These data will be compared to 2022 sampling taking into account the effect that trees' health status (declining/healthy) might have on the composition of the virosphere in each of the habitats. This approach constitutes a starting point to search for novel viruses that might be participating in unknown infectious pathways within forests and potentially posing a threat to the human being.

Spray-Induced Gene Silencing (SIGS) for controlling Phytophthora cinnamomi, the causal agent of Holm Oak decline

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

Irene Teresa Bocos-Asenjo[1, 2]

Abstract: *Phytophthora cinnamomi* is an oomycete pathogen that induces root rot in several plants, including forest species such as *Quercus ilex,* causing a disease called Holm Oak decline. Currently, no effective control measures for managing this pathogen exist. Chemical products cannot be applied in EU forests, which makes it difficult to control the disease. Spray-induced gene silencing (SIGS) represents a potential environmentally friendly tool to control *P. cinnamomi.* This strategy is based on RNA interference (RNAi), which is a conserved gene-silencing mechanism inherent to eukaryotic cells. RNAi is initiated by double-stranded RNA (dsRNA), which triggers the degradation of homologous messenger RNAs (mRNAs), preventing protein translation. SIGS strategy consists of externally applying dsRNAs molecules targeting essential genes of the pathogen. While this approach is actively being developed for agricultural pathogens, its exploration in forestry, and particularly for oomycetes, remains limited. Our research group designed and synthesized dsRNA molecules to silence important metabolic pathways for the survival of *P. cinnamomi* and evaluated their efficacy on different plant tissues and seedlings. We observed a reduction in symptom severity and delayed onset in seedlings when dsRNA was applied to the roots before infection. These findings indicate the potential utility of targeting essential genes with dsRNA to manage *P. cinnamomi*. Nowadays, forests are more threatened than ever before due to globalization and climate change, and the use of this technology to control forest pathogens is a novel approach that could offer an alternative to conventional management.

Spray-induced gene silencing (SIGS): An effective strategy to control Pine Pitch Canker caused by Fusarium circinatum

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

HUMA AMIN[1]
IRENE TERESA BOCOS ASENJO[1], SANDRA MOSQUERA LOPEZ[1], MIREILLE GINESY[1], JULIO JAVIER DIEZ CASERO[1], JONATAN NIÑO SANCHEZ[1]
[1] Department of Plant Production and Forest Resources, University of Valladolid, Spain. iuFOR-Sustainable Forest Management Research Institute, University of Valladolid–INIA, Spain

Abstract: *Fusarium circinatum*, an invasive fungal pathogen, is responsible to cause causes pine pitch canker (PPC) disease in Pine and other coniferous tree species. *F. circinatum* being a ubiquitous pathogen is responsible to target novel hosts and influencing million-hectare loss to forest stands worldwide. Current management practices are not able to pace up the forfeiture and outbreak of PPC, therefore novel and sustainable strategies are required to manage forest disease. Our present study is aim to control pathogenic fungus *F. circinatum* through SIGS (Spray-induced gene silencing). SIGS is based on RNA interference (RNAi), a conserved eukaryotic gene-silencing mechanism naturally occurring in cells. RNAi pathway is triggered by double-stranded RNA (dsRNA), which in turn, manipulate the expression of gene by the degradation of homologous dependent messenger RNAs (mRNAs) and disrupt the functioning of protein. The exogenous application of dsRNA through SIGS allows the uptake of molecules by fungus and thus exploiting RNAi mechanism. In our studies, we designed dsRNA molecules targeting essential genes of pathogen that are important to block various imperative pathways, crucial for pathogenicity and survival of *F. circinatum.* For a quick effectivity test of our pool of dsRNA molecules that target several genes of the essential fungal pathways, inoculation assays were conducted in Spinach leaves. The leaves of spinach showed inhibition of fungal growth. Subsequently, the designed dsRNAs were also applied exogenous on pine seedlings inoculated with *F. circinatum* and it ensued inhibition of fungal growth and delayed symptoms development. *F. circinatum* was able to uptake dsRNA to trigger RNAi and it was demonstrated by confocal assays. Transcriptomics analysis also support the reduction of infection in inoculated experiments. We also demonstrated the efficacy of same designed target dsRNAs on *Fusarium graminearum* and they were found successful to reduce symptoms of infection on wheat spikelets. This is the first ever work that described the use of RNAi in forestry to control *F. circinatum.* RNAi as a novel technology, can bring an innovative paradigm in forest disease management as SIGS is proficient, effective and eco-friendly strategy that can prove a promising tool to combat PPC pathogen in forest.

Virus elimination and effect assessment in isolates of Phytophthora cinnamomi

T1.35 Use of RNA strategies for the control of forest pests and diseases: mycoviruses and interfering RNA

Katerina Kovacikova[1]
Thomas Jung[1], Marilia Horta Jung[1], Leticia Botella[1]
[1] Phytophthora Research Centre, Department of Forest Protection and Wildlife Management, Faculty of Forestry and Wood Technology, Mendel University in Brno, Zemědělská 1, 61300 Brno, Czech Republic

Abstract: Over the past years, the presence of a variety of RNA viruses has been confirmed in a global collection of isolates of the panglobal invasive plant pathogen *Phytophthora cinnamomi*. These viruses are potentially useful as BCAs (biological control agents). To further investigate the effects of viral presence, absence and load on the biology of their host isogenic virus-free isolates were produced for comparative studies with naturally virus-infected isolates. Several virus elimination methods were combined, including monosporic and monohyphal isolation, polyethilene glycol (PEG) treatment and thermotherapy, to eliminate viruses from *P. cinnamomi*. Then, total RNA extraction and cDNA synthesis was carried out, followed by RT-PCR using specific primers to confirm whether viruses were eliminated. An *in vitro* experiment comparing virus-hosting and virus-free isolates was performed to assess significant differences in the temperature-growth relations and growth rates of these *P. cinnamomi* isolates.

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Active Timber Management by Outsourcing Stumpage Price Uncertainty with the American Put Option

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Sun Chang[1]
[1] Sun Joseph Chang School of Renewable Natural Resources Louisiana State University Agricultural Center Baton Rouge, LA USA 70803

Abstract: Timber production is an inherently risky business. Stumpage price fluctuates all the time, creating price uncertainty for forestland owners and managers. In this paper, we address this challenge by outsourcing it with an American put option to determine the reservation prices at different ages and calculate the corresponding reservation prices. When the spot price exceeds the reservation price at a particular age, the high stumpage price triggers an immediate timber harvest. The resulting harvest value and age are then incorporated into the generalized Faustmann formula to determine the corresponding land expectation value.

The simulation results showed that outsourcing stumpage price uncertainty with the American put option resulted in an average land expectation value of $6504/ha. This result is 37% higher than that of the $4745/ha under certainty assumption. But the average harvest age of 46 years is 50% longer than the 31 years under certainty assumption. Moreover, the result with the American put option approach is $101/ha less than that of the Brazee and Mendelsohn reservation price approach. To further enhance the outcome of the American put option approach, different partial put option coverages of the stand volume at age 70 were explored. A partial put option coverage of 60% of such volume resulted in an average land expectation value of $7116/ha with an average harvest age of 35.51 years, essentially the same as the $7121/ha and 35.45 years under the Brazee and Mendelsohn method. More importantly, the curvilinear relation between partial put option coverage and the average land expectation value provides intriguing opportunities to balance uncertainty tolerance and the average land expectation value. For example, an aggressive uncertainty seeking 30% partial coverage will produce a result of $6538/ha, slightly better than the $ 6504/ha of a conservative 100% coverage. Yet, the 26.85 years average harvest age of the former is less than 58% of the 46.15 years of the latter. Consequently, by balancing uncertainty and return with partial American put option coverage forestland owners become active stumpage price setters . It will usher in a new era of forest management with profound social and economic impacts.

Addressing uncertainty in forest carbon policy analysis

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

David Wear[1]
Matthew Wibbenmeyer[1]
[1] Resources for the Future, Washington DC, USA

Abstract: Policy analysis using forest and land sector models is sensitive to several factors that influence projections including model specification, measurement error, aggregation/attenuation bias, and uncertainty about future conditions. This paper considers the effects of modelling choices and of climate variation on carbon sink potential in the United States and estimates of potential policy efficacy. Our analysis is based on a coupled land use-carbon dynamics model we call the Carbon and Land Use Model, or CALM, that simulates land use changes between all persistent land uses on nonfederal lands and the resulting effects on carbon sequestration based on the dynamics of forest inventories for all ownerships (growth, disturbances, and harvesting) across ecological regions (we also account for carbon dynamics on other land uses). We estimate the influence of model specification choices in both land use choice and carbon components of the model on projections of national carbon sinks. Both are sensitive to how data are aggregated for modeling—i.e., the spatial scale of analysis—but also to model specification. Forest carbon projections are especially sensitive to how yield curves are specified. In addition, we consider the dual climate-driven effects of shifting forest productivity and forest disturbance regimes on these estimates. We explore model-averaging strategies for addressing risk and uncertainty in our policy modeling. However, while these sources of uncertainty may influence the precision of projections it's not clear that they alter, or bias policy prescriptions given the high social costs of greenhouse gas emissions.

Armington models within the framework of a partial equilibrium model for forest products markets

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Christian Morland[1]
[1] Johann Heinrich von Thünen Institute

Abstract: Trade plays an important role in the explanation of economic development, wealth, and intercultural exchange. Therefore, bilateral forest products trade is one key factor in the analysis of national and international policies and political strategies. In this context, side effects caused by shifting trade patterns, like leakage or changing production and trade structures, could undermine efforts for, e.g., climate protection or the preservation of biodiversity. The aim of this study is to analyse bilateral trade patterns in forest product markets and adapt them for scenario-based policy impact assessments within a global partial equilibrium model, namely the global forest products market model (GFPM). Currently, the model framework builds on the basic assumption of perfect competition and homogeneity of wood-based products across the world. Trade within such frameworks is only driven by prices and transport costs. However, this so-called "law of one price" (LOP) has a major disadvantage: if trade barriers or consumer preferences exist, the response of such a model may become unrealistic. Hence, we adopt and implement an alternative modelling approach, named the Armington model. The main assumptions within this framework are that (I) each country produces a certain type of good and that (II) consumers, depending on individual consumer preferences, want to purchase products from each country to a certain degree. This approach mirrors the idea of imperfect substitution between products of different origins. The key parameters in the framework are Armington-elasticities. They can be described as elasticities of substitution between domestic and foreign goods. Implemented in a partial equilibrium framework, it is assumed that these parameters will help to model more realistic response patterns for bilateral trade than market models based on the assumption of product homogeneity would. This study will outline how Armington-elasticities can be estimated for different wood-based products traded in international forest products markets, and it will be shown how these parameters can be implemented in the GFPM for scenario-based policy impact assessments.

Balancing Carbon and Costs: Unveiling the Climate Change Mitigation Potential and Opportunity Costs of Forest Lands Diverted from Forestry use

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Cornelius Regelmann[1]
Marlen Brinkord[1], Joachim Rock[2], Lydia Rosenkranz[1], Björn Seintsch[1], Matthias Dieter[1]
[1] Thünen Institute of Forestry
[2] Thuenen-Institute of Forest Ecosystems

Abstract: The revision of the Climate Protection Act in Germany has led to the adoption of more stringent climate protection targets. To accomplish this goal, specific carbon reduction targets have been established for the LULUCF sector by 2045. One potential measure for mitigating climate change and achieving LULUCF objectives is the permanent cessation of raw timber production in commercial forests. However, this cessation would also increase the risks of stand mortality due to climate change impacts as forests age. Unfortunately, there is a lack of comprehensive knowledge regarding the long-term effects of this climate change mitigation option on the various carbon pools within forests.

In order to bridge this knowledge gap, a study was undertaken to evaluate the ramifications of climate change on the storage capacity of various carbon pools within forests, as well as the associated opportunity costs of setting aside forested areas in Germany, considering diverse RCP scenarios. The study employed the Forest Economic Simulation Model (FESIM) as a tool for analysis. To facilitate our research, we have constructed a series of idealized exemplary forest enterprises by leveraging data from the German Forestry Accountancy Data Network. This approach enabled us to capture the diverse spectrum of forest production in Germany, illustrating the pronounced regional variations. The preliminary findings of the study indicate that set-aside forestland plays a crucial role in sequestering carbon dioxide. Furthermore, the study identified key factors influencing the effectiveness of set-aside forest land in mitigating climate change. Moreover, the study explored the opportunity costs linked to set-aside forest land, which refers to the foregone benefits incurred by allocating land for forest protection and climate mitigation instead of other potential uses such as timber production.

The study's outcomes aim to support policymakers and forest landowners in making well-informed decisions regarding the establishment of set-aside forest lands, while also estimating their opportunity costs. Additionally, the results underscore the importance of considering the trade-off between the beneficial and protective functions of forests and the associated opportunity costs. Furthermore, it presents a case study from Germany that can assist decision-making processes in other regions grappling with similar challenges.

Diversification of tree species selection at different spatial scales to adapt forest enterprises to climate change and extreme weather events

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Jasper M. Fuchs[1]
Kai Husmann[1], Carola Paul[1, 2]
[1] Department of Forest Economics and Sustainable Land-use Planning, University of Goettingen, Germany
[2] Centre of Biodiversity and Sustainable Land Use, University of Goettingen, Germany

Abstract: Climate change and increasing extreme weather events challenge future productive potentials of forest enterprises. Diversifying the tree species composition is a frequently discussed adaptation strategy. It promises advantages for forest enterprises through product diversification and a potentially higher biophysical stability of mixed stands compared to monocultures. However, it has been rarely studied whether diversification can mitigate the economic consequences of increasing extreme weather events at different spatial scales.

We investigated (1) how diversification strategies perform compared to other adaptation strategies under climate-driven disturbances at the stand level, (2) which consequences extreme weather events have on wood revenues at the regional scale, and (3) whether diversification across regional spatial scales buffers the economic consequences of extreme weather scenarios for large forest enterprises.

To address these questions, we further advanced simulation-optimization approaches based on Modern Portfolio Theory (1, 3). Econometric time series analysis (2) was used to inform spatial upscaling from a stand-level portfolio model (1) to a large forest enterprise with several planning units (3).

We found that proactively diversifying tree species composition, including non-native, highly productive species, outperformed reactive adaption strategies, such as bark beetle management (1). At the stand level, adjusting tree-species composition compensated for the adverse economic effects of increasing climate-driven disturbances. The econometric analysis revealed that market oversupply, rather than quality losses, decreased wood revenues after large disturbance events at the regional scale (2). Applying this result in the enterprise-level model (3), we found that the optimal species diversity decreased under increasing probabilities of extreme weather events. Under a risk-averse objective function, stand types with low investment risks were preferred. Diversifying tree-species allocation across regional spatial scales did not buffer the economic consequences of extreme weather events.

Our results underline the importance of larger spatial scales for assessing the consequences of extreme weather events on possible economic adaptation strategies of forest enterprises. Our new insights challenge the hypothesis that diversification strategies also buffer the economic consequences of climate change at larger scales. They point to the need to reduce investment risks for production-oriented forest enterprises if society seeks stable, diverse forests that provide multiple ecosystem services.

EU high resolution forest resources and mill site analysis for Sustainable Development in the Forest Industry

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Abstract: The forest industry plays a crucial role in the production of various wood-based products, ranging from lumber and paper to furniture and bioenergy. As the demand for these products continues to grow globally, questions arise regarding the ability of wood resources to meet this increasing demand. In the European Union (EU) currently over 500 million m3 of wood are harvested annually. The wood industry processes the majority of the harvested wood, but little is known about the interplay between industry demand and the availability of timber resources. In this study, it is evaluated to what extent regional wood supply meets the demands of local wood industry across the EU. To investigate this, we used the EFISCEN_space model, which offers a spatially explicit distribution of wood resources on National Forest Inventory plot level data, including assortment details about the species and diameter composition. For the demand side, we compiled the European Forest Industry Database (EUFID), which encompasses the location and capacity of 6,000 forest industry facilities, categorized into three value-chains: sawmills, pulp and paper, and bioenergy. We then compared the balance between wood supply (derived from EFISCEN-space) and wood industry demand (derived from EUFID) to evaluate to what extent regional wood supply meets the demands of local wood industry. Our study demonstrates that an optimal allocation of local wood resources may not only supply the volume needed by the sawmills, but also have a significant potential for increase. However, in such reallocation scenarios the available feedstock falls short in meeting the capacity of pulp and bioenergy mills. Through the use of high-resolution spatial models of resource supply and industry demand, analysis of the potential of bioeconomy trends becomes feasible. This contribution offers preliminary insights into the regional wood

industry chain. By assessing the compatibility between wood supply and industry demand, we contribute to a deeper understanding of this sector, by building a reliable database and methodology upon which to base future projections for a sustainable development of the forest industry.

Justifications for improving site productivity evaluations in forest planning: a Value of Information approach

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Olha Nahorna[1]
Maria Moan[1], Lennart Noordermeer[1], Kyle Eyvindson[1, 2]
[1] Norwegian University of Life Sciences, Faculty of Environmental Sciences and Natural Resource Management, Campus Ås, Norway
[2] Natural Resource Institute Finland (LUKE), Bioeconomy and Environment Unit, Laatokartanonkaari 9, 00790 Helsinki, Finland

Abstract: Forecasting the development of the forest requires accurate information about the current state of the forest and the site productivity. Forest site productivity is commonly quantified as a 'site index', providing information on current and potential future stand growth. Accurate evaluations of the site index can improve growth projections and ensure effective forest planning. Previous research has detailed negative impacts on net present value estimations that could arise from inaccurate site index estimates and consequential incorrect timing of management decisions. While improved estimates of site index are possible, they require high-quality data that will substantially increase the total inventory cost. To ensure cost efficiency of the data, the value of information (VoI) should be assessed.

We quantify the VoI for a range of inventory methods for site index evaluation. The methods include a direct method based on combinations of multi-temporal airborne laser scanning (ALS) and digital aerial photogrammetry (DAP) data, a curve-fitting method based on the same data, as well as conventional practices, i.e., the site index obtained from an operational forest management inventory. The direct method predicts the site index from ALS or DAP variables, while the curve-fitting method evaluates the site index from the predicted dominant height development over time. The direct method based on ALS data is currently in operational use in the Norwegian forestry sector. However, alternative methods for site index evaluation that could potentially reduce the costs and ensure better management decisions are of interest to decision-makers.

To calculate the VoI, we use a stochastic programming model that accounts for the uncertainty in the site index estimates. The model aims to simultaneously maximize the net present value and minimize conditional value at risk, considering specific economic goals and ecological indicator thresholds. We explore the difference in VoI across the site index estimates, according to the decision maker's goals and risk aversion preferences. The results of the study will assist decision-makers to identify the best site index estimation method to use in their forest inventory that will ensure optimal management decisions.

Potential contributions of the forest sector to 1.5°C-compatible socioeconomic pathways (SSP) considering parametric uncertainties

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Tomke Honkomp[1]
Franziska Schier[1]
[1] Thünen Institute of Forestry, Leuschnerstraße 91, 21031 Hamburg, Germany

Abstract: Forest-based measures to mitigate climate change are increasingly recognized as critical components of emission abatement portfolios to reach the global temperature target of the Paris Agreement. The impact on forestry and wood products markets of the growing integration of forest-based measures to achieve climate change mitigation targets remains not well understood from a global perspective. This could partly be attributed to the lacking specificity regarding the targeted contribution of the forest sector in global climate change policies (e.g. nationally determined contributions (NDC)).

To address this research gap, this study calculates reductions in greenhouse gas (GHG) emissions necessary to reach country-specific emission levels described in the SSP1-1.9 scenario (1.5°C-compatible) relative to emission levels projected under the SSP2-4.5 scenario (reference) as a potential mitigation gap. In a scenario-based analysis, the impacts on forestry and wood products markets resulting from a gap reduction via forest-based measures for climate change mitigation are studied using the Global Forest Products Model (GFPM).
Across the scenarios, the gap in country-specific emission levels is closed stepwise up to 50% using different combinations of forest-based measures for climate change mitigation. For this analysis, the GFPM is extended to integrate projected carbon removals and emissions from forestry and wood products as well as related substitution effects as optimization constraints.

The effects of uncertainties related to parameters used to quantify the carbon removals and emissions from the forest sector on the impact on forestry and wood products markets are evaluated by applying Monte Carlo simulations.

This study simultaneously provides insights into the potential contribution of forest-based mitigation measures in reaching 1.5°C-compatible emission levels and explores the resulting impacts on the forest sector when parametric uncertainties are considered. In this way, this study aims at supporting the specification of emission mitigation contributions of the forest sector in global climate change policies.

Predicting bilateral trade flows in wood markets by using gravity models and neuronal networks

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Christian Morland[1]
Julia Tandetzki[1], Franziska Schier[1]
[1] Johann Heinrich von Thünen Institute

Abstract: Trade data are often inconsistent and fragmented, economic shocks jolt market response behaviour, and effects ramify across sectors and countries, which are highly interwoven via international trade in a globalized economy. Therefore, uncertainty is an important factor in modelling international trade flows. One of the first attempts to deal with these issues was the gravity model of trade. These started as mere econometric models to explain bilateral trade flows and became popular in wood market analysis as they gained empirical evidence. Over time, the theoretical foundation has improved, and with it, predictions made with such deterministic models have become even more precise. Nowadays, data driven machine learning methods such as artificial neuronal networks (ANN) offer the possibility to further enhance accuracy in the predictions of complex non-linear relationships. However, the major disadvantage of such data-driven modelling procedures is that the resulting parameters of ANN cannot be directly interpreted. Thus, this "black box" approach has the potential to reduce uncertainties in the prediction of existing bilateral trade flows while simultaneously having reduced explanatory value compared to deterministic gravity models. Against this background, the aim of this study is to compare the ability to predict bilateral trade flows of ANN and gravity models. Therefore, we apply both methods to model bilateral trade flows for different types of forest products on a global scale for the same sets of data. Our results show that the data-driven ANN tends to predict existing bilateral trade flows in wood markets more accurately than gravity models and thus can help to further tackle uncertainties in general trade projections. However, forecasting with ANN is only possible in case that no structural changes are implemented in this procedure, as ANN are explicitly trained to match the existing data. This is where deterministic models can deliver more reliable results.

Profit efficiency of the Cross Timbers region in the production of ecosystem services: an application of stochastic frontier analysis

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Andres Susaeta[1, 2]
Brian Sancewich[3], Kotryna Klyzentyte[2], Jose Soto[4], Omkar Joshi[5]
[1] Oregon State University
[2] University of Florida
[3] Fort Hays State University
[4] University of Arizona
[5] Oklahoma State University

Abstract: The Cross-Timbers is a forested region that stretches from southern Kansas to central Oklahoma and into Texas. As an essential transitional ecotone between the eastern forest and Great Plains grassland biomes, this region is crucial for maintaining biological diversity. Much of this land is not actively managed for the critical ecosystem services that benefit people living in the region. The Cross-Timbers face threats from natural and anthropogenic factors, including climate variability. The lack of proper forest management (prescribed fires and thinnings) has resulted in a reduction of wildlife habitats and water availability, and an increased risk of wildfires surrounding human development. These losses in ecosystem services are concerning given the high population pressure, with over 17 million people projected to be directly dependent on these services by 2040.

Therefore, analyzing the economic capacity of the region to efficiently use and provide natural resources is critical for improving economic wealth. Efficient forest management practices can result in increased forest productivity and profitability, leading to the development of markets for other non-timber benefits, such as carbon sequestration, hunting, biodiversity, water production, and recreational activities. These practices can position the Cross-Timbers forests as a feasible commodity for emerging natural resource markets.

To assess the economic efficiency of the region's forests, we applied stochastic frontier analysis, which measures profit efficiency. Using data from the USDA Forest Inventory and Analysis program at the forest plot level between 2004-2019, we examined the impacts of forest management practices, natural disturbances, and climatic variables on profit efficiency. Our results indicate that the Cross-Timbers forests are economically inefficient in the provision of ecosystem services. Damage caused by abiotic factors reduces profit efficiency by 3.4%, while damage caused by biological factors increases profit efficiency by 23%. The productivity of the site also increases profit efficiency by 17%. Overall, forests in this region generate negative profits when providing ecosystem services. Kansas forests generate higher and more stable profits over time than those in Oklahoma and Texas, and managing softwoods shows to be a more economically attractive alternative than managing oaks, which show the largest variability in profits across the three states.

Simulating international forest-based value chains under supply shocks – An agent-based approach

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Christine Pichler[1]
Franziska Hesser[1], Tobias Stern[2]
[1] Wood K Plus — Competence Centre for Wood Composites and Wood Chemistry, Kompetenzzentrum Holz GmbH, Altenberger Straße 69, 4040 Linz, Austria
[2] University of Graz, Institute of Environmental Systems Sciences, Merangasse 18/1, 8010 Graz, Austria

Abstract: International forest-based supply chains face inherent risks and uncertainties stemming from diverse factors, including political and climate change, market fluctuations, and supply disruptions. Agent-based modeling (ABM) provides an approach to improve the understanding of the complex interactions between natural, social, and economic factors. ABM consists of autonomous agents and their environment, utilizing a bottom-up modeling approach where complex system states emerge from the behaviors of individual components.
We present the design of an empirically based ABM focusing on international markets within forest-based supply chains, aiming to gain insights into factors influencing resource availability. The modeling framework incorporates five distinct agent species: foresters, sawmills, intermediaries, producers, and consumers. The modelling environment consists of a forest module and four market modules. In this round-based simulation, agents either act as suppliers or demanders negotiating based on their inventories and price expectations. Each stakeholder group is highly dependent on upstream and downstream markets. Other markets and macroeconomic developments are considered but not explicitly modeled, thus defining the model boundaries. While the model is implemented with data from multiple sources, abstract parameters were determined by calibration. Simulation results were validated with historical production data of the modelled nations. Integrating empirical data can enhance the realism and relevance of ABMs, but it necessitates a thorough understanding and analysis of the input data. Challenges associated with addressing data inconsistencies are discussed.
The developed model serves as a platform to assess what-if scenarios, wherein agents follow defined sets of rules that can be modified, as for example adjusting demand, production capacities or preferrences in suppliers. This allows to test effects of various policies and agent strategies. Furthermore, the model facilitates the examination of market disruptions resulting from e.g. environmental changes. Simulating the impact of these disruptions provides insights into the system's vulnerability to changing conditions, crucial to foster sustainable development and avoiding unintended repercussions.

THE COSTS OF SUSTAINABLE FOREST MANAGEMENT IN BRAZILIAN FOREST CONCESSIONS

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Felipe Corrêa Ribeiro[1]
Sebastião Renato Valverde[1], Carlos Moreira Miquelino Eleto Torres[1], Lucas Abreu Kerkoff[1]
[1] Departamento de Engenharia Florestal, Universidade Federal de Viçosa, Brasil

Abstract: The Amazon Rainforest is the world's foremost managed rainforest for providing both timber and non-timber products. Because more improved management techniques are required, the costs of sustainable forest management (SFM) are high and different from traditional logging or legal deforestation in Brazil. Identifying and characterizing SFM costs allow defining the average production cost and determining its economic viability. Thus, the objective of the study is to define the average production cost of round wood originating from the SFM of a forestry concession in Brazil. The study area is the FLONA of Caxiuanã, more precisely the FMU III, under concession by CEMAL since 2016. The FMU III has an effective management area of 49,182.48 hectares and a cutting cycle of 30 years.That Indicates Units of Annual Production with an average area of 1,640 hectares. Cost data refers to the year 2020 and are categorized into different groups defined by the concessionaire and the research group, namely: administrative, taxes/fees, concession (price paid to the Brazilian Forestry Service for the volume of wood harvested), depreciation, insurance, interest on invested capital and operation (logistics, employees and parts and maintenance). With the collected data, the average cost of production (APC) was defined. Exploration and concession costs represent more than 71% of total costs, with wood transportation being the costliest exploration activity representing less than half of the concession cost. Of the total costs, 77.83% are variable according to wood production and 22.17% are fixed costs.That is, they do not change with the increase or decrease in production. The Average Cost of Production found is US$ 91.31 per cubic meter, which is the minimum value for selling log wood. The high presence of variable and exploration costs indicate the possibility of improving economic viability with increased productivity in the area. The high impact of the concession cost indicates the importance of a good definition of the minimum price of the logged wood in the Brazilian forest concessions.

Using large-scale forest inventory data and robustness tests to discern uncertainty in industry-related carbon effects

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Francisco Aguilar[1]
Houston Sudekum[2], Dohun Kim[1]
[1] Swedish University of Agricultural Sciences
[2] Advantage Capital NYC

Abstract: National forest inventory (NFI) data offer a wealth of information that can help assess forest conditions including carbon stocks in different pools and at multiple scales. The spatially-explicit incorporation of ancillary information such as wood products industry location can help discern how industrial activity affects total and individual carbon pools. Large data availability supports statistical inference, but methods used to infer statistical impacts are not free of uncertainty. Here, we present analyses aimed at inferring land rent curves reflected on how carbon pools within live trees, dead trees, and soils vary along distance from NFI plots to the wood products industry. We rely on data from the US National Forest Inventory and Analysis Program database with additional spatial-explicit information from the Southeastern US to infer these relationships using panel models after propensity matching algorithms. Specifically, we focus on industry-carbon relationships in the case of the wood pellet industry as a fast-growing sector of international relevance. We illustrate how model specifications and other common approaches to test the robustness of findings yield expected varying results. We discuss how differences in estimated industry-carbon relationships might point to inherent uncertainty emerging from underlying data, and how these might vary by particular carbon pool. This is of direct relevance to climate policy where best available data and analyses should help examine how the wood products industry can support a carbon neutral agenda.

Value of information in the planning of cost-effective operational forest inventories

T2.1 Accounting for risks and uncertainties in forest-based businesses, sectoral projections, and policy design

Santeri Karppinen[1]
Juha Karvanen[1], **Lovisa Engberg Sundström**[2], Liviu Ene[2]
[1] Department of Mathematics and Statistics, University of Jyväskylä, Finland

Abstract: Operational decisions regarding the harvest of forest stands are typically informed using standing volume estimates of assortments in forest stands. Often, such estimates come with high uncertainty, and to ease decision-making, pre-harvest inventories are carried out to reduce uncertainty. However, both the prior volume estimate and the inventory data subject to measurement error constitute a source of uncertainty that should be accounted for in decision-making. Furthermore, the collection of inventory data comes with costs that may offset the gain from the reduction in uncertainty.

We present an approach for the planning of cost-effective operational pre-harvest forest inventories based on forest stand data and uncertainty information. Our approach is formulated around a sequential, two-stage Bayesian decision-theoretic planning problem involving an inventory decision and a harvest scheduling decision. The inventory decision considers the choice of the accuracy of forest inventories, which influences the harvest timing decision through the data obtained from the choice of inventory. Subject to a forest inventory budget, the developed approach can be used to find the inventory decision that maximises the value of information with respect to the harvest timing decision.

We develop a computational method for approximately solving the planning problem, and apply the developed method with realistic data derived from Swedish forest stands, obtaining optimal inventory decisions under a range of planned inventory budgets.

T2.2 At the edge: (Il)legal and (il)legitimate

A monitoring framework for planned (legal) and unplanned (illegal) deforestation to support climate change mitigation strategies in Indonesia

T2.2 At the edge: (Il)legal and (il)legitimate

Abstract: Globally, deforestation continues to take place at alarming rates. Indonesia is one of the tropical-developing countries with relatively high deforestation rates. Indonesia has been increasingly pursuing actions to curb deforestation, as one of the key strategies in climate change mitigation. In early 2022, the Government of Indonesia (GoI) launched Indonesia's 'FOLU net sink 2030', a scenario where the absorption of greenhouse gasses (GHG) is targeted to be balanced or higher than emissions in the forest and other land use (FOLU) sector in 2030. Preventing or avoiding deforestation, particularly from illegal/unplanned sources, will be the key strategy to achieving this target. In implementing the strategy, the GoI has specifically developed a framework to identify potential locations for planned and unplanned deforestation using past deforestation data, where locations with higher deforestation possibility can be prioritized in monitoring and prevention activities. Nonetheless, the framework does not identify actual planned and unplanned deforestation which is important to support law enforcement against illegal deforestation. As an academic exercise and also to complement the framework developed by the GoI, this study developed a framework, consisting of a set of criteria and indicators, that can be used to monitor actual planned and unplanned deforestation in Indonesia. The criteria and indicators were developed based on the definition of planned and unplanned deforestation adopted by the GoI and the national laws and regulations. Criteria used to monitor planned deforestation include: burning done by traditional communities/indigenous peoples; business licenses; social forestry; and national priority projects. Criteria for monitoring unplanned deforestation are uncontrolled forest and land fires; and forest encroachment. The application of the criteria may lead to different results in different contexts. Indonesia may face some challenges in applying this framework, namely: potential overlapping land-use rights; the development of burning maps, and data and information accessibility. In addition, this study should also be complemented by a test trial of the framework using spatial analysis.

Abstract: Some Western Balkan countries are among high-risk timber exporting countries as they are considered to comprise the corridor of illegal timber and timber products from the East to the West. In general, research on deforestation and illegal forest activities in Balkan countries received less attention compared to other high-risk regions and countries, such as tropical ones. Although some studies focus on the legal aspects associated with forest management, timber harvesting and processing in the Western Balkan countries, they mostly target the topic just partially (e.g., focusing on trade data and trends) or pay attention to the role of existing policy tools (e.g., forest certification) in coping with the problem. This paper aims to approach timber legality issues in the Western Balkans from a different angle. Building on public policy and environmental governance studies, we approach the issue of timber legality in the Western Balkans by investigating the coherence of the national policy frameworks of five selected Western Balkan countries (i.e., Slovenia, Croatia, Serbia, Montenegro and the Republic of Srpska - BH) to the European Union Timber Regulation (EUTR) requirements. By adopting a multiple embedded case study design, we investigated national policies and regulations related to the prevention and tackling of illegal logging, as well as those dealing with the trade in timber and timber products in targeted countries and conducted a qualitative content analysis of retrieved documents to check the extent to which EU requirements are covered. Moreover, interviews with more than 30 key informants were performed across selected countries. We analyzed interviewees' perceptions about EUTR and the forthcoming EUDR looking into five main dimensions, i.e., awareness, transparency, information flow, resources, and challenges of ensuring timber legality. Following actor-centred institutionalism we further distinguished institutional and actors-oriented factors influencing the transposition of EUTR and forthcoming EUDR requirements into national policies and forest management practices. Our contribution will offer a comparative gap analysis about EUTR and forthcoming EUDR requirements' incorporation within the national policy frameworks of targeted countries as well as an overview of common and opposing perceptions on timber legality and legitimate forestry practices of key stakeholders in five Western Balkan countries.

Leveraging legality along China's and Vietnam's timber supply to reduce deforestation

T2.2 At the edge: (Il)legal and (il)legitimate

Hin Keong Chen[1]
[1] TRAFFIC

Abstract: Illegal and unsustainable markets for timber species have significant detrimental impacts on biodiversity and can have severe consequences for indigenous peoples and local communities who depend on nature for their livelihoods. These illegal wood markets disrupt ecosystems, fuel organised crime and corruption. When governed effectively, legal and sustainable wood-based markets incentivise and contribute to biodiversity conservation, enhance the livelihoods of IPs and LCs and benefit other stakeholders involved in the supply chains.

Achieving good governance of nature markets requires a combination of international cooperation, national laws and regulations, established financial mechanisms, market-based initiatives, accurate, up-to-date data and information, traceability and transparency.

TRAFFIC approached these timber-related issues through leveraging stakeholders along the supply chain. TRAFFIC is implementing a project, funded by NORAD NICFI that leverages China's and Vietnam's significant market role in the timber supply chain from source countries in the Congo Basin, to reduce unsustainable forestry operations and illegal timber trade.

In China, which bought 67% of global tropical logs in 2018, the project prioritises three approaches:

- with customs and enforcement agencies, using tools and training to verify timber legality entering China
- with the private sector, leveraging TRAFFIC's relationships with major timber trade associations to enhance industry standards and incorporate legality verification systems into purchasing
- with China's huge public procurement that includes wood-based products, public procurement auditors to verify timber legality along the supply chain

Vietnam, another key importer of timber, shares similar approaches to building capacity of customs and forestry staff to verify imported timber legality; and work with the wood-based private sector to enhance industry standards.

At the source countries of Cameroon and the Republic of Congo, TRAFFIC is building enforcement agencies' capacity to verify timber legality and track revenue from legitimate forest sources. With community networks, it assists community forestry operators to operate and export legally, increasing income while managing forests sustainably. A timber tracking tool will reduce opportunities for corruption and help customs identify legal/illegal timber shipments at the borders.

Along the supply chain, knowledge products, work with the financial sector and support for communication/coordination between agencies will increase detection and investigation, further deterring illegality.

Mapping (i)legality: Spatial Assessment of athorized, and illegal suppression of native vegetation in the State of São Paulo, Brazil

T2.2 At the edge: (Il)legal and (il)legitimate

Felipe Rosafa Gavioli[1, 2]
Paulo Guilherme Molin[1, 3]
[1] Federal University of São Carlos - Graduate program in Planning and Use of Renewable Resources - PPGPUR
[2] Environmental Agency of São Paulo State
[3] Federal University of São Carlos - Center for Nature Sciences (UFSCar/CCN)

Abstract: Deforestation of tropical forests and native vegetation poses a significant threat to biodiversity conservation. In Brazil, the protection of native vegetation is governed by a complex legal framework that permits authorized suppression under specific circumstances. However, remote sensing data often indicate that a substantial portion of deforestation exhibits signs of illegality, while studies comparing the dynamics of total, authorized, and illegal suppression of native vegetation remain scarce. Addressing this knowledge gap, our study aims to provide a spatially explicit analysis of three databases related to native vegetation suppression in the state of São Paulo: (1) authorizations for vegetation suppression issued by the government's environmental licensing agency, (2) areas of illegal deforestation that have been effectively surveyed, and (3) the overall extent of native vegetation suppression and restoration. We collected and processed data from the São Paulo government and the Mapbiomas initiative spanning the period from 2009 to 2020, utilizing a geographic information system (GIS) environment for analysis. During this period, a total of 189,547 hectares of native vegetation were deforested in the state of São Paulo, while 673,000 hectares underwent restoration, indicating a net increase in native vegetation coverage. Among the deforested areas, 62,229 hectares (32.83%) were found to be associated with illegal deforestation, resulting in environmental enforcement actions and penalties, while 7,688 hectares (4.05%) were authorized for legal suppression. Despite the enforcement efforts targeting approximately one-third of the total deforestation events, an alarming 119,630 hectares (63.11%) of the deforested areas exhibited signs of illegality. Our study also identified distinct temporal and regional patterns in the dynamics of total, illegal, and legal suppression of native vegetation across the territory. Notably, the majority of native vegetation suppression in the state of São Paulo is attributable to illegal activities, suggesting the need for enhanced command-and-control measures to effectively reduce deforestation rates. This is particularly critical in regions characterized by a high concentration of illegal deforestation. Our findings underscore the urgency of strengthening enforcement actions to curb unlawful deforestation and protect the integrity of native vegetation in the state of São Paulo.

Putting numbers on (un)certainties in the traceability-illegality-risk nexus: the case of Pará, Brazil

Abstract: Timber extraction is a key proximate driver of forest degradation in primary and naturally regenerating forests across the Amazon. Yet we still lack elementary understanding of the supply-chains that link consumers across the world to timber extraction and associated socio-ecological impacts. Here we use data from Brazil's systems for licensing, origin control and commercialization of timber products as well as remote sensing-derived data on forest disturbances due to logging, quantifying (un)certainties and documenting (ir)regularities to assess the degree of illegality-risk of timber from native forests. We focus on the case of Pará – a top timber producing state in Brazil and contested forest frontier – using timber transport data, logging permits substantiating these, and observed forest exploitation for the period between 2009-2019 to quantify connection between reported activities (i.e. volume commercialized, area authorized for extraction) and observed forest activity (i.e. area of forest exploited). While nearly all roundwood entering the supply chain in this period can be linked to existing logging permits, only about half of the volume can be connected to a polygon that delineates an area authorized for logging. Further, only 22% of forest area identified as exploited (through remote sensing) overlaps spatially with authorized areas.The remaining exploitation displays different degrees of illegality risk, with varying levels of uncertainty in links to logging permits and upstream supply-chain actors. 16% of exploitation falls completely outside the Environmental Rural Cadaster (CAR) areas (including in protected areas and indigenous territories), carrying the highest illegality risk. By documenting limitations of the existing traceability systems, this study provides inputs to the debate surrounding the effectiveness of existing environmental regulations in Brazil, identifying loopholes in existing systems that need to be addressed in order to improve policy implementation. It also provides practical insights on how shortcomings in transparency and data quality of the the existing traceability system can be overcome to help identify illegality risks.

The EU Deforestation Regulation's perceived legitimacy

T2.2 At the edge: (Il)legal and (il)legitimate

Laila Berning[1]
Daniela Kleinschmit[1]
[1] The University of Freiburg

Abstract: The aim of our presentation is twofold. First, we theoretically contribute to legitimacy scholarship by expanding the theoretical concept of legitimacy beyond the EU and its Member States, assessing the role of legitimacy in EU policies affecting external states. Second, we empirically analyze how the perceived legitimacy of EU external action-oriented trade policies by EU and third-country state and non-state actors influenced the new EU Deforestation Regulation's (EUDR's) regulatory design and potential effectiveness in driving desired behavioural changes of target actors and halting global deforestation and forest degradation. The EU adopted the EUDR in 2023 to close regulatory gaps in not regulating supply chain sustainability, neither of timber and timber products nor agricultural commodities. The EU does not have the jurisdiction to regulate legal and sustainable production processes abroad and can only influence those through demand-side and supply-side oriented policy instruments such as trade rules, trade agreements, and conditional development support. EU trade rules could support cleaning up EU supply chains and help meet the EU's climate neutrality target, as defined in the European Green Deal. However, trade and market leakage incentives to divert trade flows of illegally and unsustainably produced commodities to less regulated markets can reduce potential global environmental impacts. The perceived legitimacy of legislative interventions is assumed to affect behavioral changes. Legitimacy requirements for political procedures beyond the state level are well-researched in the context of the EU issuing authoritative decisions that bind its Member States. However, EU decisions and policies like the EUDR also affect states beyond the EU. Drawing on legitimacy scholarship, key informant interviews, and a review of key policy and legislative documents, we analyze the EUDR's perceived legitimacy and potential effectiveness as an external action-oriented EU trade policy from the perspective of EU and Indonesian state and non-state actors.

Who defines legality? The competing legitimacies of EU, national and traditional laws in Ghana's cocoa forest landscapes

T2.2 At the edge: (Il)legal and (il)legitimate

Constance McDermott[1]
Eric Kumeh[1], Mark Hirons[1]
[1] University of Oxford

Abstract: This paper examines the political ecology of competing discourses around legality, social justice and legitimacy across international to local scales. It draws on the indicative case of the European Union's recently enacted deforestation-free regulation (EUDR) banning the import of cocoa and other key commodities found to be produced through deforestation and/or violation of forest laws, and struggles over legal and traditional tree tenure on cocoa forest landscapes in Ghana.

This research is grounded in analysis of 93 formal submissions to EUDR consultations by different stakeholder groups, combined with case study research in two cocoa forest landscapes in Ghana, involving 44 interviews, participant observation and 32 focus groups. We examine different stakeholder framings relating to the relative social justice and legitimacy of the EUDR and/or national and customary tree tenure laws in Ghana. In regards to the EUDR, we find a diversity of international stakeholders in support of the EU's prohibition on both legal and illegal deforestation, as well as requirements for in-country legal compliance. In other words, these international actors support the unilateral imposition of the EU's normative priorities for forests on external countries in ways that may exceed national laws, while also demanding strict enforcement of national laws. Within Ghana, we find government actors supporting the state's centralized control over native trees on cocoa farms. Farmers, in turn, perceive injustice in the state's implementation of existing tree tenure laws. Meanwhile within the context of the EUDR, farmers cannot produce cocoa on their privately owned forestlands post the cut-off date established by the EU. Within such a context, international laws such as the EUDR that impose additional sanctions on local use of forest resources, while reinforcing exclusionary state laws, risk exacerbating inequalities in access and benefits from forest resources, and deepening local perceptions of injustice and illegitimacy.

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Heterogeneous Utilization of Domestic and Imported Wood Resources in the Republic of Korea

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

[2] University of British Columbia, Faculty of Forestry

Abstract: In the case where the pattern of wood resource utilization within a country varies depending on its origin, the activity data used for wood carbon accounting should be collected separately for domestically produced and imported wood. This distinction is crucial due to economic, technical, and cultural variations in the usage of domestic and imported wood, which further reflect stakeholder interests and industry context in natural resource utilization. We performed a comprehensive material flow analysis distinguishing between domestic and imported wood. The methodology captures all stages from harvesting and manufacture, to use and disposal, shedding light on each utilization flow. This approach allows identifying areas where efforts are required to enhance resource efficiency, and provides valuable data for calculating carbon storage in harvested wood products, contributing to the national greenhouse gas inventory. In our analysis, we compared the utilization patterns of domestic and imported wood concerning carbon storage efficiency. Further, new indicators for raw wood and production self-sufficiency were introduced to assess the global impact of specific wood products utilized in Korea. The findings were used to infer potential applications of carbon storage accounting methods within the context of Korea's wood usage. Our analysis revealed that domestic wood, primarily used in fragmented product production, displayed medium-term utilization and low carbon storage potential. Conversely, imported wood, procured from higher quality sources, was used for long-term products like construction materials, offering higher carbon storage potential akin to global averages. The indicators of domestic raw wood and production self-sufficiency showed significant skewness across different wood products. This study offers valuable insights for policymakers in devising strategies to enhance carbon stock and improve the efficient utilization of wood resources.

Analysis of Carbon Emission Reduction Effects of Timber Construction

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

MinJi Kim[1]

[2] Chungbuk National University

Abstract: The effect of reducing carbon emissions of timber buildings can be defined as the carbon storage effect of wood as a building material and the substitution effect of carbon-intensive materials such as steel or concrete to wood, which is a carbon neutral material. The carbon storage effect in timber building can be easily estimated by accounting the amount of wood used. However, the carbon substitution effect can be evaluated by comparing the amount of greenhouse gases emitted when a building of equal scale and design is constructed with wood and other building materials.

This study was conducted to showcase the contribution of mitigating climate change by expanding the long-term use of domestic wood resources. A standard model for wooden houses in Korea was developed to expand the demand of domestic wood resources. The area of standard models is 84 m2, 108 m2, and 136 m2, and are designed to apply domestic structural glued laminated timber as structural members. The amount of wood used in the model was 25.4 m3, 29.7 m3, and 41.3 m3 for each model, including structural members and panel products. The amount of equivalent carbon dioxide emitted during the manufacturing and construction stages of raw materials was 27.4 tCO2, 34.1 tCO2, and 48.4 tCO2, respectively. In order to analyze the effect of reducing greenhouse gas emissions of timber buildings, the concrete structure with the same design with the model was developed. As a result, concrete building emitted 57.7 tCO2.62.8 tCO2 and 93.3 tCO2 at the construction stage.

As the results reviewed in the study, when a concrete building was substituted to a timber building, it showed a carbon dioxide emission reduction effect of about 0.3 tCO2 per m2. The increase of timber construction using domestic wood has proven to reduce climate change by replacing carbon-intensive materials such as concrete or steel, a major building material. This study is significant in quantifying carbon emission reduction effects by replacing building materials with forest based structural materials.

Anticipated carbon mitigation from a potential establishment of a domestic mass timber supply network in the United States

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Vaibhav Kumar[1, 2]
Prakash Nepal[1], Richard D. Bergman[1], Neelam C. Poudyal[2]
[1] USDA Forest Service, Forest Products Laboratory, Madison WI 53726, USA
[2] School of Natural Resources, University of Tennessee, Knoxville, TN 37996 USA

Abstract: As a sustainable and cutting-edge building solution, mass timber construction has recently attracted more attention in the United States. Mass timber use in construction aligns with the rising demand for environmentally and energy-friendly structures. A few benefits of mass timber include lowered carbon emissions, quicker construction times, and improved aesthetic appeal. Given the limited domestic supply of mass timber especially cross-laminated timber, importing it from other regions, including Canada, Europe, and New Zealand, is currently unavoidable. Using life cycle assessment (LCA), this study aims to evaluate the potential environmental benefits of manufacturing and supplying mass timber domestically compared to the business-as-usual case, where most of the current U.S. mass timber demand is met through imports from Europe and Canada. A lower carbon footprint and other reduced life-cycle environmental impacts are anticipated due mainly to reduced transportation distance and the optimized domestic mass timber supply chain network The findings from this study will help forestry stakeholders and regional planners understand the scope of economic and environmental benefits attributable to establishing a domestic mass timber supply network.

Abstract: Pathways to reach climate targets that limit global warming typically include the contribution of forests to provide resources that can replace fossil-based materials and energy, and to act as a carbon sink. To assess national and global biomass and bioenergy demand given different climate change mitigation policies, both global demand models as well as models for national forest resources and product uses must be applied.

In this study we analyzed three global biomass and bioenergy demand scenarios that would limit global warming to 2°C above pre-industrial levels and their outcome in terms of climate impact at the national level for Sweden. The methodological approach included global demand estimations based on simulations by GLOBIOM and simulations of the development of the Swedish forest resource conditioned on the global demand estimates. Time-dependent life cycle assessment (LCA) was used to quantify the climate impact, accounting for biogenic carbon including harvested wood products, forest value chain emissions and avoided emissions from substituted products. Consequential LCA was applied where scenarios were assessed in relation to a baseline, representing current forest management and current demand for wood for energy and products. Besides the demand scenarios, we also assessed a maximum potential harvest scenario.

The harvest level of all global demand scenarios was higher than the baseline throughout the simulations, but clearly below maximum potential harvest during the first 35 years. The demands were met, except in the most intense bioenergy scenario where harvest exceeded growth after ca 70 years. The increased harvest levels compared to the baseline reduced the forest carbon sink in all studied scenarios, while the carbon in harvested wood products increased. Higher harvest levels coupled with higher consumption of products and energy resulted in a *net warming effect* compared to the baseline, when only accounting for biogenic carbon balances. However, given that the increased output of biogenic products and energy was used to replace fossil-based products and given our LCA-settings, all studied scenarios resulted in *net cooling effect* compared to the baseline. These contrasting results highlights the importance of assumptions about substitution for the outcomes of climate impact assessments of forest systems.

Climate effects of forests and wood industry - Tightrope walk between chances and pitfalls

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Esther Thuerig[1]
Nele Rogiers[2], Nicklas Forsell[3], Golo Stadelmann[1]

Abstract: The contribution of forests and wood products to mitigate global CO_2 emissions is highly debated in science and policy. The climate services of forests are influenced by forest management and timber use. Quantitative studies on carbon sinks in the forest and timber sector show a wide range of forest management and timber use scenarios. They range from reduced management with increasing carbons stocks in forests, to increased harvesting with the aim of substituting fossil resources.

In 2010, a Swiss study concluded that in the long term, scenarios with slightly increased forest management, subsequent production of long-living products with possible end-use for energy achieved the highest climate service. In our recent study, results for Switzerland are ambiguous. For this study, we combined a model framework of Massimo/Yasso07 for Switzerland and Globiom/G4M to account for the European effects. We explored the difference between national and European perspectives and further studied the effects of discounting displacement factors. If future production of steel and concrete will become less CO_2-intensive due to decarbonization of industrial processes, displacements factors of today will most probably be reduced in future.

Preliminary results show that discounting displacement factors can shift the scenario results completely. Moreover, only considering the national perspective produced rather different scenario results than also accounting for the European forest.

We conclude that both the handling of displacement factors in the light of future climate policy and the national versus international trade balances and system boundaries are crucial to simulate global climate integer scenarios for the forest and timber sector. Main gaps we see in considering different approaches such as the production or the consumption approach. However, compliance with international negotiations and national incentives often promote national production approaches, only. Further, increasing risks of drought, biotic diseases and windthrow should be better reflected in the models.

In an ongoing project we therefore develop a national dynamic carbon-accounting framework for woody biomass, timber products and their substitution effects for fossil material and energy. In this study we plan to incorporate changing disturbance regimes in forests, new possibilities for long-living material use, material recycling, and different accounting approaches.

CO2 emission factors and carbon pay back for forest biomass for energy

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Niclas Scott Bentsen[1]
Thomas Nord-Larsen[1], Anders Tærø Nielsen[2]
[1] University of Copenhagen, Department of Geoscences and Natural Resource Management
[2] Remixed Nature ApS

Abstract: District heat and electricity production in Denmark has over the last 30 years seen a significant transition from fossil fuel to renewables in the form of biomass, wind, and solar energy. Forest biomass make up the majority of renewable energy consumption but the ability of forest bioenergy to mitigate global warming has been questioned due to concerns over the risk of over-exploiting forest resources and the temporal shift between CO_2 emissions from wood combustion and re-sequestration of CO_2 in new forest biomass.

Building on a consumption-based accounting framework, we modelled the temporal carbon dynamics of wood chips and wood pellets supply chains for 12 utilities in Denmark covering 67% of wood chips and 96% of wood pellet consumption. A wide range of utilities in terms of size, sourcing countries, biomass origins, and heat and power production were included. Furthermore, we analysed the carbon debt and payback time of the 12 utilities' fuel transition from coal or natural gas to forest biomass.

As forest ecosystems are highly dynamic, estimates of CO_2 emissions attributable to the use of forest biomass for heat and electricity are meaningless without specification of temporal scope. We found a specific CO_2 emission for the average use of forest biomass in Denmark of 28 kg CO_2 GJ^{-1} in a 30-year perspective and 5-10 kg CO_2 GJ^{-1} in a 100-year perspective.

Transitions from fossil to forest fuel generates a carbon debt. For transitions from coal to biomass, the carbon payback time ranged from 0 to 13 years indicating that carbon emission benefits were achieved at the latest 13 years after transition. Relative cumulative net carbon emissions 30 years after the fuel transition, RCCE(30), ranged from 0.29 to 0.85 corresponding to emission savings of 15–71% relative to continued use of coal. For fuel transitions from natural gas to biomass, the carbon payback time ranged from 9 to 34 years and RCCE(30) from 0.81 to 1.03.

Contributions of wood to decreased environmental load of construction sector

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Henrik Heräjärvi[1]
Adam Taylor[2]
[1] University of Eastern Finland, Faculty of Science, Forestry and Engineering, Finland
[2] University of Tennessee, Center for Renewable Carbon, USA

Abstract: Making and using materials for building construction is responsible for environmental impacts that are increasing due to population and wealth growth. The most effective ways to decrease the impacts of construction would be not to build at all or to renovate existing structures rather than to demolish and rebuild. If new construction cannot be avoided, the associated environmental impacts should be minimized. Wood is generally understood to cause less environmental impact than other materials. However, wood has limited global potential in construction due to limitations on the scale of production. Global concrete production, as an example, is volumetrically at least 10 times larger than the production of wood products for construction applications. Thus, it is not realistic to envision volumes of wood that could fully replace concrete. The smaller environmental impacts of wood use have inspired other materials improving their performance. While wood is no real threat to the continued use of other materials in terms of volumes, it does offer the exemplar for the greening the construction sector. Sustainably sourced wood can act, and has acted, as a 'pacesetter' in the race to develop greener construction. While wood's role in substituting fossil-intensive materials has been subject to active scientific work recently, its pacesetting role in greening the construction sector's huge environmental load is poorly understood, so far. For the forest products industries, the business case is a paradox: inspiring other businesses into improvements will decrease the relative advantage of wood, given that the wood sector's opportunities for further greening are modest. In general, the greening investments should be allocated in sectors with expectedly greatest or most rapid impacts. All materials will likely be needed in the future. There is a great chance to improve the greening speed of the whole construction sector offered by wider adoption of already available environmental frontrunner solutions. The immediate impacts would be smaller environmental footprint of the construction sector and more time to develop better solutions.

Estimating GHG substitution effects in the building sector based on LCA data and statistics in line with IPCC requirements

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Sebastian Rüter[1]
[1] Thünen-Institute of Wood Research, Germany

Abstract: The greenhouse gas emissions associated with the use of the renewable material wood can be divided into three main effects. On the one hand, The biogenic CO_2 emissions and their removals in sinks associated with the two carbon pools "forest" and "Harvested "Wood Products" as part of the biogenic carbon cycle. The third impact relates to the other emissions of the wood processing industry as part of the manufacturing sector.

The quantification of these climate relevant effects is carried out by means of various calculation methods on different scale levels with mostly different system boundaries (land or product system) and concerns temporally and spatially divergent dimensions (retro- and prospective effects). However, a well-founded and robust analysis of the climate relevance of the forest-based sector must always take into account all effects and impacts. This, in particular, applies to the estimation of possible indirect greenhouse gas reduction effects (substitution potentials) associated with the use of wood. For this purpose, several sources of data must thus be consistently combined with each other in accordance with the relevant methodological requirements.

Whereas the biogenic CO_2 emissions and their removals are best estimated in line with the the methodological requirements of the Intergovernmental Panel on Climate Change, the non-biogenic emissions of the wood processing industries cannot be determined with methods provided for national greenhouse gas inventories. This is why other approaches must be used. For this purpose, the internationally standardised Life Cycle Assessment method provides a sound basis. Especially for the construction sector, a European horizontal set of standards allows for consistently assessing the environmental performance of building products and buildings, including their Global Warming Potential.

The presentation shows how potential emission reduction effects associated with an increased utilization of wood in the contruction sector can be assessed in line with requirements of Intergovernmental Panel on Climate Change and those international Life Cycle Assessment standards from the construction sector on the basis of a combination of i) standard-compliant and representative Life Cycle Assessment data of real existing wooden buildings and their functional equivalents ii) national building statistics, and iii) well-founded housing market forecasts.

Global projections for carbon storage and substitution benefits in forest products in alternative market and policy scenarios

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

A. Maarit I. Kallio[1]

[1] Norwegian University of Life Sciences, Faculty of Environmental Sciences and Natural Resource Management, Norway.

Abstract: Forestry and the forest sector directly and indirectly contribute to climate-change mitigation. The use of harvested wood products (HWPs) can result in greenhouse gas emission savings if these products replace materials with a higher carbon footprint. Also, wood products may delay the release of carbon stored in trees after harvest, thus lengthening the time carbon remains stored and increasing the mean volume of carbon stock connected to a forest stand during its economically feasible rotation time. This study examines carbon substitution and storage benefits on a global scale and at the EU level. The assessment of forest sector development relies on the FORMEQ model, which is a partial economic equilibrium model for the global forest sector. The calculations are based on alternative medium-term scenarios owing to the significant uncertainties surrounding the future of the global forest sector. Factors such as geopolitical and economic turbulence, as well as environmental and economic policies such as trade embargoes, the EU biodiversity strategy, and climate policy regulations related to the forest sector can have substantial implications for the sector. Carbon storage calculations employ default parameter values from the Intergovernmental Panel on Climate Change guidelines, whereas avoided emissions are calculated using carbon replacement factors derived from recent studies. Without the substitution benefits resulting from the use of HWPs considered in this study (paper and paperboard, textile fibers, and mechanical forest industry products), global greenhouse gas emissions could have been up to 6% higher at the beginning of this decade. In addition, the HWP pool acted as a carbon sink, its carbon storage increasing approximately 317 Mt CO_2/a globally. In the baseline scenario, global substitution benefits increase to approximately 2.6 Gt CO_2 by 2030, whereas the aggregated HWP sink changes only moderately. Environmental policies that reduce harvest levels decrease the carbon storage and substitution benefits of HWPs. Several uncertainties are associated with the data and projections used in the calculations, and their impacts are assessed and discussed.

Greenhouse gas mitigation potential of wood products: A global multi-model assessment

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Abstract: Recent literature highlights the important role of forests in long-term climate action. Mitigation options in forestry include improved management of existing forests, stock preservation through avoided deforestation, reforestation/afforestation, and use of forest biomass in bioenergy systems. However, missing from most climate policy projections is a more explicit accounting of carbon stored in wood products. Wood products can provide a significant source of carbon storage in long-lived pools, and could potentially replace emissions-intensive building materials. However, we have limited information on the extent of wood product supply across long-term global climate policy scenarios, including how long-lived wood products interact with bioenergy and terrestrial carbon sequestration policies.

We build on a Forest Model Inter-Comparison (For-MIP) analysis of more than ninety scenarios using three detailed global forest sector models of (Daigneault et al., 2022). For-MIP projections reflect variation in both future socioeconomic change (SSPs) and climate policy ambition, reflected through relative concentration pathways (RCPs). In these forest sector pathways, total wood product supply increases over time, ranging 0.5 – 8.0 Billion m^{-3} by end of century. Hardwood product C increases for most, but not all scenarios, as the allocation of pulpwood to bioenergy in some scenarios reduces C storage in products despite the increase in removals relative to the baseline. However, carbon sequestration intensity of forests increases over time in almost all modeling scenarios, implying opportunities to co-produce terrestrial and wood product C storage.

Finally, we use projected bilateral trade flows from modeled scenarios to estimate regional product carbon consumption over time, and then link this with the IIASA IAM-SSP database to assess wood product carbon storage relative to cumulative anthropogenic emissions from the energy and industrial sectors. We explore drivers of regional variation in this mitigation factor to understand how socioeconomic and policy factors affect the sector's net mitigation potential and contributions to decarbonization goals relative to investments in energy and industry. Our regionalized results provide valuable policy insight on the potential role of long-lived wood products in decarbonization scenarios. We discuss policy implications and directions for future research, including the importance of considering permanence tradeoffs in mitigation policy design in forestry.

How can innovative engineered wood products contribute to climate change mitigation?

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Pau Brunet-Navarro[1]
Jordi Gené Sera[1], Neus Puy Marimon[1, 2]
[1] Forest Science and Technology Centre of Catalonia; Bioeconomy, health and governance Programme; Solsona; Spain
[2] Universitat Autònoma de Barcelona; Department of Chemistry; Spain

Abstract: The building sector along its life cycle is responsible for a significant share of national greenhouse gas emissions. Manufacture of traditional construction materials, inefficiently isolated buildings or end of life demolition are life cycle phases with relevant emission sources in this sector. Wood has been demonstrated to be a sustainable construction material suitable to reduce the environmental impact of the building sector since it grows naturally, it is thermally efficient and can be reused and recycled.

After a literature review on wood product modelling, the CASTLE_WPM model was published incorporating key functionalities to estimate carbon stock changes of harvested wood products. This model was useful to identify lifespan and recycling rate as key parameters to define climate change mitigation strategies. This work and other literature identified a high climate change mitigation potential when extending lifespan of low-quality wood products traditionally employed for short-lived uses. The application of later CASTLE_WPM model versions incorporating the substitution effect identified an expiry date of this substitution effect due to decarbonisation pathways in line with the Paris Agreement commitment.

Based on this knowledge, a new research line started to evaluate the potential use of low-quality pine wood from Mediterranean forests, commonly employed to produce short-lived pallets for transportation of goods, as construction material. Manufactured prototypes, tested and demonstrated in operational environments, already showed the potential use of Cross Laminated Timber made with local maritime pine combined with cork as isolation material for structural and non-structural elements. To test its reusability, fabricated modules were assembled and disassembled to be reassembled on different locations.

Future research directions at the Forest Science and Technology Centre of Catalonia aim to build on this knowledge to develop new bio-based products and evaluate the potential use of local wood for innovative construction solutions. Wood combinations from different Mediterranean species (soft and hardwoods) and sources (virgin, reused and recycled), as well as bio-based glues, will be employed to manufacture and test innovative engineered wood products. In parallel, life cycle analysis of the current construction materials employed at local scale will serve to quantify the substitution effect of the engineered wood products developed.

Impacts of Forest Management in Protected Areas in SR on Carbon Balance in Harvested Wood Products

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Hubert Paluš[1]
Martin Moravčík[2], Ivan Barka[2], Matej Schwarz[2], Ján Parobek[1], Miroslav Kovalčík[2], Michal Dzian[1]
[1] Technical University in Zvolen
[2] National Forest Centre

Abstract: Sustainable forest management is an internationally established holistic concept that is able to dynamically adapt to changing conditions, including responding to climate change. Prioritizing certain ecosystem services over others can have a direct impact on the ability of forests to fulfil their functions in a balanced manner. The efficient utilisation of wood, as one of the forest products produced within the SFM process, aimed at the production of harvested wood products (HWP) has an additional added value in the form of their substitution for other fossil-based materials and fuels. At the same time, it improves the contribution of the sector to the carbon balance. The ongoing transformation of national parks in Slovakia, is characterized by the transfer of management of public forest lands from the governance of the Ministry of Agriculture and Rural Development of SR to the Ministry of the Environment as well as by the creation of new no-management zones, envisages leaving up to 75% of the area of national parks without any human interference. The aforementioned change in the care for forest ecosystems will affect, among other things, the production of wood. In addition to social and economic impacts on the affected rural areas and the availability of wood for related industries, the expected reduction in wood production and supply will also result in a change in the volume of carbon stored in HWP. The aim of this paper is to quantify the impacts of management changes in national parks on the volume of carbon in HWP due to the reduction of the available of wood raw material. The analysis is based on empirical data and forecasts of the development of standing volume and level of timber harvesting as a result of the expansion of the no-intervention management regimes. Input data on the available volume of wood were redistributed into the roundwood quality categories based on the current and predicted structure of assortments. The standard IPPC procedures were used for conversions and calculations into outputs. The volume of carbon stored in the HWP by 2023 is compared with its projected scenario by 2030 under changed forest management.

Including time and future technologies in substitution factors of wood use – towards a framework for dynamic-prospective Life Cycle Assessment

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Amelie Müller[1, 2]
Giuseppe Cardellini[2], Timokleia Orfanidou[3, 4], Bernhard Steubing[1], Jeroen Guinée[1]
[1] Leiden University, Institute for Environmental Sciences (CML), Netherlands

[3] European Forest Institute (EFI), Bioeconomy Programme, Finland
[4] Aalto University, Department of Bioproducts and Biosystems, Finland

Abstract: Wood use is a popular climate change mitigation strategy due to the dual advantage of product carbon storage and substitution of fossil-based alternatives. Yet, the future climate benefit of wooden products is highly uncertain because of the time-dependency of the type of product, the substituted material, the production technology, end of life and the decarbonization of the broader economy. The climate benefit of wood products in forestry assessments is typically assessed with substitution factors, which are derived using comparative Life Cycle Assessments (LCA) of the wood product and the replaced conventional product. Previous research on the temporal sensitivity of substitution factors has strengthened the consensus that LCAs for wood products should be dynamic, considering the timing of carbon sequestration, storage, and release. In addition, recent developments in prospective LCA have allowed to incorporate future economy-wide decarbonization effects into Life Cycle Inventory databases, yielding background data for scenario-based LCAs at distinct future years.

This work proposes a novel framework to link the use of prospective Life Cycle Inventory databases with dynamic Life Cycle Assessment. It showcases why it is necessary to combine both dynamic and prospective LCA to obtain an accurate, time-explicit assessment of the current and future substitution effects of wood products. The proposed prototype approach uses the life cycle inventory from the corresponding time-specific database for each time-specific process in the product system to calculate the dynamic LCA. This approach is novel as it treats time consistently across all four life cycle assessment steps: goal and scope, life cycle inventory, life cycle impact assessment and interpretation. The method is demonstrated with wood products but it is applicable to any product or system. Obtained results are compared with the results of static, dynamic and prospective LCAs, each applied individually. The proposed framework can help to gain greater certainty on future substitution impacts and climate change mitigation potential of wood and wood-based products, as well as guide policymakers to the most climate-smart uses of wood. One future application is to link this method to a wood flow analysis of the European Union to quantify future substitution effects on a continental scale.

Long-lived wood products, a life cycle assessment to minimize environmental impacts and maximize climate mitigation

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Tim Rowe[1]
Kato Van Ruymbeke[1], Liesbet Vranken[1]
[1] Society Environment Interactions group, Department of Earth and Environmental Sciences, KU Leuven

Abstract: The use of long-lived wood products, over non-renewable alternatives, is increasingly being suggested as a way to lower CO_2 emissions and increase carbon storage. By utilizing wood for long-lived applications, i.e. in construction, furniture etc., its carbon content can stay locked away from the atmosphere for decades. In the meantime the growing trees in the regenerating forest will take up CO_2 from the atmosphere.

This study aims to identify optimal uses of (long-lived) wood products to reduce overall environmental impacts, with a particular focus on increasing carbon storage and thus climate change mitigation. The lifetime environmental impact of several, market relevant, long-lived wood products will therefore be compared to that of non-renewable alternatives. The selection of the long-lived wood products will be based on a literature review and stakeholder consultations within the 'ClimbForest' project (Horizon Europe), with a specific focus on the construction sector. This sector has a large growth potential for the use of long-lived wood products, as well as the potential to replace carbon intensive products like concrete and steel. Data on forest management, tree species distributions, harvesting techniques and value chains will also be obtained from the stakeholder consultations in order to create a set of realistic European case study areas.

A cradle-to-grave life cycle assessment (LCA), following the ISO 14040 and 14044 guidelines, will be used to calculate the lifecycle environmental impacts. In order to approach real markets as closely as possible a consequential LCA methodology will be used. The results will be analyzed and presented following the product environmental footprint (PEF) guidelines set out by the EU.

In line with recent findings in literature, we expect to generally see lower life cycle emissions for the long-lived wood products compared to their non-renewable alternatives. The aim is to identify the products and production methods whose potential emission savings are the greatest. The obtained results will be used to formulate policy recommendations and advice to the forestry sector on the optimal production, distribution and use of wooden forest products from an environmental impact standpoint.

Net Zero, Climate Positive Supply Chains for the Pulp & Paper Industry

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Camille Rebelo[1]
Troy Wiseman[1], Samantha Wilde[1]
[1] EcoPlanet Bamboo

Abstract: The world's wood is sourced from the harvesting of tree plantations, some of which are certified as sustainably managed under long rotations, or the clearing of natural forests. Globally, 25% of global GHG emissions are attributed to deforestation and land use change. 10% of global deforestation is attributed to wood products, with pulp being a component. Pulp production utilizes a kraft process that is characterized by high energy, water, and chemical inputs, and generates significant air and water pollution. In 2021 the pulp and paper sector was responsible for about 190 Mt of CO2 emissions, about 2% of all emissions from industry and a historic high. As paper production is projected to increase through 2030 this footprint can be expected to continue to rise, and have climate change impacts along the length of the supply chain.

As a result of these pressures, the pulp & paper industry is primed to transition to a new model that offers a solution for a sustainable feedstock and green manufacturing.

EcoPlanet has developed a resource base of sustainable bamboo reforestation projects, set to remove >10Mt of CO2e over the next 10 year period. The sustainable thinning of the planted bamboo provides a vast potential resource that is carbon positive and deforestation free. On the upstream side, along with technology partners, we are pioneering a green manufacturing strategy centered on a net zero, zero waste biorefinery pulping technology. Biorefineries are to be developed adjacent to each restoration initiative, eliminating the multiple transportation steps of the current supply chain, and associated GHG footprints. This innovative new generation technology will enable the production of a high quality bamboo pulp and associated paper products that allow the pulp and paper industry, to transition to a climate positive strategy, along the length of the supply chain.

This presentation will discuss the innovation associated with the technology, the carbon savings of the pulp production, and the carbon removal benefits of the bamboo resource itself, towards a holistic, climate positive landscape that can be both scaled and replicated to meet growing market demand for paper and in the future, textile products.

Next generation carbon stock and stock change modelling in wood use: towards contributing to climate change mitigation pathways

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Timokleia Orfanidou[1, 2]
Giuseppe Cardellini[3], Amelie Müller[3, 4], Hans Verkerk[1]
[1] Bioeconomy Programme, European Forest Institute (EFI), Finland
[2] Department of Bioproducts and Biosystems, Aalto University, Finland
[3] Flemish Institute for Technological Research (VITO), Sustainable Energy for the Built Environment (SEB), Belgium
[4] Leiden University, Institute for Environmental Sciences (CML), Netherlands

Abstract: Ambitious goals are set globally to reduce greenhouse gas emissions and achieve climate neutrality by 2050. This necessitates urgent societal and economic reforms, as well greenhouse gas reductions across all sectors. Wood use plays a critical role but estimating its contribution to climate change mitigation is hampered by limited information notably on the final uses of wood. Consideration of the final uses of wood and their lifespan is crucial since it influences the carbon storage and determines the substitution potentials. To address this knowledge gap, we conducted a dynamic material flow analysis for Europe that connects existing statistics on the production, consumption, and trade of semi-finished products to final uses.

We employed the Open Dynamic Material Systems Model (ODYM), which has been calibrated to track wood flows and temporary carbon storage in harvested wood products while taking their final uses into account, in accordance with the Intergovernmental Panel on Climate Change guidelines. Our findings will provide an understanding of how wood has been used in the European Union from the 1900s to the present, from wood production to final uses (construction, furniture, paper and packaging, energy, chemicals, and others). This dynamic material flow analysis is carried out as a first step towards a better understanding of the dynamics of the wood carbon stocks and flows in the European Union, with the goal of linking it to Life Cycle Assessment tools and approaches to quantify substitution effects.

On the origin of substitution impacts from wood use: A supply vs. a demand perspective

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Maximilian Schulte[1]
[1] Swedish University of Agricultural Sciences (SLU)

Abstract: Climate change mitigation assessments of the forest sector from a system perspective include balances of biogenic carbon in (i) forests and (ii) wood products, as well as fossil greenhouse gases from (iii) forest supply chains, and avoided emissions, i.e. (iv) substitution impacts. For (i), (ii), and (iii) established assessment methods exist, yet for (iv) no universal approach is given. However, whether and when, e.g., a certain forest management may lead to a net climate benefit as compared to an alternative can be highly dependent on the substitution impact. A common approach in assessing the substitution impact is that of applying a supply-perspective, i.e., "from-the-forest-to-the-wood-use", often by using substitution, or displacement factors. The supply-perspective, however, suffers from two major shortcomings: (i) it presupposes information as to the shares of different applications of intermediate or final wood products, something which is seldom, or outright never, at hand, and (ii) there are no safeguards against unfeasible outcomes in terms of the amount of different wood product applications/functional units. Wood product substitution effects can thus easily be overestimated. In order to address these inconsistencies, a demand-perspective for modelling climate change mitigation potentials of wood use can be applied. In contrast to the former, this perspective follows "from-the-wood-use-to-the-forest", targeting a specific wood product application/functional unit, e.g., multi-family housing construction or textile fibers. By that, this approach does not require knowledge about intermediate or final wood product shares, and, making the outcome in terms of the amount of the application/functional unit explicit, provides checks for unfeasibility. Here the estimation of substitution, or displacement factors is an optional feature. With the case of increased wood use in Swedish multifamily-housing construction based on official housing projections, this project gives an example of a substitution impact and climate change mitigation assessment from a demand-perspective for a targeted wood product application.

Optimization of wood shifts and wood substitution impacts from a system perspective

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Theresa Boiger[1]
Claudia Mair-Bauernfeind[1], Raphael Asada[1], Tobias Stern[1]
[1] Institute of Environmental Systems Sciences, University of Graz, Graz, Austria

Abstract: Wood-based products contribute to climate change mitigation through substitution effects. Substitution effects can be generated by increasing harvest, which is limited in a sustainable forest management and can have negative effects on the forest carbon pool, or by changing import or export patterns, which influences the carbon balance of other countries. Substitution effects that are not subject to these limitations can be achieved by altering wood utilization patterns that generate additional substitution effects by increasing the amount of wood in industries with high substitution effects and decreasing in industries with low substitution effects.

Both short-term and long-term effects of altered wood utilization patterns need to be considered. On the one hand, substitution effects might change over time due to a changing energy mix. On the other hand, altering wood utilization patterns leads to changes in the carbon storage pool of harvested wood products. This raises the question of how to distribute wood over the wood utilization system in the best way in terms of climate change mitigation.

The System Dynamics Model "WOODSIM" is used to quantify substitution effects on a market level including value chains from the forest to all wood-processing industries. Additionally, a harvested wood product pool model is applied to show carbon storage effects. A simulation-based optimization is performed for the Case Study of Austria where the sum of avoided GHG emissions through substitution effects and carbon storage effects is maximized. Sensitivity analyses show the influence of assumptions and data uncertainties on the results.

Results will show the wood utilization patterns generating the highest Global Warming Potential savings and will provide information about where wood should be used to be most beneficial for climate change mitigation. Further research should also consider implications of altered wood utilization patterns on the social and economic dimensions of the system. Trade-offs between the dimensions of sustainability need to be considered.

Salvation by substitution? Identifying substitutes for wood-based textile fibers

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Elias Hurmekoski[1]

[1] University of Helsinki, Department of Forest Sciences, FI-00790 Helsinki, Finland

Abstract: The estimation of substitution impacts relies on a host of market assumptions. Some of the most critical uncertainties include, which non-wood products do the wood-based products substitute for, and to what extent. This study introduces a systematic framework for identifying the existence and rate of substitution based on microeconomic theory and econometric analysis, taking the case of staple fiber market.

Four datasets and three theoretical models were applied for a set of empirical model formulations. The theoretical models included i) a linear approximate almost ideal demand system (LA-AIDS), ii) a conventional demand equation quantifying cross-price elasticities, and iii) an ad hoc formulation quantifying the response of the consumption of RCFs to the consumption of alternative textile fibers. The empirical models for the latter two theoretical models included OLS in first differences, autoregressive distributed lag (ARDL), and vector error correction (VECM) models. The selection of empirical models was informed by tests for non-stationarity, cointegration, autocorrelation, multicollinearity, normality and heteroskedasticity.

The results point to regenerated cellulosic fibers (RCFs) being imperfect substitutes for cotton with an empirical substitution ratio of 13-34%, and mostly independent from the demand for polyester with an empirical substitution ratio of 0-18%. With a substitution ratio of 1:1, the marginal substitution impact would be -1.43 tonnes of fossil carbon avoided per tonne of biogenic C contained in RCFs (tC/tC). With the empirical substitution ratios, an additional unit of RCFs produced leads to an increase of fossil emissions of 0.12-0.71 tC/tC. The explanation is that only part of the RCF supply replaces alternative materials, while the rest merely increases overall textile supply and thereby the overall fossil emissions. This result highlights the difficulty of decoupling the environmental footprint of the textile sector from the growing consumption by substitution alone.

Empirical substitution ratio points to historical evidence, and may not necessarily reflect future market conditions, given evolving product properties, prices, and preferences. For novel wood-based textile fibers, the substitution ratio may be higher and the fossil emission lower. The empirical substitution ratio can, however, be used as a reasonable baseline for identifying substitute products and the closeness of the substitutes.

Sustainability Impacts of Wood- and Concrete-Based Frame Buildings – a Lithuanian case study

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Povilas Žemaitis[1]
Edgaras Linkevičius[2], **Marius Aleinikovas**[1]
[1] Lithuanian Research Centre for Agriculture and Forestry, Instituto al. 1, Akademija, Kėdainiai District, LT-58344, Lithuania
[2] Vytautas Magnus University, Agriculture Academy, Faculty of Forest Sciences and Ecology, Studentų 13, Akademija, LT-53362 Kaunas dstr, Lithuania

Abstract: In recent years, wood has received increased interest in the European building sector. The trend is driven by the recognition that wood, as an environment friendly material, can contribute to bioeconomy development and climate neutrality by 2050. In Lithuania, the main construction material among residential and public buildings is cement, even though Lithuania has a strong wood-based industry and sufficient timber resources. On the other hand, Lithuania has a strong cement industry, which gives an opportunity to compare wood- and concrete-based building materials sustainability impacts throughout the production value chain – from raw material extraction to manufacturing using the same method, while documenting and assessing the material sourcing stages consistently and transparently. In Lithuania, multi-storey wood-based building is still at the level of policy and political discussions. Therefore, the presented research focuses on quantification and comparison of the sustainability impacts of both wood- and concrete-based building materials value chains and provides applied scientific knowledge relevant to decision-makers and in this way contributes to mitigation of the climate change. In this study, we designed two- and five-floor wood- and concrete-based building material alternatives in order to compare the impact of the construction size on sustainability values. In discussion with study partners twelve environmental, social, and economic indicators were selected to perform the sustainability impact assessment of selected building materials and designed buildings. Building materials were compared by using a decision support tool ToSIA. The relevant data was gathered from local, well-known companies in the national and international arena. Findings revealed the potential of glue-laminated timber frames as a more sustainable alternative to precast reinforced concrete in the construction of public low-rise buildings in Lithuania, and they showed great promise in reducing emissions and increasing the sequestration of CO2. An analysis of environmental and social indicators shows that the replacement of precast reinforced concrete frames with glue-laminated timber frames in the construction of low-rise public buildings would lead to reduced environmental impacts, alongside a range of positive social impacts.

Sustainability of mass timber school buildings of the United States gauged by comparative Whole Building Life-Cycle Analysis

T2.3 Contribution of wood-based products to climate change mitigation: State-of-the-art and research directions

Marco Lo Ricco[1]
Vaibhav Kumar[1], **Prakash Nepal**[1]
[1] USDA, Forest Service, Forest Products Laboratory

Abstract: School facilities are vital to communities of the United States because they primarily provide the space to educate youth from kindergarten through high school (K – 12) and secondarily provide assembly spaces and emergency shelter from natural and human-induced disasters. The magnitude of public infrastructure dollars spent on school facilities is second only to highways, yet the generally poor condition of school buildings across most of the United States reflects underinvestment and a lack of cohesive building and maintenance strategies. Over a third of schools, furthermore, rely on portable buildings to meet increasing demands. While mass timber buildings currently represent a minute fraction of school facilities and construction overall, case studies specific to K – 12 schools have been growing, and there is ample research and development to demonstrate the resilience of mass timber structures to a variety of wind, seismic, and blast hazards. Mass timber framing, trusses, panels, and modular assemblies offer the versatility needed for a variety of classrooms, laboratories, meeting rooms, and emergency shelters commonly built on school grounds. Through comparative Life-Cycle Assessment of mass timber and hybrid structural systems of steel and reinforced concrete masonry, this study demonstrates that global warming emissions and the amount of energy consumption of school buildings may be cut as much as one third, while other quantifiable performance aspects are improved, through greater use of mass timber school buildings.

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Blockchain Technology in Forest Supply Chains

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Lukas Stopfer[1]
Thomas Purfürst[1]
[1] University of Freiburg

Abstract: Blockchain technology has the potential to revolutionize the forestry industry by providing a transparent and secure method for tracking and verifying the origin and movements of forest products.

By enabling secure tracking of forest products, blockchain can improve the forestry industry. Transactions in the supply chain can be recorded in a decentralized ledger. This increases transparency and traceability, helping to combat illegal logging, deforestation and fraudulent labelling.

The technology can also streamline processes and reduce errors and fraud, leading to cost savings and increased confidence in the sustainability of products.

Blockchain also has the potential to track CO2. But there are challenges, including ensuring accurate data and engaging actors.

However, it is important to note that the implementation of blockchain technology in the forestry industry is still in its early stages, and there are challenges that need to be overcome such as ensuring the accuracy of the data recorded on the blockchain and ensuring the participation of all relevant stakeholders in the supply chain.

In the joint project "Blockchain technology as a driver for the digitalization of forestry", potentials are being specified, the technical prerequisites are being worked out and the potential and acceptance of the market participants are being determined through a large representative survey.

The presentation will present the results of a feasibility study on the use of a blockchain-mapped supply chain for the entire forestry and timber industry, from forest to customer.

At the same time, the follow-up project to implement a prototype blockchain application in wood supply chain will show initial results, opportunities and challenges.

In addition, the technical and software requirements and possible implementation options for the use of blockchain technology in forestry business processes will be discussed. Furthermore, the results of the nationwide survey among different actors in the forestry-wood chain are explained and classified.

Climate resilience in boreal wood supply – developing technologies and emerging enablers

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Dag Fjeld[1]
[1] Swedish University of Agricultural Sciences

Abstract: In later years the topic of supply chain resilience has received increasing R&D focus. In the forest sector, supply operations in the boreal zone have always been subject to seasonal restrictions for site availability. The gradual increase in temperatures over time has driven a corresponding development of harvesting and transport practices. However, acceleration of climate change in the north during recent decades has required increased agility in management of supply operations.

This presentation starts with a review of recent frameworks developed for capturing climate-driven risks and relating these to managerial response on strategic, tactical and operational levels. In this context the development of long-distance multimodal supply systems and sector-wide digital infrastructures provide stable channels for material- and information flow as a foundation for increased structural flexibility. At the same time developing digital technologies offer the potential for increased operational agility.

The presentation covers recent work with developing digital technologies and positions them in the framework in terms of their role for enabling climate resilience in boreal wood supply. The empirical results cover the potential effects of integrating current digital maps sources with operations data as well as grid-based weather data and satellite radar. In this context, making the jump from static to dynamic prediction of trafficability with correspondingly flexible decision support emerges as a bottleneck for both operational efficiency and environmental sustainability.

Decision making aware of uncertainty – how does it affect operational decisions in the Swedish large-scale forestry?

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Lovisa Engberg Sundström[1], Liviu Ene[1], Babooshka Shavazipour[2], Santeri Karppinen[2]
[1] Skogforsk - Forestry Research Institute of Sweden, Sweden
[2] University of Jyväskylä, Finland

Abstract: In a forestry striving for higher precision, accurate pre-harvest inventory is required. However, conducting precise inventory is both resource-intensive and time-consuming. Current pre-harvest inventory practices in the forestry industry are merely basic in the sense that only the mean values, such as estimated stand volumes, are collected. The resulting lack of information about standard deviations within forest stands complicates the decision making of individual planners, who currently must rely on their skills and domain knowledge to interpret the data and adjust for uncertainty. To make more informed decisions, new practices are needed in which uncertainty is systematically collected and accounted for, as well as minimized in some relevant sense. The latter requires tools for cost-effective allocation of pre-harvest inventory resources.

To evaluate how a possibility to account for and minimize the uncertainty would influence the decisions of planners, a group of forestry professionals were presented with a prototype tool for multicriteria decision making, designed and developed in the project. The tool enables decision-makers to balance pre-harvest inventory costs with planning accuracy. In this particular prototype, the planning accuracy relates to the expected deviation of an annual harvest plan to the monthly industry demand.

With the use of this type of tools, our ambition is to enable forestry professionals to make decisions while systematically taking uncertainty into account. While this tool is primarily concerned with pre-harvest inventory, the methods are applicable for other decisions throughout the value chain. By utilizing these results it will be possible to make informed decisions and, when the uncertainty is minimized in some relevant sense, cost-effectively increase the precision in the value chain.

Developing and managing logging entrepreneurs for a resilient forest supply chain

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Luc Lebel[1]
Shuva Gautam[1]
[1] Université Laval, Département des sciences du bois et de la forêt

Abstract: In today's global landscape, it has become a common practice to engage independent small and medium enterprises (SMEs) for forest harvesting and transport operations. The decision for forest companies to rely on SMEs instead of in-house capacities can be influenced by various factors, including market conditions, company strategies, and labor market considerations. Nonetheless, it is widely acknowledged that forest entrepreneurs offer several economic, financial, productivity, and flexibility benefits (Eriksson et al., 2017; Erlandsson and Fjeld, 2017).

From an economic and financial standpoint, the employment of entrepreneurs has enabled companies to reduce operational costs and allocate or generate capital more effectively. Furthermore, subcontracting SMEs bear the immediate consequences of demand fluctuations and market conditions. On the productivity and motivation front, studies have shown that the utilization of entrepreneurs leads to increased performance and motivation (Drolet and LeBel, 2010).

More recently, there has been discussion regarding both the advantages and limitations of wood supply systems relying on independent SMEs (Johansson, 2023). This presentation aims to provide an overview of the current knowledge surrounding wood supply systems and logging entrepreneurs. It will explore the means and strategies available to adjust wood flow and propose a framework to address the expected impacts of demographic shifts, technological advancements, and disruptions in fiber supply.

If the primary motivation for employing SMEs was to enhance productivity and cost control, their future role within the forest supply chain could potentially involve facilitating better interoperability and establishing more robust delivery systems.

Dynamic recovered-wood-system-simulation model for a sustainable material recovered-wood use on a regional scale

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Mika Hayashi[1]
Michael Risse[1], Gabriele Weber-Blaschke[1]
[1] Technical University of Munich, TUM School of Life Sciences, Chair of Wood Science, Research Area Resource Flow Management, Hans-Carl-von-Carlowitz-Platz 2, 85354 Freising, Germany

Abstract: The necessary transformation from a fossil-based to a bio-based economy suggests an increased use of wood with new market players. In this context, a circular wood economy is essential for an efficient resource utilization and long-term carbon sequestration. Currently, however, about 80% of the recovered wood produced in Germany is used for energy generation and only about 20% for material applications. For a quick implementation of innovative circular utilization pathways, however, the complexity of the recovered wood system is not fully understood due to a lot of influencing factors.

Therefore, our goal is to build up a dynamic recovered wood system simulation model, which can be used for regional scenario assessment exemplified by the case study of Bavaria, Germany. In scenarios, e.g. regulatory or incentive approaches, competing uses, supply risks and feedbacks on the forest wood supply will be analyzed and recommendations for political and industrial decisions will be derived.

We will present the first modelling approaches, following the steps (1) identification and selection of the most relevant influencing factors regarding legal regulations, technical implementation, market effects, environmental impacts, stakeholder involvement, social acceptance, etc., (2) analysis of their interactions and feedback mechanisms, (3) development of the agent-based regional recovered wood market model, and (4) evaluation of different recovered wood innovation pathways developed by project partners.

Enhanced control of wood supply chains based on Apps of wood stacks measurements

T2.4 Developing digital drivers for risk mitigation in forest supply chains

[2] The Navigator Company
[3] Altri Florestal
[4] Sonae Arauco Portugal

Abstract: Uncertainties in wood supply caused by weather changes, such as prolonged dryness, must be mitigated in particular in Portugal where forest residues and wood stacks stored in the forest could represent an increased risk of forest fires. Knowing the precise location and volume of wood stacks in the field is important for both: a) optimal supply chain planning (minimizing operational costs); b) forecasting priority intervention areas with an increased risk of fire, and c) ensuring traceability of the wood along the value chain. In order to provide the required information in time, new technologies based on photo-optical stack measurement running in portable devices and smartphones have been tested. This study extends these tests beyond the state-of-the art by doing an extensive comparison amongst innovative technologies and with traditional wood stack methods in use in Portugal. Hence, this study aims to a) determine the accuracy of stack measuring for different smartphone applications for Iberian Eucalyptus and Maritime-pine, and propose the most suitable; b) assess the productivity, and cost-benefit of these apps; c) propose a new methodological approach to estimate the net volume and weight of log stacks, making use of the most suitable app. The tests consist of field measurements performed with different applications, assessments of net and gross volume measured with the apps. The manual method is based on the German standard of stack manual measurements. Furthermore, the estimated volume will be compared with Lidar technology and 3D modelling of wood piles using a DRONE. The productivity will be estimated based on time study measurements. Preliminary results indicated a reduction of circa 60% in time-consuming measurement with the apps. However additional tests are required to conclude about the accuracy of the measured apps. The wood supply managers in some of the forest industries in Portugal will be involved in this study to provide their experts knowledge and assist in the cost-benefit analysis. This will be instrumental to conclude about the more suitable method for the Portuguese forest sector which could improve the wood stock control supporting the chain resilience and minimize the risks caused by adverse weather conditions.

Integrated modelling of strategic forest management and industrial capacity planning for a more resilient and sustainable forest sector

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Gregory Paradis[1]

[1] Department of Forest Resources Management, The University of British Columbia

Abstract: Sustainability is a fundamental goal of Canadian forest policy. In practice, implementation of sustainable forest management (SFM) in Canada is distributed across strategic forest management planners and industrial fibre procurement planners. The current SFM paradigm implicitly assumes that forest harvesting activities are sustainable as long as aggregate harvest levels remain below annual allowable cut (AAC) volumes determined by strategic forest management planners, yet recent studies have shown that this assumption does not always hold true. Maintaining the status quo SFM planning process may leave the Canadian forest sector (and Canadian ecosystems and society) exposed to risk of sustainability failures (e.g., fibre supply shortages, mill closures job loss, ecosystem degradation, reduced economic opportunities for future generations).

Thus, a shift in the way we approach and implement SFM is necessary to ensure continued integrity of Canadian forest ecosystems as well as a thriving and sustainable forest products sector. The current SFM paradigm features poorly aligned goals and large information gaps between government and industrial agents in the planning process—these misalignments and information gaps are poorly documented, and their net effect of the SFM planning process is poorly understood. Using a systems engineering approach, we document these gaps and explore innovative solutions for integrated modelling of strategic forest management and industrial capacity planning in the Canadian forest sector.

Activities in this ongoing research program include: development of a flexible, re-usable, open-source, reproducible modelling framework that can be used to simulate the net cumulative effects of status quo distributed planning processes; adaption of existing methods or implementation of new mathematical and data-centric modelling methodologies (e.g., simulation, optimization, hybrid simulation-optimization, machine learning and artificial intelligence methods, etc.) to model hypothetical new planning processes and business models; development and integration of powerful open-source forest carbon modelling tools to track cradle-to-grave net carbon emissions directly within the integrated SFM planning process; case studies in various Canadian jurisdictions.

Mitigating wood quality decay risks by weather data powered transport decision support

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Peter Rauch[1]
Christoph Kogler[1]
[1] University of Natural Resources and Life Sciences Vienna (Austria)

Abstract: Climate crisis induced forest calamities such as windstorms followed by insect infestations challenge wood supply chain management. To fulfil increasing production amounts in a more sustainable, resilient, and quality-preserving manner, wood logistics decisions need to incorporate plenty of data (e.g. weather, road trafficability). Discrete event simulation proved to be an excellent means for a digital representation of wood supply chains. Further strengths in facilitating stakeholder participation and establishing credibility through visualization enable the implementation of quantitative decision support. Consequently, a virtual wood supply chain environment containing dynamic altitude zone-based risk forecasts for blue stain and insect infestations was developed. Unimodal and multimodal wood supply chains were simulated to track sawtimber quality development from roadside stocks to the wood-based industry. This enabled identifying and modelling the relationship between lead time and wood quality devaluation as well as applying this knowledge to evaluate innovative transport strategies. Complete avoidance of wood value loss can be achieved if transport capacities are synchronized with harvesting capacities to keep lead times short. Increasingly frequent and extensive forest calamities limit those coordination capabilities and produce salvage wood amounts that dramatically exceed regional available transport capacity. Under these circumstances, strategies using wood quality forecasts significantly outperform those currently being used by preventing, on average, 57% of the sawtimber devaluation. Moreover, 73% of the devaluation can be avoided if up to 25% additional truck transport capacity is deployable in peak periods of wood devaluation risks. If no additional self-loading truck transport resources are available, still 67% of the devaluation can be prevented by using the bottleneck resource of self-loading trucks more efficiently through transferring 20% of the sawlogs to rail wagons leading to a more sustainable and resilient wood procurement.

OPTIMIZING THINNING SCHEDULING, CARBON STOCKS, AND WOOD SUPPLY IN MEDITERRANEAN PINE PLANTATIONS UNDER THE RISK OF FIRE

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Mauricio Acuna[1]
Rafael Navarro-Cerrillo[2], María Angeles Varo-Martínez[2]
[1] Natural Resources Institute (LUKE), Finland
[2] University of Cordoba, Spain

Abstract: Carbon pricing can be essential in promoting adaptive silviculture in Mediterranean pine forests. Commercial thinning in these forests can improve carbon sequestration and stocks, contributing to climate change. However, thinning scheduling decisions must also consider the risk of fire that affects these pine forests every year. Fires can critically impact the supply of timber products from these plantations and result in increased carbon emissions, offsetting the benefits associated with carbon sequestration. Thus, this scenario with increased uncertainty requires more robust planning approaches along the supply chain that can react and secure the delivery of products demanded by end customers. This paper presents a solution approach that combines optimization with Monte Carlo simulation to optimize the stand's thinning schedule and maximize Net Present Value (NPV) over a 10-year planning period. In addition to harvesting and transport costs, the model included revenue from two sources: sawlogs and biomass extracted during the thinning and credits from carbon stocks at the end of the planning period. The study area is in Andalusia, southern Spain, totalling a forest area of nearly 30,000 ha. Airborne Lidar data and allometric biomass models were used to estimate above-ground forest biomass, including commercial timber and carbon stocks. Airborne Lidar and Satellite imagery were also used to develop fuel and fire risk models, which in turn, were used as input in the thinning scheduling and supply chain model. The analysis focused on the impact of carbon prices on NPV, optimal thinning schedules, flows of sawlogs and biomass products to customers, and carbon stocks at the end of the planning period. Carbon prices and fire risk also impacted the flow of sawlogs and biomass delivered to end customers. These results reveal that thinning schedules, wood supply, and NPV are very sensitive to carbon prices and damage by fire.

Towards an innovative digital architecture for more resilient forest-based supply chains

T2.4 Developing digital drivers for risk mitigation in forest supply chains

Reinaldo Gomes[2], Dag Fjeld[3], Mikael Ronnqvist[4], Ana Póvoa[5], Pedro Amorim[2]
[1] FORESTWISE - Collaborative laboratory for integrated forest & fire management, Portugal
[2] Inesctec
[3] Swedish University of Agricultural Sciences, Sweden
[4] University of Laval
[5] Instituto Superior Técnico, Universidade de Lisboa

Abstract: Supply chain planning aims to balance wood flow availability and consumption, thereby minimizing operational costs and raw material deterioration/value loss. In reality, wood availability is subject to seasonal restrictions and fluctuations (in quantity and quality), which can be amplified by climate-driven hazards such as forest fires. Hence, forest industries are interested in knowing how they can design and coordinate supply chain operations to become more resilient and better respond to those extreme events that likelier will be intensified by climate change.

The foundation for this is a novel digital architecture anchored in Business Analytics and Decision Support Systems, which integrates and processes data flows from multifold sources, to predict the impact of the disturbances at supply chain level and define contingencies for rapid operational response, ensuring robust supply. The key elements of this architecture are a) the *tower view* that consolidates information along the value chain to provide an instant “snapshot” vision of the entire supply chain, with emphasis on wood flows, capacity and stocks; b) the *decision theatre* that provides the intelligence layer enabling insight on the impacts of disturbances as well as the simulation of possible contingencies actions.

This study with present the detailed architecture and technical specification of these key components, based on a literature review and benchmark of existing models and methods. The outcomes will be instrumental for developing an initial prototype that can be applied in the pulp and paper supply chain in Portugal, in a region that has been historically affected by forest fires.

T2.5 Economics of forest plantations in Latin America: advances, challenges and opportunities

Comparison of weight in three sections of Eucalyptus under natural drying conditions

T2.5 Economics of forest plantations in Latin America: advances, challenges and opportunities

Carlos Leandro Benitez Aranda[1]
Alexander Abdel Fleitas Saucedo[1], Maria Laura Quevedo Fernández[1], Lila Mabel Gamarra Ruiz Diaz[1], William Tomas Folmann[2]
[1] Universidad Nacional de Asunción
[2] SJ Green

Abstract: One of the factors that has a significant influence on transportation costs of forest products it its weight. The main objective of this study was to compare the weight loss of different log sections from green weight to dry weight under natural drying conditions. Based on an inventory and considering the normal distribution of diameters, 33 individuals from a forest plantation of hybrid clones of *Eucalyptus grandis x E. urophylla* in Itacurubi de la Cordillera, Paraguay, were selected. The selected trees were harvested, and three logs were extracted from each individual at 0.3m to 1.3m, 5m to 6m, and 10.05m to 11.05m. The measurements were weighed to obtain the green weight with bark, and subsequently, they were weighed 19 times in an open-air environment from 2 days after harvest, to 225 days after harvest at varying intervals, with a higher intensity near the harvest date. Once the weight was stabilized, the percentage of weight loss was determined. The results showed that, on average, after 225 days of harvest, 44.77% of weight was lost in section 1, 44.37% in section 2, and 43.50% in section 3. Having in count these results we can determinate that the weight loss in harvested forest products is quite significant, and it is necessary to consider these results when deciding the optimal time for transportation.

ECONOMETRIC MODEL FOR AGRICULTURAL LAND PRICES BASED ON DETERMINING FACTORS OF THE MICRO-REGION OF CANOINHAS, SANTA CATARINA, BRAZIL

T2.5 Economics of forest plantations in Latin America: advances, challenges and opportunities

José Sawinski Júnior[1]
Paulo Cezar Gomes Pereira[1, 2], João Carlos Garzel Leodoro da Silva Garzel Leodoro da Silva[1, 3], Romano Timofeiczyk Junior[1, 3], Vitor Afonso Hoeflich[1, 3]
[1] Federal University of Paraná, Postgraduate Program in Forestry Engineering, Brazil
[2] Federal Rural University of the Amazon, Campus Paragominas, Brazil
[3] Federal University of Paraná, Department of Rural Economy and Extension, Brazil

Abstract: Collecting real field information for land prices is a costly activity, demands time, care with sample selection, and may represent expectations more than land prices themselves. The modeling helps in understanding the dynamics of the land market, in order to enable the design and application of a set of policies capable of making the land market more transparent and effective, seeking to reduce the asymmetries of market information between sellers and buyers. Considering that each region of the country has its particularities, there is no single, standard model applicable to the entire Brazilian territory, but rather a consolidated and widely tested methodology. The aim of this study was to apply a multiple linear regression model for agricultural land prices based on their determinant factors in the microregion of Canoinhas/SC, Brazil. The model had the land price (Lp) as the dependent variable, and the exchange rate (camb), inflation rate (sel), leasing price of land for soy (arrend), regional agricultural GDP (GDPagr) and the Regional Price Index (IPR) as independent variables (PIBagr). The assumptions of the model were tested, meeting the reliability requirements and multiple linear regression analyzes were carried out. The results showed high significance of the regression model, with coefficient of determination (R2) = 0.820, explaining 82.0% of the variance, and the model: Lp = 29195.298 + (3137.469*camb) + (-353.511*sel) + (11.862*arrend) + (-

0.010*GDPagr) + (-138.714* IPR). All independent variables had an impact as a determining factor on the dependent variable (land price), with leasing being the factor that most contributed, along with the Regional Agricultural GDP and the Regional Price Index, which indicate advances in regional agricultural production and greater demand by lands. Understanding the behavior of the exchange rate and inflation rate can help predict the future land market. It is recommended the periodic evaluation of these variables and their projections, as an additional tool for understanding the dynamics of the regional land market, developing strategies that can generate better conditions of competitiveness, especially for small producers, avoiding loss of interest in agricultural activity.

Key words: land, linear regression, price

EVALUATION OF THE EFFECTS OF PRICE, EXCHANGE, AND VOLUME ON THE GROWTH OF REVENUES FROM BRAZILIAN EXPORTS OF WOOD PRODUCTS

T2.5 Economics of forest plantations in Latin America: advances, challenges and opportunities

José Sawinski Júnior[1]
João Carlos Garzel Leodoro da Silva[1], Ademilson Souza Maciel[1], Vitor Afonso Hoeflich[1]
[1] Pos Graduation in Forest Engineering - Federal University of Paraná State

Abstract: Brazil has advanced in export volume but has not been able to increase prices over the last decade for wood products. This work seeks to contribute to the understanding of this conflicting scenario, evaluating the growth in the revenue of Brazilian exports of these products during two periods: 2011-2015 and 2016-2020, as well as decomposing its effects in price, exchange rate, and volume. The method applied was the *shift-share*, widely used to identify determinants of sectoral and regional economic growth, being a precursor to the approach in the analysis of forest sector exports. Historical series for 5 (five) categories of wood products were analyzed, with export data from the Ministry of Economy. The historical series of nominal exchange rates from the Institute of Applied Economic Research (IPEA) was used. The real effective exchange rate (RER) followed the methodological note of the IPEA. All product categories analyzed had positive effects in terms of volume, for both periods, with a greater proportion in the second being driven by the exchange rate, although with a loss in real price, failing to offset inflation. The only exception was wood manufacturers, a product with higher added value, which presented gains in volume, exchange rates, and price. The volume effect was the most relevant, followed by the exchange rate as a result of the appreciation of the dollar against the real against the exchange rate and control of inflation in terms of the divergent effects on the national and international scenario. The price presented negative variations in export revenue, with a decline over the period. In addition to the added value of exported products, world stocks and levels of consumption may have contributed negatively to this scenario, affecting all categories of exported products, except for manufactured wood products, the only category that did not reflect such justifications.

Keywords: export; shift-share; wood

How MNE operations shaped the process of industry emergence and SME development in Uruguay's pulp sector?

T2.5 Economics of forest plantations in Latin America: advances, challenges and opportunities

Sini Rantanen[1]
Veera Tahvanainen[2], Irina Mihailova[2], Mika Gabrielsson[2], Jouni Pykäläinen[2]
[1] Karelia University of Applied Sciences
[2] University of Eastern Finland (UEF)

Abstract: The development of the Pulp Industry to a global, multinational business has enabled the emergence and growth for numerous small and medium sized enterprises (SMEs). These SMEs have adjusted their business and obtained different positions and roles within the multinational Pulp Industries complex business environments. The impact of MNEs on developing economies has been largely studied by examining the productivity changes generated by spillovers which have produced mixed results. In this study we expanded this research by unraveling the content and outcomes of the interaction between MNEs and local actors during the process of MNE-led industry emergence. We focus on a single industry setting, - Uruguay's forest-based pulp sector. In particular we aimed to answer the question *how MNE operations have shaped the process of industry emergence through various spillover mechanisms, linkages, and externalities*? The data consists of interviews with managers and CEOs of companies in the Uruguayan pulp industry and SMEs operating in this value chain: eucalyptus seedling nursery, silviculture, harvesting, and wood logistics. The SME interviews included descriptions of the start-up process of the firm and how the firm developed its business model and perceives its role in the industry's global value network. In addition, we interviewed experts in key public and private institutions and organizations involved in the forest industry in Uruguay. These interviews concentrated on describing the industry and its development in Uruguay, the socio-technical regime of the pulp industry, and the future perspectives of the industry as well as the megatrends affecting it. In addition to the interviews, secondary sources, including scientific articles, statistics, reports, firm websites, and local newspapers were analyzed. The findings shed light on how the pulp industry in Uruguay followed a path-dependent evolution triggered by MNEs presence and establishment of local linkages with business and public actors. The study also developed information for the policy-makers about the conditions when MNE operations create long-term economic and social consequences.

Structure of pulpwood markets in Latin America: a study case of price strategies

T2.5 Economics of forest plantations in Latin America: advances, challenges and opportunities

María Emilia Arriaga Tamosiunas[1]
Virginia Morales Olmos[2]
[1] Departamento de Evaluación de Políticas y Nuevos Proyectos, Dirección General Forestal, Ministerio de Ganadería, Agricultura y Pesca, Montevideo, Uruguay.
[2] Departamento de Ciencias Económicas, Universidad de la República-Sede Tacuarembó, Tacuarembó, Uruguay.

Abstract: The forestry sector in Uruguay has increased relevance in the last decade. The pulp value chain shows the greatest development based on attracting foreign direct investment. Its final product represents 75% of the annual value of the sector's exports. One of the challenges faced nowadays is the spatial dispersion of the roundwood supply within the country relative to industry's location which increase logistic costs. Worldwide, the pulpwood market is characterized by an oligopsonic structure, with strong incentives to exercise market power to reduce costs, mainly transportation costs. The asymmetric information between pulp industries, public sector and small forest producers leads to the use of FOB price as proxy of timber price in investment projects, supply negotiations and market regulation, ignoring other types of price's strategies. The objective of this presentation is to describe the current pulpwood market in Uruguay and to discuss alternatives prices strategies. One of the challenges faced in the study was the data available. Therefore, simulations were conducted to fill these gaps. Results show that from the supply side there are several producers with different characteristics and from the demand side there are mainly two mills. In addition, the mills own their own forests, and have different agreements with producers. Finally, it is shown that both companies have similar price discrimination strategies. These results should be considered when implementing land-use planning policies that could affect the distribution of the resource in relation to the location of industries. Furthermore, production cycles and land-use planning affect roundwood availability. Then, although genetic improvements and silvicultural innovations to shorten production cycles, favoring roundwood availability, the potential will be determined by the site.

Wealth and income generation in the forestry value chains in Minas Gerais, Brazil

T2.5 Economics of forest plantations in Latin America: advances, challenges and opportunities
Roberta Afonso[1]
[1] Central Bank of Brazil

Abstract: Globally, Brazil is one of the most important producers of wood products from forest plantations. The area devoted to forest plantations in Brazil is rapidly increasing, driven by climatic conditions suitable for high productivity, land availability, and strong market demand. Since most of the harvest is exported, wood production brings important macroeconomic benefits. However, knowledge of the economic impacts of forest plantations at regional and local levels remains limited. This study investigates this issue by analyzing the economic impacts of tree plantations across Minas Gerais, the state with the largest plantation area in Brazil established since 1980. This study focuses on the main forestry sectors – forest plantations, wood products, furniture, and pulp and paper – and how they interact with other important economic sectors to generate wealth for different income classes from both production and consumption. I employ a multi-regional input-output model with a Miyazawa extended framework covering 13 regions, 16 sectors, and 10 income classes. This is a novel approach for sub-state forestry sectors in Brazil. Results show that forestry sectors are important for income generation in the state, especially for lower income classes. More industrialized regions receive income from either an increase in production or in consumption; the resulting income is concentrated in the top income class. Although the impact of income generation through forest plantation expansion is small, most of it remains in the same region in which the plantation is located and principally accrues to lower income classes. These results are consistent with previous findings linking forest expansion to less poverty over time (Afonso, R. and Miller, D.C. *Forest Policy and Economics 133 (2021): 102618*). Conversely, the cellulose and paper sector pays higher salaries, but most of the wealth leaks to other regions both inside Brazil and out. These findings help provide a foundation for policies that promote forestry industry's role in fostering economic growth in remote and less developed areas and it also sheds light on understanding Brazil's forestry value chain.

T2.6 Ensuring healthy trees for high quality wood products

Electric Resistance Tomograph (ERT): Innovative non-destructive method in analysing interiors of standing trees in tropics

T2.6 Ensuring healthy trees for high quality wood products

BARAGUR NEELAPPA DIVAKARA[1]
MADAN PRASAD SINGH[1]
[1] Institute of Wood Science and Technology, Malleshwaram, Bangalore – 03, Karnataka, India.
*Corresponding author – bndsira@gmail.com

Abstract: Electric Resistance Tomograph (ERT) was first applied to trees in 1998 to study internal details. Experiments using ERT were started to determine fungal decay inside the trees, to estimate sapwood and heartwood width for many temperate species. However, for the first time an innovative non-destructive method in analysing interiors of standing trees using Electric Resistance Tomograph (ERT) for tropical timber species has been developed. Our main aim is to understand the internal wood structural details using 2D and 3D images of Electric Resistance Tomograph (ERT). Combined effects of resistivity offered by heartwood and moisture content in the sapwood developed a non-invasive 2D and 3D cross sectional images with colour differentiation from dark brown (high resistance) to blue (low resistance). The resistivity pattern for some species consisting of high resistivity in the inner part of the stem with lower resistivity on the outside are mostly due to changes of wood moisture content in heart wood and sap wood. Efforts have been made in economically important timber species like sandalwood and red sanders to standardize the ERT equipment in estimation of heartwood content in standing trees. In sandalwood the resistivity pattern varied from 60 to 1739.7 ohms and ERT estimated heartwood is showing 90 % similarity with observed heartwood diameter. Similarly, resistance ranged from 69 to 2945 ohms for red sanders and ERT estimated heartwood is showing 92 % similarity with observed heartwood diameter. Added to this, Electric Resistance Tomograph (ERT) can be used to analyse moisture distribution and current flow in the tree trunk. ERT also has been successfully used to estimate tree trunk decay, differentiating the sapwood-heartwood boundary, detecting and understanding hollowness in standing trees in tropics. This technique can be applied to visualize the heterogeneous distribution of resistivity in stems, mainly affected by the different physical characteristics of trunk and this can greatly vary between species to species in both ER magnitudes and patterns. The method has the advantage of being non-destructive, and relatively speedy at a low cost.

An ecological assessment of insect pests in Moringa oleifera Lam. progeny trials in Kenya

T2.6 Ensuring healthy trees for high quality wood products

Emmanuel Makatiani[1]

[2] Centre for Ecology and Hydrology, CEH Edinburgh, Bush Estate Penicuik, Midlothian, EH26 0QB, United Kingdom.

Abstract: Abstract

Insect pests damage crops and trees resulting lower yield and quality of trees and crops worldwide. *Moringa oleifera* Lam. (Family: Moringaceae) has many potential health benefits and ability to cure several ailments in both humans and animals but suffer attacks from various types of pest and diseases. A survey of insect pest infestation on *M. oleifera* growing in three progeny trials under different eco-climatic conditions found in Kibwezi, Kitui and Ramogi (Kenya) was undertaken. The three trials were established in October 2019 (Kibwezi and Ramogi) and November, 2020 (Kitui). The trials have ten replicates each with seven families from 13 accessions of *M. oleifera* collected from different agro-ecological zones of Kenya, with families completely randomized within the replicates. We examined different parts of the *M. oleifera* plants, such as flowers, fruits, leaves, stems and trunks for symptoms of insect damage. The progeny trials contain thirteen provenances (eight naturalized Kenyan populations and five exotic accessions). Plant samples were visually examined in the field and with the aid of a stereomicroscope in the laboratory. Although *M. oleifera* produce phytochemicals that act as biopesticides, the plant is attacked by a significant number of pests that thrive on its nutritious parts. Our results show that *M. oleifera* is attacked by a number of pests. Notable pests of potential economic importance included: *Noorda blitealis* and *Eupterote molliefera* (Lepidoptera), leaf and flower defoliators; *Gitona distigmata* Meigon damage green pods; a tree girdler-*Paranaleptes reticulata* (Coleoptera) pruned the branches; termites (*Microtermes* sp. and *Odontotermes* sp. (Isoptera), foraged on live and dead moringa tissues; an unidentified stem borer that caused up to 45 cm length and diameter range of 8-15 mm tunnels in the leading tree stems. Thus, our preliminary insect pest survey indicates that *M. oleifera* in Kenya is attacked by plant hoppers and stem borer. Although infestation was estimated visually at 10%, and therefore at low economic thresh hold level, pest management strategy should be developed as *M. oleifera* is already gaining popularity in most east African countries and the world at large, in food and nutrition safety programmes.

Keywords: Insect pests, *Moringa oleifera*, progeny trials.

Establishment of serological detection methods for novel emaraviruses in oak and ash trees

T2.6 Ensuring healthy trees for high quality wood products

Marius Rehanek[1]
Lisa-Marie Schmid[2], Simone Bode[2], Susanne von Bargen[1], Carmen Büttner[1]
[1] Humboldt-Universität zu Berlin, Albrecht Daniel Thaer-Institute of Agricultural and Horticultural Sciences, division Phytomedicine, Lentzeallee 55/57, D-14195 Berlin

Abstract: The emerging group of emaraviruses (order *Bunyavirales*; family *Fimoviridae*) is strongly increasing in recent years with species that infect a variety of host plants. These worldwide occurring, plant pathogenic viruses, recently summarized by Rehanek et al. (2022), are naturally transmitted by gall mites and contain a segmented, single-stranded, negative-sense RNA genome. It comprises a core of four genome segments (RNA1-RNA4), with each RNA encoding a virus-specific protein (Rehanek et al. 2022).

In Europe, numerous novel emaraviruses have been described in important deciduous trees species of forests and urban green. In common oak (*Quercus robur* L.) and common ash (*Fraxinus excelsior* L.), two emaraviruses associated with characteristic virus-suspected leaf symptoms were identified by high-throughput sequencing (HTS). The common oak ringspot-associated virus (CORaV) and the ash shoestring-associated virus (ASaV) represent distinct species within the genus *Emaravirus* and are widespread in different European countries (Rehanek et al. 2021; Gaskin et al. 2021; Svanella-Dumas et al. 2022). While RT-PCR is established as the standard diagnostic method for the detection of most emaraviruses, serological detection methods, especially for forest tree-infecting emaraviruses are rarely available. GST-tagged-P3 proteins of CORaV and ASaV were expressed heterologously and purified for immunization in order to obtain polyclonal antibodies against the viral nucleocapsid proteins encoded by RNA3. Leave samples from oak and ash trees were collected at different locations Europe-wide. Applying obtained antibodies we developed diagnostic ELISAs for the CORaV and ASaV detection in the economically important tree species oak and ash. Screening results are presented.

Evaluation of wood decay proportion and dynamic modulus of elasticity by acoustic tomography

T2.6 Ensuring healthy trees for high quality wood products

Abstract: Sugar maple wood is highly prized for its appearance and structural applications. However, the incidence of decay in maple trees decreases their value and degrades their wood properties. Fifty-three trees were sampled from two sites to investigate the potential of acoustic tomography to detect decay in sugar maple trees and to assess its impact on the wood's mechanical properties. Acoustic tomography determined the proportion of decay and evaluated the dynamic (DMOE) modulus of elasticity of the sampled sugar maple stems. The sound propagation speed in wood and its density determined the DMOE. In addition, eighteen maple trees were sampled and felled from two other sites to validate the potential of acoustic tomography for predicting the wood's mechanical properties. Parallel compression and flexural properties were measured on clear wood samples. The DMOE was also measured by acoustic tomography and ultrasound methods to investigate the relationship between the wood moduli of elasticity measured by destructive and nondestructive methods. Acoustic tomography accurately predicted the proportion of decay in maple trees. The DMOE measured on trees correlates well with the static and DMOE measured on destructive samples. Decay decreased the mechanical properties by up to 60%, depending on its stage.

Identification of cell structure related vibration characteristics of wooden plates by high resolution laser scans

T2.6 Ensuring healthy trees for high quality wood products

Oliver Dünisch[1]
[1] Master School for Carpentry and Cabinetmaking

Abstract: The vibrational properties of wood are of special interest for the production of some of the most valued timber products like music instruments. Therefore this study was carried out with special emphesis on the identification of anatomical key factors for the vibrational behaviour of wood as a basis for adapted forest management practices. The vibrational behaviour of wooden plates from Norway spruce (*Picea abies* (L.) Karst.) with transverse, radial, and tangential oriented impact planes was studied under controlled conditions. The square plates with a side length of 300 mm and a thickness of 5 mm were fixed on all four sides and set into vibration by means of a pendulum. The vibration of the plate was directly measured by line scans carried out by a high resolution laser scanner. The spatial resolution of the system was 31 µm, the accurracy of the measurement was +/- 0.6 µm. The vibrational behaviour of the plates was analysed in terms of the frequencies, the amplitudes, and the damping of the overlapping waves identified in the vibration spectra by means of Fast Fourier Transformation analyses. The anatomical structure of the wood from the area under investigation was studied by means of light microscopy. The comparison of the vibration spectra obtained from measurements carried out in earlywood and latewood zones of the plates showed that the distribution of earlywood and latewood in the plates had a significant influence on the vibrational behaviour of the plates. The analyses of line scans parallel to the grain and along radial and tangential oriented cell walls indicated differences in the vibration characteristics between radial and tangential cell walls of the tracheids. The results are discussed with regard to the wood structure of Norway spruce and the outstanding importance of this timber species for the production of resonance wood.

IMPROVED INDEXING METHOD FOR SELECTION OF SUPERIOR GENOTYPES OF MELIA DUBIA CAV.

T2.6 Ensuring healthy trees for high quality wood products

Jyoti Khatana[1]
Bhumika Kaushik[1], Aman Mahajan[1], Ashok Kumar[1]
[1] Division of Genetics and Tree Improvement, Forest Research Institute, Dehradun-248006, Uttarakhand, India

Abstract: *Melia dubia* Cav. is a fast-growing multipurpose tree species occurs in Northern Himalayas, North Bengal, Western Ghats, Sikkim, and other parts of India under various afforestation schemes for fodder, timber and industrial woods. It is known as money spinning tree due to its great economic returns. Identification of superior genotypes of *Melia dubia* under different ecological conditions with promising characteristics such as growth, productivity and stability will enhance productivity to maximum level to meet ever-increasing demand by establishing commercial plantations. Information on genetic structure and diversity of tree provide base for efficient utilization of genetic resources to comprehend potentiality for maximizing growth and yield. During present study, selection and screening of promising genotypes of *Melia dubia* was carried out by applying index method of selection with minor modifications. The multitrait selection resulted in higher expected response and combined information on all traits of interest into a single index. Moreover, it became useful as each trait played an important role and all individuals were ranked according to one scoring system. A total of 788 genotypes were screened based on height, collar diameter, diameter at breast height, clear bole height, straightness, and branching behaviour. Out of these, 61 genotypes were selected with index value of 100. Similarly, significant improvements could be contemplated in various forestry tree species by screening promising genotypes using proper selection method(s).

Keywords: *Melia dubia*, multitrait, superior genotypes.

Influence of Crown Defoliation Degree on Value of Produced Norway Spruce (Picea abies (L.) Karsten) Roundwood

T2.6 Ensuring healthy trees for high quality wood products

Branko Ursić[1]
Dinko Vusić[1], Andreja Đuka[1], Stjepan Posavec[1], Ivan Žarković[1], David Janeš[1]
[1] University of Zagreb Faculty of Forestry and Wood Technology

Abstract: Norway spruce (*Picea abies* (L.) Karsten) is the second most common coniferous species, with a share of 2.3% in the total wood stock of Croatian forests. Almost 60% of Norway spruce trees in Croatian forests have crown defoliation to some degree, indicating often poor health condition of spruce trees. Bark beetle outbreaks in Croatian forests resulted in the massive death of Norway spruce trees and decreased value of produced logs. This research aims to investigate the assortment structure and value of produced assortments from healthy trees and trees affected by crown defoliation caused by some biological factor and climate changes. The research was conducted in the summer of 2022 during a salvage felling of Norway spruce in the Gorski Kotar region (N45.647754, E14.578801). Sampled trees were classified as a »healthy« tree (if crown defoliation was not higher than 10%), as a »3b« tree (if crown defoliation was between 80–99%), and as a »dead« tree (crown defoliation was 100%). Trees that were damaged during earlier timber extraction were not included during the tree selection. After a tree was cut down and logs were produced, they were measured, and roundwood scaling was done according to the HRN standard. According to the price list used by the biggest Croatian state forest company (which manages 75% of all forest land in Croatia), the average value of each defoliation degree was calculated. In total, 55 -Norway spruce trees were recorded, and their breast-high diameter was 10–74 cm. The whole technical usability was the highest in the category of »healthy« trees (82.4%), followed by »3b« trees (81.5%), and the lowest was in the category of »dead« trees (78.2%). The average value of produced assortments was 57.90 EUR/m^3 in the category of » healthy « trees, 58.96 EUR/m^3 in the category of »3b« trees, and 45.18 EUR/m^3 in the category of »dead« trees. Considering the decrease in technical usability and the average value of the assortments essential produced from dead trees compared to the healthy trees, and trees in the category »3b«, it is essential to recognize weakened trees and use them before value could decrease significantly.

Precision forestry for reducing the impacts of root rot in boreal forests

T2.6 Ensuring healthy trees for high quality wood products

Abstract: Root rot caused by Heterobasidion spp. causes severe growth decline, root and stem decay and carbon balance losses in Norway spruce forests across Europe. Root-rot spreads from tree to tree through root contacts and by spores that colonize fresh cut stump surfaces - both mechanisms benefitting from industrial forestry and tree-root injuries. Once established, root-rot eradication requires several decades and a change of tree species. We used geo-located tree-level cutting data from hundreds of harvesters around Finland, a tree-root rot model, and novel statistical methods to study mechanisms, risks, and economically optimal regeneration strategies of root-rot infected stands in southern Finland. We were guided by a vision that someday harvester data could routinely be uploaded to central database and used for sustaining and improving forest health, more diverse regeneration strategies, and resilience. Root-rot infected trees were clearly more clustered than the trees normally are, a process which we explained with a Bayesian model containing the root-contact model. This lays foundations for precision forestry, as economically the most profitable spruce can be planted on uninfected patches, while rest of the area can be planted with other species. We further optimized the stand regeneration strategies by balancing economic and mitigation goals for root-rot infected stands. Warm conditions, high root-rot incidence, site fertility and interest rate favoured replacement of spruce with birch after clear cut, while at the opposite side of the gradient, Scots pine was favoured. Spruce mixtures remained the most competitive in the middle of the gradients. The results of spatial and economic-ecological analyses were encapsulated into an AI-based tool that was able to generate a regeneration recommendation for any new stand with harvester data. Risk maps based on harvester data for Southern Finland were consistent with those based on forest inventory data, but showed finer detail, and patchiness in the range of 10 km. Harvester data, when combined with root-rot identification and modelling provides excellent opportunities for precision forestry and risk mapping. The next challenge, as shown by our stakeholder consultation process, is to create common rules and databases for storing harvester data and for using these data in practice.

Relationship between decay of Populus tremuloides caused by Phellinus tremulae and tree age

T2.6 Ensuring healthy trees for high quality wood products

Tod Ramsfield[1]
Bradley Tomm[1], Michael Michaelian[1], Ted Hogg[2]

[2] Northern Forestry Centre, Canadian Forest Service, Natural Resources Canada (Retired)

Abstract: Trembling aspen, *Populus tremuloides*, can become infected by the heart rot fungus *Phellinus tremulae*, leading to decay of standing trees. Prior to fungal infection, carbon is sequestered in the stem of the tree as it is actively growing; however, following infection by *P. tremulae*, trees can transition from a carbon sink to a carbon source as heartwood is decayed and carbon dioxide is released to the atmosphere through the decay process. Losses to decay also reduce wood quality. Through repeated observations of established field trials, it was observed that *P. tremulae* incidence increased at the stand level with increasing stand age. In a laboratory study, we determined the optimum temperature for decay under controlled temperatures by assessing mass loss of inoculated aspen blocks over time. We also assessed basidiospore dispersal by the fungus within stands containing infected trees. Through these experiments the optimum decay temperature was determined and we found that basidiospores are present throughout the growing season. It is difficult to determine the amount of carbon lost to decay as *P. tremuloides* stands age; however, this process has been observed at every plot within the study area, suggesting that harvest should be timed to minimize losses to *P. tremulae* while maximizing wood quality.

Resistography as low-invasive method for early detection of Fistulina hepatica in wood-productive plantations of Castanea sativa

T2.6 Ensuring healthy trees for high quality wood products

Abstract: Sweet chestnut (*Castanea sativa* Mill.) is one of the most profitable forest species in southern Europe because of its high-quality wood and fruit production. This species is facing a generalized silvicultural abandonment in the north-east region of Spain since the 1980's, caused by Chestnut Blight (causal agent *Cryphonectria parasitica* (Murril) M.E. Barr) and by uncertain market conditions. In the 1990's Chestnut Red Stain (CRS), a heartwood discoloration caused by the fungus *Fistulina hepatica* (Schaeff.) With., became another economic concern. At early stages, the structural properties of the wood seem not to be affected, nevertheless, the timber's economic value drops up to 70% by preventing its use as quality saw timber or veneer. CRS causes uncertainty to forest managers since it could only be detected when the stands are thinned or cut. CRS can be detected through molecular methods but it is costly. The main objective of this work was to develop an efficient detection method to provide an easy and reliable tool to detect the presence of *F. hepatica* in early stages of productive periods. A total of 75 trees were analysed through molecular methods to determine the presence of *F. hepatica*. After that, an IML-RESIF300-s resistograph was used to characterise the wood of sampled trees. Thirteen wood-quality indexes were calculated and their correlation with the presence of the pathogen was evaluated using linear mixed models. We found clear differences between healthy and diseased trees in four indexes: 1)maximums average; 2)minimums average; 3)maximums average minus total average; 4)absolute minimums. The results support the hypothesis that, although CRS does not impact seriously the wood properties at early stages, it modifies them enough that its presence can be detected through inexpensive and fast mechanical methods. This will allow forest managers, to evaluate the incidence of CRS, target thinnings and adjust rotations accordingly.

T2.7 Fast growing trees in support of sustainable bioeconomy

Biomass production in the second rotation of poplar plantation – effects of thinning strategies

T2.7 Fast growing trees in support of sustainable bioeconomy

Tetiana Svystun[1]
Henrik Böhlenius[1]
[1] Swedish University of Agricultural Sciences, Southern Swedish Forest Research Centre, Sweden

Abstract: Poplars plantation have shown an ability to provide large volumes of biomass on agricultural land during the first rotation cycle with planted trees. However, there is limited knowledge about poplars biomass production during the second rotation, established by re-sprouting after the final felling. Here, we analysed the effects of different thinning strategies on the biomass production in the second rotation plantation of poplar clone OP42 (*Populus maximowiczii* Henry × *P. trichocarpa* Torr. and Gray) in Southern Sweden. Four treatments with different thinning intensities were applied at the age of seven years after clear felling: (1) unthinned with an average stand density of 6000 stems ha^{-1}, (2) light thinning with removal of every second tree row to a density of 3000 stems ha^{-1}, (3) medium thinning from above to 1100 stems ha^{-1}, (4) heavy thinning from above and removal of every second tree row to a density of 550 stems ha^{-1}. Assessments of stem wood volume/biomass production were based on volume functions, using stem diameter and tree height measurements at a two-year intervals during 11 years, post-thinning. All thinned stands had a gradual increase of the mean annual increment of a standing volume/biomass production (MAI) throughout the entire study period. MAI of the unthinned treatment peaked at 30.1 m^3 ha^{-1} yr^{-1} (10 ton DM ha^{-1} yr^{-1}) after four years, followed by a slight decrease. After 11 years, MAI and a standing volume/biomass production did not differ significantly between unthinned, light and medium thinning, with the average MAI of 26.1 m^3 ha^{-1} yr^{-1} (8.7 ton DM ha^{-1} yr^{-1}) and the standing volume/biomass production ranging from 443 to 486 m^3 ha^{-1} (148-163 ton DM ha^{-1}). Additionally, thinning with a medium intensity produced higher total stem wood volume/biomass (including living, dead and trees removed by thinning) compared to the other treatments. Our results also indicated a gradual reduction in the stem number for the unthinned and light thinning as a consequence of self-thinning. This study suggests that the second rotation of poplar plantations can be considered as an alternative to planted poplar stands in Sweden, demonstrating great potential to produce substantial amounts of biomass.

Climate-sensitive modelling of Poplar Short-Rotation Coppice for a Low-Carbon Bioeconomy

T2.7 Fast growing trees in support of sustainable bioeconomy

[3] Projects and Planification PROEPLA, University of Santiago de Compostela (USC), C/Benigno Ledo s/n, E-27002 Lugo, Spain

Abstract: The production of woody biomass as a source for energy and/or bioproducts is widely recognized as a crucial resource in the transition towards sustainable energy systems.
Producing lignocellulose biomass, such as from short-rotation plantations and increasing the potential use of lignocellulosic biomass as bioproducts are among the most promising opportunities in the forest-based sector. Climate-sensitive forest growth models can be used to calculate future estimates of biomass yield under changing environmental conditions. Process-based models are considered promising in this context.
From this perspective, this study deal with lignocellulose biomass produced from poplar Short Rotation Coppices (SRC) systems under Mediterranean conditions in order to assessing the potential of these plantations to contribute to a low-carbon bioeconomy. We simulate biomass growth of a complete plantation cycle of 12 years (4 rotations 3 years each) taking into consideration the effects of 50% reduction in irrigation (T50), compared to optimal irrigation (T100) on the productivity and carbon stocks of these poplar plantations in Spain. The simulation was conducted in an area where prior information from a three-rotation trial was available to validate the obtained data. To achieved this, an adapted version of 3-PG model to poplar at high density, incorporating species-specific parameters for the genotype 'AF2' (*Populus* × *canadensis* Mönch) was used. In addition to calculate biomass production, stem, leaf and root were also analysed for their carbon sequestration potential. A reduction of 25% and 28% of stem and root biomass was found in the first rotation when 50% water irrigation restriction was applied (T50). After the establishment of the root system, in consecutive rotations the reduction in productivity was comparatively less pronounced for all biomass fractions (stem, root and leaf). The above and below-ground C stocks of a standard poplar SRC system under Mediterranean conditions and 12-year plantation cycle (4 rotations of 3 years each) play an active role in mitigating global warming (10 Mg C ha^{-1} yr^{-1}) but even this is relevant under restrictive water irrigation conditions (8.2 Mg C ha^{-1} yr^{-1}).
This study enhances awareness regarding the potential of poplar short-rotation coppice (SRC) systems in contributing to a low-carbon bioeconomy

Differences in the Timing of Growth Cessation as a way of Selecting Poplar Clones for Various Climate Conditions

T2.7 Fast growing trees in support of sustainable bioeconomy

Michalina Grabowska[1]
Mateusz Liziniewicz[2], Anneli Adler[3], Henrik Böhlenius[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Alnarp, Sweden
[2] The Forestry Research Institute of Sweden (Skogforsk), Ekebo, Sweden
[3] Department of Crop Production Ecology, Swedish University of Agricultural Sciences, Uppsala, Sweden

Abstract: The current and future demand for woody biomass will increase, thus require an increase in the productivity of the current forest systems. There is also a need to search for alternative tree species as a complement for two of the most common tree species in Swedish forestry, Scots pine and Norway spruce as they are now subjected to severe pathogen and insects outbreaks. *Populus* and their hybrids are one alternative due to their high growth potential and short rotation, reaching at optimal conditions volume production of 30 m^3 $h^{-1}yr^{-1}$ under a rotation length of 20 years.

Several studies have shown that poplar clones have high variability in growth rate between clones. During the last decades, a large effort have been made to identify *Populus* clones with high and secure biomass production at different climatic zones.

In this project, we will develop new selection methods to identify poplar clones adapted to the present and future climate to secure a high biomass production.

We are going to use timing in growth cessation in fall as a method to identify poplar clones adapted to a specific climate condition. As a first step we will identify variation in growth cessation among 120 commercial available poplar clones and thereafter discuss how this can be used to maximize production capacity by using the entire growth period (timing of growth cessation in fall) in a common-garden experiment.

Distribution, Benefits, and Risk of Spreading Alien Forest Tree Species in Lithuania

T2.7 Fast growing trees in support of sustainable bioeconomy

Lina Straigytė[1]
[1] Department of Forest Sciences, Agriculture Academy, Vytautas Magnus University, Kaunas, Lithuania

Abstract: The understanding of the role of alien tree species in forests varies among different interest groups. This presentation addresses the question of whether alien tree species can provide greater economic benefits or result in ecological damage.

The study raised the following research questions: to map the distribution of alien tree species in the country; to estimate the invasiveness score of tree species that have crossed the naturalization barrier; and to evaluate timber supply potential of alien tree species in Lithuanian forests.

Maps displaying the distribution of alien tree species were created based on data from the state forest cadaster, referring to the year 2017, which was compiled using information from stand-wise forest inventories. The same data source was used for the volumes and other dendrometric characteristics. The invasiveness score was assessed following the first part of the Victorian pest plant prioritization process methodology, which focused solely on spread.

The study identified 23 alien tree species growing in Lithuanian forests, of which 13 are conifers and 10 are broadleaves. The area of stands with alien tree species accounts for only 0.7 % of the total forest area. These alien trees have produced a total of 531800 cubic meters of wood, with the largest volume shared by *Larix* at 265,558 cubic meters. In terms of stand productivity and economic efficiency, growing alien species such as *Populus sp., Larix sp., and Quercus rubra* appear to be competitive or even more attractive compared to native tree species. However, three tree species - *Acer negundo, Prunus serotina,* and *Robinia pseudoacacia* - have crossed the naturalization barrier and are included in the list of Lithuanian invasive plants. Among these, *Acer negundo* exhibited the highest invasiveness score of 0.79, while *Robinia pseudoacacia* had the lowest score of 0.35. It is recommended to avoid these invasive tree species in Lithuanian forests.

Does fertilization effort pay off at harvest? A case study from 50 years old birch plantations for sustainable bioeconomics

T2.7 Fast growing trees in support of sustainable bioeconomy

Justyna Nowakowska[1]
Wojciech Kędziora[1], Radosław Kanabus[1]
[1] Warsaw University of Life Sciences, Institute of Forest Sciences, POLAND

Abstract: Producing additional wood raw material in a relatively short time can be achieved by forest trees plantation. Ensuring high-quality planting material they reach an early peak in average growth of total production. Forest plantations are usually established with fast-growing species – not always native.

This study evaluated the production effects of plantation of the silver birch (*Betula pendula* Roth) using various agrotechnical and agro-melioration treatments in different habitat systems. The evaluation of production effects was conducted based on analysis of selected growth and development traits, which included: survival rate, average dimensions (DBH and height), silvicultural quality, and the average growth in total production volume.

Timespan of this study covers period 1971-2022. Four plantation experimental plots were established in habitats of different fertility with different variants. To eliminate variation in growth conditions, each variant was repeated four times in a random block design. The survival rate of the trees was recorded after the end of the growing season. Determination of the silvicultural quality was conducted using the modified Schädelin biological classification. The average annual increase in total production was determined for each measurement period.

The most productively effective was the variant of full ploughing and fertilisation with potassium, phosphorus, and nitrogen. After 20 years of growth, it has the highest percentage of best-quality trees and the lowest percentage of worst-quality trees. Trees growing in this variant are characterised by the largest average dimensions. Volume and average growth are slightly lower, but this variant has the lowest number of trees per unit area.

Intensive soil cultivation had a positive effect on birch survival. No significantly better success rate was observed in variants with peat ballast or full ploughing. In low fertility habitat, the variant of planting in cavities with peat and NPK fertilisation around the seedlings gave the best results. The average values of the analysed traits achieved in this variant do not differ significantly from the variants with more intensive soil cultivation. For degraded habitats, soil preparation should include full ploughing, mineral fertilization and peat topping. The latest is particularly important as it gives better results than intensive mineral fertilization.

DYNAMICS OF CARBON STOCKS OF BIRCH PLANTED ON PREVIOUS NORWAY SPRUCE SITES

T2.7 Fast growing trees in support of sustainable bioeconomy

Aureo Aparecido Abreu Junior[1]
Per-Anders Hansson[1], Ragnar Jonsson[1]
[1] Swedish University of Agricultural Sciences

Abstract: The increasing demand for tree biomass and byproducts in Sweden is triggering the interest in replacing slow-growth species. The substitution of traditional tree species, such as Norway Spruce (*Picea abies*), for a fast-growing species is aimed and also has a high ability to mitigate the climate impacts in the short term. Birches (*Betula spp.*) are the main fast-growing species naturally regenerated in Sweden and present this potential. The general objective of the study was to simulate carbon stocks above and belowground of Birches, growing in previous Spruce forests after the clear-cut, using different management strategies. The period evaluated was 180 years, meaning that Birch had three rotation periods of 60 years (with two thinnings at 20 and 40 years) and Spruce had two rotation periods of 90 years (with three thinnings at 40, 60, and 80 years). The simulations were done using the CO2FIX model which has Yasso soil dynamic model integrated into the software to predict carbon stocks both in the tree biomass and soil (total carbon stock). Experimental data were used in the simulation for both non-genetic improved species. The results indicated that Birch had about 85 MgC/ha of total carbon stock after the first rotation period, while Spruce spent 80 years to reach the maximum of 80 MgC/ha of total carbon stock. The soil carbon stock was initially equal for both plantations (40 MgC/ha), but after 180 years they had about 45 and 35 MgC/ha, for Birch and Spruce, respectively. We can conclude that Birch has the potential to substitute Spruce plantations in shorter rotations acting like quick carbon sinks in both soil and biomass. Nevertheless, future research is needed on product substitution effects, testing genetically improved materials, and different management strategies to support smart-climate decisions for a large-scale implementation.

Enhancing knowledge-sharing on fast-growing trees: the expertise of the International Commission on Poplars and Other Fast-Growing Trees (IPC)

T2.7 Fast growing trees in support of sustainable bioeconomy

Martin Weih[1]
Faustine Zoveda[2], Thais Linhares-Juvenal[2]
[1] Swedish University of Agricultural Sciences, Dept. of Crop Production Ecology, Uppsala, Sweden
[2] Food and Agriculture Organization of the United Nations, Forestry Division, Rome, Italy

Abstract: Enhancing knowledge-sharing on fast-growing trees: the expertise of the International Commission on Poplars and Other Fast-Growing Trees (IPC)

Protecting, restoring, and adapting planted forests, including especially those composed of fast-growing trees, is a prominent nature-based solution in the transition towards carbon-neutral economies, sustainable landscapes, and better livelihoods. Fast-growing trees are growing roughly more than 10 m^3 per hectare and year, with a capacity of high annual increments already in a young age; which is the reason for the high land use efficiency that can be achieved with these trees.

Within the framework of FAO, a specific treaty-based statutory body, the International Commission on Poplars and Other Fast-Growing Trees Sustaining People and the Environment (IPC), is dedicated to fostering the sustainable management of fast-growing trees. This Commission works as a science-policy implementation platform. Established in 1947, it is a proven model for international technical cooperation in forestry which can contribute achieving the global sustainability goals. Traditionally, the IPC focused on poplars and willows, but in 2019, the IPC broadened its scope to all fast-growing trees that sustain people and the environment.

This new IPC mandate envisages an expansion to new regions and countries, enlarging the geographic, biological and technical scope of the IPC by including a wider range of fast-growing genera/species with similar attributes in terms of industrial and energy uses and environmental applications compared to poplars and willows. Thus, the new IPC mandate will support the sustainable provision of wood and ecosystem services by transferring the long-term expertise and the lessons learnt on poplars and willows to other fast-growing species in forestry and agroforestry systems of tropical countries and strengthening the contribution of fast-growing trees to food security, sustainable livelihoods and land use in rural areas.

Evidence of adaptability and genetic potential of pine hybrids for commercial plantation forestry in Kenya

T2.7 Fast growing trees in support of sustainable bioeconomy

Stephen Omondi
Joram Mbinga[1], Leonida Cherotich[1], Jason Kariuki[1]
[1] Kenya Forestry Research Institute, P.O Box 20412-00200 Nairobi

Abstract: *Pinus patula* has been among the major plantation species grown in Kenya over several decades. However, narrow range of commercial plantation species in the country, risks associated with climate change, and need to improve productivity per unit area have necessitated screening of new pine germplasm. Our study evaluated survival and growth performance of 13 pine hybrids in Kenya at the age of 12 years. Significant differences were observed among hybrids for survival, height, diameter at breast height (dbh) and volume ($P < 0.001$). The average survival rates across the sites was 60 % and varied from 26 % to 87.8 %. Mean tree height varied from 13.3 for *P. caribaea* x *P. elliotii* hybrid to 17.5 m in *P. patula* x *P. tecunumanii* hybrid with a mean of 14.4 m. The dbh range from 20.2 cm in pure *P. patula* to 24.7 cm in *P. patula* x *P. tecunumanii* hybrid with a mean of 22.8 cm. The mean volume was 0.228 cm^3, ranging from 0.165 cm^3 (*P. patula* x *P. gregii* hybrid) to 0.322 cm^3 (*P. patula* x *P. tecunumii* hybrid). In each trial, the best-performing hybrid clones grew better ($P < 0.05$) than pure *P. patula*. Relative performance of the best hybrid clones showed consistency in ranking for growth across the sites. The study also revealed low genotype-by-environment interaction showing stability of the hybrids across environments. Overall, the findings show that *P. patula* x *P. tecunumanii* (low elevation) and *P. patula* x *P. tecunumanii* (high elevation) hybrids had better performance than the pure species and other hybrids. This indicates the potential of these hybrids as alternative plantation species to *P. patula.* However, a comparison of growth performance showed statistically significant differences ($P < 0.001$) among clones within the sites indicating that site specific hybrid clones should be considered during selection. We recommend that the two superior hybrids could be considered for pilot plantations in major pine plantation areas in Kenya.

Keywords: Improved productivity, growth performance, genotypes, pines, pine hybrids

Expanding the Potential of Populus Species for Biomass Production: Clonal Selection for Boreal Forests Conditions

T2.7 Fast growing trees in support of sustainable bioeconomy

Abstract: The future increased demand for biomass as a renewable energy source necessitates an increase in biomass production. In this context, fast-growing broadleaf species i.e. *Populus* species, offer significant potential due to their high production rates and short rotations. While traditionally planted on agricultural land, recent interest has emerged in utilizing different tree species on forestland as an alternative to Norway spruce (*Picea abies L.*) which is severely damaged by climate change and insect outbreaks.

The boreal forests are spanning across Scandinavia, northern Russia, China, and North America, and are characterized by podzol soils with acidic pH levels. The acidic soil pH poses challenges to plant growth, including increased plant mortality caused by excessive protons (H^+) that is linked to elevated aluminium (Al) levels, leading to inhibited water uptake and nutrient deficiencies. Previous studies have shown large variations in aluminium tolerance both within species and between *Populus* species. Consequently, the successful cultivation of *Populus* species in boreal forest sites requires the selection of *Populus* genotypes (clones) with tolerance to aluminium.

In this study 75 poplar clones (*P. deltoides x P. nigra, P. maximowiczii x P. trichocarpa, P. maximowiczii x P. nigra, P. trichocarpa x P. trichocarpa and P. maximowiczii x P. deltoides*) were screened to their tolerance to aluminium toxicity at varying aluminium concentrations. The results revealed variations in performance, with certain clones exhibiting higher relative growth and relative root biomass, indicating a genetic basis for aluminium tolerance. To evaluate their performance in practical forestry, the top and least-tolerant clones were grown in greenhouse conditions in a gradient in soil acidity from acidic forest soil to neutral agricultural soils. This result will give insight into the interaction between soil acidity and aluminium tolerance of poplar clones. Furthermore, the outcomes of this study will enhance our understanding of methodology in clonal selection towards aluminium tolerance and future breeding strategies in *Populus* species, specifically concerning their adaptability to boreal soil conditions, thereby expanding the potential for sustainable biomass production for the future.

Mixing tree species to increase tree performance – Synthesizing 23 years of research in the world's largest platform of tree diversity experiments

T2.7 Fast growing trees in support of sustainable bioeconomy

Kris Verheyen[1]
Leen Depauw[1], Emiel De Lombaerde[1], Els Dhiedt[1], Haben Blondeel[1], Lander Baeten[1]
[1] Forest & Nature Lab - Department of Environment - Ghent University, Ghent, Belgium

Abstract: International ambitions for massive forest restoration are high. To make these investments sustainable and resilient under future climate change, science is calling for a shift to planting mixed forests. But what is the scientific basis for promoting diverse plantations, and what is the feasibility of their establishment and management? The largest global network of tree diversity experiments, TreeDivNet is uniquely positioned to answer these pressing questions. Building on 428 peer-reviewed TreeDivNet studies, combined with the results of a questionnaire completed by managers of 32 TreeDivNet sites, we aimed to answer the following questions: (i) How and where have TreeDivNet experiments enabled studying the relationship between mixing trees and their performance? (ii) What are the key knowledge gaps in our understanding of the relationship between tree diversity and performance? (iii) What practical insights can be gained from the TreeDivNet experiments for operational, real-world management?

We developed a conceptual framework that identifies the variety of pathways through which tree performance is related to local neighbourhood diversity and mapped the research efforts for each of those pathways. Experimental research on forest mixtures has mainly focused on direct tree diversity effects on productivity, with fewer studies focused on indirect effects mediated via biotic growing conditions (e.g. soil microbes and herbivores) and resource availability and uptake. Tree diversity effects on the abiotic growing conditions (e.g. microclimate, soil properties) and resource-use efficiency have been less well studied. The majority of experiments is situated in temperate forests, while (sub)tropical forests, and boreal forests in particular, remain underrepresented.

TreeDivNet provides evidence in favour of mixing species to increase tree productivity while identifying a variety of different processes that drive these effects. The design, scale, age, and management of TreeDivNet experiments reflect their focus on fundamental research questions pertaining to tree diversity-ecosystem function relationships and this focus complicates the translation of findings into management guidelines. Future research could focus on (i) filling the knowledge gaps related to underlying processes of tree diversity effects in order to better design plantation schemes, (ii) identifying optimal species mixtures, and (iii) finding smart solutions to give experimental mixed plantations a more management-oriented focus.

New varieties of fast-growing trees for sustainable production of biomass under climate change conditions in temperate climate region – field results

T2.7 Fast growing trees in support of sustainable bioeconomy

Jan Weger[1]
Jaroslav Bubeník[1], Kamila Vávrová[1]
[1] Silva Tarouca Research Institute for Landscape and Ornamental Gardening, Publ. Res. Inst.

Abstract: For sustainable biomass production and provision ecosystem services of fast-growing trees (FGT) an assortment of new cultivars is needed which could replace current in case of expected decline of production potential due to growing biotic and abiotic risks (pests, deseases, climatic extremes, pollution etc.). In our contribution we present results of long-term testing of new cultivars of FGT in conditions of the Czech Republic which is characterized by variety of soil types and transitional oceanic-continental weather.

For early evaluation of new FGT cultivars in field conditions we have used network of small experimental plots (clone/cultivar tests) on more sites in the 1990th. Our current assortment in experimental plots consists of 40 poplar and 11 hybrid/allochtonous and native/autochnous poplars and willows including willows Rokyta′, ′Stvola′ and ′Vetla′ and poplar ′Kaktu′ form our breeding. As a control in experimental plots we use poplar clone Max-4 (*Populus nigra* × *P. maximowiczii*), which is the most often planted in Central European (85% of SRC in Czech Rep.). We have measured periodically production and biometric parameters of tested trees (yield, height, survival rate) and studied influence of climatic and biological factors on their growth e.g. recent droughts periods (2016-2019: sum of precipitation -213mm; average annual temperature +1,8°C from climatic normal).

From our long-term field testing we can conclude that there are good alternatives to the most common poplar clone Max-4 witch have different genetic origin, better yield potential and also better adaptation to climatic and ecological condition of Central Europe also with regards to expected predictions of climate change. Namely we can mention poplar cultivars ′AF8′, ′AF13′, ′AF2′, ′AF24′, ′AF28′, ′Bakan′, ′Kaktu′, ′Monviso′, ′Skado′ or ′Vesten′ and willows ′Rokyta′ and ′Tora′. Some of these cultivars were yielding up to 50% more biomass than Max-4 in our experiments. Many of them performed better also during drought period (3-4years) in which yields decreased in our experiments between 18 and 52% from expected amounts (yield curves). Effect of the research gap have to be taken into account which includes lower quality of agronomy and pest control when growing new cultivars in real field conditions.

ontribution of the IUFRO task force “Resilient Planted Forests Serving Society & Bioeconomy” to societal debate and science frontiers

T2.7 Fast growing trees in support of sustainable bioeconomy

Abstract: Planted forest covering only 7 % of the globe’s land surface contribute more than 40 % of timber production with demand expected to increase significantly. These forests also contribute actively to land protection and restoration and provide many important ecosystem services.

This essential resource is facing many challenges: political, related to climate change responses; environmental with climate change, pest and diseases, abiotic risks increasing all over the world; social, associated with competition with other land uses and public perceptions of forests; and finally economic. Managers lacking technical support to face these challenges while, in some places of the globe, communities still struggle with the trade-offs between agriculture and forest land use.

The task force “Resilient Planted Forests Serving Society & Bioeconomy”has addressed some of these points through papers and events. Three aspects will be covered in this paper. As the resource provided by planted forests is essential for bio economy it is important to produce new perspectives on how these forests will evolve globally to respond to changing wood markets Secondly, as planted forest are based on genetic resources selected by the forest manager origin and genetic resources have been addressed related to climate change.. Finally on the societal challenge of perception we will show how the New Generation Plantations approach applied in Europe can contribute to dialogue and depolarisation of opinions.

Responses of swine manure for seven willow species distributed in Eastern Japan

T2.7 Fast growing trees in support of sustainable bioeconomy

Masazumi Kayama[1]
Satoshi Kikuchi[1], Akira Uemura[1], Masayoshi Takahashi[1]
[1] Forestry and Forest Products Research Institute

Abstract: In east Asia, short rotation coppice system was developed for production of renewable energy, and two willow species distributed in boreal region was utilized. However, other willow species was not utilized. To establish a short rotation coppice system at temperature region of east Asia, we planted cuttings of *Salix eriocarpa*, *S. gilgiana*, *S. gracilistyla*, *S. integra*, *S. sachalinensis*, *S. serissaefolia* and *S. subfragilis* distributed in eastern part of Japan. On the cultivation, compost made by swine manure, which was low cost and sustainable fertilizer was added. We established control (no addition), low manure (5 Mg ha^{-1}), and high manure (10 Mg ha^{-1}) treatments, and seven willows were raised for two growing seasons. The density of clones was 10,000 cuttings ha^{-1}.

Swine manure was contained high concentration of nutrients, and all of willow species were accelerated their growth by addition of swine manure after two growing seasons. The averages of annual biomass production of seven willows grown under control, low manure, and high manure treatments were 0.2 Mg $ha^{-1}yr^{-1}$, 5.3 Mg $ha^{-1}yr^{-1}$, and 8.5 Mg $ha^{-1}yr^{-1}$, respectively. Especially, high manure treatment of *S. sachalinensis* and *S. subfragilis* showed large biomass, and their value per year was 14.1 Mg $ha^{-1}yr^{-1}$ and 13.7 Mg $ha^{-1}yr^{-1}$, respectively. On two species under high manure treatment, *S. sachalinensis* had the thickest shoots, and *S. subfragilis* had the tallest shoots. These growth characteristics of *S. sachalinensis* and *S. subfragilis* were originated from their high biomass production. We concluded that *S. sachalinensis* and *S. subfragilis* were potentially feasible candidates for short rotation coppice system in the temperate regions of east Asia.

The Mid-Atlantic Sustainable Biomass Consortium (MASBio): Delivering sustainable and feasible biomass for a value-added product system

T2.7 Fast growing trees in support of sustainable bioeconomy

Robert Burns[1]
Jingxin Wang[1]
[1] West Virginia University

Abstract: The goal of this project was to deliver sustainable and feasible biomass for value-added product system in the Mid-Atlantic region of the U.S. through implementation of the Mid-Atlantic Sustainable Biomass Consortium (MASBio). This integrated and transdisciplinary research, education and extension project will facilitate and foster development of the bioeconomy and rural prosperity in the region. Specific project objectives to achieve the project goal include; (1) recognize and demonstrate feasible, sustainable and cost-effective approaches to soil amendment and feedstock production to increase yield of biomass agroecosystems on reclaimed and marginal lands, (2) demonstrate efficient and effective harvest and logistics strategies for an optimized, integrated agricultural-forestry feedstock supply chain for continuous industrial procurement, (3) develop and optimize multiple bioproduct conversion processes through collaborations with industry partners, (4) improve the sustainability of the biomass supply for value-added products with best management practices (BMPs), (5) conduct system and scale-up analyses using robust artificial intelligent (AI)-based data analytics, (6) engage the next generation of biomass products leaders through education and internship programs, (7) engage with stakeholders to promote bioeconomic development through extension outreach programs. Significant differences in cultivar performance have been noted across marginal agricultural sites and reclaimed mine lands (Caterino et al. 2017; Nobert et al. 2016). Soil amendments using biochar and fertilization had mixed effects for plant growth and survival. Biochar (poultry litter) increased growth during the establishment year by 80% (Nobert et al. 2016), whereas controlled release and traditional inorganic fertilizer blends had limited impacts after two growing seasons (Caterino et al. 2019). Growth of switchgrass varieties on reclaimed lands have achieved dry matter yields of greater than 3 tons/ac per year and on some sites Cave-in-Rock switchgrass has achieved more than 22.4 Mg/ha (Scagline-Mellor et al. 2018). Hybrid willow trials on marginal land have shown biomass yield of 8-12 odMg/ha. This integrated and transdisciplinary research, extension project will facilitate and foster development of the bioeconomy and rural prosperity in the region.

The Role of Fast-Growing Trees in Agroforestry Systems: Perspectives from the IPC of the United Nations' Food and Agriculture Organization

Abstract: Agroforestry systems (AFS) are sustainable land management systems that consist of agricultural crops and/or livestock intentionally integrated with woody species on farmed fields or in forested areas. AFS provide environmental, economic, and social benefits that contribute positively to sustainable development and other societal goals, including improvement of bioeconomies. Fast-growing trees (FGTs) such as acacia (*Acacia* Mill.), casuarina (*Casuarina* L.), eucalyptus (*Eucalyptus* L'Hér), gliricidia (*Gliricidia* Kunth), leucaena (*Leucaena* Benth.), melia (*Melia* L.), pine (*Pinus* L.), poplar (*Populus* L.), and willow (*Salix* L.) maximize the benefits from AFS within short timeframes (< 30 years). The International Commission on Poplars and Other Fast-Growing Trees Sustaining People and the Environment (IPC, https://www.fao.org/ipc/en/) is a treaty-based statutory body placed within the framework of the Food and Agriculture Organization of the United Nations (FAO) that has decades of leadership in FGTs and AFS. The IPC serves as a knowledge and capacity development network and offers a science-policy-practice platform that converts science-based approaches into practice. The IPC facilitates technical knowledge exchange on research and sustainable management of FGTs through the guidance, activities, and networking of five working parties (WPs): **Genetic Resources** (WP-GEN), **Production Systems for the Bioeconomy** (WP-PRO), **Environmental and Ecosystem Services** (WP-ENV), **Policy and Livelihoods** (WP-POL), and **Communication and Outreach** (WP-COM). We will highlight the potential of the IPC and its WPs to contribute to sustainable development and adoption of FGTs within AFS on a global scale, and will discuss the role of FGTs in AFS, along with barriers and opportunities for adoption that may impact the bioeconomy. To do so, we will present three international case studies: 1) diversifying traditional crop rotations through on-farm planting of short-rotation trees (India), 2) the

benefits of pollarding poplars and willows to provide stock fodder (New Zealand), and 3) short rotation coppice (SRC) combined with poultry breeding and homegardening (Czech Republic). We will discuss opportunities for the IPC to enhance the global knowledge exchange on FGTs in AFS, including the role of agroforestry in the sustainable bioeconomy, as well as technical services offered by the IPC to assist mobilization of new partners and resources.

The role of planted forests in the bioeconomy

T2.7 Fast growing trees in support of sustainable bioeconomy
Vincent Gitz[1]
Thais Linhares-Juvenal[2], Alexandre Meybeck[2]
[1] CIFOR-ICRAF
[2] FAO

Abstract: The bio-based economy idea emerges from societal concerns and expectations for sustainable sourcing, to curb the use of fossil-based and non-renewable materials and reduce environmental impacts. This agenda will require a substantial growth and carefully planned development of the planted forests, through an integrated approach where a diversity of planted forests systems is properly planned into the landscape, and whereby forest and farm communities can deliver a diversity of products, for a diversity of modern and traditional uses and reuses. This will require planted forests to fully embrace the social and environmental dimensions that, if not addressed, could drive negative perceptions of plantations by local populations and global consumers.

The presentation will address key questions, such as : how can commercialization best bring socioeconomic benefits back to local communities that can become central agents of the bioeconomy? Where to plant what, and which tools and approaches for that? How to ensure legitimacy and inclusive and evidence-based decision in developing plantations into landscapes? What potential for agroforestry systems, trees on farms, and well-designed diverse tree species planted forests that can provide diverse uses, ecosystem services and habitats connectivity for wildlife populations?

It will propose key elements for a coordinated approach between developing bioeconomy and planted forests, through policies and incentives, market and product regulations, value chains coordination, innovations, and capacitation, including of local actors, and consideration of environmental and social factors. If well managed, the successful integration of planted forests into the bioeconomy can be one key example on how to synergize economic development with environmental stewardship.

Value creation and distribution of benefits along the Acacia mearnsii woodlot charcoal value chain

T2.7 Fast growing trees in support of sustainable bioeconomy

Derbabaw Fentie[1]
Asmamaw Alemu[1], Erik Karltun[2], Linley Chiwona Karltun[3]
[1] Dept. of Forestry, University of Gondar, Ethiopia
[2] Dept. of Soil and Environment, SLU, Sweden
[3] Dept. of Urban and Rural Development, SLU, Uppsala

Abstract: As the demand for energy consumption increases in urban cities of Ethiopia, a rapid land use transition and expansion of smallholder plantations has occurred in the highlands of Ethiopia. Specifically, Acacia mearnsii woodlots dominate the smallholder agricultural system. Drawing on a randomly selected sample of 148 producers and snowball sample of 52 traders, primary data on value addition, economic benefit and contribution to livelihood was collected from value chain actors using a semi-structured questionnaire. The data was supplemented with 7 key informant interviews, 6 focus group discussion and field observations. The results revealed that charcoal produced from the smallholder Acacia woodlots extend from the Fagita Lekoma district to the capital Addis Ababa and other major cities such as Bahirdar and Gondar. Several value chain actors are engaged in the Acacia cultivation, charcoal production, transport and sales, which creates employment opportunities along the value chain and a rural urban linkage. The direct charcoal value chain actors include seed collectors, seedling producers, woodlot producers, charcoal producers, daily labourers, brokers, commission agents, wholesalers, retailers and consumers. Indirect actors such as the Woreda Offices of Agriculture, Finance and Trade are engaged in the facilitation and regulation of the value chain. Smallholder producers gain an average annual income of 1936 USD contributing to 35% of their annual household income from the woodlots and charcoal alone. The average annual net income was 4952, 6560, 4612, 30184, and 2120 USD for local intermediates, brokers, local collectors, wholesalers, and retailers, respectively. The royalty fee for exported charcoal is the major contributors of government revenue in the district. The results also indicated an upward skew of benefit distribution. The total relative commercialization margin was 58%, indicating that actors involved in product marketing received a larger share of the final market price, while farmers that engaged in plantation and charcoal making activities received 42% of the end market prices. In conclusion, the market-driven production of Acacia woodlot profits value chain actors and generates rural government revenue, while also contributing to employment creation, rural livelihoods and well-being.

[3] Institut de recherche sur les forêts (IRF), Université du Québec en Abitibi-Témiscamingue, 79 rue Côté, J0Z 3B0 Notre-Dame-du-Nord , Québec, Canada

Abstract: The ever increasing international demand for wood products puts a lot of pressure on natural forests, being exploited always further north from urban centres and mills. Simultaneously, Québec's northern rural areas are experiencing a decline in agricultural activity, leaving many lands abandoned well suited for afforestation with fast-growing plantations.. Furthermore, afforestation of abandoned farmland is seen as one strategy among others for mitigating the consequences of climate change by increasing carbon sequestration in soils and woody biomass. However, in the absence of active reforestation, secondary succession takes place on abandoned lands that gradually but slowly evolve into forest ecosystems. These abandoned farmlands are also likely to sequester large quantities of carbon and eventually allow the establishment of forest species. We therefore wondered whether reforestation of abandoned farmlands with hybrid poplars was an appropriate solution for promoting carbon sequestration and the establishment of forest species while providing large quantities of wood. To address this issue, we sampled 16 near mature hybrid poplar plantations associated with adjacent non-afforested areas in which we measured soil carbon stocks, understorey vegetation diversity and soil microbial communities. We expected to see a reduction in biodiversity in the plantations compared with non-afforested land and a strong variation in microbial communities due to the disturbance caused by reforestation operations and initial weed control of plantations. However, we also expected the plantation soils to contain more organic carbon due to the rapid growth of the trees. Overall, we believe that the effects of reforestation abandoned farmlands will depend on the previous land use that preceded afforestation and the stage of the secondary succession when plantations were installed. Our initial results suggest that hybrid poplar plantations did not accelerate recolonisation of the environment by forest species, and that ruderal species persist within the plantations. Even though afforestation with hybrid poplars had little or no effect on plant biodiversity, it is nevertheless a useful tool for intensive wood production to release the pressure on native ecosystems of the boreal forest.

Agroforestry phytoremediation buffer systems: nature-based solutions in the Great Lakes Basin, USA

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Ronald Zalesny[1]
Ryan Vinhal[1], **Elizabeth Rogers**[1, 2], Chung-Ho Lin[2], Richard Hallett[1]
[1] USDA Forest Service, Northern Research Station, USA
[2] University of Missouri, Center for Agroforestry, USA

Abstract: Fast-growing trees such as poplars (*Populus* sp.) and willows (*Salix* sp.) are integrated into nature-based solutions in temperate ecosystems more than any other genera. Poplars and willows are adept at greening and cleaning brownfields, mine sites, landfills, and other contaminated areas across the urban to rural continuum given their extensive root systems, elevated biomass productivity, and ability to regulate their water use. This combination of traits is ideal for phytoremediation, the most common phytotechnology worldwide, which utilizes trees to enhance ecosystem services across degraded landscapes. Exploiting processes taking place in the soil, roots, wood, and leaves of the trees to immobilize, degrade, and extract contaminants, phytoremediation alleviates anthropogenic impacts to water quality and quantity as well as soil health. The need for such nature-based solutions is prevalent in the Great Lakes Basin of eastern North America, a vast region covering more than 777,000 km^2 (i.e., 1.5 times the total area of Sweden), containing 20% of the global freshwater supply (i.e., 95% of the United States' surface freshwater), and providing nearly 35 million people in the United States and Canada with a multitude of ecosystem services. To address this need, USDA Forest Service researchers and their partners developed the largest field-based, phytotechnology monitoring and testing network in the world, consisting of sixteen agroforestry phytoremediation buffer systems (i.e., phyto buffers) at landfills within the Lake Superior and Lake Michigan watersheds. We will provide information on the establishment success of these phyto buffers, as well as on their ability to provide ecosystem services. In particular, we will present mid-rotation (i.e., seven years after planting) results for biomass production and carbon storage of twelve poplar clones grown at six of the phyto buffers in southeastern Wisconsin, USA. We will highlight differences in biomass and carbon among the clones and their four genomic groups (*Populus deltoides* Bartr. Ex Marsh 'D'; *P. deltoides* × *P. maximowiczii* A. Henry 'DM'; *P. deltoides* × *P. nigra* L. 'DN'; *P. nigra* × *P. maximowiczii* 'NM') and will translate these research results into practical recommendations for nature-based solutions that are geographically robust, being regionally designed yet globally relevant.

Abstract: "Bamboo" is not only a global but also an oriental Viridiplantae. It is a fast growing and green sustainable material and a solution based on nature. At present, there are not a few human beings in the global state of Suboptimal health. Our staff engaged in ecological environment landscape, combined with the reflection before and after the epidemic, tried to explore a way to build a healthy, harmonious and natural circular operation of the natural environment in the process of planning and updating various urban centers and urban and rural green space, create a landscape close to nature, heal people and nature, and promote the survival and healthy growth of all things. This report combines a number of different types of practical projects (exhibition garden, flower border, bamboo landscape construction, blocks) in Shanghai (Chongming Island), Chengdu (Qinglong Lake), Beijing (Wangjing Peony Bamboo Garden) and other places in China, and uses "bamboo", a solution based on nature, to make full use of its material properties on the one hand, and use its natural properties on the other hand to scientifically match with native garden plants and flowers, It not only conforms to the meaning of time planting, but also deduces the use of healing plants, carries out practices close to Natural landscape, and brings people a beautiful and healthy living environment.

Biomass production potential of hybrid aspen and silver birch plantations on former agricultural land

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Abstract: The short rotation plantation forestry (with focus on wood for energy use) on former agricultural land has great potential to produce biomass and mitigate climate change. Silver birch (*Betula pendula* Roth) and hybrid aspen (*Populus tremula* L. × *P. tremuloides* Michx.) trees are pioneering species in post-industrial habitats. Various fertilizers (both organic and inorganic) containing heavy metals have been used on former agricultural lands. For example, phosphorus fertilizers contain several heavy metals (Cu, Zn, Mn and Mo). Literature data suggest that heavy metals cause a wide variety of changes in plants. Exposure to toxic metals negatively affects plant–water balance (e.g. root permeability, stomatal opening). The aim of the study is to assess the dynamics and interactions of heavy metals (Mn, Cu, Pb, Zn, Cd, Cr, Co, Fe, Mo, Ni, As) in plant-soil system of silver birch and hybrid aspen plantations on former agricultural land at the end of the potential rotation cycle (+20 years). We want to know which factors affect the uptake of heavy metals by trees. The hypotheses of the study are; (I) the quantity of heavy metals (Mn, Cu, Pb, Zn, Cd, Cr, Co, Fe, Mo, Ni, As) changes with the age of birch and aspen, and (II) the quantity of the components varies between bark and wood. The findings will help to understand the changes in the tree-soil growth environment and prognosticate possibilities of using hybrid aspen and silver birch for afforestation of former agricultural land. The study includes 22 hybrid aspen and 11 silver birch stands growing on former agricultural lands with different soils types all over Estonia. Concentration of heavy metals (like Cd, Cr, Cu, Fe, Mn, Ni ja Zn) in older wood (formed 11-21 years ago) is higher than in younger wood (formed during the last decade. Higher amounts of heavy metals have been accumulated in stem wood (Cr, Cu, Ni, Zn, Mn, Fe) than in bark biomass (except Cd). This research is supported by the Estonian Research Council grant PRG1007 and European Commission's Horizon 2020 programme under grant agreement No 101000406 (project ONEforest).

Cadmium accumulation by Phragmites australis and Iris pseudacorus in floating treatment wetlands

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

[3] Department of Environmental Protection, Gdynia Maritime University Maritime Institute, Gdynia, Poland

Abstract: The detrimental effects of urbanization, industrialization, mining, and stormwater runoff on ecosystems have led to growing concerns regarding water pollution worldwide. Floating treatment wetlands (FTWs) offer a sustainable solution by utilizing plants to accumulate and immobilize pollutants from wastewater. This study aimed to evaluate the influence of Cadmium (Cd) on the growth parameters (height, biomass, root length, and chlorophyll content), anatomical characteristics, Cd accumulation in biomass, and the capacity of *Phragmites australis* and *Iris pseudacorus* to remove Cd in the presence of nitrogen (N) and phosphorus (P). Seedlings of both plant species were grown in simulated stormwater in FTWs at the department of Sanitary Enegineering, Gdansk University of Technology Poland for 50 days. The simulated stormwater artificially amended with varying concentrations of Cd, along with a constant N concentration of 4 mg L^{-1} and P concentration of 1.8 mg L^{-1}. The experimental treatments included a control (Cd_0), as well as Cd_1, Cd_2, and Cd_4 mg L^{-1}. *P. australis* produced the highest plant height, root length, and total dry biomass production in the Cd_2 treatment, while the chlorophyll index (CCI) exhibited the greatest increase in the Cd_4 treatment compared to the other treatments. For *I. pseudacorus*, maximum values for plant height, total dry biomass production, root length, and CCI were observed in the Cd_1 and Cd_4 treatments, respectively, compared to the other treatments. Cd accumulation analysis revealed that *P. australis* accumulated the highest Cd concentration in roots (1821.59 μg · $(0.05\ m^2)^{-1}$) than shoots (334.65 μg · $(0.05\ m^2)^{-1}$) in Cd_4 treatment. Similarly, *I. pseudacorus* also exhibited the highest Cd accumulation in roots (4900 μg · $(0.05\ m^2)^{-1}$) as compared to shoots (609 μg · $(0.05\ m^2)^{-1}$) under the Cd_4 treatment. The translocation factor for both species was observed to be less than 1, while the bioconcentration factor was greater than 1, indicating their potential for phytostabilization. In conclusion, our findings demonstrate that *P. australis* and *I. pseudacorus* could be implemented in FTWs to remediate contaminated waterbodies, restrict the movement of pollutants into unpolluted sites, and effectively remove Cd and nutrients from the water column.

Carbon and energy balance in poplar plantations fertilised with pelleted sludge

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Almir Karacic[1]
Anneli Adler[1], Lorenzo Menichetti[1], Mindaugas Salininkas[2]

Abstract: Transformation towards a circular economy and sustainable land use requires improved availability of locally and regionally produced woody biomass. The Nordic-Baltic poplar feedstock is used for heat and electricity production or mixed with other tree species in pulping industries. Still, the potential use includes building materials, refined fuels, and nature-based circular models for recycling nutrients and carbon storage. This project developed a full-scale circular economic model based on recycling pelleted sludge from the wastewater plant in Vilnius, Lithuania. The short-rotation poplar plantations were established on 900 hectares of abandoned arable and marginal land, representing a vital element of an integrated solution for recycling the processed and biomass yield improvement.

To analyse the energy and carbon balance of the sludge recycling system, we developed a growth model for three production levels in 20-year rotations with 10.7-12.9 tonnes of dry biomass per hectare and year, assuming a yield increase of 10% and 20% as a result of sludge fertilisation. In addition, we analysed the soil carbon storage across different types of land use, including cropland, grassland, and the land converted with poplars, hybrid aspen, and birch. The data was collected between 2000 and 2020 on seven locations in Sweden, including plots 10 to 35 years old.

Our results showed higher soil carbon storage under poplars and grasslands than cropland, while birch plantations accumulated less soil carbon than all other alternatives. The energy balance was slightly higher in the unfertilised system due to using pelleted sludge as fuel in waste incineration plants. However, fertilised systems were better at sequestering CO_2, reducing the greenhouse effect over 100 years due to higher soil carbon storage. The poplar plantations established in Lithuania with productive clones could reduce the amount of CO_2 in the atmosphere by 1.2 to 2 tonnes and produce 207-248 GJ of heat energy per hectare per year. However, to meet the heating needs of all apartment-block houses in Sweden while reducing the amount of CO2 in the atmosphere by approximately one million tonnes per year, up to 450,000 hectares of poplar plantations would be required.

Ecosystem services from Populus bioenergy plantations - evaluation of soil health

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Courtney Siegert[1]
Heidi Renninger[1], Austin Himes[1], Waqar Shafqat[1], Andrea Drager[1], W. Cade Booth[1], Randall Rousseau[1]
[1] Mississippi State University

Abstract: Short rotation woody crops such as *Populus* species and their hybrids are important components of the bioenergy landscape in the US. These trees grow quickly both above- and belowground and have the potential to increase soil carbon storage and sequestration, providing additional ecosystem services beyond biomass feedstock. To understand the relationship between productivity and soil carbon and nitrogen, two experimental plantations were established in Mississippi, USA with five *Populus* taxa (*Populus deltoides* × *P. deltoides* (D×D), *P. deltoides* × *P. maximowiczii* (D×M), *P. deltoides* × *P. nigra* (D×N), *P. deltoides* × *P. trichocarpa* (D×T), *P. trichocarpa* × *P. maximowiczii* (T×M), representing more than 100 unique clones. Soil carbon and nitrogen were measured annually at depths from 0 to 30 cm, along with tree productivity. Half of the experiment was coppiced on a two-year cycle.

At the end of four growing seasons, growth differences were observed among taxa while soil carbon and nitrogen differences were not. D×D clones had the greatest biomass index (BI = diameter at breast height^2 x height) regardless of site or coppice history. In non-coppiced stands, average D×D clonal BI (696.5 ± 30.4) was 1.2 to 6.1 times greater than other taxa and in coppiced stands (127.8 ± 5.4) was 1.8 to 2.6 times greater than other taxa. Across all taxa and coppice treatments, soil carbon increased by 18% and soil nitrogen increased by 34% from the initiation of the trial. Aboveground productivity was not strongly correlated to changes in soil carbon and nitrogen stocks within taxa, coppice treatment, or soil depth ($R^2 < 0.10$). As such, this study suggests that Populus plantations have the potential to increase carbon and nitrogen storage in soils independent of biomass productivity. Results also suggest that coppicing has no immediate detrimental impacts to soil nutrients and that plantations will continue to store carbon in belowground pools. As such, belowground inputs (e.g., root exudates, turnover) may be more important sources of carbon in bioenergy plantations compared to losses from aboveground biomass removal, especially when coppicing occurs post leaf fall.

Evaluation of physical, mechanical and anatomical properties of Melia volkensii – a fast maturing species grown in drylands of Kenya

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

[1] Kenya Forestry Research Institute (KEFRI), National Forest Products Research Programme, P.O. Box 64636 – 00620, Nairobi, Kenya (*corresponding author: nelliecoduor@gmail.com)
[2] Forest Tree Breeding Centre, Forestry and Forest Products Research Institute, Japan
[3] Kenya Forestry Research Institute (KEFRI), PO Box 20412 – 00200, Nairobi, Kenya

Abstract: *Melia volkensii* an indigenous tree species growing in arid and semi arid areas in Kenya has shown promise as a fast-maturing species. Its timber is highly valued for furniture, joinery and interior panelling. This study investigated the wood quality of 10, 12 and 14- year-old *Melia volkensii* trees grown at Tiva, Kitui. Height and diameter at breast height were taken before the trees were felled. The wood properties studied were basic density and the stem analysis which comprised of; the ring width, heartwood/sapwood ratio, roundness and decentering. The variation of mean tree height and basic density against age was not significant with the mean height being 9.86m and basic density ranging between 341-561 Kg/m^3. However, the difference in diameter at breast height was significant where the maximum and minimum was 25.9 cm and 16.7 cm. The volume of wood was notable and significant with age – the older the tree the higher the volume. At 14 years the average volume was over 40% more that at 10 years. The heartwood ratio was highest at age 14 at 79±5 % indicating its high marketability with over 75% heartwood. The percentage decentering was lowest at age 14 years at 116±7 %. Generally, a negative correlation was found between pilodyn and basic density of 0.54 which was consistent with the gradual increase of basic density across the grains from pith to bark. This study has shown that Melia volkensii is not only fast maturing but has great potential to offer nature based solutions in the drylands of Kenya

Explore the Mechanism of Fast Growing Bamboo and Promote Internode Elongation

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Jian Gao[1]
Yuchong Bai[1]
[1] International Centre for Bamboo and Rattan, Key Laboratory of National Forestry and Grassland Administration/Beijing for Bamboo & Rattan Science and Technology

Abstract: Most tropical and subtropical bamboo species have high biomass, short maturity period of bamboo timber and great carbon sink function. Bamboo is a very important fast-growing renewable resource to reduce global wood pressure. Moso bamboo (*Phyllostachys edulis*) has one of the fastest growth rates among all plants. The shoot can grow as fast as 1.2 m/day at peak growth and reach heights of 20 m in 45–60 days. The length of bamboo internode and plant height determine the yield of bamboo timber. However, how to obtain long internode by means of breeding and cultivation has been an unsolved problem.

We analyzed the plant height growth law of the Moso bamboo, with more 5 million hectares, representative bamboo species in China, and studied the effect of hormone treatment on the change of internode length. The main pathway of auxin synthesis in Moso bamboo was local auxin biosynthesis. The main sites of auxin synthesis were identified by immunofluorescence. In situ hybridization analysis of YUC gene further identified the tips of bamboo shoots and young bamboo sheath as the main sites of auxin synthesis. Major auxin synthesis, transport and signal transduction genes were identified. Auxin was involved in plant height regulation through plant hormone pathway, amino acid biosynthesis pathway, protein processing pathway and energy metabolism pathway at the levels of transcription, translation and post-translational modification. Targeted metabolomics analysis based on MRM (multi-reactive ion monitoring) revealed that auxin co-regulates internode elongation with ETH (ethylene) and GA (gibberellin). The analysis of PheAUX/IAA34, a key auxin signal transduction factor, showed that it could interact with JA (jasmonic acid) signal transduction factor PheTIFY28 and participate in plant height regulation. These results revealed the crosstalk among auxin and GA, ETH and JA.

With a price of about RMB 300 yuan per hectare, hormone treatment offers a low-cost way to improve the economic and ecological benefits of bamboo forests. The cloning and functional identification of key genes provide genetic resources for molecular breeding of bamboo.

Exploring the potential of multifunctional fast-growing tree plantations using geoexplicit modeling

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Abstract: Strategically introducing fast-growing tree plantations in intensively managed agricultural landscapes can supply biomass to the bioeconomy while mitigating a number of environmental impacts. However, the environmental benefits in any given location depend on landscape specific biotic and aboitic characteristics. To understand the suitability of multifunctional production systems in specific locations and the overall potential at larger scale, spatially explicity methods are necessary.

Here, we summarize the outcomes and experiences of multiple recent studies in which we have modeled the potential for multifunctional production systems based on fast-growing tree plantations and grass at the European scale. Our models cover > 81,000 sub--watersheds in EU27 + UK (Europe) and can identify and quantify suitable areas for three production systems: riparian buffers, windbreaks, and grass in rotation with annual crops. For each sub-watershed, the models quantify suitable areas for the production systems, based on existing environmental impacts and current land-use, and the corresponding (i) biomass--and protein supply, (ii) soil organic carbon sequestration, (iii) reductions in nitrogen emissions to water, (iv) wind erosion, and (v) water erosion. The models also provide information about possible flood mitigation.

The results indicate that both nitrogen emissions to water and soil loss by wind erosion can be decreased to acceptable levels by establishing riparian buffers and windbreaks, respectively, on a very limited land area—provided that fast-growing trees are established and managed in a suitable way, in suitable locations. The environmental co--benefits are in several cases notable—in some cases exceeding the estimated mitigation needs. The effects on agricultural production can vary substantially, depending on the degree of land-use change and biomass end-use. Incentivizing widespread deployment will require supportive policy measures that acknowledge the value of environmental benefits as well as new local biomass markets.

We will also introduce ongoing research efforts to understand how fast-growing tree plantations can support biodiversity by strengthening ecological connectivity, using novel modeling approaches.

From growth to carbon: evaluating the impacts of fast-growing trees on soil organic carbon storage

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Toky Jeriniaina Rabearison[1]
Vincent Poirier[2], Annie DesRochers[1]
[1] Institut de Recherche sur les Forêts, Université du Québec en Abitibi-Témiscamingue, 341 rue principale Nord, Amos, Québec J9T 2L8 , Canada
[2] Station de Recherche Agroalimentaire, URDAAT, Université Du Québec en Abitibi-Témiscamingue, 79, Rue Côté, Notre-Dame-du-Nord, Québec J0Z 3B0, Canada

Abstract: Increasing soil organic carbon (SOC) storage is one of the promising solutions to mitigate climate change. Fast-growing trees are a potential tool in this context as they rapidly accumulate C in their biomass and could transfer more organic matter (OM) into the soil. However, the relationship between aboveground productivity and SOC storage remains poorly understood. Five clones with different growth rates were selected from a 14-year-old hybrid poplar plantation located in New Liskeard, ON, Canada. We collected soil cores at 87.5 and 175.0 cm distance from the stem and at 0-20, 20-40 and 40-60 cm soil depth for soil C concentration analysis. The most productive clone DN2 (*Populus deltoides* x *P. nigra*) stored less SOC (83 Mg ha^{-1}) between 0 and 60 cm depth than the mid-productive clones 1079 *(Populus* x *jackii* (*P. balsamifera* x *P. deltoides*)) and 915005 (*P. maximowiczii* x *P. balsamifera*) (95 and 96 Mg ha^{-1} respectively), while the least productive clone 747210 (*P. balsamifera* x *P. trichocarpa*) also had a lower SOC stock (85 Mg ha^{-1}) compared to the other clones, but not significantly. SOC stocks were not correlated with aboveground productivity but differed between clones. Total SOC stocks increased by 6 % when the sampling distance was closer to the tree stems. The difference in SOC stocks between clones was mostly observed at the 20-40 cm depth suggesting the significant effect of roots on SOC storage. Soil C/N ratios were significantly different between clones at 0-20 and 20-40 cm depths suggesting differences in OM decomposition rates between clones. There could be a trade-off between aboveground productivity and litter decomposition rate and the species selection is important to increase SOC storage.

Great Lakes Phyto: An international partnership developing phytotechnologies as nature-based solutions for rural and urban communities

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Ryan Vinhal[1]
Ronald Zalesny[1], **Elizabeth Rogers**[1, 2], Chung-Ho Lin[2], Richard Hallett[1]
[1] USDA Forest Service, Northern Research Station, USA
[2] University of Missouri, Center for Agroforestry, USA

Abstract: The Great Lakes of eastern North America provide substantial ecosystem services to nearly 35 million people in the United States and Canada. In addition to supplying clean and abundant water, the Great Lakes provide jobs, food, and energy; moderate the climate; deliver outdoor recreation opportunities that enhance community livelihoods; and offer diverse habitat for plants, wildlife, and fish. Despite these economic, social, and ecological benefits, human activities have resulted in disturbed terrestrial water cycles, diminished water quality and quantity, and loss of habitat, thereby threatening the ecosystem services provided by the Great Lakes. While some engineering approaches have been successful at reducing ecological impacts of human activities, tree-based systems are cost-effective alternatives that offer sustainable solutions for mitigating these impacts. Therefore, in response to environmental challenges faced by the Great Lakes region, USDA Forest Service researchers and their partners developed and installed a network of sixteen agroforestry phytoremediation buffer systems (i.e., phyto buffers) throughout the Lake Superior and Lake Michigan watersheds of the Great Lakes Basin, USA. By reducing untreated runoff and groundwater and filtering contaminants, the goal of these poplar and willow-based buffers is to reduce non-point source pollution entering the Great Lakes tributaries and nearshore waters. As a direct result of the establishment of this regional phyto buffer network, researchers, land managers, industry professionals, regulators, government officials, and community members from around the world formed Great Lakes Phyto, an international partnership that develops phytotechnologies to enhance ecosystem services in rural and urban communities. Great Lakes Phyto seeks to reduce impacts from degraded lands and waters in the Basin by using phytoremediation and associated phytotechnologies that maximize the social, ecological, and economic benefits provided by the Great Lakes. Since its formation in 2016, Great Lakes Phyto has strived to enhance quality of life, stewardship of ecosystem services, and profitability for landowners through the development of phytotechnology best management practices. We will highlight current efforts of Great Lakes Phyto, focusing on numerous applications of fast-growing trees as nature-based solutions for cleaning and greening the environment.

How does understory vegetation diversity and composition differ between monocultures and mixed plantations of hybrid poplar and spruce?

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Mialintsoa Aroniaina Randriamananjara[1]
Nicole J. Fenton[2], Annie DesRochers[1]
[1] Institut de Recherche sur les Forêts, Université du Québec en Abitibi-Témiscamingue, 341 rue principale Nord, Amos, Québec J9T 2L8, Canada
[2] Institut de recherche sur les forêts, Université du Québec en Abitibi-Témiscamingue, 445, boulevard de l'Université, Rouyn-Noranda, Québec J9X 5E4, Canada

Abstract: Although monocultures are important for timber production, they have often been perceived as biological deserts. Thus, mixed plantations have been suggested as a way to enhance biodiversity because of their inherent compositional diversity. However, there is no consensus on the impact of mixed plantations compared to monocultures on understory vegetation diversity and composition. The objective was to assess how differences between monocultures and mixed plantations of fast-growing hybrid poplar (*Populus* spp.) and spruce (*Picea* spp.) species established 20 years ago on abandoned farmlands and a forest site influence understory vegetation (vascular plants, bryophytes, and lichens) diversity and composition. We also evaluated the effects of plantation type on bryophyte and lichen diversity and composition in tree microhabitats: soil, tree bases, and tree trunks. We found a total of 115 understory vegetation species including 50 vascular plants, 46 bryophytes and 19 lichens species. We found similar understory vegetation diversity in spruce and mixed plantations, greater than in hybrid poplar plantations. We also found that mixed plantations harbored more bryophyte species compared to hybrid poplar plantations as the addition of spruce in mixed plantations created microhabitats and conditions which were favorable for their establishment. Our results also showed that short-rotation hybrid poplar plantations in mixed plantations favored the occurrence of epiphytic lichens and could provide temporary habitats for lichens. We also found that the dissimilarity in the microhabitats created by hybrid poplar and spruce in mixed plantations promoted the establishment of both terrestrial bryophytes and epiphytic lichens. Finally, our results highlight that vascular plant composition was more sensitive than bryophyte composition to the land-use history as abandoned farmland sites were composed of more ruderal vascular plants, while the previously forested site was composed of species typically found in the surrounding natural forests. Our study advances our understanding of how monoculture and mixed plantations affect understory vegetation diversity and composition and highlight the importance of considering land-use history.

Hybrid Poplar for Alternative Veneer Source, Carbon Credits, and Water Conservation in the Appalachian Mountains, USA

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Elizabeth Guthrie Nichols[1]
Sam Blumenfeld[1], Solomon Ghezhei[1]
[1] Department of Forestry and Environmental Resources, North Carolina State University, Raleigh, NC USA

Abstract: Hybrid poplar (*Populus* spp.) is grown globally for bioenergy, value-added products, sawmill, and veneer. We have cultivated selected poplar clones that grow well in the mountains of western North Carolina (WNC) and yield high-value veneer wood logs within 8-12 years. This area supports a robust industry of short-rotation fir production for Christmas trees but is faced with soil pathogen and climate-warming challenges. Veneer poplar is an alternative high-value crop to mountain bottomlands, slopes, and ridges that no longer support fir production and need water and soil management control. To increase confidence in commercial deployment, both productivity and profitability models were developed to assess economic viability for existing mills, producers, consultants, and markets. An existing 3-PG productivity model for hybrid poplar across the Piedmont and Coastal Plain of North Carolina was adapted to WNC-specific conditions and coupled to a WNC poplar-veneer enterprise budget to produce an feasibility and profitability tool using a publicly-accessible google sheet. An added feature is cost comparisons between veneer-poplar cultivation and current agricultural production yields and profits from pasture, hay, and pumpkin crops. The cost comparison includes estimation of carbon credits for poplar growth on former pasture or row crop agriculture. New programs for federal water conservation also provide incentives. There is landowner interest in alternative forestry-markets in WNC, particularly lands once in cultivation for profitable Fraser fir and now unusable due to the soil pathogen *Phytophthora*.

Industrial wastewater for lignocellulosic biomass production: A Green and Circular solution

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Nerea Oliveira[1]

[4] University of Alcalá, 28871, Alcalá de Henares, Spain
[5] Export Trading Group - Carbon Project Development and Nature Based Solutions, 28224, Pozuelo de Alarcón, Spain

Abstract: Biomass is an important raw material for the development of a sustainable bioeconomy, and the plantations that generate it can also play a key role in short term carbon sequestration in the context of global change. The use of specific short-rotation plantations for biomass production, such as *Salicaceae*, ensures a reliable and complementary supply in areas where needed. Under Mediterranean conditions, and increasingly in other climate zones given the ongoing climate change, irrigation appears to be essential for the survival and productivity of these plantations. However, current water resource challenges make this a critical problem. Therefore, the use of wastewater emerges as a promising solution, effectively reusing a valuable resource and representing one of the most impactful ecosystem services these plantations can provide, alongside their carbon sequestration capacity.

In this context, two consecutive greenhouse trials were conducted under controlled conditions to compare the suitability to produce biomass using two different wastewater from the agri-food industry (brewery), both sourced from the same Wastewater Treatment Plant (WWTP): first trial with secondary wastewater (SW) and second trial with dischargeable treated wastewater (TW). This study involves the monitoring of six different poplar and willows genotypes during the initial months of growth. Biomass production was evaluated, differentiating each fraction, and relevant relations such as root:shoot ratio and tolerance index were determined. While differences among genotypes were observed in both trials, treatment differences were only found for the SW in relation to the control, but not in the TW trial. No genotype-treatment interactions were observed in any of the trials. The average reduction in above-ground woody biomass was 17% with TW, and 33% with SW, with the exception of the *Salix* genotype 'Levante' that showed only a 17% reduction with SW and even a 28% increase with TW, suggesting a potential fertilizing effect. In addition, the nutritional status and physiological variables were also evaluated, with particular focus on total nitrogen (N) concentration due to its importance in this type of wastewater.

The reuse and regeneration of industrial wastewater while producing a key feedstock is a crucial nature-based solution for water-constrained short-rotation plantations.

Influence of Green Manure on the Initial Performance of Forest Species Implanted in an Experimental Forest Landscape Restoration Plot in Paraguay

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Alexander Abdel Fleitas Saucedo[1], Maria Laura Quevedo Fernández[1], Lila Gamarra Ruiz Diaz[1], Lidia Perez de Molas[1], Haroldo Silva Imas[2]
[1] Universidad Nacional de Asunción
[2] Itapu Binacional

Abstract: Green manure plays an important role in protecting seedlings against extreme weather conditions, as well as providing nutrients to the soil and other benefits. Therefore, this study aimed to compare the influence of green manure on the initial performance of implanted species in terms of Diameter at Collar Height (DCH), Height (H), and Crown Area.The research was conducted in an experimental plot for Forest Landscape Restoration at Itaipu Binacional, located in the district of Hernandarias, Alto Paraná Department, Paraguay. The experiment consisted of 2 treatments and 5 blocks. The treatments were planted in strips, including a conservation strip and a production strip. The production species were native species with energy purposes. The treatments differed in the planting of green manure (Cajanus cajan L. Mills) in the inter-row of the plantation.After 12 months of planting, the experiment was evaluated considering the variables of height, crown area, and DCH of the 21 forest species.The results show a greater crown area in species planted without green manure, with an average of 1.1767 m2, as well as a higher DCH without green manure, with an average of 22.2037 mm. However, regarding height, the plantation with green manure had an average of 98.3180 cm, while the plantation without green manure had an average of 98.7262 cm.In conclusion, green manure influences the growth of different variables, particularly benefiting height.

Phytotechnologies at Stillmeadow Community PeacePark Forest

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Nancy Sonti[1]
Max Piana[1], Rich Hallett[1], Ronald Zalesny[1], Morgan Grove[1]
[1] USDA Forest Service Northern Research Station

Abstract: Forests in cities contribute to critical biophysical and socio-cultural ecosystem services, and provide outdoor classrooms for unique educational experiences. Threats from invasive plants, deer browse, and introduced pests and disease often prevent native forest regeneration, particularly when coupled with existing anthropogenic impacts. Fast-growing trees present an opportunity to establish canopy cover and enhance soil organic matter in challenging site conditions where keystone native species (e.g., *Quercus* and *Carya* spp) struggle to establish. The USDA Forest Service (USFS) is implementing this approach in an 'urban silviculture' experiment in partnership with Stillmeadow Community Projects, a non-profit organization based in Baltimore, Maryland, USA. Stillmeadow Church owns 4 hectares of forested land known as the PeacePark. The Church and PeacePark are located in a community comprised of predominantly African American households that have been historically underserved, and are vulnerable to flooding and heatwaves. The PeacePark forest was ecologically degraded due to intense deer browse, invasive understory plants, poor soil quality, and extensive mortality of ash (*Fraxinus* spp) canopy trees due to the invasive Emerald Ash Borer. As a result, USFS scientists partnered with Stillmeadow to install phytotechnologies designed to foster 'anthropogenic succession.' Six poplar and six willow genotypes were planted in experimental plots throughout the forest, and a wood chip ground cover treatment was incorporated to suppress invasive plants. The trees were planted as hardwood cuttings and as potted saplings, testing the effectiveness of these approaches in rapid establishment of forest canopy cover as well as their success as community planting techniques. Planting and maintenance of the experiment has been led by the Stillmeadow community, providing educational experiences and workforce training opportunities. Early results indicate that both species planted from one-gallon containers are capable of high survival rates and vigorous growth in the first years after planting, but cuttings planted directly in the ground suffer much higher mortality in these site conditions. However, community-led planting was very successful, as was the community nursery established to grow potted poplar and willow trees. Phytotechnologies are a viable nature-based solution that may be applied to other urban forest or vacant land sites throughout Baltimore City and beyond.

Potential of short rotation willow systems for water treatment

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Abstract: Increasing resource consumption and growing impact of climate change necessitate resource reuse and development of resilient systems. Collection and treatment of domestic wastewater in rural areas and effective management of stormwater in urban areas pose significant challenges globally, leading to extensive research and implementation of resilient nature-based solutions (NBS).

Municipal wastewater is characterized by a continuous flow of organic matter, nutrients, and water, while stormwater is sporadic and depends on rainfall, resulting in variable loads and volumes. NBS incorporating fast-growing trees are effective for addressing both water sources. While these systems are widely used in Northern Europe, their application in sub-Mediterranean climate with higher and more intense rainfall requires specific adaptations. This paper addresses the design and performance of short-rotation willow systems for the treatment of (a) municipal wastewater and (b) stormwater runoff applied in Slovenia.

The wastewater treatment system (a) comprises a watertight, soil-filled basin planted with fast-growing clones 'V 160' (*Salix alba* L.), 'V 052' (*Salix alba* var. *calva* x *S. alba*), and 'V 093' ((*Salix alba* x *S. alba* var. *vitellina*) x *S. alba*). A clay layer is incorporated near the soil surface, and drainage pipes are installed to prevent rainwater from entering the system. Mechanically pre-treated water is pumped into the system and used for plant growth and evapotranspiration. As a zero-discharge system, it is suitable for environmentally sensitive areas with strict discharge requirements or for areas where infiltration of treated water is not possible. Among the clones, 'V 052' has shown the highest conversion rate of wastewater to woody biomass (8.5±0.6 kg per m^3 of wastewater) and was therefore selected for the stormwater treatment system (b). This system functions as a flow-through system for 10- and 60-minute rainfall with a 10-year return period. Stormwater is introduced at the top and is treated as it vertically passes through the media and willow root system.

Both systems described represent the first application of NBS using fast-growing trees in this European region. Therefore, it is crucial to present their performance and co-benefits for the environment and people, such as biomass production, habitat function, microclimate improvement and esthetic value.

Potential to increase the availability of a hybrid poplar resource for Engineered Wood Products based on Agroforestry production systems

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Joris Van Acker[1]

[1] UGent-Woodlab, Laboratory of Wood Technology, Ghent University

Abstract: The agricultural sector is often disconnected from the forestry wood chain especially with regard to green building. Innovative agroforestry systems create potential for the agricultural sector to diversify and increase incomes. However, there is a need to develop specific road maps towards green building. Hybrid poplars are a main component for this strategy. Alongside the more general introduction of this fast-growing trees suitable for engineered wood products, the advantages for the agricultural, forestry and construction sectors are very relevant. For the agricultural sector this is mainly related to climate change impact and environmental aspects and for the forestry and construction sector this will clearly contribute to the need for extra wood resource to enable bio-based building materials to be used more generally. Integrating these sectors is a timely challenge that needs advancements in research and innovation. There is a clear need to bring together experts and also to communicate on current research and results obtained in the near future on a national and international level. Networking in a multi-, inter and transdisciplinary way, experts from agricultural, forestry and bio-based building related industry will create not only a platform for exchange of research outcomes but also have a major impact on socio-economics in a pan-European context. This AGROPOPTECH network as part of the FAO structure IPC (International Commission on Poplars and Other Fast-Growing Trees Sustaining People and the Environment) creates a unique opportunity to build communities and pursue new ideas to impact the wide range of countries to get involved in agroforestry based on fast growing tree/wood species like hybrid poplar.

Abstract: Abstract

Post plantation seedling management activities are the most important factors that determine survival rate and growth performance of tree seedlings. The objective of this study was to investigate and compare growth performance of four tree species (*Cordia africana, Croton macrostachyus, Acacia abyssinica* and *Grevillea robusta)* with and without applying different management regimes (weeding, watering and fertilizer application). Half of the seedlings were fertilized with 138 gram of Phosphorus and 123 gram of Nitrogen per plant. Moreover, half of the seedlings were also weeded and irrigated with 15 liter per seedling per week for twenty months. Accordingly, split-split-split plot design with three replications having sixteen seedlings each was planted at four meter spacing. Plant height, root collar diameter and survival rate were collected starting from one month after plantation for twenty months. As no initial data (at planting) were taken, the data collected one month after plantation were used as covariate. This is because; there were significant effects in some treatments one month after plantation. The collected data were subjected to multivariate analysis of variance. Analyzing both height and diameter at twenty months after planting with one month as a covariate indicated that no interactions were significant, while, fertilizer and weeding had clear main effects. The twenty months survival rate was unaffected by main effects or interactions. Gravilia robusta was the most sensitive to weed competion compared to others explained by higher plant height when weeded than not. Similarly, *Cordia africana* and *Croton macrostachyus* revealed higher sensitivity to fertilizer application. The no response in growth performance of seedlings to the supplementation of water during the dry season could signify that moisture was not a growth limiting factor in the area during the growing season. Application of different management regimes, particularly fertilization and weeding was essential in improving growth performance of tree species in the area. Hence, treatment effects on survival rate might have been expressed indirectly through improving growth performance of the species. In general, further studies should be conducted to obtain optimum water and fertilizer requirements of the different tree species.

Key words: *Fertilizer, watering, weeding, plantation*

The implications of fast-growing broadleaved trees for lichen diversity in northern Europe

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Jaime Luna[1]
Adam Felton[1], Per-Ola Hedwall[1], Anne-Maarit Hekkala[2]
[1] Swedish University of Agricultural Sciences, Southern Swedish Forest Research Centre, Sweden
[2] Swedish University of Agricultural Sciences, Department of Wildlife, Fish and Environmental Studies, Sweden

Abstract: Sweden aims to achieve a 70% reduction in greenhouse gas emissions by 2030, and reach net zero from 2045. Bioenergy will be an indispensable piece of the puzzle for achieving both energy and climate policy goals. Currently, bioenergy supplies approximately 25% of energy in Sweden, most of which is sourced from the forest sector. However, this sector is dominated in Sweden by conifer forestry, an increasing proportion of which is experiencing problems with abiotic and biotic disturbance. This has spurred calls for a more diversified forestry, to help ensure that the future of forest biomass provision is sustainable and resilient to the risks and uncertainties of anthropogenic climate change. One prominent path to diversification is the wide-spread adoption of fast-growing broadleaved tree species (FGB), which include silver birch, poplar, aspen, and hybrid aspen. However, the use of such intensive forestry will have important but potentially complex implications for biodiversity. FGB combines the use of intensive even-aged disturbance regimes, with either native broadleaf tree species, or broadleaves of hybrid or introduced origin, with potentially adverse biodiversity outcomes due to the simplified forest systems that result. In contrast, the increased use of fast-growing broadleaves is consistent with attempts to diversify the uniformity of Sweden's conifer-dominated production lands, and their adoption could benefit at least some aspects of Sweden's diverse broadleaf dependent flora and fauna. Due to the counteracting drivers involved, the potential implications of fast-growing broadleaves for biodiversity remains unclear for many broadleaf associated taxa. Lichens are a key component of this diversity in forest systems, are directly coupled to the tree species grown and forest management intensity, and are overly represented on the Swedish red-list. Here we provide results from lichen surveys conducted in FGB stands as part of the Trees For Me project. We highlight differences in the diversity and prevalence of lichen species found, and link these patterns to the species of FGB planted, stand characteristics, landscape context, and management regimes employed. By providing targeted knowledge regarding the biodiversity implications of FGB, landowners and society can better make evidence-based decisions regarding the advantages and disadvantages of the choices available.

Transcriptome and metabolism reveal different mechanisms of cadmium absorption, accumulation, and resistance between female and male Salix viminalis

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Junzhu Zou[1]
Junxiang Liu[1], Ao Li[1], Yuancheng Wang[1], Yaofang Hu[1], Zhenyuan Sun[1]
[1] Key Laboratory of Tree Breeding and Cultivation of National Forestry and Grassland Administration, Research Institute of Forestry, Chinese Academy of Forestry; Haidian District, Beijing 100091, China

Abstract: *Salix viminalis* is a typical dioecious and fast-growing shrub willow, which has been widely used in phytoremediation for heavy metal-contaminated soil due to its characteristics of fast growth rate, deep root system, and resistance. It has been reported that dioecious plants present sex-specific responses when exposed to biotic and abiotic stress. However, sex-specific response mechanisms to cadmium stress of male and female *S. viminalis* remain undefined. In this study, the growth, cadmium absorption and distribution, root physiology, transcriptome, and metabolism of male and female *S. viminalis* under cadmium stress (200 μM) were investigated to identify sexual differences. The results showed that female *S. viminalis* suffered more severe impairment than males. The cadmium net influx rate of males (139.67 $pmol \cdot cm^{-2} \cdot s^{-1}$) was significantly faster than that of females (76.64 $pmol \cdot cm^{-2} \cdot s^{-1}$). Furthermore, the abilities of cadmium transportation and enrichment of males were much stronger than those of females. Transcriptome and metabolism analysis showed that both male and female *S. viminalis* up-regulated *ZIP2*, *AtbZIP6,* and *ZIP11* to activate transmembrane transporter activities. Male clones of *S. viminalis* synthesized more phenolic acids, lipids, and organic acids, and up-regulated *ZIP1* and *ATNRAMP6* to improve cadmium absorption. Female clones up-regulated more ABC transporter family genes (*ABCA3* and *ABCC3*) and stress-related genes such as *PCR2*, *GSTU7*, and *ATMT-1*, which were involved in the mitigation of cadmium toxicity, and synthesized more flavonoids such as myricetin, quercitrin, and alfalfa 5-*O*-glucosides, and amino acids such as glutamate and L-threonine for antioxidant defense against cadmium impairment. In conclusion, this study revealed the physiological and molecular mechanisms in cadmium resistance between male and female *S. viminalis*, providing strong evidence for the phytoremediation application of dioecious fast-growing trees on heavy metal-contaminated soil.

Urban phytotechnologies for forests in cities: using hybrid willow and poplar in urban afforestation and forest restoration projects

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Max Piana[1]
Richard Hallett[1], Ronald Zalesny[1], Maximilian Blaustein[2], Aelin Compton[2], Dhan Parker[2]
[1] Northern Research Station, USDA Forest Service
[2] City of Philadelphia Parks & Recreation

Abstract: Phytotechnologies lend themselves to the challenges (e.g. disturbed sites and contaminated soils) and management priorities of greening efforts in cities (e.g. stormwater and heat island mitigation). In urban natural areas, early-successional, fast-growing trees such as hybrid willow and poplar may support management efforts to create new forests (i.e. urban afforestation) and restore existing forest ecosystems in cities. For example, these trees may both tolerate urban site conditions and provide rapid greening that accelerates succession, controls invasive plant establishment, and facilitates the establishment and growth of later-successional trees that are desired by municipal forest managers. These trees are relatively easy to propagate and can be used as part of a cost-effective strategy that supports the broad goals of municipal forestry divisions.

Here we present two studies that test strategies using hybrid willows and poplars in natural land settings in Philadelphia, PA, USA. The Parkwood Afforestation study was installed in 2022 in a disturbed landscape, characterized by compacted and anthropogenic soil, with the goal of establishing a new forest stand. The study compares the tolerance (i.e. survival and growth) of native Populus and Salix species to hybrid Populus and Salix, as well as the potential for hybrid willow and poplar to act as nurse trees and facilitate the establishment of mid-successional tree species. The Three Springs Canopy Gap study is located in canopy gaps within a mature oak-tulip forest, where the goal is to establish advance regeneration of native mast tree species via direct planting. In this study, we compare traditional pre- and post-planting treatments, including mechanical removal of invasive plants and vines, herbicide application, and co-planting hybrid willow and poplar with mast trees in order to provide rapid canopy closure to suppress invasive plants and facilitate mast tree establishment (ie nurse tree strategy). We present preliminary findings and how phytotechnologies have been adopted by a municipality with the goal of scaling-up operations and integrating fast-growing trees across management practices.

Using shrub willows and soil amendments for biomass production and site remediation on reclaimed mine lands and marginal agricultural lands

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Jamie Schuler[1]
Shawn Grushecky[1]
[1] Division of Forestry and Natural Resources, West Virginia University, Morgantown, WV, USA

Abstract: The Mid-Atlantic region of the U.S. has over 10 million acres of mined and marginal agricultural lands that can be reclaimed and used to produce biomass crops without occupying or competing with food crops for existing cultivated areas. Both reclaimed mine sites and marginal agricultural lands present challenges to growing biomass crops. Soil physical and chemical characteristics often limit productivity and reduce ecosystem services provided. We explored the use of shrub willow biomass crops on six sites in the Mid-Atlantic region (3 reclaimed mine sites and 3 marginal agriculture sites) to assess the potential for biomass production and overall site reclamation. To overcome site limitations, soil amendments consisting of nitrogen fertilization and biochar additions were imposed. After 3 growing seasons, growth and survival were substantially greater on the agricultural areas. Despite intensive establishment efforts, the site conditions on the mine sites presented significant problems to willow establishment. The effects of the amendment treatments on both site types will be discussed in the content of biomass production and changes in plant and soil health.

Using specialized trees and biochar to remediate and stabilize mining waste for the Keweenaw Bay Indian Community (KBIC)

T2.8 Fast-Growing Trees for a Greener Future: Global Applications of Nature-Based Solutions

Elizabeth Rogers[1, 2]
Ronald Zalesny[1], Ryan Vinhal[1], Erin Johnston[3], Chung-Ho Lin[2]
[1] USDA Forest Service, Northern Research Station, Rhinelander, Wisconsin, USA
[2] University of Missouri, School of Natural Resources, Center for Agroforestry, Columbia, Missouri, USA
[3] Keweenaw Bay Indian Community, Natural Resources Department, L'Anse, Michigan, USA

Abstract: The Keweenaw Bay Indian Community (KBIC) is a federally recognized Indian Tribe consisting of the L'Anse and Ontonagon Bands of the Chippewa Indians, and is located along the shores of Lake Superior in the Upper Peninsula of Michigan, USA. Lands surrounding the KBIC are abundant in mineral resources that historically have been exploited by industrial mining activities. During the 20th century, a nearby copper ore stamp mill (Mass Mill) processed and dumped over six billion pounds of copper ore processing waste, known as stamp sands, into the Keweenaw Bay less than five miles north of the KBIC. These stamp sands have been redeposited by lake currents at Sand Point, an area of significant cultural, recreational, and subsistence value to the KBIC. Elevated levels of heavy metals in the stamp sands, as well as their erosion-prone nature, together pose risks to human health and the wetlands, meadows, wild rice beds, and pine forests that border Sand Point. To date, restoration activities at the site have involved soil capping of stamp sands, placement of mounds and boulders to provide protection from the wind, and annual plantings of trees, shrubs, and herbaceous native plants. Despite these efforts, the stamp sands continue to impair many of the beneficial uses of Sand Point. Therefore, researchers at the USDA Forest Service and University of Missouri have partnered with the KBIC to design and deploy an adaptive silvicultural system that combines specialized, fast-growing trees with biochar soil amendments to enhance stamp sands phytoremediation and phytostabilization. Poplars and willows are ideal fast-growing trees for meeting the restoration objectives of Sand Point due to their rapid growth, extensive rooting, and ease of propagation. Multiple greenhouse cycles of phyto-recurrent selection will be employed to select superior varieties for outplanting in a demonstration system at Sand Point. We will present updates on field establishment of the demonstration site, including results on establishment success. We also will discuss the engagement and outreach activities we conduct with the KBIC that promote knowledge exchange among community members and researchers and enhance the dissemination of information to guide management decisions for stamp sands affected lands.

Benefits of biochar in sustainable agricultural operations

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

Deborah Page-Dumroese[1]
Carlos Rodriguez-Franco[2], Derek Pierson[1]
[1] USDA Forest Service, Rocky Mountain Research Station
[2] USDA Forest Service, Washington DC

Abstract: Forest restoration and fuel reduction treatments are often used to reduce wood volume in overstocked forested lands in an effort to reduce wildfire risk and the incidence of insect and disease outbreaks. However, these forest treatments produce large quantities of woody residues. If no use or consumer is identified for the woody residues, they are often disposed of by on-site burning. As a management adaptation, woody residues can be converted to biochar and either used on-site or moved to local agricultural producers to improve soil conditions. Biochar can be used to enhance soil organic matter levels and can provide a variety of benefits. For example, biochar can store more plant available water, reduce nutrient leaching, reduce soil bulk density, raise soil pH, and sequester large quantities of carbon to mitigate climate change. In short, biochar's unique chemical and physical properties improve microbial activity, minimize offsite movement of pesticides, facilitate C storage in the soil, and can increase plant growth and yields. The largest yield improvements on biochar-amended soils tend to be on nutrient-poor or coarse-textured soils that benefit from additional soil organic matter. Biochar created from forest operations offers a way of restoring forest ecosystems and degraded soils by redistributing excess organic matter from forest sites into soils that lack organic matter.

Exploring Biochar Production from Residual Biomass in Colombia: Potentials, Prospects, and Barriers

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

Eileen Torres-Morales[1]
Dilip Khatiwada[2], Maria Xylia[1], Francis X. Johnson[3]
[1] SEI Stockholm Environment Institute, SEI-HQ
[2] Division of Energy System, Department of Energy Technology, KTH Royal Institute of Technology
[3] SEI Stockholm Environment Institute, SEI-Asia

Abstract: Biochar is recognized as a land-based net-negative emissions technology (NET) that plays a crucial role in supporting the targets of the Paris Agreement. It has significant potential for climate change mitigation and offers opportunities for co-benefits such as soil quality maintenance and facilitating the growth of new products. By converting residual biomass into biochar, the release of CO2 emissions into the atmosphere can be mitigated, providing an alternative to the decomposition of residual biomass in open fields. Biochar derived from residual biomass can be utilized for various applications, including soil amendment, remediation of contaminated soils, water treatment, and as an additive in construction materials, among others. While biochar production and usage can be adopted worldwide, tropical countries possess an advantage due to their abundant year-round availability of residual biomass.

This study presents the results of an investigation into the potential for biochar production from diverse residual biomass sources, using Colombia as a case study. The research involved conducting interviews with experts, an expert elicitation on agricultural residual biomass, and an estimation of agricultural residues for biochar production. The examination of potential biomass sources revealed that invasive plant species could be of interest for biochar conversion and subsequent soil incorporation. The valuable insights obtained from literature and expert interviews were analysed using a Policy, Environmental, Social, Technological, Economic, and Legal (PESTEL) approach. The findings indicate that approximately 10% of the residual biomass derived from key agricultural products (such as sugarcane, plantain, potato, rice, banana, cassava, oil palm, corn, pineapple, tomato, and coffee) could be transformed into biochar and reintegrated into the soil. Our conclusions present prospects and barriers of biochar production in the Colombian context. Our findings can be used internationally for navigating the biochar production and barriers of biochar production, and devising deployment strategies.

Phenotypic variability of fruits among provenances of Moringa oleifera Lam. in Kibwezi, Kenya

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

Emmanuel Makatiani[1]
Asenath Adienge[1], John Otieno[1], Charles Oduor[1], David Odee[2], Annika Perry[2], Stephen Cavers[2]
[1] Kenya Forestry Research Institute, P.O. Box 20412-00200, Nairobi Kenya
[2] UK Centre for Ecology and Hydrology, Bush Estate, Penicuik, Midlothian, EH26 0QB, United Kingdom.

Abstract: ABSTRACT

Phenotypic characterization of plant species is the basis for selection, conservation as well as improvement. *Moringa oleifera* Lam. belongs to the monogeneric family, Moringaceae. In Kenya, *M. oleifera* occurs in different agro-ecological zones, and is grown for its multiple uses that include medicinal, vegetable and as food supplements. The leaves and young pods are a rich source of minerals and vitamins; cooking oil can be extracted from the seed; and the back and roots can be used as medicine. This study reports on the evaluation of intraspecific phenotypic variations among eight Kenyan *M. oleifera* provenances (namely, Kibwezi, Ramogi, Kitui, Msambweni, Mbololo, Kilifi, Mtongwe and Gede) in a three-year old progeny trial established in Kibwezi. Our results indicate significant statistical differences ($p<0.05$) in quantitative fruit traits. The trait range was: pod length (Ramogi, 30.92 to Kibwezi, 35.95 cm), pod diameter (Msambweni, 1.50 cm to Kitui, 1.71 cm), weight of 100 seed (Msambweni, 16. 9 g to Mtongwe, 24.5 g) number of seeds per pod (Ramogi, 14.5 to Kibwezi 18.2) and number of locules per pod (Msambweni, 15.6 to Kibwezi 18.2) among families and provenances. **Pearson** correlation (r) results at $p=0.05$ revealed that the seed weight had a significant, positive correlation with pod length ($r=0.38$), pod diameter ($r=0.46$), and number of seed ($r=0.59$). The number of seed per pod was positively correlated to pod length ($r=0.39$) and pod diameter ($r=0.06$). There was a negative correlation between pod length and pod diameter ($r=-0.02$). Significant and positive correlations among traits of fruits show potential of simultaneous and direct selection for farmers' desired traits. The present results provide insights into the diversity of *M. oleifera* genotypes for fruit productivity and calls for further improvement in the species to suit various eco-climatic conditions found in Kenya.

Keywords: *Moringa oleifera*, phenotypic variation, morphometric, cluster analysis, characterization.

Potential of rice husk biochar as a forest soil amendment in Asia

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

[3] Department of Forestry Science, Faculty of Agricultural & Forestry Sciences, Universiti Putra Malaysia, Sarawak Campus

Abstract: Biochar is any biological residue from any organic-based materials including forestry by-product, manures or agriculture waste which were produced through gasification or pyrolysis at 300-600 degree Celsius under the exclusion of oxygen. Many studies show that biochar is one of the best options for agriculture and forestry sectors to use as a soil amendment to increase soil fertility. Besides that, biochar also enhances soil carbon sequestration.

About 600–800 million tons of rice straw is produced every year in Asia, while globally about 800–1000 million tons of rice straw is produced. Furthermore, the world annual production of rice husk and rice bran are 120 tonnes and 76 million tons respectively. The rice husk is partially used as fuel in rice mills to generate heat to dry paddy and burning of rice residue.

Some farmers burn rice residue because it is a cheaper and easier option to manage rice residue and contribute to soil nutrient cycling. There is also a belief among rice farmers that it will contribute to soil nutrient cycling. However, prolong burning of rice waste contributes to air pollution and increases greenhouse gas emissions. Thus, not only a sustainable approach to rice production is needed, but also in rice residue management. Converting rice husk into biochar has the potential to address both of these issues.

Rice husk biochar has high silica content which increases its adsorptive capability, enhanced nutrient retention, plant turgidity and structure. In forestry plantations especially in Malaysia, biochar is not used as soil amendment, as compared to the usage of rice husk biochar on agricultural farms. This work objective is to explore the benefits of using rice husk biochar to fertilize forest soil, thus, reducing the application of chemical fertilizer.

Properties of self-binding particleboard made of sweet corn stalk (Zea mays L.) and citric acid for furniture purposes

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

Lilik Astari[1]
Benoit Belleville[1], Kenji Umemura[2], Barbara Ozarska[1], Robert Crawford[3]
[1] School of Agriculture, Food, and Ecosystem Sciences, The University of Melbourne, Melbourne, Australia
[2] Research Institute for Sustainable Humanosphere, Kyoto University, Kyoto, Japan
[3] Melbourne School of Design, The University of Melbourne, Melbourne, Australia

Abstract: Particleboard fabrication faces challenges in utilising conventional adhesive and the shortage of wood particles as the main component. Agricultural by-products have the potency to substitute wood chips as raw material for particleboard due to their lignocellulosic components. Corn stalks are agricultural by-products that are abundant globally and widely available. Citric acid is reported as a cross-linking agent that can improve particleboard properties. This research investigated the physical-mechanical properties of particleboard made of sweet corn stalks (*Zea mays* L.). One-layer particleboards were fabricated with dimensions 28.2 x 20.8 x 1.2 cm with the targeted density of 0.5 and 0.7 g/cm^3. Citric acid with a solid content of 59% was added with three different percentages, i.e. 0, 10%, 15% and 25%. The pressing temperature was 200°C, ten minutes, and the pressure was 2.4 MPa. Properties were determined for their physical and mechanical properties according to JIS A 5908-2003. The chemical composition of the corn stalks was investigated using Fourier-transform infrared (FTIR) and Pyrolisys-GCMS (Py-GCMS). The result shows that the higher the particleboard's density, the better the mechanical properties of the particleboard. The bending strength of particleboard with 0.5 g/cm^3 density was 3.2-3.8 MPa. The bending strength for 0.7 g/cm3 particleboard was between 6.02-7.47 MPa. The bending strength value from 0.7 g/cm^3 is imminent to the standard. The internal bonding (IB) and screw-holding power (SHP) results in line with the bending strength results. The higher the board density, the higher IB and SHP value. On the other hand, the particleboards' water absorption (WA) and thickness swelling (TS) properties showed better results in lower-density particleboard. The WA and TS values of 0.5 g/cm3 particleboard were found to be 77.82-88.84% and 3.13-5.48% consecutively. For 0.7 g/cm^3 particleboard, the WA and TS values were 49.95-62.39% and 8.70-19.90%. The TS value for 0.5 g/cm^3 particleboard met the base particleboard standard. FTIR characterisation shows that corn stalk has noticeable peaks at 3300, 2900, 1700, 1200 and 600 cm^{-1} wavenumbers. Py-GCMS analysis results show that cellulose/carbohydrate has the highest percentage of pyrolysis products with 67.88%, followed by lignin at 24.16% and extractives at 7.33%.

Restoring degraded peatlands for food, biomass, and energy: Challenges and Opportunities in South Sumatera, Indonesia

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

Yustina Artati[1]
[1] Center for International Forestry Research (CIFOR)

Abstract: Indonesia is the home of the largest tropical peatland in the world with a total area of 13,43 million hectares which provides multiple ecosystem services essential for climate and water regulation, home to flora and fauna biodiversity, and livelihoods of local communities. However, Indonesian peatland has undergone land use transformation from forest to other land use systems, especially, agricultural systems. Further, peatland mismanagement has led to an increase in emissions, fires occurrence, and soil subsidence that cause environmental and economic problems and health issues. Indonesia pledged to restore nearly 2,5 million hectares of degraded peatland through three approaches: Rewetting, Revegetation, and Revitalization (3R). This study aims to present the potential of agrosilvofishery as a climate-smart peatland management model, to improve ecosystem services and livelihoods from degraded peatlands. Early findings from a 3 hectares trial plot of agrosilvofishery model in Perigi, Ogan Komering Ilir, South Sumatera province, show that potential accumulative avoided emission from fire and revegetation is about 217 $tCO2e^{-ha}$ in 30 years. Additional direct economic benefits are from food crops and fish, such as paddy, pineapple, and medicine plants. However, the model requires capital and technical support to overcome capacity constraints. Uncertain climate leading to drought and flooding significantly affects tree growth and food crop production. In addition, the pest is also a challenge to fish and food production if the practice only locates in small areas. Expansion of large-scale agricultural plantations is indicated leading to changes in water conditions in agrosilvofishery areas which affect tree growth and food production as well. Adopting agrosilvofishery for climate and livelihoods improvement, therefore, requires investment support from the government or private sectors as well as collaboration among stakeholders on the landscapes.

Significance of forest in maintaining ecosystem services of bees in croplands in Kangsabati South Forest Division, Purulia, India

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

PALLABI DAS[1]
V.P. UNIYAL[1]
[1] Landscape level planning and Management, WILDLIFE INSTITUTE OF INDIA, India

Abstract: Ecosystem service is a concept of any positive benefits that wildlife or ecosystem provide to human beings. Ecosystem services can be categorized into four different categories; crop pollination belongs to sub categories of supporting category. Ecological intensification enhances crop production with supporting and regulating ecosystem services management in agriculture practices. Agroforestry provide foraging, nesting and mating sites for all bees and also provide diverse floral resources throughout bees' active period. In croplands, bees and other pollinators are essential for improvement of crop quality or quantity, genetic diversity which will enhance the crop production and food security. Crop pollination by bees is a valuable ecosystem services in many mixed agricultural landscape and natural habitats.

The experiment conducted in agro forestry ecosystem which supports a huge habitat and food preference for bees. The studied area Kangsabati South Forest Division in Purulia, is characterized by undulating topography with hilly terrain in the western and southern parts which are continuations of the Chotanagpur Plateau. Mixed cropping system is practiced dominantly in the studied area. The experimental study was conducted in various farm lands from March – April 2022. The aim of the study was to find out the comparison of diverse bee population between croplands adjacent and distant to forest areas.

The study was conducted in seven plots for each crop (sunflower, cucumber, sesame) and fourteen forest areas in peak flowering period. Observation study performed at three time hour i.e. - 8.30-9.30hr., 11.30-12.30hr., 15.30-16.30hr., transect walk and focal observation followed to record bee abundance and species richness. GPS location of survey plots were also recorded. The abundance of *Apis* bee species were prominently observed in the crops fields nearby human habitat than crop fields surrounded by natural vegetations. Diverse wild bees population noticed in croplands adjacent to forest edges. Wild bees are more effective pollinators than honey bees. Alternation of nesting and resources site affect bee population composition and dynamics. The correlation between ecosystem service of bees and natural habitat can be utilized for conservation and restoration.

Keywords: Ecosystem services; Crops pollination; bees; agroforestry

Sustainability impacts of firewood and charcoal production and consumption in Tanzania analyzed using a new bio-economic model

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

Abstract: Forest degradation and land rehabilitation are major concerns in Tanzania. The wood harvested for charcoal, firewood and poles constitutes more than 90% of the country's estimated total forest harvest. This study evaluate forest sustainability impacts of the future production and consumption of firewood, charcoal and poles by developing and utilizing a dynamic forest sector model for mainland Tanzania. The model integrates detailed forest data from 32,773 sample plots in Tanzania's National Forest Inventory (NFI) with data on production costs, transport costs and demand for wood products. The developed model (TanzFor) is an intertemporal dynamic, spatial partial equilibrium model and links in an economic consistent framework the spatial supply and demand for fuelwood, poles and charcoal. The study is the first in Africa applying this type of a model with data from a detailed NFI and newly developed forest growth functions as basis for future wood supply. The study results shows alarming negative impacts on forest growing stocks by the steadily increasing consumption of firewood and charcoal in Tanzania, mainly caused by high population growth, high urbanization rates, low efficiencies in both charcoal production and consumption, and free access to common pool resource land. Future promising research tasks include further use of the NFI data, provision of more accurate data on the present and future consumption of charcoal and firewood, analyses of property regimes' effect on wood supply, improvement of TanzFor and its application in policy analysis related to land use and forest climate change mitigation and adaptation.

The economics of producing biochar from forest biomass to meet demand in agriculture

T2.9 Forest to Food: Developing synergies across forest restoration, the bioeconomy and sustainable agriculture

Nathaniel Anderson[1]
Debbie Page-Dumroese[1], Han-Sup Han[2], Dan McCollum[1], Woodam Chung[3], Derek Pierson[1]
[1] U.S. Forest Service

[3] Oregon State University

Abstract: Biochar is an anthropogenic charcoal used as a soil amendment. It can be made from forest biomass using a wide range of methods, from wooden ricks and simple kilns to large-scale industrial pyrolysis systems that produce heat, power and sometimes liquid fuels and chemicals as co-products. This presentation is focused on understanding the potential costs and benefits of using woody biomass from forest management to produce biochar used as a soil amendment in agriculture. The authors synthesize the results of multiple published studies and ongoing field research cutting across both investment-oriented financial analysis and broad economic analysis that includes non-market benefits and ecosystem services. Technoeconomic analysis is presented for a variety of biochar production pathways at mobile, modular and centralized scales. The agricultural end uses considered are soil amendment for row crops, orchards and vineyards, and biochar use as an adsorbent in bedding material in dairy and cattle operations. Results show that the benefits of biochar systems linking forestry and agriculture are likely to be undervalued when calculated strictly on a financial basis. For example, under the standard practice of disposing of slash through pile-burning, the net present value (NPV) of fuel treatment thinning to reduce wildfire risk on 138,034 ha over 20 years is -$275 million. If the biomass is used for energy at market value, NPV improves to -$178 million without consideration of nonmarket benefits. However, NPV of the same forest management regime improves to -$25 million (with 27.7% of outcomes having positive NPV), if nonmarket benefits associated with better forest health, lower wildfire likelihood, expanded renewable energy, and better air quality are included. Project NPV improves significantly further into positive outcomes (>$10 million over 20 years) if carbon offsets are generated from biochar application in agricultural settings under existing incentives and carbon offset protocols, depending on price. Biochar production for agriculture provides an opportunity to efficiently use a variety of forest biomass feedstocks that are otherwise treated as waste biomass, and the authors provide recommendations to improve the financial viability and economic value of biochar supply chains that link the forest and agricultural sectors.

T2.10 Forest-based Bio-economy Prospects in Africa

Assessing the ambiguity in socioeconomic outcomes of plantation forest companies: reconciling decades of contrasting evidence from Sub-Saharan Africa

T2.10 Forest-based Bio-economy Prospects in Africa

Aruna Kainyande[1]
Sherry Kyamagero[2], Kendisha S. Hintz[1]
[1] Institute of International Forestry and Forest Products, Chair of Tropical and International Forestry, Technische Universität Dresden, Germany
[2] Faculty of Agricultural, Environmental and Food Sciences, Free University of Bozen-Bolzano, Italy

Abstract: Forest plantation companies have been recognized as leading providers of socio-economic development and investments in rural communities in sub-Saharan Africa (SSA). Yet, negative consequences of their associated socio-economic impacts have been flagged, begging for insights on their potential to drive sustainable bioeconomy transitions. This study aims to understand the socio-economic outcomes of large-scale forest plantation companies in SSA as a proxy for deriving further research avenues toward promoting their positive contributions while mitigating the negative ones.

A review of the literature is complemented by two independent case studies portraying the roles of large-scale plantation forest companies in a) advancing socio-economic development in rural communities in Sierra Leone; and b) developing farmers' silvicultural capacity through an out-grower scheme in Uganda. Semi-structured interviews were conducted in Sierra Leone (n=125) and Uganda (n= 80), complemented by key informant interviews of five officials from the plantation forest companies in both countries.

The forest plantation company in Sierra Leone contributed to providing income diversification opportunities through salary and land lease payments, supplying fuelwood, generating employment, and providing on-the-job training for the workers. The employment contribution was ranked as the most important, followed by income, fuelwood, and capacity building. The findings from Uganda demonstrated that the training provided by the plantation forestry company significantly benefited the smallholders in the out-grower scheme in developing their capacity to engage in sustainable tree management practices. The farmers also acknowledged the program to enhance their access to high-quality planting materials and farm credits.

Therefore, to contribute to the empirical evidence of how forest plantation companies can further build resilience in rural areas, we derived further research agenda regarding the trade-offs between land allocation for large-scale plantation forestry and other alternative land uses, the effectiveness of benefit-sharing mechanisms and land tenure security issues and how these shape the potential for large-scale plantation forestry companies to deliver societal-desired socio-economic outcomes in rural areas. Our results suggest the need to leverage the potential contribution of plantation forest companies as key players in the global forest-based bioeconomy agenda to balance social, ecological, and economic demands.

Building Communities Resilience to Climate Change Through Sustainable Green Businesses in Semi-Arid Regions of Kenya

T2.10 Forest-based Bio-economy Prospects in Africa

Jonah Kiprop[1]
Anthony Macharia[2], Violet Oriwo[1], Joram Kagombe[1], Monica Muroki[1]
[1] Kenya Forestry Research Institute
[2] Ministry of Environment Climate Change and Forestry

Abstract: Arid and Semi-Arid Lands (ASALs) occupy 80% of Kenya's lands area and home to 70% of the total livestock population and 90% of wildlife. These regions have been impacted by periodic cycles of devastating droughts over the years impacting on local communities' main source of livelihood which is livestock keeping. The abundance of resins and gums producing tree species in these regions presents untapped green business opportunities for local communities to tap into. The Kenya Forestry Research Institute through the TWENDE (Towards Ending Drought Emergencies) is supporting local communities dealing in gums and resins to upscale sustainable trade by providing climate resilient investment in value chain. To ensure sustainable production and consumption of gums and resins the project designed a sustainable green business model with five key interventions targeting various nodes of the gums and resins value chain activities. This paper presents key findings and observations from rapid appraisal surveys undertaken on 689 beneficiaries from six local community groups and 1 cooperative in Sabarwawa and Mid tana Landscapes covering five arid Counties of Marsabit, Samburu, Isiolo, Garissa and Tana River. Key bottlenecks in the value chain observed include; low productivity linked to drought cycles, limited value addition due to lack of basic equipment and requisite knowledge, low market prices due to exploitation and information asymmetry among actors where middlemen have more information than the collectors, high transportation costs, limited market for some products. To address the value chain challenges the project has rolled several interventions including training on sustainable production of gums and resins, harvesting/collection and post-harvest handling and processing, sustainable harvesting, and compliance procedures. To support market development a web based and mobile system for linking producers and buyers of gums and resins to markets is being developed. To ensure sustainability of the interventions past the project period a local a Value chain technical assistance plan will be defined for the gums and resins producing Counties to mainstreamed within their County Integrated Development Plans (CIDPs)

Economic value of selected Non Timber Forest Products towards household food security and income in Niassa Special Reserve, Mozambique

T2.10 Forest-based Bio-economy Prospects in Africa

Gerald Lubega[1]
Falcão, Mario Paulo da Silva[1], Joseph Ssekandi[2], Ribeiro Natasha[1]
[1] Department of Forest Engineering, Faculty of Agronomy and Forest Engineering, Eduardo Mondlane University, P.O.Box 257, Maputo, Mozambique
[2] Department of Agricultural Sciences, Faculty of Agriculture and Environmental Sciences, Kabale University, Kabale, Uganda

Abstract: An assessment on the economic value of selected Non Timber Forest Products (NTFPs) towards household food security and income was done on the selected households in selected villages in Mecula-Marrupa corridor in Niassa Special Reserve (NSR). The sampling framework was the households from selected villages, local leaders, traditional healers, and officials managing NSR. The study utilized household survey method and market survey in collection of data. Once the NTFPs collected and produced in the study were identified, household surveys were conducted to attach value on the different NTFPs, locate the main area where each household collects NTFPs, the amount collected per year, and what income they generate from the sales. During market survey, information on market price, how prices change across seasons, market capacity and quantities of different NTFPs that reach the market was collected. Types, prices, and amounts of NTFPs supplied and sold to the market were recorded. Total sales per year were also determined to obtain the total income. The economic value of each NTFP was obtained basing on Shackleton and Shackleton model. It was established that the mean annual value of the identified NTFPs ranged from 600.00MZN/$6.68 to 6.000.00MZN/$96.77 which meant that the community attached much economic value to firewood, mushrooms, medicinal plants, and honey which was statistically and economically true. It was thus learnt that collection, production and selling of NTFPs have a positive and significant influence on rural livelihoods. Such practices pose a great potential to conserve forests in the area since they always fight to ensure that their source of income and food is never interrupted. These can be important practices in addressing concerns of food insecurity, unemployment, and poverty alleviation in Mecula-Marrupa corridor, NSR of Mozambique and other parts of Sub-Saharan Africa. The study recommended that domestication of indigenous tree species should be encouraged for the reduction of poverty and for balance to be maintained in the ecosystem. The government should also encourage the cultivation of edible and medicinal tree species around homes incorporated with honey production. This will reduce encroachment into the forest for tree species exploitation for economic and medicinal reasons.

Enabling policy and private investments as requisites to improved non-timber forest products' contribution to people's income and national economies

T2.10 Forest-based Bio-economy Prospects in Africa

[7] Université d'Abomey Calavi, Cotonou, Benin

Abstract: Recent estimates (2022) show that about 677 million African households use NTFPs for subsistence and income. However, many of them still face food insecurity and high poverty rates, partly due to under-exploitation of the opportunities offered by NTFPs. Indeed, despite the globally recognized potential of NTFPs, the sector faces many challenges of which, the lack of, or poor policy frameworks is critical. This paper synthesizes evidence to drive interest of policymakers in strengthening an environment conducive for NTFPs value chain development. Literature review and field case studies are used to document the contribution of NTFP to household livelihoods and economies for communities and countries in Africa. Results show that NTFPs are crucial to household subsistence and income of rural African people, in particular women and indigenous people. Case studies, for instance, in DR Congo, Ethiopia, Benin and Burkina Faso show that NTFPs contribution to households' income can be as high as 32 - 45%. Income from NTFPs has also an equalising effect on income inequality. NTFPs are recognised as safety nets for communities whose agricultural activities are impacted by climate change; yet how NTFPs themselves are affected by climate is not enough studied. However, due to informalities, there is limited evidence on the contribution of NTFPs to GDP; about 5% is reported for Burkina Faso and Mali; in Sudan, gum Arabic alone contribute about 4% of the GDP. These statistics are of course underestimated. In many countries, the NTFP sector remains informal and mostly serves only local markets; there is urgent need for private investment to develop NTFPs-based industries with added value such as employment and taxes. This potential NTFP development pathway is constrained by the fact that NTFP are not duly addressed in sectoral policies aiming at socio-economic development. Areas that still need attention to provide more evidence to policymakers include: how to effectively monitor and improve the contribution of NTFPs to national economies? This will require an improved understanding of the dynamics of the resource base (extent and quality) in the changing land uses and climate, and related impact on livelihood and income, access and benefit sharing mechanisms.

Lessons Learnt from Forest and Landscape Restoration of Arid and Semi-Arid Lands (ASAL) of Kenya through Bio-Enterprise Development

T2.10 Forest-based Bio-economy Prospects in Africa

Meshack Muga[1]
Patrick Mugi[1], Elijah Mboko[1], Philip Kisoyan[1], Benjamin DeRidder[1], James Ndufa[2], Patrick Maundu[3], Peterson Kamau[4], Rose Akombo[5]
[1] Food and Agriculture Organization of the United Nations
[2] Kenya Forestry Research Institute
[3] National Musuems of Kenya
[4] Ministry of Environment Climate Change and Forestry
[5] Kenya Forest Service

Abstract:
The Food and Agriculture Organization of the United Nations in collaboration with the Kenya Forestry Research Institute and other partners implemented a project in Mount Kulal Biosphere Reserve in Marsabit County and Mukugodo forest landscape in Laikipia County. These two landscapes are degraded and vulnerable to climate change. An integrated approach was adopted to address deforestation, land degradation and biodiversity loss, targeting policy and institutional capacity while supporting community-led forest and landscape restoration (FLR) and the development of alternative sources of livelihoods. The national and county level policy and regulatory frameworks were strengthened to support FLR in the two counties and the country at large. At the national level, a forest and landscape restoration implementaion plan (FOLAREP), forest regulations on benefit sharing and a strategy on non-timber forest products and services (NTFPs) are in place. Total economic valuation for the two ecosystems was carried out and estimated at US$ 85million /year for Mukogodo and US$ 187.97 million/year for Mt. Kulal. Participatory forest management plans and forest management agreements for the two forests have been signed, launched and operaionalised. So far, a total of 1165 ha and 193,931 ha of land have been directly and indirectly restored, respectively, using various options identified during ROAM assessment. Gums and resins, aloe, honey and ecotourism were identified as key bio-enterprises with great potential for development and income generation. 40,913 beneficiaries (21,766M, 19,147F) from 8,182 households had their capacity strengthened in FLR and bio-enterprise development. The project developed 17 bankable projects, several knowledge products and established a knowledge management portal for sharing the generated information. Some of the key lessons learnt include: sensitization of local communities on protection of worked sites; prioritization of land tenure in ASALS; long and extended dry spells and pandemics (COVID-19, Desert Locust) may affect FLR results; development of bio-enterprises as low ly-ing fruits for FLR is critical; public-private sector partnership in bio enterprise development is crucial; knowledge products to be uploaded to the Knowledge Management portal for ease of access; synergies and complementarities critical for greater impact and that domestication of the developed FOLAREP in counties is essential and urgent.

Net Zero Bamboo Pulp Production – A Forest Based BioEconomy for Africa

T2.10 Forest-based Bio-economy Prospects in Africa
Camille Rebelo[1]
[1] EcoPlanet Bamboo

Abstract: Africa's growing populations present a unique opportunity for a sustainable forest-based bioeconomy. In 2021 South Africa imported \$187M of toilet & tissue paper, and \$133M of wood pulp. Ghana imported \$64M of toilet & tissue paper, and \$20M of wood pulp. Even the tiny nation of Rwanda imported \$5.88M of toilet & tissue paper and \$1.2M of wood pulp. These imports represent a significant loss of export dollars for these African economies. The opportunity for domestic forest based industries to replace imports for consumer pulp and paper products is high. Yet this transition does not require the traditional focus on monoculture plantations for fast growing timber, and its subsequent conversion in antiquated chemical based kraft pulping.

In contrast, bamboo provides an opportunity for a holistic framework for African nations to leapfrog technology and develop reforestation strategies, hand in hand with next generation, net zero biorefineries for the production of a truly green climate-friendly pulp.

Since 2012 EcoPlanet Bamboo has been working towards the development of such a forest-based bio-economy in these three countries – Ghana, South Africa and Rwanda - through a multi-phase approach. Phase I restores degraded lands integrating select species of bamboo with remnant forest patches to create biodiverse permanent forested ecosystems that have the potential to produce a long-term, deforestation-free source of wood while utilizing a fraction of the land area of traditional plantations. Phase II utilizes harvested bamboo in a biorefinery for the production of a high quality pulp, and a lignin by-product. This patented next generation technology is net zero, while also being energy and water neutral, relying on bioenergy from a portion of the bamboo harvest, and the water content of the fiber itself.

With just over 22,000 hectares undergoing such restoration to date on the African continent, these forest based operations are creating more than 1,500 generational job opportunities, sequestering >8M tons of CO_2, creating microclimates that provide mitigation and adaptation benefits, reduce pressure on degrading landscapes, and have the long term potential to create scaleable and replicable forest-based bio-economies that can meet the growing demand for toilet and tissue paper products.

Non-Timber Forest Products (NTFPs)-based Bioeconomy transition for community livelihoods in Cameroon: A gendered perspective

T2.10 Forest-based Bio-economy Prospects in Africa

Nyong Princely Awazi[1, 2]
Jude Ndzifon Kimengsi[3, 4], **Marie Louise Avana-Tientcheu**[5, 6], Gadinga Walter Forje[5], Barnabas Neba Nfornkah[2], Chimi Cedric Djomo[7]

[7] Institute of Agricultural Research for Development (IRAD), Yokadouma, East Region of Cameroon.

Abstract: Cameroon is endowed with over 710 non-timber forest products (NTFPs), with 16 of the commonly exploited NTFPs generating a total annual income of USD 64.7 million. The NTFPs resource base in Cameroon is enormous making an NTFPs-based bioeconomy transition very feasible. The wide array of NTFPs are already playing a vital role in community livelihoods particularly in the forested regions of Cameroon. Despite the important role being played by NTFPs, little is known about the role an NTFPs-based bioeconomy transition can play in community livelihoods especially along gender lines. The objective of this study is to bridge this knowledge gap by assessing the contribution of an NTFP-based bioeconomy transition to community livelihoods with emphasis on gender. Three NTFPs (Bamboo, Rattan and Bush Mango) are selected for the study. Data were collected from 563 randomly selected households across Cameroon using a structured survey. Findings reveal that women and men in the target communities obtain different unprocessed and processed products from Bamboo, Rattan and Bush Mango which support their livelihoods. Unlike Bush Mango harvesting, processing and trading where 80% of the harvesters, processors and traders are women; most (95%) of the harvesters, processors and traders of Bamboo and Rattan are men. Unprocessed and processed Bush Mango generates a total annual income of USD 45,730,000 and USD 7,080,000 with women accounting for USD 36,584,000 and USD 5,664,000, respectively. For Bamboo, unprocessed and processed products generate a total annual income of USD 354,000 and USD 12,434,400 with women accounting for USD 17,700 and USD 621,720, respectively. For Rattan, unprocessed and processed products generate a total annual income of USD 876,000 and USD 24,606,000 with women accounting for USD 43,800 and USD 1,230,300, respectively. From the foregoing, it can be deduced that, while Bush Mango contributes more to the livelihoods of women, Bamboo and Rattan contribute more to the livelihoods of men. An NTFP-based bioeconomy transition geared towards enhancing community livelihoods in Cameroon therefore needs to factor in the gender dimension of NTFP harvesting, processing and trading for a more balanced and robust transition.

Key Words: Non-timber forest products; Bioeconomy; Livelihoods; Gender; Cameroon

Preserving Gardenia erubescens: Unveiling its Value and Ensuring Resilience in Burkina Faso amidst Climate Change

T2.10 Forest-based Bio-economy Prospects in Africa

Kangbéni Dimobe[1]
Korotimi Ouédraogo[2], Marie-Louise Avana-Tientcheu[3], Adjima Thiombiano[2]

[3] African Forest Forum C/O CIFOR-ICRAF, United Nations Avenue, Gigiri

Abstract: The conservation of local fruit trees and their contributions to food security, biodiversity, and ecosystem services are increasingly recognized. This study explicitly examines *Gardenia erubescens* Stapf & Hutch.—a plant species classified as least concern (LC) by the International Union for Conservation of Nature (IUCN). However, the species along with 59 others isthreatened in Burkina Faso due to excessive harvesting, The main goal of this study is to create a scientific database that will help in the development and conservation of the species in the context of climate change. Specifically, it aims to (i) evaluate the use value and factors influencing G. erubescens' utilization in Burkina Faso, and (ii) assess the impact of climate change on its distribution and conservation.

A semi-structured survey was conducted with 514 informants from 15 villages bordering three community forest areas. Ethnobotanical indices were computed to assess G. erubescens' use and cultural importance, considering variables such as gender, ethnicity, age groups, and geographic location. Geostatistical and species distribution modeling techniques were used to evaluate the vulnerability of *G. erubescens* to climate change and project its future distribution under two climatic scenarios (optimistic RCP 4.5 and pes- simistic RCP 8.5).

The results indicate that *G. erubescens* has multiple uses, with its various organs involved in over thirty different applications. The study identified eleven socio-cultural groups, with the Gourounsi (29.77%), Gourmantché (23.54%), and Mossi (13.04%) being the most prominent. The modelling results suggest that climate change will adversely affect the distribution of *G. erubescens* in Burkina Faso by 2070. Under the RCPs 4.5 and 8.5 scenarios, habitats currently favourable to the species are projected to decrease by 18% to 53%. These findings underscore the potential for integrating these species into production systems in Burkina Faso and highlight their significance in implementing ecosystem-based approaches for climate change adaptation.

Status and opportunities for value addition of Non-Timber Forest Products (NTFPs) in Africa

T2.10 Forest-based Bio-economy Prospects in Africa

Ben Chikamai[1]
Suzana Augustino[2], Marie Louise Avana[3], Daud Kachamba[3], Dietrich Darr[4], Kathrin Meinhold[4]
[1] Network for Natural Gums and Resins in Africa, Nairobi-Kenya
[2] Nelson Mandela African Institution of Science and Technology, Arusha-Tanzania
[3] African Forest Forum, Nairobi-Kenya
[4] Hochschule Rhein-Waal University-Germany

Abstract: Inadequate value addition of NTFPs in Africa affects their trade and, thus, negatively impacts on sustainable forest management and livelihoods. The process of value addition entails three processing aspects, namely: primary (harvest and post-harvest handling), secondary and product formulation. Considering the diverse types of NTFPs that exist, only four categories will be used for illustration: gums and resins, bee products, indigenous fruits, and herbal products.

Considering gums and resins, primary processing has progressed substantially, due to awareness and training programmes that have been carried out in the region since the 2000s. Nowadays commodities entering the market meet the quality requirements in most countries, as improved equipment has been developed enhancing the quality and quantity of the produce. However, secondary processing and product formulation remain a big challenge resulting in exports of raw form, and hence generally low prices.

Similarly, considering bee products, Africa has great potential, yet trading is so far mainly based on raw products such as raw honey, wax, and propolis, due to lack of knowledge and skills for production of more advanced products, that could boost farmer income.

With regard to indigenous fruits, value addition activities on all levels have only been more professionally advanced for selected species across the African continent. One such example is the baobab tree (*Adansonia digitata* L.), for which adequate harvesting and storage practices, supply chain management and quality control mechanisms, processing technology as well as novel product development have been realized. However, the potential for many other species has not been realized.

Finally, Africa can also tap into the global demand for chemicals and products derived from herbal plants, e.g. for affordable healthcare, creating entrepreneurial opportunities. However, progress in this front is minimal, due to lack of appropriate technologies and agronomic practices, among others.

This paper will be based on extensive review of literature and case studies where applicable. A broad scope for each category and level will be covered to reflect regional experiences in regard to existing technologies and best practices. Opportunities for scaling up relevant and suitable technologies will be explored, and recommendations made.

Sustainable industrial process-heat from African forests: Kenya's tea industry and implications for bio-economy prospects in Africa

T2.10 Forest-based Bio-economy Prospects in Africa

Thomas Buchholz[1, 2, 3]
Stephen Kiama[2], Hilarious Kifalu[2], Veronica Ngunzi[2], Geoffrey Ronoh[2], Sarah Odeira[2], Izael DaSilva[2]
[1] Gund Institute for the Environment, University of Vermont

[3] Spatial Informatics Group LLC

Abstract: Industrial energy needs in Africa are increasing. To fuel a bio-economy, energy sourcing needs to be climate-conscious. Forest based bioenergy can be particularly beneficial in rural areas by creating and sustaining green jobs. However, bioenergy is a major risk to existing tree cover in Africa. Forest based bio-economies in Africa must acknowledge that risk while tapping into its potential – particularly for industrial process-heat where often no alternative exists to, frequently imported, fossil fuels. We present on an enduring and large industry in Africa: Kenya is the world's largest exporter of black tea. Tea contributes around one third to Kenya's GDP, and is the country's largest employer (>10% of Kenyans depend on tea for income). Over the past century, fuelwood has provided process-heat required for drying tea at Kenya's ~100 tea tea factories. Fuelwood quality, supply security, sustainability and price are major concerns to the tea industry. Energy expenses are the second highest cost category after labor costs.

A key to a sustainable bio-economy in this context is to identify drivers of heat energy cost and specify performance and spread of two thirds of Kenya's tea factories. Research objectives were design an analytical framework covering i) fuelwood and ii) alternative biomass fuels supply chains, iii) onsite fuel logistics, and iv) boiler operations; followed by field surveys, data analysis, factory ranking, and information gap identification.

We surveyed 65 tea factories and collected data on over 50 variables for fuelwood supply, plantation data, alternative biomass fuel use, and boiler performance, respectively. We also explored the impact and risk of sourcing fuelwood from the open market as well as from dedicated fuelwood plantations.

The industrial process-heat sector is responsible for over 25% of Kenyan oil consumption; impacting Kenya's climate footprint and trade deficit. We demonstrate that bioenergy based industrial-scale process-heat is cost effective and scalable for an entire industry. Switching from oil or coal to wood heat can reduce costs by over 20%. Efficient and sustainable bioenergy systems can therefore allow for further growth and 'greening' of industries in need of process heat, such as the regional beverage, food-processing, and cement industry.

The contribution of indigenous knowledge in advancing domestication of Non-Timber Forest Products species in Africa

T2.10 Forest-based Bio-economy Prospects in Africa

Marie Louise Appolinaire Avana Tchamdjou Epse Tientcheu[1]
Kangbéni Dimobe[2], Suzana Augustino[3], Peter Minang[4]
[1] 1.African Forest Forum, C/O CIFOR-ICRAF, United Nations Avenue, Gigiri, Nairobi - Kenya

Abstract: Domestication of indigenous plant species for producing non-timber forest products (NTFP) in agricultural landscapes is promoted to sustain their access and use while conserving their natural resources. In Africa, the decentralized participatory domestication approach has been adopted, which provides opportunity for communities' engagement and the use of traditional knowledge (TK) in shaping locally accessible technologies that address context-specific challenges hindering NTFP species management and cultivation. The paper focuses through literature review and case studies on key progress achieved in the domestication of NTFP-based species. It highlights the contribution of TK systems in advancing the process. So far, more than 59 candidate species for domestication have been documented on a wide range of topics from their ethnobotanical use and management, including resource and socioeconomic assessments to set priority among targeted species to the adoption, uptake and impacts of newly developed cultivars, skills, techniques and strategies capturing the benefits associated with production and marketing of NTFPs in human-managed landscapes.

The first step in the domestication process is the identification and characterization of existing diversity within and among populations based on end-users preferred traits and guided by TK. In all African subregions, morphological, biochemical, and genetic descriptors have been applied to selected priority species. However, the mapped "ideotypes" still poorly contribute to cultivars' development through breeding and improvement.

Low-technology and low-cost propagation techniques have been co-developed and applied to produce and distribute improved planting materials. However, intensive cultivation of NTFPs species in agricultural landscapes is challenged by the lack of capacity and skills to scale up the technologies to other species and contexts. Hence, many of them are still being sourced exclusively from the wild. TK on farmer-managed natural regeneration is contributing to preserving locally valued species in natural and agricultural landscapes.

Emerging trends in NTFP' species domestication are focusing on the impact of climate change on their distribution and conservation through niches modelling based on climatic scenarios and communities-led resources mapping, as well as exploring entrepreneurship opportunities and technologically efficient value addition processes for a better contribution to the development of NTFP-based bioeconomy.

The economic potentials of wood offcuts; an entry point to forest-based bio-economy in Ghana

T2.10 Forest-based Bio-economy Prospects in Africa

Mary Adu-Sarpong[1]
Hayford Eshun[1]
[1] Timber Industry Development Division of Forestry Commission - Ghana

Abstract: The versatility of timber makes it a unique raw material that can be processed into various products with enormous benefits. As a flexible raw material depending on the targeted end-use, off-cuts are generated along the production value chain. In the forest, only the merchantable parts of harvested trees (timber) are conveyed to the mill leaving the branches, buttresses, etc. behind notwithstanding the multiple arrays of benefits that could be accrued from these parts by other wood users, reducing the economic net value of the wood. This study aimed to unravel the economic potential of other products derived from offcuts both at the forest floor and mills to improve recovery toward sustainable forest management.

The study used random and purposive sampling techniques for selecting respondents from bush managers, lumber processing firms, domestic wood market dealers, and tertiary wood dealers. Additionally, the views of respondents were sought through semi-structured questionnaires and interviews conducted with key informants in Ghana's wood industry and regulators.

The result indicates that approximately 28.7% of the harvested trees were left on the forest floor as waste whilst 71.3% were conveyed for further processing. It was also revealed that, a lot of economic viable and useful products can be generated from the logging offcuts to diversify income and businesses along the timber production value chain. Lastly, through the study, we find out that efficient use of harvested tree can contribute to sustainable forest management by reducing the number of trees that could otherwise have been harvested

Owing to the economic benefit coupled with the secured wood source to the small-scale wood user, a call for review of the Manual of Procedures (MoPs) governing Timber Resource Management and Legality Licensing Regulations, 2017 (L.I. 2254) is timely. Thus, the allocation of timber to factor in leftover tree parts to serve as the legal wood source for carvers and other small-diameter machinery processors. Securing legal wood sources could help meet the heightened demand for the domestic market as well as serve as a tool to curtail illegal chain saws.

The Wood Solution–An integrated industrial system in which wood buildings drive large-scale restoration & sustainable development across the tropics

T2.10 Forest-based Bio-economy Prospects in Africa

Rosa Goodman[1]
Berty van Hensbergen[2], Klas Bengtsson[2], Aaron Kaplan Kaplan[2]
[1] Swedish University of Agricultural Sciences
[2] Eco-Innovation Foundation

Abstract: The demand for housing will skyrocket throughout the century. Building in wood is broadly considered a climate-positive solution, but it is hotly debated whether increasing demand for wood would lead to positive or negative outcomes for forests and biodiversity. Within the current tropical timber industry, increasing harvests from natural tropical forests would almost inevitably degrade the remaining primary forests; and increasing tree plantations would likely come at the loss of natural tropical forests. To be maintained across the landscape, natural tropical forests must generate substantial value to compete with other land uses. Including them in this emerging new market for wood buildings can drive this value generation. We advocate for looking at the mechanisms that lead to positive or negative outcomes and create a system that promotes wholly positive outcomes for people and nature.

We propose a new and integrated industrial system in which cities, forests, and industry are directly linked. “The Wood Solution” enables an enormous shift in the tropical timber industry. Instead of degrading pristine forests through selective logging, degraded natural forests can be restored through active management that includes logging. The key to making this work is adapting timber processing systems and markets to utilize small- and medium-sized trees of diverse species. A variety of engineered wood products will be needed, and knowing these products in advance will enable efficient and high-value use of the wood.

Our analysis shows that restoring the 1.2 billion ha of non-primary forests could sequester over 34 PgC without any change in land use. More importantly, this system improves profitability at each step of the value chain, especially close to the forest resources. Forests could gain 10 times their value; and operating margins in the local sawmills can increase nearly 28 times with an optimal mix of products and markets. Mass timber building is completely possible in tropical environments. Tapping into the \$US10 trillion year^{-1} construction and engineering industry[87] could serve as a massive market driver for large-scale forest restoration and management and the creation of a new, regenerative industry.

Valorization of the nutritional and functional properties of Non Timber Forest Products (NTFP) in the district of Bignona , Senegal

T2.10 Forest-based Bio-economy Prospects in Africa

Antoine Sambou[1]
[1] Assane Seck University of Ziguinchor

Abstract: In the Ziguinchor Region, forests provide a range of valuable products for the population, especially in rural areas. Among these products, non-timber forest products (NTFPs) play an important role in improving livelihoods. Despite its importance, the nutritional and functional contribution of NTFPs is not well known by stakeholders. For this reason, this research aimed to study the nutritional and functional value of NTFPs for better valorization. To do this, surveys and quality analyses were conducted. The NTFPs most consumed by households in the study area were *Saba* senegalensis A. DC. Pichon (90.5%), *Landolphia heudelotii* P. Beauv (67.55%), Detarium senegalense J.F. Gmel (51.19%), Sesbania sesban L. Merrill (40.63%) and Adansonia digitata L. (32.98%). The three most traded NTFPs were Saba senegalensis, Detarium senegalense and Landolphia heudelotii. The results of quality analysis of the NTFPs showed that the nutritional elements of the processed forest fruits differed significantly ($p < 0.05$) among the products. For Saba senegalensis, jams were richer in protein (0.1%) and phosphorus (20 mg) than syrups. As for *Detarium senegalense*, the marmalade contained more protein (0.43%), phosphorus (20 mg) and iron (61 mg) than the syrup. However, syrup has higher carbohydrate content than jam and marmalade. There is a variation in nutritional properties between the raw and processed products. The raw products contained significantly higher protein, phosphorus, lipid and vitamin C content than processed products. While, processed products were richer in carbohydrates. NTFPs were rich in nutrients but processing reduced the nutritional value.

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Adaptation, mitigation or sequestration? An analysis of storylines reiterated in the public discourse in the sustainability transformation

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Annechien Dirkje Hoeben[1]
Tobias Stern[1]
[1] Institute of Environmental Systems Sciences at the University of Graz, Austria

Abstract: Context: The main aim of the European Commission's new EU Forest Strategy for 2030 is to ensure that European forests are resilient and multi-functional ecosystems. In the short-term they need to provide society with products to replace fossil-based materials and energy flows. In the long-term, they need to be climate-smart and adapted to increasing forest disturbances. Simultaneously, forests need to provide a merit of other forest functions, such as sequestering carbon, controlling temperature and safeguarding biodiversity. All these efforts need to be streamlined with different EU programs, such as the EU Bioeconomy strategy or the EU Biodiversity strategy.

Such interconnected but diverging goals present a complex challenge of adaptation, mitigation and sequestration, which could lead to trade-offs. For instance, simply storing carbon in forest ecosystems could increase risk in the event of natural disturbances, and disregards the need to decarbonise the global economy. In contrast, overusing forests might compromise carbon sequestration, water (in)filtration, temperature control and biodiversity goals.

Specific topic of the study: As many different players take interest in a forest, different opinions on which function to prioritise exist. It is necessary to increase knowledge on climate-smart, multifunctional forestry to foster synergies, minimise trade-offs and derive lessons for operational guidance towards enhancing climate resilience in European forests.

Methods: In this study, we combine a print media analysis with data on forest disturbances and forest-based sector market reports in Austria over the last 20 years to get a better picture of the different storylines reiterated in the public discourse. In this regard, print media is seen as a means to represent the public opinion and policy agenda, particularly on issues that might lead to conflicts.

Preliminary results: From our preliminary analysis, we can derive that reporting on forest disturbances and adaptation of forest management have increased over the last 20 years and align with major disturbance trends. Following discussions about biodiversity loss and climate change, sequestration storylines have become more prominent. Lastly, discussions on how to optimally use wood and mitigate climate change are intensifying. At the time of the IUFRO Stockholm 2024, we will present the final results.

Balancing of assembly lines in industrial house building

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Maria Anna Gartner[1]
Tobias Weberhofer[1], **Manfred Gronalt**[1]
[1] Universtity of Natural Resources and Life Sciences, Vienna; Department of Economics and Social Sciences; Institute of Production and Logistics

Abstract: The production of prefabricated houses enables the continuous use of wood and is an important part of the supply chain in this sector. It is characterised by a high degree of standardisation. Wall panels are manufactured in the factory, transported to the site and assembled. Our focus is on the factory process and the production of prefabricated elements, including external and internal walls and ceilings, on a mixed model assembly line.

Although many of these production processes still require large numbers of workers, companies are considering automating the production lines. The question is what these lines should look like and how the potential of digitalisation can be used in the best possible way.

We are developing a model for balancing a multiple, mixed-model assembly line that takes into account the requirements of variable work processes, workers and material consumption. Our goal is to maximise production output for a given number of workers. An optimisation model is built and solved exactly, as well as heuristic approaches are developed.

Our approach combines this optimisation model (based on average production values) with a simulation model for concrete situations (taking into account specific order situations and variable processing times). We use discrete event simulation, which allows us to look in detail at processes, sequences and production possibilities for wall elements (such as number of windows, doors and installations).

Our simulation model is validated using real-time data from our industry partner's enterprise resource planning system. It is planned to use the optimisation model continuously to evaluate different configurations until we reach a predefined output limit.

In our work, we compare the optimal configuration of production lines - for example, a single line, multiple lines, production cells, or even alternative or duplicate stations. The robustness of the determined optimal configuration is then evaluated using the simulation model.

Our results show that our approach is suitable for determining the optimal configuration of production cells and lines for wall elements in industrial prefabricated house building.

Can planted and natural forests be distinguished in forest area development assessing different drivers?

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Julia Tandetzki[1, 2]
Margret Köthke[1], Franziska Schier[1], Holger Weimar[1], Christian Morland[1]
[1] Johann Heinrich von Thünen-Institute of Forestry
[2] Georg-August-University Goettingen

Abstract: Global forest area dynamics can be represented as a function of drivers using the concepts of the Environmental Kuznets Curve for deforestation (EKCd) and the Forest Transition Hypothesis (FTH). Several studies have already analyzed the determinants of these concepts but a widely accepted consensus is still lacking. Based on a systematic literature review, we analyze the selection and significance level of socio-economic variables used in studies estimating EKCd and FTH. For this purpose, we extract independent variables used in 85 heterogenous estimation models. Across these studies, we identify 150 different drivers and assign them to 12 main categories according to their type (e.g., income factors or institutional factors). Our results reveal that the main drivers of forest area development are income, demographic, and trade factors. We also observe variations in the identified drivers when the choice of geographical scope and respective data selection, dependent variable, and the EKCd and FTH concepts are considered. We find that the latter influence the significance level of independent variables in relation to forest area development. We also find differences in the identified drivers across various continental studies, e.g., the forest area of Latin America is more strongly influenced by income variables when compared to forest areas in Asia or Africa. A closer analysis of the EKCd and FTH concepts, in our scrutinized studies, reveals unsolved challenges related to their application in developed countries. In particular, the afforestation component of the FTH has not yet been thoroughly explained. Thus, in a subsequent step, we develop the FTH concept further and split the curve shape of the FTH into two sigmoid functions. We then re-estimate the econometric model with significant economic drivers while differentiating the forest area types based on natural forests and planted forests and plantations. Our approach isolates individual drivers of forest area change and enhances the analysis and projection of forest area development thus contributing with a deeper understanding of global forest area dynamics.

Carbon pricing policies in the forestry sector: Possible leakage effects when accounting for intra- and inter-sectoral dynamics

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Tomke Honkomp[1]
Franziska Schier[1], Holger Weimar[1], Tobias Heimann[2]
[1] Thünen Institute of Forestry, Leuschnerstraße 91, 21031 Hamburg, Germany
[2] Kiel Institute for the World Economy, Kiellinie 66, 24105 Kiel, Germany

Abstract: Forest-based measures for climate change mitigation are acknowledged to hold the global temperature target of the Paris Agreement in reach. To foster carbon sequestration in forests and in forest products, carbon pricing policies appear to be promising approaches. Forest sector models are established instruments to assess the impacts of carbon pricing policies on forestry and wood product markets as well as on forest-based mitigation potentials.
Modelling researches reveal that leakage effects might undermine the climate change mitigation potential of carbon pricing policies in the forest sector. Limited by the system boundaries of forest sector models, past assessments are mainly focused on intra-sectoral dynamics. Especially the spatial displacement of economic activities between regions pursuing a carbon pricing policy and foreign regions is analysed. However, the forest sector is embedded in the overall economy and increases in forest-based carbon sequestration might be offset by economic dynamics in other sectors. Therefore, the consideration of inter-sectoral implications seems important for quantifying leakage effects.

In this study, the Global Forest Products Model (GFPM) is linked to DART-BIO, a computable general equilibrium (CGE) model, to complement modelling approaches of leakage effects related to carbon pricing policies in the forest sector. Through the linkage, inter- and intra-sectoral dynamics are analysed simultaneously when carbon sequestration in the forest sector is valued. For this analysis, varying carbon tax and subsidy policies are integrated into the GFPM to value carbon fluxes. The sensitivity of inter- and intra-sectoral leakage effects is analysed over a range of carbon prices and through changes in valued carbon pools.

The results show a need to evaluate climate change mitigation policies involving forest-based measures from an overall perspective to achieve effective GHG reductions at the global level.

Could forest biodiversity and carbon sequestration be enhanced without harming forest industry and rural development?

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Lucas N. Lopez[1]
Francisco X. Aguilar[1, 2], Hanne K. Sjølie[1]
[1] Inland Norway University of Applied Sciences, Faculty of Applied Ecology, Agricultural Sciences and Biotechnology, P.O. Box, 2400, Koppang, Norway
[2] Swedish University of Agricultural Sciences, Department of Forest Economics. SLU skogsekonomi, Umeå, 90183, Sweden

Abstract: It is of global importance to manage boreal forests sustainably as it is one of the most extensive biomes and the largest area of coniferous forest in the planet. The forest sector contributes significantly to the rural economy of Nordic countries where even-aged management with clearcutting is the dominant silvicultural regime. In this context, policies seeking to increase carbon sequestration and preserve biodiversity need to recognize its potential impacts on the forest industry. In this study, we assessed the impacts of biodiversity and carbon policies on the Norwegian forest industry competitiveness and employment, applying a simulation-optimization framework. First, we simulated stand growth dynamics and yields for common management practices in Norwegian forests using the tree-level simulator *TreeSim*. Second, we applied the partial equilibrium model *NorFor* to project national and regional levels of harvest, industrial production, trade and labor. We compared three scenarios of high policy relevance that combine carbon and biodiversity against a baseline BAU: (a) BioDiv scenario restricts harvests of old forests and deciduous forests important for habitats; (b) Carbon scenario aims to enhance net carbon sequestration through a tax and subsidy scheme and (c) BioDivCarbon scenario combines the BioDiv and Carbon policies. Impacts on the rural economy employment were assessed through combining data of industry localization, degree of rurality and employer multipliers with industrial output. Contrasted to the baseline scenario, all policy scenarios led to reduced timber harvest with the impacts being most marked in the BioDivCarbon scenario, which led to long-term reduction of 20% compared to the BAU level of 15 million m^3. In the Carbon scenario, long-term timber harvests declined by up to 15%, contrasted to 5% in the BioDiv. Pulp and paper and sawn wood industries were considerably harder impacted by the policies than boards and bioenergy industries, with the carbon policy having larger effects than the biodiversity policy. Long-term reductions amount to 12% for the pulp and paper industry and 20% for the sawn wood industry. In overall, we see that forest industry outputs have larger trade-offs with forest carbon sequestration than with forest biodiversity preservation.

Effects of the reform of state-owned forest areas on the common prosperity of state-owned forest industry enterprises: A quasi-natural experiment

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts
Shaopeng Zhang[1]
Hongge zhu[1], Linji Cheng[1], Yue Ren
[1] Northeast Forestry University

Abstract: Common prosperity is an essential requirement of socialism with Chinese characteristics and an important feature of China's modernization. As a characteristic economic and social organization located in the key state-owned forest areas in China, state-owned forest industry enterprises are of great significance to the realization of the goal of common prosperity in China, but few studies focus on this issue. Especially in the policy background of the reform of state-owned forest areas, the policy impact on the common prosperity of state-owned forest industry enterprises is more worth exploring. Based on the panel data of 87 state-owned forest industry enterprises in key state-owned forest areas in 2012-2020, this study measures the common prosperity of state-owned forest industry enterprises from the dual perspective of internal and external income gap between enterprises, and further analyzes the policy effect of the reform of state-owned forest areas on the common prosperity of state-owned forest industry enterprises. Our results indicate that: a) the internal income gap of state-owned forest industry enterprises shows an overall decline, while the external income gap of enterprises rises; b) the reform of state-owned forest areas can significantly reduce the internal income gap of enterprises, and the impact on the income gap between labor and capital income is significantly higher than that on the income gap between managers' and ordinary workers' income; c) the reform of state-owned forest areas has a negative influence on the external income gap of enterprises, which is mainly reflected in the income gap between 87 state-owned forest enterprises.

Forest management strategies to address climate roadmap 2045 strategy in Swedish context

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Bishnu Chandra Poudel[1]
Ljusk Ola Eriksson[1], Andreas Stephan[1]
[1] Department of Forestry and Wood technology, Linnaeus University, Sweden

Abstract: Sweden's climate policy aims at to have zero net GHG emissions by 2045 and continue as negative emission nation thereafter. There is a growing concern that urgent action is needed to reduce atmospheric carbon. Land forest cover is seen as one of the best solutions to mitigate climate change because of its pivotal role in binding and storing carbon. For this reason, forest policies are expected have a major impact on society in the near future. However, the effects of instruments such as conserving forests for increasing carbon stocks or of managing forests for climate mitigation are still not fully understood. Using a forest sector model (SWEFOR), we investigate the implementation of a carbon mitigation payment system. Alternative policies such as lengthening rotation age, increasing conservation area and promoting biodiversity will affect forest owners and thereby payment is a mechanism to compensate forest owners for positive externalities and forest management opportunity costs.

This study aims at evaluating the consequences of forest management decisions for carbon mitigation payments. By implementation and simulating using the forest sector model SWEFOR, we describe the effects of innovative forest policies for optimal payment levels, potential mitigation measures, payment mechanisms, and transactions in the system. Further, we analyze the implementation of strategies such as variable set aside areas, and the costs to implement such strategy, gains in terms of nature conservation and carbon storage. Our study will provide new insights regarding pathways to carbon neutrality through the instrument of payments to forest owners.

SWEFOR model is equipped with national forest inventory data, process-based model, forest planning model, product flow and carbon balance models and economic models integrated for the analysis. Our preliminary results show that the various projected prices for carbon for the payment services would help to increase carbon sink in the forest, but it will also affect forest industry and product markets and consumer's demand in the economy. Evaluation of model results show that payment contracts could support achieving negative emission goals also after having achieved carbon neutrality.

Key words: Forest sector model, SWEFOR, national policy, carbon credits, LULUCF, transaction costs, ecosystem services.

Geospatial Decision Support Systems for Sustainable Management of Dry Forest Land and Ecosystem Services: A review of approaches and methods

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Meley Mekonen Rannestad[1]
Bianca Wulansari Kassun[1], Abrha Megos Meressa[1]
[1] Faculty of Environmental Sciences and Natural Resource Management (MINA), Norwegian University of Life Sciences (NMBU)

Abstract: Dry forests, on which millions of the world's poorest and most marginalized people depend, are among the most threatened and neglected ecosystems globally. Nevertheless, the demands for their land and ecosystem services are increasing with increasing conflict with each other. While addressing some demands such as reducing CO_2 emissions require conservation, other demands such as meeting domestic energy needs require utilization of different forest products and services. Making decisions to meet these conflicting demands while addressing the problems of deforestation/forest degradation and subsequent loss of important ecosystem services is very complex. The implementation of forest policies at multiple levels (global, national, and local) extends the complexity of the problem. Consequently, there is a growing demand for tools that enable decisions related to sustainable management of forest land and resources given the complexity of the above-mentioned problems. There has been a significant increase in the development and implementation of Geospatial Decision Support Systems (S-DDS) over the last decade. However, efforts to use such tools for forest planning and management in dryland countries have been limited due to, among other things, the lack of S-DDS development guidelines that are accustomed to the given country's forest types and socio-economic context. The objective of this study is therefore to review approaches and methods in S-DSS and select a combination of approaches and methods for developing S-DSS that enable ex-ante assessments of policies, management measures, resource use plans, and technologies that minimize trade-offs and maximize synergies between different forest ecosystem services and between global, national, and local objectives. We reviewed the approaches and methods of 25 widely used S-DSS in forest planning and management. Accordingly, we proposed a framework for developing a S-DSS for sustainable management of dry forest land and ecosystem services in East African countries, where dry forests are the dominant vegetation types. The framework and thus S-DSS will also enable to assess the forest sector's potential in contributing to sustainability.

Greener homes: Factors underpinning Europeans' intention to live in multi-storey wooden buildings

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Dohun Kim[1]
Florencia Franzini[2, 3], Bo Jellesmark-Thorsen[4], Sami Berghäll[3], Francisco X. Aguilar[1]
[1] Swedish University of Agricultural Sciences
[2] European Forest Institute
[3] University of Helsinki
[4] University of Copenhagen

Abstract: Climate policies aimed at curbing greenhouse gas emissions embodied in the built environment support the wider implementation of multi-storey wooden buildings. A body of research on public perceptions toward wood as a structural building material is emerging, but close examination of behavioral factors underpinning prospective dwelling is scarce. We used contextualized constructs from the theory of planned behavior to quantify and compare the roles of attitudes, subjective norms, and perceived behavioral control on intentions to dwell in multi-storey wooden buildings. Structural equation models were fitted to survey data from seven European countries (Austria, Denmark, Germany, Finland, Norway, Sweden, United Kingdom; *n*=7,056). We found that attitudes consistently explain intention to dwell in multi-storey wooden buildings. We also found a varied pattern of relationships between factors underpinning intention across countries. An implication of our results is that national-level policies aimed at promoting social acceptability of dwelling in multi-storey wooden buildings should universally address attitudes towards such novel buildings. But in some countries policies might in addition be tailored to emphasize citizens' subjective norms or perceived behavioral controls.

Keywords: Multi-storey wooden buildings, wooden construction, theory of planned behavior, structural equation model, Europe.

Harvest and Its Impacts on Climate Mitigation Policies in the Forestry Sector

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Yusuf Serengil[1]
[1] Istanbul University Cerrahpasa, Faculty of Forestry

Abstract: Parties to the Paris Agreement seek ways and alternatives to reach their carbon neutrality targets. For carbon neutrality, the GHG emissions must be balanced with the removals. Harvest and the use of wood products have a substantial influence on the forestry sector carbon removals. On the other hand, the wood products industry has increasing raw material demands in developing economies, and every increased harvest may harm the biogenic removals. An opposite scenario is also possible. Low harvest rates may reduce the increment if the forests are not appropriately managed and stands start to age. Therefore, the balance between the increment rate and harvest has to be established for a significant and sustainable removal rate. The wood production in Türkiye increased from 18.7 to 31.9 Mm3/yr during the 2011-2021 period, reaching 69.8 percent of the increment. The standing stock stabilized at 121-123 m3/ha for the period indicating a slowdown in growth. To project the 2053 net zero target, we used harvest rate scenarios and their effects on biogenic removals. Based on the increment and harvest relationship on the national scale, the 15 Mm3/yr has been determined as a threshold for supporting increment. Harvests over this value will reduce the removals from forests. We presented the projection results and discussed the consequences and possible policy alternatives to increase forest carbon stocks sustainably.

How do increased reuse of wood affect the forest sector and the overall economy?

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Tom Erik Thorkildsen[1]
Erik Trømborg[1], Eirik Ogner Jåstad[1]
[1] Norwegian University of Life Sciences (NMBU)

Abstract: Climate change mitigation is urgent, and the forest sector plays an important role when aiming for net zero emissions. The EU Waste Framework Directive requires all member countries, including Norway, to gradually increase the reuse rate of materials to 65 percent by 2035. The European Waste Hierarchy provides guiding principles suggesting that the reuse of wood takes precedence over energy recovery. In practice it also involves implementing a cascading strategy where wood products are systematically retained in the loop on the highest possible level of quality.

Shortages of timber in the world market are already restricting sustainable development. At the same time, the forest sector is facing a need for major transition with focus on increased resource efficiency and a value chain for reuse. Relevant analysis must rest on capable understanding of forest product markets and the end-user markets will evolve over time.

To analyze sectoral impacts of increased reuse of wood, we apply a partial forest sector model covering the Nordic countries and Baltic countries on a regional level. Various scenario analyses are conducted to assess uncertain political and technological implications towards 2040.

The results show how increased reuse rates of wood affect the consumption of harvested wood products, regional production, harvest decisions, and trade patterns. The trade-offs between persecuting a cascading strategy and utilizing discarded wood for energy recovery is also analyzed. Wood cascading and reuse follow the logic of basic sustainability principles and provide important environmental benefits. Policymakers should nevertheless carefully consider trade-offs and consequences, before executing policy measures.

Impact of raising protection targets on the future EU forest-based bioeconomy

Abstract: The EU Biodiversity Strategy (EUBDS) for 2030 aims to protect 30% of EU land. That includes to strictly protect at least 10% of it (including all primary and old-growth forests) and to manage the remaining area (at least 20%) with Closer-to-Nature management. Currently, 23% of EU forests are protected and 5% are strictly protected. The ambitious target is expected to further strengthen the conservation of Europe's biodiversity. In this study, we investigate how different approaches to distribute the protection targets among member states and habitats may affect the future EU forest-based bioeconomy, with a focus on woody biomass harvest volumes, forest products trade and spatial allocation of harvested areas. The analysis is based on the global spatially explicit forest sector model GLOBIOM-forest. We show that the impact of the EUBDS depends on how the protection is allocated among member states and habitats. If the "Closer-to-Nature" management – interpreted in our modelling as harvesting maximum 50% of merchantable woody biomass potential – is to be applied on 20% of the forest area, the EUBDS would lead to a 7-12% long term (by year 2100) reduction in EU forest biomass harvest volume compared to a baseline. This 7% reduction represents the implementation of the target at EU scale, while the higher reductions represent implementation at country (9%), or finer spatial scale as a green infrastructure (12%). All scenarios lead to lower harvest levels and thus lower net exports of EU forest products, affecting the EU forest bioeconomy, which may lead to leakage effects to other regions (mainly boreal) and sectors. If considering set aside to be applied in the whole protected area (30%), the EU harvest level decreases by 22%, and the EU could become forest products net importer after 2050. The general conclusion of the analysis is that EU forests can preserve forest-based bioeconomy if the spatial allocation of new protected areas is shared across the EU regions and protection

managements also allow for wood procurement. However, even if spreading the protection target across EU, biodiversity cannot be claimed to be preserved as it will not represent the diversity of EU habitats.

Investigating Forest Growth-to-Drain Ratio and Its Affecting Factors at County-Level in Arkansas, USA

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Sagar Godar Chhetri[1]
Pradip Saud[2], Matthew Pelkki[1]
[1] Arkansas Center for Forest Business, University of Arkansas at Monticello, Arkansas, USA
[2] College of Forestry, Agriculture, and Natural Resources, University of Arkansas at Monticello, Arkansas, USA

Abstract: The forest growth-to-drain ratio (FGDR) is an indicator of forest sustainability. Forest managers tend to keep FGDR close to one to balance the forest growth and removals. A few past research shows FGDR has changed in the southern United States. However, the recent state-level ratio is not available for Arkansas. The study attempted to fill the gap by collecting the data for ten years from various sources and employing the mix-effects models. Results found that Arkansas has 1.6 FGDR suggesting that the forest growth rate was higher than the removal rate. Also, the ratio was higher in hardwood as compared to softwood because the demand for softwood was higher and most of the mills were utilizing the softwood in the state. The study further found that South Central Plains (SCP) has the lowest FGDR among the four ecoregions. The reasons were that the SCP region has dominated by pine forests and most of the forest products industries were located in the region. The study founds that the number of consulting foresters and the area of forestland showed negative statistical significance to the FGDR whereas income from forestry showed positive statistical significance. The study concluded by suggesting that surplus forest products should be utilized by establishing the forest product industries and expanding the existing industry in order to reduce the possibility of wildfires, diseases, pests, and insects. Also, outreach programs should be developed and conducted to increase public acceptance of wood utilization.

Structure and dynamics of the roundwood trade from a network analysis perspective: Increasing tensions over wood resources.

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Valentin Mathieu[1]
David W. Shanafelt[1]
[1] Université de Lorraine, Université de Strasbourg, AgroParisTech, CNRS, INRAE, BETA, 54000 Nancy, France

Abstract: Sustainability and climate change concerns have led to a greater integration of wood products in construction and energy transition policies, which is reflected in an increase in international timber trade. However, this poses a potential problem as international demand for wood products significantly contributes to global deforestation.

While the literature provides comprehensive studies on international timber trade, few consider the physical structure of the trade network in their analyses. This study adopts a network-theoretic approach to deepen our understanding of the wood product trade. We analyze the structure and dynamics of the international roundwood trade network between 1983 to 2022, and use machine learning techniques to forecast future network structures. Over the historical study period, the trade network experienced an increase in value while maintaining a relative stable size. Moreover, it became more interconnected, indicating growing interdependencies among participating countries. Furthermore, we observed an increasing concentration in the global network, particularly highlighting the growing market power of China and its dominance over roundwood trade in the first half of the 21st century. We attribute temporal changes in network structure to three main categories of events: economic disruptions, political events, and natural disasters. By 2050, we expect the trade network to tend toward a monopsony of China.

The implications of our findings extend to forest policy, as local or regional shocks can cascade throughout the global trade market. Moreover, growing polarization centered around key trading partners can exacerbate trade tensions in the forest-based sector. Understanding the dynamics of the roundwood trade network are necessary for policymakers and stakeholders in the forest-based sector to develop efficient strategies that promote sustainability and mitigate risks associated with global trade.

The potential of forest resource as a chemical source: in the contexts of Japan and World

T2.11 Forest-based sector in sustainability transformation: opportunities and sectoral impacts

Keito Mineo[1]
Masaharu Nakamura[1], Hisashi Hasegawa[2], Naoko Tokuchi[2]
[1] Institute for Chemical Research, Kyoto University, Japan
[2] Field Science Education and Research Center, Kyoto University, Japan

Abstract: Woody biomass can be used not only as an energy source but also as a source of chemicals. Material for chemicals such as plastics accounts for 12% of the world's petroleum demand and is expected to increase in the future. Their reduction is important for the sustainability transition. Although the modern energy use of wood biomass is expanding, chemical applications that can store hydrocarbons in society may be advantageous in terms of carbon balance. The conversion technology of woody biomass has been studied abundantly, but there are few studies from the viewpoint of forest science. We examine the potential use of wood biomass for chemicals in two contexts: in the world with a growing population, and in Japan, where forests are underutilized.

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Agricultural residues from Western Africa to produce biocomposite panels for building applications.

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Souha MANSOUR[1]
Amandine VIRETTO[1], Marie-France THEVENON[1], Loïc BRANCHERIAU[1]
[1] BioWooEB, Université de Montpellier, CIRAD, Montpellier, France

Abstract: This work is part of the BIO4AFRICA project (H2020-Nº 101000762) which aims to diversify incomes in rural areas of Africa through sustainable and locally replicable solutions. The project focuses on developing technologies adapted to the environment and improving traditional techniques in African rural contexts with the local biomass available to develop bio-sourced materials for habitat. In this context, three agricultural residues issued from Côte d'Ivoire and Senegal were selected to produce composite panels for building applications as non-load-bearing materials. The selected biomasses are oil palm empty fruit bunch, rice husk, and cocoa pods. All the listed biomasses have no nutritional value and their use in such applications is beneficial, first economically and second to reduce waste and solve the induced health and environmental problems; they are left on plantation sites, which is the main cause of many diseases in the Western Africa area. They are available in large quantities, seasonal, and present different inherent properties.

Firstly, the biomasses are pre-treated using dry fractionation process. The resulting lignocellulosic fillers are chemically, biologically, physically, and thermally characterized in order to study their effect on the panel production and properties. For this, biocomposite formulations are prepared using a conventional binder (melamine urea-formaldehyde). Many parameters can affect the final properties of the panels such as the inherent properties of the biomass (chemical composition, size, density, porosity…), the type of the binder, and the ratio between biomass and binder. Our aim is to obtain particle panels with interesting mechanical, insulating acoustic, and thermal properties, fire resistance, and durability regarding the international standards; while taking into consideration the climate of Western Africa where the panels are destined to be applied. The tropical climate is known for its high temperature and humidity levels which are two major factors that can affect the service life of biocomposites. Therefore, it is necessary to develop durable and resistant panels in these conditions.

Characterization of the properties of pulpwood chips based on near-infrared spectroscopy

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Ting Wu[1]
Long Liang[1], Guigan Fang[1], Kuizhong Shen[1]
[1] Institute of Chemical Industry of Forest Products, Chinese Academy of Forestry

Abstract: In China, the supply of high-quality wood is insufficient, and the raw material for chemi-mechanical pulping is mainly woodchips from fast-growing trees, the quality of which fluctuates greatly. To ensure stable pulp quality, the mills generally suffer from high drug consumption and high electricity consumption. The research on the characterization of pulpwood chips based on near-infrared(NIR) spectroscopy is expected to enable timely adjustment of pulping and papermaking process parameters through real-time monitoring of pulpwood chips properties and to achieve energy saving and consumption reduction.

Through the NIR dynamic monitoring of moisture desorption of water-saturated woodchips, the variation of the NIR spectrum with the moisture content of woodchips was revealed. The second-order derivative spectrum of water-saturated woodchips were used to build the basic density prediction model of woodchips, and the external parameter orthogonalization(EPO) algorithm was used for spectral moisture correction, which effectively eliminated the spectral variability caused by moisture variation and improved the anti-interference ability of the model. The model was used to predict the basic density of woodchips with different moisture contents with the root mean square error of prediction(RMSEP) as low as 22.66 kg/m³ and the residual prediction deviation(RPD) value of 2.10.

For the problem of overlapping and redundant wavelengths of NIR spectral signals, which affects the prediction of chemical components of woodchips, the competitive adaptive reweighted sampling(CARS) algorithm was used to screen the lignin-related wavelengths, and the RMSEP of the lignin content model was 0.76% and the RPD reached 3.49. The successive projections algorithm(SPA) was applied to optimize the relevant wavelengths of the holocellulose prediction model, the RMSEP of the model was 0.91% and the RPD reached 3.43.

The experimental spectrometer and industrial spectrometer were used to establish models for the analysis of woodchips properties. The modeling results were compared, and suitable model transfer techniques were selected to enhance the industrial application of the models according to the characteristics of the woodchips properties. Based on the results of this study, an intelligent analysis system for woodchips properties was developed, which can be initially applied to the control of raw material quality and the production process of chemi-mechanical pulp.

Concentration of Ash-Forming Elements in Poplar Biomass from Second Rotation Plantation

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Seyed Mohammad Razavi[1]

[1] Energy Engineering, Division of Energy Science, Luleå University of Technology, Luleå, Sweden
[2] Southern Swedish Forest Research Center, Swedish University of Agricultural Science, Alnarp, Sweden

Abstract: The utilization of forest biomass in thermochemical conversion processes as an alternative to fossil fuels can alleviate the climate change crisis. Sustainable use of those biomass feedstocks can be assured just if efficient biorefining and bioenergy production methods are developed. Determination of the chemical composition of biomass is a step towards the development of efficient biorefinery processes. Among other factors, the concentration of ash-forming elements can affect combustion, gasification, and pyrolysis processes by producing ash-related operational problems such as slagging and fouling. In the present work, concentrations of ash-forming elements in different tissues of hybrid poplar, a fast-growing tree and a promising feedstock for biofuel production, were determined. Biomass samples were collected from a second rotation poplar plantation located in southern Sweden (age 18 years – 10 years after thinning treatment). Samples were classified based on the thinning treatment as untreated (6000 stems per ha), light thinning (3000 stems per ha), medium thinning (1100 stems per ha), and heavy thinning (550 stems per ha). In each treatment samples of stem wood, bark and branches of trees with different diameters (7, 15, and 25 cm) were collected and analyzed for different ash-forming elements including Ca, Mg, Na, K, Al, Fe, Si, S, P and Cl. Almost in all tissues, the highest concentrations were detected for Ca and K, followed by Mg and P. The results showed significant differences in elemental concentrations between different tissue types. When compared to wood tissue, bark and branches had higher amounts of different ash-forming elements. The results of this work can be used for the evaluation of the potential ash-related problems in different thermochemical processes for the production of bioenergy from poplar biomass.

Decision support system for optimized value chains in bioeconomy

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Erik Rönnqvist[1]
Mikael Rönnqvist[1], Mikael Frisk[1]
[1] Creative optimization

Abstract: In the large ongoing transition towards a low-carbon society, bioenergy is an essential part of the new emerging bioeconomy needed to meet several of the sustainable development goals. In this transition, the bioenergy sector has the potential to produces, among other things, heat, electricity, biochar, and other biomass products using sustainable and renewable resources or feedstocks from biomass, such as wood residues, agricultural crops, forest residues, and organic waste. Managing the supply chain for these feedstocks involves multiple activities including biomass sourcing, transportation, processing, production, and distribution. This give rise to complex challenges in evaluating profitability, increasing performance, and managing integrated planning. The challenges include handling processes, coordination of multiple assortments and different value chains, for example, forest and agriculture. The supply chains are also difficult to integrate due to the difference in assortment attributes, conversions, and processes.

Woodflow is a decision support system that considers factors such as distance, mode of transport, storage, processes, and handling requirements to determine the most efficient and cost-effective transport and logistics solutions. One key element of Woodflow is an integrated distance calculator which based on local road network information calculates accurate distances with very high resolution and efficiency. The system is flexible and efficient in using optimization for modeling the supply chain. It enables Woodflow to meet the needs and challenges of the bioenergy supply chain, including the essential steps for bioenergy utilization.

Woodflow ensures the efficiency of the supply chain by integrating all stages, feedstocks with business decisions, and thus, reducing costs, increasing profitability, and ensuring due diligence. The results also offer a reduction in waste, better supply balancing and improvement of the sustainability using multiple different biomass feedstocks at a lower cost. Combining forest, agro and waste streams in a more integrated approach to help deliver the right biomass, in the right form, to the right customer at the right time is important when assessing future smart and efficient biomass mobilization and logistics. Woodflow is therefore utilized for developing the future bioeconomy, bioenergy production, creating input data for policy decisions and supporting the development of biomass-based industries.

Effect of pre-hydrolysis on the hardwood pulp dissolution in ionic liquid

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

M Sarwar Jahan[1]
M. Mahbubur Rahman[1]
[1] Pulp and Paper Research Division, Bangladesh Council of Scientific and Industrial Research

Abstract: Cellulose is the most abundant and sustainable bio-resource generated on earth. Cellulose and its derivatives have been utilized for various purposes in our daily life. Due to the crystalline structure of cellulose, it is extremely difficult to dissolve in common solvents. The cellulose is derivatized to dissolve it, such process is called the viscose process. Viscose is produced from dissolving pulp, which is produced by the pre-hydrolysis kraft process. Pre-hydrolysis is carried out prior to pulping to remove hemicellulose from the lignocellulosic, which creates problems in viscose processing. Ionic liquids (ILs) are potentially alternative solvents for cellulose dissolution. It is interesting to gather knowledge on, how hemicellulose affects pulp dissolution in ionic liquid and the regeneration process.

In this investigation, hardwood pulps were produced by kraft (KP) and pre-hydrolysis kraft (PHKP) processes. The α-cellulose and residual pentosan contents were 95.6% and 4.2% in PHKP and 84.3% and 9.9% in KP, respectively. Both pulps were dissolved in 1-Butyl-3-methylimidazolium chloride $[C_4mim]Cl$, 1-Butyl-3-methylimidazolium acetate $[C_4mim]CH_3CO_2$ and their double salt at the ratio of 6:4 ($[C_4mim](CH_3CO_2)_{0.6}Cl_{0.4}$) at 90°C. It was observed that PHKP had slightly higher solubility in both ILs and double salt. The dissolved pulps were regenerated by water and characterized by FTIR, TGA, X-ray diffraction, and viscosity. All pulps and regenerated pulps showed cellulose I structure, and the crystallinity index of regenerated cellulose decreased. As observed in FTIR, the regenerated cellulose showed a stronger absorption band at 1647 cm^{-1} corresponding to the C–O stretching vibration of C–O–H. The viscosity of regenerated KP was higher than PHKP, which affected the strength of produced cellulose film.

Forests barking: How to obtain value-added compounds from forestry side-streams – case studies across the supply-chain

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Tuula Jyske[1]
Hanna Brännström[1], Petri Kilpeläinen[1], Jaana Liimatainen[1], Jenni Tienaho[1], Susan Kunnas[1], Saija Rasi[1], Kimmo Rasa[1], Krista Peltoniemi[1]
[1] Natural Resources Institute Finland (Luke), Viikinkaari 9, 00790 Helsinki

Abstract: Polyphenolic stilbenes and tannins are abundant in the fresh bark of Norway spruce (*Picea abies* [L.] Karst.) trees. Bark extracts could be industrially utilized due to their antioxidative, and antimicrobial properties [1]. The postharvesting conditions, especially industrial debarking, influence the chemical properties of bark. Inherent variation in high-value compounds of bark is assumed to be offset by modifications within bark supply chain; essential quantitative information is still rare but needed for optimizing the bark supply chains for biorefinery purposes. We have elucidated the magnitude of variation in the stilbenoid and tannin content and composition of Norway spruce bark due to (1) geographical origin of Norway spruce seeds, (2) geographical location of the growing site, (3) within-tree variability, (4) storage time and type; and (5) industrial handling and pilot-scale extraction and fractioning processes. The inherent variation in stilbenoid content was large: the total average stilbenoid content of inner bark varied from 70 to 110 mg/g of dry weight [2]. Sampling position in the stem and growing site explained over 50% of the total variance in stilbenoid content. Trees with a northern origin of seeds had a different compositional ratio of stilbene glucosides than the trees with a southern origin of seeds, regardless of their growing site. Industrial bark from sawmills showed a significantly higher total stilbenoid content in winter than in summer. Stilbenes rapidly degraded during storage, but tannins were more stable: 5–7% of the original stilbene amount and 30–50% of the original amount of condensed tannins were found after 24-week-storage [3]. Summer conditions led to the faster modification of bark chemistry than winter conditions. Changes in antioxidative activity were less pronounced than those of analyzed chemical compounds. Inner bark preserved its activities longer than outer bark - intact bark attached to timber is expected to maintain its activities longer than debarked one. To ensure prolonged quality, no debarking before storage is suggested, sampling of northern forests and short handling times in supply chain are recommended. To increase economic feasibility, cascade processing of bark is discussed [4,5].

Fuel composition and thermophysical properties of poplar from second rotation plantation

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Sruthy Vattaparambil Sudharsan[1]
Seyed Mohammad Razavi[1], Henrik Böhlenius[2], Marcus Öhman[1], Kentaro Umeki[1]
[1] Luleå University of Technology
[2] Swedish University of Agricultural Science

Abstract: Biomass is one of the few resources that has the potential to meet the challenges of sustainable and green energy systems. Fast-growing broadleaved (FGB) trees are very suitable for energy production as these tree species are economically viable, has higher growth rate, and can be harvested at much shorter intervals. The production of chemicals and energy from FGB trees can be achieved by coupling efficient conversion processes and technologies. Tree species, forest management, and consequent growth rates have a significant effect on the feedstock properties and fuel conversion characteristics. Efficient thermal conversion processes for FGB trees can be developed by understanding these effects.

This study presents how the forest management methods affect fuel and material characteristics of various assortments of feedstock. Physical, structural, and chemical compositions of biomass feedstock will be analyzed in detail, for example, macromolecular composition, particle density, and thermophysical parameters.

Second rotation poplar trees of 18-10 years of age after thinning treatments (untreated (6000 stems per ha), retention of biggest sprouts (1100 stems per ha), retention of biggest sprouts and removal of every second tree row (550 stems per ha), removal of every second tree row (3000 stems per ha)) were collected from Sturup, Southern Sweden. Stem wood, bark, and branches of trees with different diameters (9, 16, 26, and 35 cm) were selected from each thinning treatment.

As a result of these studies, we are going to present how the above-mentioned thinning treatments and stem diameters of second rotation poplar trees affect the feedstock composition which include elemental composition (organic elements), macromolecular composition (cellulose, hemicellulose, lignin types, extractives), fuel composition (volatile matter, fixed carbon, ash content), structural parameters (density, cell wall thickness, and pore size distributions), and thermophysical parameter (specific heat, conductivity, etc.). In addition, we will present how such properties will affect the pyrolysis behaviour, for biochar and bio-oil production. We will also discuss the suitability of biomass properties for various future biorefinery value chain.

Further development of the measurement and quality determination of raw wood to include future needs and requirements of the wood industry

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Tobias Cremer[1]
Järmo Stablo[2]
[1] Eberswalde University for Sustainable Development, Chair for Forest Utilization and Timber Markets, Eberswalde, Germany
[2] Standing Committee on the Framework Agreement for the Trade in Raw Wood, Germany

Abstract: Central elements of the raw wood supply are the measurement and the quality determination of the raw wood. The framework agreement for the raw wood trade has provided the basis for this in Germany since 2014. Based on intensive discussions and negotiations, the framework has undergone numerous changes since its creation in order to adapt it to the needs and requirements of the market partners.

Various industry trends and influencing factors have been significant for these adjustment processes: These include, among others, the changing wood quality requirements of the different industries due to new developments in the processing of the wood, the pressure for rationalization on both the supplier and the customer side, as well as the situation of the raw wood markets influencing the availiability of raw wood. In addition, the (expected) distribution of revenues in the value chain, silvicultural trends towards a higher portion of hardwood instead of conifers, technological and legal developments - such as the approval of devices for photo-optical stack measurement -, as well as the possibilities of the market partners to include these new technologies in the wood logistics chain play a decisive role. These influencing factors and industry trends will be discussed and analyzed with regard to their significance for the future development of the measurement and quality determination of raw wood in Germany and Europe and the related consequences for an economic supply of raw wood for traditional wood industries as well as future biorefineries.

Potential of Calophyllum inophyllum for bioenergy and landscape restoration

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Abstract: Land degradation is acute in tropical countries, such as Indonesia which has ~14 million ha of degraded land. In 2018, the Government of Indonesia launched an initiative to restore degraded land by 2030 to achieve national goals in climate and landscape resilience, including bioenergy production. The restoration target includes 12 million and 2 million hectares of degraded mineral soil and peatlands, respectively. The Government also committed to provide energy to all its population through the National Energy Policy, which highlights the importance of diversification, environmental sustainability and enhanced deployment of domestic energy resources. The contribution of new and renewable energy (NRE) to the nation's energy supply is mandated to reach 23% by 2025, of which biofuel is an important NRE alternative. If developed appropriately at landscape scale, bioenergy plantings have the potential to restore degraded land and support biodiversity and multiple ecosystem services. Our study assessed the potential of *Calophyllum inophyllum*, a biofuel species known by various local names in Indonesia and herein called 'Tamanu', for land restoration and production of biofuel, using climate-smart agroforestry approaches. We demonstrated that seed can be harvested for up to 50 years, maintaining high levels of kernel oil and providing high volumes of non-edible oil. In natural forests, *C. inophyllum* seeds produce Tamanu Crude Oil (TCO), refined TCO and Tamanu Biodiesel, ranging 37–58%, 36–53.8% and 17–33%, respectively. Through breeding programs and improved oil pressing methods, the TCO can reach 64–67% (mechanical method) and 72–85% (solvent method), making it ideal for biofuel production. Apart from biodiesel, tamanu oil also has the potential to produce bio-aviation fuel and the waste from biodiesel production process as by-products can be used as raw material in pharmaceuticals and cosmetic industries and as compost for soil enrichment. Our study also demonstrated that various cash crops (rice, maize, cassava, peanuts, soybeans, fodder grass) can grow with *C. inophyllum* in climate-smart agroforestry systems to spread risk and provide income to farmers, thus creating added value. The species can grow in a wide range of environmental conditions and has proven to be a good candidate for landscape restoration.

Supply chain determines the quality of forest biomass for biorefining

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Pekka Saranpää[1]
Hanna Brännström[1], Eelis Halmemies[1], Johanna Routa[1]
[1] Natural Resources Institute Finland (Luke)

Abstract: Forestry value chains produce lignocellulosic biomass from both harvesting and processing residues, which have the potential to be used in a cascade manner in biorefineries. Currently, the side streams like tree bark are almost solely utilised for combustion and energy production. New technologies for fractionation of the recalcitrant biomass enable the production of high value-added products derived from carbohydrates, lignin and especially extractives like resins and phenolics. In order to control the raw material quality for biorefineries, it is crucial to know how various processes affect the biomass properties along the harvesting, transport and storage value chain. This presentation gives a brief review about the chemical, physical and biological processes that influence the extractive content and composition in wood and bark. Potential ways to limit the degradation and losses of extractives prior to processing are discussed.

Wood press water as a sawmill side-stream can boost the production of biotechnologically relevant enzymes in filamentous fungi

T2.12 Future biorefineries: forest biomass and side streams supporting circular economy

Manfred J. Reppke[1]
Elisabeth Windeisen-Holzhauser[1], Klaus Richter[1], **J. Philipp Benz**[1]
[1] Technical University of Munich, TUM School of Life Sciences, Freising, Germany

Abstract: The mechanical drying of wood chips with a roll press is an innovative method that improves the heating value of sawmill by-products in a cost-effective and energy-efficient continuous process. The moisture that comes out of the wood chips as press water (PW) contains a variety of dissolved and undissolved organic substances. The disposal as wastewater would generate additional costs offsetting the benefits associated with the reduced energy demand. On the other hand, the high levels of wood-derived compounds make this side-stream very interesting for applications using lignocellulolytic filamentous fungi. Hence, the aim of this study was to examine the potential of PW as a novel substrate or media supplement, respectively, for enzyme production by the industrially used fungus *Trichoderma reesei* RUT-C30.

Our results demonstrate that the addition of PW from Douglas fir (*Pseudotsuga menziesii*) to the cultivation medium can significantly boost the production of cellulase and hemicellulase enzymes, while allowing to replace salts and trace elements of the conventionally used media, such as Ca^{2+}, Mg^{+}, K^{+}, Fe^{2+}, Zn^{2+}, and Mn^{2+}, as well as an equal volume of fresh water. Further experiments demonstrated that this effect occurs mostly by genetic induction of the cellulolytic response and not by improving fungal biomass generation during submerged fermentation. On the other hand, supplementation with PW was found to enhance the growth rates of several wood-degrading basidiomycete fungi, and their mycelial networks were able to bio-clarify the PW by filtering out the suspended particles.

Finding innovative use cases for problematic side-streams from the sawmill industry by fungal biotechnology supports their transformation towards modern, resource-efficient biorefineries with broadened and value-adding product portfolios.

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Challenges of realizing ambitious reforestation goals in Hawaiʻi

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Emily Thyroff[1, 2]
Douglass Jacobs[2]
[1] University of Hawaiʻi at Mānoa, Honolulu, Hawaiʻi, USA
[2] Purdue University, West Lafayette, Indiana, USA

Abstract: There are ambitious goals for reforestation in Hawaiʻi to both restore native ecosystems and to expand commercial plantings for sustainable timber harvest. As outlined by reforestation leaders, there are many challenges to the reforestation pipeline. Perhaps these challenges are most poignant in the context of one of the most isolated island archipelagos. Hawaiʻi lies within the tropics, with the main islands between 18° and 22° north formed from volcanoes erupting from an undersea hot spot. Hawaiʻi is comprised of 27 of the 38 Holdridge life zones and home to a large range of forest types from warm wet, to dry scrub, and sub-alpine. Hawaiʻi is also commonly referred to as both invasive species and extinction capitals. The microcosm of ecological variety and threats to endemic biodiversity add heightened importance and complication to reforestation efforts. Several prominent land stewards have acquired funds to plant hundreds of thousands of trees, but reaching that capacity is proving difficult. Identified pressing difficulties include nursery capacity on island, diverse seed availability, and recruiting a resilient workforce. There are several examples of programs being limited due to infrastructure and reforestation resources in Hawaiʻi to consider, learn from, and support. Embracing Indigenous Hawaiian perspectives and protocols can help build reforestation capacity. In doing so, there is great potential in Hawaiʻi to address these challenges and meet profound reforestation goals.

Development of Growth and Yield Curves for Melia volkensii Tree Species used in Afforestation and reforestation Programs in the Drylands of Kenya

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

[5] Better Globe Forestry LTD, P.O. Box 823 – 00606, Nairobi Kenya

Abstract: Predicting tree growth, timber volume and biomass accumulation in any given site can be important for decision- making in forest management practice and planning. It is determined using species-specific site index models that take into account climatic and edaphic factors. *Melia volkensii* (Guerke) is a fast growing indigenous multipurpose tree species in the family Meliacease and is endemic to the drylands of eastern Africa. In Kenya, the species has been over-exploited because of its high quality timber and non-timber products. Melia is currently being promoted for growing by smallholders and private companies for timber production and carbon credit. The species has a relatively shorter short rotation period of 12–18 years. Although Melia trees have been planted actively in recent years, there is little information on the growth and yield of Melia to guide future afforestation and reforestation programs. The purpose of this study was to prepare a comprehensive Melia growth and tree volume yield model for Melia plantation that can be used to predict growth and yield and support forest planning and decision-making. Tree height, diameter at breast height and bole height data was collected from 109 temporary sample plots of 9 trees each spaced at 4m x 4m from plantations ranging in age from 3 to 20 years. There were 19, 51, 28 and 11 plots in Kiambere, Kitui, Kibwezi and Nyangoro respectively. The highest site index was for Kiambere.>Kitui>Kibwezi and lowest for Nyangoro. The results showed that there was difference in height growth ($p=0.01$), tree basal area ($p=0.03$), tree volume ($p=0.02$) and above ground biomass ($p= 0.02$) which did not corresponded to annual rainfall of site. Diameter growth of the low tree density was larger than that of the high tree density and great in the case of high site index. Apart from climatic factors, additional site variables such as edaphic factors are recommended to be taken into account in future when developing the Melia growth curves. The developed Melia growth curve were useful in determining Melia plantation productivity and guiding investment in commercial Melia growing and planning forest restoration programs.

Forest restoration and management on Indigenous landscapes

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Jeremiah Pinto[1]
[1] USDA Forest Service

Abstract: Recent initiatives and targets have pushed reforestation and forest restoration agendas to the forefront of land management efforts. Action to this regard, however, needs critical planning and resources to be successful. While stitching together and ramping up the pieces of the "reforestation pipeline" might seem straight forward, is important to keep in mind the end goals of ecosystem and cultural services these restored landscapes will ultimately provide. This requires acknowledging and considering Indigenous ties to the landscape. Plants and Indigenous people have had a long rich history and connection to the land. Plants provided all the necessities for survival, and the cultures that relied on them developed appropriate knowledge systems and science to understand them. Fast forward to now, and we see land use has changed and landscapes are being damaged or degraded by altered ecosystem disturbances, all of which create unique challenges for land management. When one layers cultural plant use into this equation, land management becomes even more challenging. Currently, indigenous people are managing forests and reservation areas for contemporary multiple uses, but non-indigenous management systems have frequently conflicted with traditional values and knowledge systems. At the same time, science and theoretical concepts for land management have also largely ignored traditional knowledge for indigenous land management practices. This often creates friction when trying to integrate traditional knowledge with western science. New ways to synthesize the two valid systems are needed, especially within the reforestation pipeline. Fortunately, a conceptual model exists for producing target seedlings for indigenous people that integrates Traditional Ecological Knowledge with modern land management tactics. This presentation will cover a brief history of this approach and include some ongoing examples of successful integration of the topic.

GERMAN-UKRAINIAN EFFORTS TOWARDS BUILDING CLIMATE-RESILIENT FORESTS IN WESTERN UKRAINE

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Peter Spathelf[1]
Vasyl Lavnyy[2], **Carsten Mann**[1]
[1] Eberswalde University for Sustainable Development
[2] Ukrainian National Forestry University

Abstract: Forestry in Ukraine is still very much oriented in clearcuts and the management of pure stands. Alternative silvicultural systems such as long-term natural regeneration or other cutting systems are though well-known but not implemented in practical forestry. In the project 'Resilpine' the focus was laid on the conversion of the Scots pine dominated forest in Western Ukraine into mixed continuous-cover forests, by implementation and analysis of experimental and demonstration plots as well as further education and training.

The specific goals and measures to achieve this were to develop the state forest enterprise Lviv and Stradch Educational and Production Forest Enterprise as model forest enterprises for a near-natural and multifunctional and climate change adapted forest enterprise, to implement and analyze permanent observation plots on forest conversion (alternatives to clearcutting) and fire management, including the establishment of two marteloscopes and their integration into the international network ‚Integrate+', and to establish demonstration plots for training purposes.

The tree species and silvicultural systems analyzed were Scots pine (*Pinus sylvestris*) with shelterwood and group selection cutting, pedunculate oak (*Quercus robur*) with shelterwood cutting and European beech (*Fagus sylvatica*) with shelterwood cutting. Moreover, five demonstration plots for different thinning variants in Scots pine were implemented.
It could be shown, among other things, that Scots pine is the most abundant species in all the felling systems, with on average more than 100 k plants per ha on relatively poor soils. Other admixed tree species only occur with small shares. Natural regeneration, especially of Scots pine, was less abundant on comparatively rich soils and in shelterwood, compared to small clearcut. After the young plants have established, their abundance slightly declined in the second and third year, due to competing herbaceous plants and thick litter.

Key words: alternative silvicultural systems, close-to-nature forest management, Scots pine, Ukraine

Long-term dynamics of grasslands and livestock in Norwegian cultural landscapes: implications for a sustainable transition of rural livelihoods

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Solomon Mulat[1]
Per Angelstam[1, 2], Vladimir Naumov[1], Barbara Zimmermann[1]
[1] Department of Forestry and Wildlife Management, Inland Norway University of Applied Sciences, Campus Evenstad, Anne Evenstads Vei 80, 2480, Koppang, Norway
[2] School for Forest Management, Swedish University of Agricultural Sciences (SLU), 739 21, Skinnskatteberg, Sweden

Abstract: The abandonment of cultural landscapes in Norway has had a notable impact on grasslands and domestic livestock that depend on them. The rate and direction of these changes vary across different geographical settings. Using two contrasting regions, representing inland (Hedmark) and coastal (Sogn og Fjordane), landscapes, respectively, we analysed the temporal dynamics of grassland and livestock from 1918 to 1999 in a total of 40 municipalities in the two regions. The results showed a 66% and 20% decrease in grassland areas in Hedmark and Sogn og Fjordane, respectively. However, in Sogn og Fjordane, the cultivated grassland used for mowing increased over the years. In contrast, in Hedmark, the cultivated grassland used for mowing decreased by 70% from 1949 to 1979. This reduction coincides with the period when cultural landscapes were abandoned, and spontaneous reforestation occurred in the region. The domestic livestock, which depends on grassland for sustenance, showed differences between the two regions. In inland Hedmark, livestock experienced a huge decline, especially from 1959 when the population dropped by 35%. This decline continued in the subsequent years. On the other hand, in coastal Sogn og Fjordane, the livestock population experienced a clear drop of 18% in 1949 and then stabilized. Finally, we advocate that regional planners have to consider the historical trajectories of changes within cultural landscapes to ensure ecological services by conserving and maintaining these landscapes' valuable habitats.

Mechanical Site Preparation Across Space and Time: A Trans-Atlantic Perspective on Successful Regeneration of Boreal Forests

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Nelson Thiffault[1]
Per Nordin[2], Amy Wotherspoon[3], Karin Hjelm[4], Erika Olofsson[5]

[4] Swedish University of Agriculture, Southern Swedish Forest Research Centre
[5] Linneaus University, Department of Forestry and Wood Technology

Abstract: Successful forest regeneration is crucial for sustainable forest management. In boreal contexts, plantation forestry is notably used when natural regeneration is insufficient after harvesting or wildfires, but planted seedlings face various stresses on harvested sites, jeopardizing their survival and growth. Limited access to water, nutrients and light, plus exposure to pests, and diseases contribute to these stresses. Mechanical site preparation, disturbing the organic layer and upper mineral soil through techniques such as discing, mounding or inverting, is commonly used to mitigate post-planting stress. However, climate change, social interest in forest management, and the need to procure diverse ecosystem services require precise silviculture practices tailored to regional and local objectives. Our empirical research in boreal ecosystems of North America and Scandinavia reveals intricate interactions affecting seedling establishment after reforestation. For instance, in boreal Quebec, Canada, successful conifer seedling establishment depends on regional precipitation, temperature, and interactions with soil characteristics and microsite conditions. In Sweden, planting position within scarified sites significantly influences conifer seedling survival, but effects vary with soil moisture. Long-term silviculture studies also demonstrate the importance of early treatments for stand productivity. For example, mechanical site preparation significantly enhances seedling growth and survival, impacting sapling growth even after 18 years in boreal Quebec. We have observed that seedlings planted in scarified plots show improved water use efficiency compared to control plots. Also, we have shown that site preparation effects on standing volume and density persist for at least 30 years in Sweden. In conclusion, our empirical studies with *Pinus* and *Picea* species across multiple sites in Canada and Sweden highlight the absence of a universal solution for regeneration success in boreal ecosystems. Forest managers and decision-makers must recognize these complex interactions and support further international research collaborations. The success of large-scale forest landscape restoration and reforestation programs depends on implementing regionally tailored silviculture prescriptions based on an understanding of the mechanisms driving seedling responses.

Pine reforestation programs in Mexico

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

ARNULFO ALDRETE[1]
[1] Colegio de Postgraduados. Postgrado en Ciencias Forestales.

Abstract: Mexico is one of the six megadiverse countries in the world, with around half of the world´s pine species. *Pinus* is one of the most economically and ecologically important forest genera in Mexico. However, in accordance to some authors, deforestation rates in México are about 370,000 ha/year. This threatens the richness of forest genetic resources in México, causing the disappearance of locally adapted populations and rare and endangered pine species. Reforestation programs in Mexico have been used to respond to deforestation problem since many years ago. In addition, these programs can be used as an important strategy for rehabilitating ecosystem structure and function in degraded lands. Restoration of ecosystems is a long process that involves reforestation as a main element. For sites where conditions present several adverse factors for seedling establishment the challenge to recover degraded areas is bigger. One of these programs was located in the central part of Hidalgo State in Mexico. People from Community El Porvenir, Hidalgo have been planting pine trees since 25 years ago trying to recover degraded lands. Several studies regarding performance of these plantations were done during last two decades. Evaluation includes species adaptation, seedling survival and development, richness and abundance of species of shrubs and herbaceous plants in the plantations, etc. We also interviewed people from the community involved in reforestation process to obtain information about the practices applied before, during plant establishment and maintenance after planting. Results show that degraded lands have been slowly recovered. Two promising species were *Pinus greggii* var *australis* and *Pinus cembroides*. Results indicated that survival, growth, and adaptation of these two species is good. One of the studies found a total of 44 species of vascular plants in the understory distributed among 42 genera and 34 families, with 90% native species. People involved in tree plantations consider three main factors for reforestation success: species selection, site preparation, and participation of most people of the community in the establishment and maintenance of the reforested areas. This evaluation demonstrates that rehabilitation of degraded lands through reforestation is possible and lead to an increase in biomass accumulation and diversity

PostCont – the technological system for the containerization of bare-rooted planting stock of trees and shrubs

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Ivan Kunes[1]
Frantisek Lopot[2], Zdenek Havranek[2], Ondrej Stocek[2], Marek Stadler[2], Jaromir Stancl[2], Martin Balas[1], Pavel Burda[3], Tomas Jiracek[4], Alena Hlidkova[5], **Katerina Peskova**[1], Vilem Podrazsky[1]

[3] Ing. Pavel Burda, Ph.D. (Forest Nurseries)
[4] Lesni spolecnost Vltava s.r.o.
[5] Suchopyr z. u.

Abstract: The poster will provide information about a semi-automatic device capable of encapsulating the roots of bare-rooted planting stock into paper pots and a growth medium based on peat (PostCont stands for post-containerization). The PostCont device does not require the purchase of containers. The production of paper pots is a part of the containerization process. Secondary raw materials (e.g., old paper, cardboard, moulded pulp) and water are used to create the pots. The paper pots are made from the feedstock in a so-called "wet process". The tested PostCont machine can recycle the surplus water extracted from the pots and the substrate when the plants are containerized. Immediately after containerization, the planting stock can be handled with some care. The PostCont plants represent a compromise between bare-rooted and standard container technology. According to our initial results, the roots of plants grow freely through the walls of the paper pots and do not show deformities. The containerization of originally bare-rooted plants by the PostCont technology has the potential to support the resistance of the planting stock to stresses during transportation and after planting on harsh forest sites (drought, unfavourable soil environment, etc.). In this respect, PostCont plants are, to a certain extent, close to the standard container stock that often shows a higher survival rate than the bare-rooted stock. However, PostCont technology demands less irrigation water, fertilizers and pesticides than container technology. This is because in the PostCont technology, the planting stock is grown on mineral outdoor nursery beds, and the containerization is completed after the plants are grown. Semi-automatic root encapsulation is faster than manual transplanting to containers. The developed PostCont device can be easily transported and utilized wherever there is a water source and a connection to the electricity grid. The PostCont technology is designed primarily for smaller mineral nurseries focusing on bare-rooted planting stock. It will allow them to containerize some part of their planting stock so that the containerized seedlings can be used on harsh sites or in less favourable planting conditions.

Potential of bamboo for forest landscape restoration following degradation by artisanal mining activities

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Ernest Foli[1]
Charles Essien[1], Theresa Peprah[1], James Govina[1]
[1] CSIR-Forestry Research Institute of Ghana

Abstract: Artisanal mining activities in southern Ghana entail methods that result in significant environmental damage, including forest degradation, air pollution and pollution of water bodies in the mining communities. Bamboo is abundant in Ghana and is known to be useful for soil erosion control, etc; but its use for restoration of degraded land has yet to be fully explored in the country. This study therefore sought to explore the potential of bamboo for reclaiming degraded mined sites and to identify suitable bamboo species for this purpose. Plots measuring 825 m^2 were demarcated on randomly selected un-mined, reclaimed mined and un-reclaimed mined sites. Seedlings of seven bamboo species were planted at 2 m x 2 m on each plot and the seedlings were assessed for survival rate, shoot production rate, height growth and qualitative phenotypic characteristics. The results indicated 97% survival of seedlings of all the species on all plots and 70% of seedlings developed new shoots on the un-mined and reclaimed sites one month after planting; with 50% on the un-reclaimed site. After three months, mean shoot production for reclaimed-, un-mined-, and un-reclaimed mined sites were 3.0, 2.0 and 1.0 shoots per clump, respectively, with corresponding mean height growth of approximately 173 cm, 113 cm and 63 cm. By the tenth month, the bamboo had formed an impenetrable barricade on the reclaimed and un-mined sites. We conclude that *Bambusa vulgaris*, being the most common in Ghana, is suitable vegetation cover for rapid reclamation of degraded mined lands in southern Ghana. In addition to curbing air pollution and improving ecosystem functioning and livelihoods of local communities in the mined sites, it would contribute significantly to Ghana's commitments to the Bonn Challenge, AFR100 and other restoration initiatives, and to Targets 3, 4 and 5 of SDG 15.

REGENERATION OF FORESTS WITH SILVER BIRCH (BETULA PENDULA ROTH): THE PERFORMANCE OF CONTAINERIZED BIRCH SEEDLINGS IN THE FIELD

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Kinga Stolarek[1]
Karin Hjelm[1], Urban Nilsson[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences, Alnarp, Sweden

Abstract: Conifer species are dominating in the forests of the boreal and nemoboreal zone. Due to climate changes, more frequent damage has occurred in recent years, especially in Norway spruce *(Picea abies* (L.) Karst.*)* stands, which is a drought-sensitive species. This concern, as well as the energy sector's transformation from using fossil fuels towards biofuels, prompted the idea of increasing the amount of fast-growing broadleaved tree species. For this goal, the Trees For Me excellence centre was created to develop the potential of Silver birch (*Betula pendula* Roth) as a complementary tree species. Artificial regeneration is a crucial step in forest management to reach the goal of highly productive birch stands. Therefore, studying containerized birch seedlings' performance in the field is of interest. At four research stations across Sweden, two different sizes of containerized seedlings were planted in 2023 and will be repeated each year until autumn 2027. Seedlings will be planted during spring, summer, and autumn. Additionally, three different site preparation methods will be tested: disc trenching, inversion, and no soil preparation. Also, fertilisation with arginine will be applied to one-third of the seedlings on each plot. Height, root-collar diameter and damage will be registered after each growing season. The data obtained from this study will allow for a comparison of growth and survival in two sizes of containerized birch seedlings using different site preparation methods and dates of planting during the year. The study will enable to distinguish favourable conditions for establishing future birch forests and optimize artificial birch regeneration.

Restoring Atlantic Forest's contributions to people

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

[5] Center of Nature Sciences, Federal University of São Carlos

Abstract: Forest landscape restoration has been promoted globally as a means to achieve multiple socio-ecological benefits, yet little is known about the relative contribution of different tree growing approaches for ecosystem services and human wellbeing. In the Brazilian Atlantic Forest, an ambitions restoration target of 15 million hectares has been promoted since 2009 by the Atlantic Forest Restoration Pact, but stakeholders' engagement has been constrained by the lack of evidence of the benefits people may get from restoring tree cover in deforested landscapes. Here, we explored how nature contributions to people are recovered by different tree growing approaches. We collected data in 700 30 x 30 m plots, using a standardized protocol focused on multiple ecosystem attributes and functions (e.g., forest inventory, soil measures, water infiltration), distributed across the Atlantic Forest in southeastern Brazil and seven types of tree cover (second-growth forests, restoration plantations, agroforests, active monocultures, unmanaged monocultures, degraded remnants, and conserved remnants). We used the IPBES framework to estimate nature contributions to people based on the ecosystem attributes and functions measured in the field. We found a broad range of variation of tree growing approaches in providing nature contributions to people and evaluated the influence of environmental factors in this process. Our results highlight the need for matching tree growing approaches with stakeholders' demands and the local socio-ecological context, as well to consider critical trade-offs when deciding why, where, and how to restore tropical forests.

Tree planting machines for effective reforestation: examining seedling supply systems that facilitate mechanized tree planting

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

Back Tomas Ersson[1]

[6] Skogforsk, Ekebo, Sweden

Abstract: In parts of the world, some reforestation is performed mechanically. To be cost-effective, all tree planting machines are dependent on efficient seedling/cutting handling and logistics (seedling supply systems). Today, seedling handling is a bottleneck that costs time and money when reloading the machines' planting devices. In our study, we present some historical attempts to develop seedling supply systems that facilitate mechanized tree planting. Some have been put into operation, while others have only been tested in development projects or as theoretical concepts.

From the nursery, seedlings can be delivered in: cultivation trays; trays with round/square plastic cultivation tubes; crates; or in cardboard boxes. With trays, the tray design can be made compatible with the planting device’s seedling feeding system. Also, the seedlings’ positions can be defined, and the seedlings can be fed automatically on the planting machine either by pushing them out or by individually grabbing and lifting them out of the tray cavities/ plastic tubes. Cohesive root plugs (or root plugs supported by e.g. paper pots) aid seedling handling and feeding; however, such solutions might add costs, require additional nursery investments, and/or deform roots. Overall, trays are robust and protect the root plug, but seedlings in cultivation trays are prone to desiccation and cannot be frozen-stored cost-efficiently.

Cardboard boxes, in which seedlings are packed either with the stems intertwined or standing up, is the second most common seedling packaging system. In boxes, seedlings can be packed densely, which is especially important if the transport distance from nursery to the reforestation site is long. However, before seedlings can be transferred to the tree planting machine's planting dibble, boxes require either manual handling or that the seedlings have defined positions in the boxes (or be band-mounted. e.g. the EcoBandPak concept) if they are to be picked automatically.

With increasing labour shortages, additional technical development, standardization, and joint research initiatives, we predict that previously failed solutions for seedling supply might become cost-efficient in the future. Nevertheless, because the international reforestation context varies widely, we conclude that there is no single global solution for seedling supply systems of mechanized tree planting.

What factors enhance survival and growth of planted saplings in clumps on sandy soils?

T2.13 Improving the flow of the reforestation pipeline to support regeneration and ecosystem function for the future

[6] Bosgroep Noorderkempen
[7] Ghent University

Abstract: In the context of afforestation and forest conversion, planting saplings is a frequent avenue to rapidly boost species richness. Planting saplings in groups of 20 to 40 trees, so-called clumps, is a management strategy with the intention of creating mixed forests. The establishment of young trees however remains a challenge - and with increasing shortages of seeds and planting material and rising costs - it is crucial that we use our available forest reproductive material efficiently. The first years after planting are generally hard as young trees coming from nurseries are exposed to difficult surviving and growing conditions. Challenges include climate change related disturbances (drought and heat stress), soil degradation (acidification, compaction, …) and high herbivory pressure from game. The addition of amendments in the planting pit and protection against game can alleviate some of these constraints. Here, we focus on species poor forests on degraded sandy soils (Pleistocene deposits of the West-European sand belt) in Southern Netherlands and Northern Belgium, where all of the above challenges are widespread and hinder successful conversion of pine monoculture to mixed forest. In this large scale observational study monitoring up to 50 000 trees planted in 3403 clumps between 2014 and 2021, we evaluated the success and growth of young trees per tree species and soil type, the effect of soil amendments (fertilizer, rock dust and/or hydrogels) in the planting pit, and the type of game protection measures. Our results indicated that water availability is the prime limiting factor for survival and growth of young trees, however most results are context dependent. The effect of amendments is variable (depending on tree species and soil type) and should therefore not be adopted as a blanket treatment. The type of wildlife protection is determinant for survival and growth of young trees: the individual, complete protection options such as tubes seem to be the most effective. The findings of this research can be taken into account by the forest manager when planting the (mixed) forests of the future.

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

20 years of forest sector innovation in Europe

Abstract: The European forestry and forest-based sector plays a crucial role in addressing global challenges related to climate change, biodiversity preservation, and the provision of forest ecosystem services. As markets evolve and consumer behaviours change, and as European policies increasingly aim to foster the development of a circular bioeconomy, understanding the role of innovation becomes increasingly important.

This presentation offers a comprehensive overview and analysis of innovation activities within the European forestry and forest-based sector over the past 20 years, with a specific focus on the key drivers and barriers that influence the development and adoption of innovations. The research methodology adopted ensures a robust and evidence-based analysis. By conducting a systematic literature review, analysing data from recent EU projects and patent database and empirical data collected through surveys conducted across EU countries and expert interviews, this presentation will provide insights into the practical challenges faced by innovators and stakeholders in the sector. The findings will contribute to a deeper understanding of the innovation dynamics within the European forestry and forest-based sector. By identifying the key factors that influence the development and uptake of innovations, policymakers, industry players, researchers, and other stakeholders can better comprehend the current innovation ecosystem. These insights can inform the formulation of effective strategies and policies to foster innovation, drive sustainability, and address emerging challenges, thereby helping forestry position itself better in the bioeconomy. By leveraging these findings, the forestry sector can seize opportunities, optimize resource utilization, and contribute significantly to the growing field of bio-based products and services.

An integrated modeling and analytical framework of machine learning and life cycle assessment in forest biomass utilization for bioproducts

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Jinghan Zhao[1]
Jingxin Wang[1]
[1] Center for Sustainable Biomaterials & Bioenergy West Virginia University

Abstract: The utilization of forest biomass for value-added bioproducts can contribute to sustainable forest supply chain management and mitigation of climate change. The diverse biomass conversion pathways and process conditions make conducting comprehensive environmental impact assessments difficult. To bridge this research gap, we developed an integrated life cycle assessment (LCA) and machine learning (ML) analytical framework to evaluate forest logging residues' life-cycle energy consumption and environmental impacts under various conversion technologies and processing conditions. A “cradle-to-gate” LCA is used to quantify the environmental impacts of feedstock harvesting, transportation, storage, preprocessing, and conversion components. ML models trained from experimental data are used to predict the yield and properties of bioproducts produced from logging residues through different thermochemical conversion pathways. The outcomes of the ML predictive modeling are subsequently incorporated as input parameters within the integrated analytical framework in conjunction with LCA. This modeling and analytical framework is applied in the eastern United States, where abundant forest biomass resources show great potential for the industrial development of bioproducts. Our results indicate that the LCA models, coupled with results derived from ML models can help minimize the environmental impacts of forest biomass utilization. The application of this integrated modeling framework can further enhance the environmental sustainability of the industrial development of forest biomass for bioenergy and bioproducts.

Bioeconomy, forest and digitalisation - developing sustainable business models

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Camilla Widmark[1]
[1] Swedish University of Agricultural Sciences

Abstract: Forests in the Nordic countries have been a source of food, products and welfare for both local communities and nations for as long as there has been settlement. More recently, the way in which forests support the climate has become more pronounced. But people are now facing major challenges due to climate change as well as societal and environmental challenges. Fundamental changes are needed to ensure future prosperity in the face of growing resource depletion, climate change and environmental degradation.

Forests are crucial for the development of a sustainable bioeconomy in forest-based countries to replace fossil fuel-based materials and energy. Forest biomass has a great potential for developing new bio-based products. However, bioeconomy and circular economy transformation depend on both technological and social innovations together with societies adapting to a bio-based sustainable future, which emphasizes the ecological, economic and social functions of forests.

This presentation discusses opportunities and challenges for the digitalization of the Swedish forestry value chain in a circular bioeconomy. The vision of project was to create digital solutions for a sustainable and efficient forest/based bioeconomy; the mission is to explore and create enablers for realizing a digital forestry value chain. The forest sector is challenged by level of digital maturity, establishment of digital ecosystems, increase in level of service innovation, and increase in digital competence. Individually these challenges are developed, however, the major challenge is to bring them together and linking business models with the digital ecosystems available and eveloped. The level of digital maturity in the Swedish forestry sector is reportedly low –both among large companies and smaller forest owners. While researchers have contributed to an increase in service innovation in the Swedish forestry sector, there remains the need to build digital ecosystems that enable an increase in digital competence across the entire value chain. This presentation discusses advancements, pending tasks, and lessons bring them together with business models togehter with the concept of Industry 5.0 –a stage in which technologies are used with a perspective that accounts for humans' fears towards digitalization— may be what Sweden needs to pursue a full-scope digital transformation.

Comparative factor analysis on consumers' preferences of wood utilization in Asian countries

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Kenji Nagasaka[1]
Masafumi Inoue[1]
[1] The University of Tokyo

Abstract: Wood demand is continuously growing in most of the Asian countries owing to increasing population and rapid economic growth. In 2021, we conducted web-based questionnaire surveys in Japan, China, Vietnam, Thailand, Indonesia, and India to understand the citizens' preferences and knowledge about forests and wood utilization. The number of valid responses counted 500 in Japan, 312 in China, 450 in Thailand, 389 in Vietnam, 216 in Indonesia, and 41 in India. Based on the collected data, we conducted multiple linear regression analysis to determine factors that influenced the preferences of wooden products including interiors and furniture, and wooden house. Regarding wooden products, explanatory variables such as 'degree to consider cutting-down forests as deforestation and destruction of nature', 'degree to be fond of entering forests', and 'frequency to enter forests' significantly influenced the degree of wooden product utilization. For instance, citizens who responded more negatively to cut down forests had significantly lower degree of wood product utilization in Vietnam, while the opposite was true in China. Considering the frequency to enter forests, citizens in Japan who frequently entered forests had significantly higher levels of wood product utilization, while citizens in China, Thailand, and Vietnam were unaffected by this factor. More than 30% of citizens in Japan, Thailand, and India indicated that they would like to live in a wooden house in the future, while more than half of the citizens in other three countries rejected the idea. In Japan, Vietnam, and Indonesia, a factor 'degree to be fond of entering forests' showed positive influence. In these countries, advertising wooden house with positive image of forests might be effective to expand wooden house market. Considering a negative influencing factor, citizens who answered 'like to feel the surface of wood by hand' had a negative opinion to live in wooden house in China, Vietnam, and India, while Japanese citizens had a positive opinion. For wood exporting countries, effective export strategies would be established for Asian market based on these science-based findings.

Do wooden buildings improve consumer perceptions of corporate sustainability?

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Erlend Nybakk[1]
Jakob Utgård[1, 2], Eric Hansen[3]
[1] Kristiania University College
[2] Oslo Metropolitan University
[3] College of Forestry, Oregon State University

Abstract: With an increasing focus on climate change and negative environmental effects caused by humans, we see increasing concern among consumers, followed by behavioural changes. Environmental considerations are increasingly important in consumer decision making. We are surrounded by corporate buildings, we pass them when traveling, we visit them, and we see them in the media. Some companies use their corporate headquarters as part of their marketing strategy, by, for example, creating iconic structures that bolster their brand. Corporate buildings are frequently strategically depicted in company homepages. Despite the attention and investment by industry, research has largely neglected the relationship between corporate building appearance, brand associations. An especially relevant question today is, to what extent do environmentally friendly corporate buildings and the materials used in those buildings affect companies' credibility when it comes to being environmentally sustainable.

We study how building materials (wood vs steel/concrete) used in corporate buildings influence perceptions of company image related to sustainability. Our theory is that building materials influence how sustainable a firm is perceived to be, but that the effect depends on perceptions of the sustainability of wood.

We therefore hypothesize that firms that use wooden (vs concrete) buildings are perceived as more sustainable by consumers, and consumers have a more positive brand attitude towards such firms. We also hypothesize that the effect of wooden buildings on perceived sustainability and brand attitude is positively moderated by beliefs about environmental attributes of wood.

We test the hypotheses using an online survey-based experiment (n=1200, UK and US-based respondents) where we manipulate the building materials of corporate headquarters (wood or steel/concrete, four different fictional companies) using realistic images and text. The analyses and results and implications will be presented.

Estimating the sustainable availability of unused woody materials for energy from planted forests in Japan

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Kazuhiro ARUGA[1]
Yusuke MATSUOKA[1], Hiroaki SHIRASAWA[2]
[1] Utsunomiya University
[2] Forestry and Forest Products Research Institute

Abstract: This study estimated the sustainable availability of unused materials for woody biomass power generation plants under operation with FIT at the end of June 2020 as the supply potential considering reforestation costs of the planted forests, about 10 million ha in Japan. As a result, supply potentials of used and unused materials were estimated at 65,413,601 m^3/year and 13,082,720 m^3/year, respectively whereas those techno-economic availabilities were estimated at 54,202,304 m^3/year and 10,840,481 m^3/year respectively. Therefore, the rate of the availabilities to the supply potentials was 82.9%. Furthermore, the rate of the availabilities to the demands was 124.8%. With woody biomass power generation plants registered in FIT at the end of June 2020, the rate of the availabilities to the demands was 98.5%. Considering the subsidy rate of 100% to secure the reforestations, the availabilities met the current demands in Japan as a whole.

Examining the paradoxical tensions of intersecting market-shaping strategies in Nordic forests

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Suvi Nenonen[1]
Kaisa Koskela-Huotari[1], Hans Kjellberg[1]
[1] Department of Marketing and Strategy, Stockholm School of Economics

Abstract: Despite decades of scientific research and international agreements, it is evident that current global efforts to address sustainability challenges such as climate change and biodiversity loss are neither substantial nor fast enough. The reason behind this relative inaction is not the lack of informative natural sciences research or policymakers' ambitions. Rather, we posit that one of the main reasons behind the slow progress is that sustainability efforts have viewed and used one of the most pervasive and potentially efficient mechanisms for allocating resources in contemporary societies – markets – in a much too narrow sense. Importantly, there is more to markets than the objective price allocation mechanism often depicted as an 'invisible hand'. Markets are complex social systems that enable exchange and value creation within open, democratic societies. Within such market systems, actors regularly engage in market shaping—reactive or proactive actions to either change or maintain the way markets work. In this study, we look at how multiple market-shaping efforts intersect and interact in the ongoing sustainability transition of contemporary society, focusing on the Nordic forestry sector. Forests are viewed as key resources in the transition towards more sustainable futures, providing vital goods and ecosystem services. At the same time, the established and industrialized forest-related markets may also be part of the problem via their emphasis on mass production and the associated forest management practices. Our initial findings suggest that some of the parallel market-shaping efforts are mutually reinforcing while others are mutually opposing. Furthermore, there appears to be no simple relation between the way such market-shaping efforts intersect and the sustainability outcomes they generate. To investigate these complex dynamics, we apply paradox theory and particularly the difference between paradoxical tensions in the epistemological realm (i.e., actors' perception of tensions) and paradoxical tensions in the ontological realm (i.e., the systemic reality underlying the tensions). As an outcome, we develop a typology of the included paradoxical tensions and elaborate how this typology can be used both to 1) improve the sustainability outcomes of multiple intersecting market-shaping efforts in the forestry context and to 2) limit the repercussions of their unintended consequences.

Gate-Gate Life Cycle Assessment of industrial metabolism of wood plastic composite to achieve circular economy

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Swati Mishra[1, 2]
Siddhartha Arya[1, 2], Shakti Chauhan[1, 2], Ritesh Kumar[1, 2]
[1] Institute of Wood Science and Technology (IWST)-ICFRE
[2] Indian Council of Forest Research and Education (ICFRE)

Abstract: Wood Plastic Composite (WPC), known for its excellent durability, dimensional stability, high rigidity, and relatively low density, is one of the largest forest bio-economic industries. WPC, as a product, are environmentally sustainable, but since it is an unorganized market, being unable to prioritize the social aspects and industrial production hinders the nation from achieving Sustainable Development Goals (SDG) 2030. Therefore, it is essential to assess the industrial metabolism of WPC to re-invent and re-introduce this market using Life Cycle Assessment (LCA) to achieve a circular economy.

The study aimed at a less attempted gate-gate LCA of WPC industries, which analyses the burdens posed on the environment at a microscopic level and corrects the faults in the industrial units such as fibre selection, route planning for internal transportation, technological and processing faults, labour resources, human safety and storage units. Evaluation and correction in these units reduce energy consumption and other costs while ensuring the safety of labour and the environment. The energy and carbon model for the next 50 years of the improved industrial hubs showed a steady decline in plastic waste and carbon footprint and an increase in economy from the green industries.

The rise of the WPC industries demands sustainable life cycle assessment (LCSA) and restoration of industrial metabolism to ensure a livable environment. These results would help to formulate better industrial designs and bio-economic policies to thrive internationally.

Keywords: Wood Plastic Composite, Life Cycle Assessment, Industrial Metabolism, Circular Economy

Housing developers' intention of reuse wood materials in building projects

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Marie Renée Gangsø[1]
Gudbrand Lien[2, 3], Hanne K. Sjølie[2], **Ståle Størdal**[2, 4]
[1] University of South-Eastern Norway
[2] Inland Norway University of Applied Sciences
[3] Norwegian Institute of Bioeconomy Research
[4] Norwegian University of Science and Technology

Abstract: The construction industry is a significant cause of greenhouse gas emissions, resource consumption and waste generation. Among other things, the industry has a large potential for increased material circularity. Therefore, the interest in circular strategies associated with reuse, repair, renovation, recycling and recovery have received increasing attention in recent years. However, a complex set of factors will affect the decision to the reuse of wood materials in the construction industry, and there exist several barriers that slow down circular development. This study investigates behavioral and institutional factors that impact the intention of housing developers to implement the reuse of wood materials in residential and leisure buildings in Norway. A quantitative cross-sectional survey was conducted in the fall of 2022 on housing development companies (N = 138) in southern Norway. A conceptual model based on the Theory of Planned Behavior and Institutional Theory was developed and tested on the data that included questions related to the research models main constructs. To test the hypotheses, Partial Least Square Structural Equation Modelling was utilized. Furthermore, a bootstrapping test was used to inspect potential mediating effects. The conceptual model explains a large proportion of the housing developers' intentions to reuse wood materials. The results indicate that previous reuse behavior, behavioral attitude, perceived behavioral control, and regulatory and market factors are positively associated with intentions to reuse, while subjective norms have no significant effect on the intention variable. To enhance the intention to reuse, this study suggests focusing on digitizing and systematizing access to materials and information, sharing knowledge through holistic collaboration, educating professionals in circular economy practices, and adapting laws, regulations, policies, and economic incentives towards more reuse and circular building activities. This requires a holistic attitude shift among individuals, governments, and businesses.

Incorporating Circular Bioeconomy Principles into Strategic Biomass Planning

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Sherry Hazelhurst[1]
[1] United States Department of Agriculture, Forest Service, Pacific Southwest Region

Abstract: Forests in the United States (U.S.) Pacific Southwest Region generally support an overabundance of biomass supply with inadequate demand and facilities to make use of the materials. U.S. Forest Service Biomass Program activities here have helped to retain 21 commercial biomass energy facilities using over 46 million board feet of timber per year, support biomass uses at over 25 other wood processing facilities and contribute toward research and development of other value-added uses for small woody materials. However, forest managers and industry often struggle to match supply with demand for a variety of reasons including high costs to extract and deliver material, unpredictable supplies, challenges from environmental groups, a dearth of skilled forestry workers/equipment, subsidized or less expensive renewable energy sources competing in the public market, and a lack of newer production facilities that can make higher value products from small wood. Applying circular bioeconomy concepts to this biomass supply and demand imbalance may lead to solutions by designing and applying technological and/or biological solutions that ultimately remove waste and pollution from the system. Some important considerations for supporting sustainable biomass components in a circular bioeconomy include:

- Assessing and developing pathways to provide consistent supplies.
- Optimizing specifications in contracts/agreements to balance economic and ecological goals.
- Investing in timely research, development, and innovation with diffusion of that technology.
- Collaborating with state, industry, partners and interest groups to promote shared stewardship.
- Facilitating education and technical expertise with a range of collaborators and stakeholders.
- Maintaining and growing partnerships that sustain wood processing infrastructure and jobs.

Developing a shared vision and strategic pathway for sustainable, effective biomass utilization is the first step toward a blueprint that could guide forest managers, stakeholders, and industry plans. To maintain and restore healthy, resilient forests and associated ecosystem services while also providing for socioeconomic prosperity, six priority strategic elements are suggested as a basis for actions: 1) address supply availability and sustainability; 2) increase collaboration on research, development & innovation; 3) integrate natural capital accounting; 4) identify sustainable funding commitments; 5) promote education programs; 6) advance positive narratives for public support.

Innovations in climate life cycle assessments for forest products: coupling forest management with wood product analysis, and policy applications.

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Thomas Buchholz[1, 2]
John Gunn[3], Carrie Levine[2], David Saah[2]
[1] Gund Institute for the Environment, University of Vermont, USA
[2] Spatial Informatics Group LLC, Pleasanton, California, USA
[3] The Nature Conservancy, Arlington, Virginia, USA

Abstract: Greenhouse gas life cycle assessments (GHG LCA) play a key role in identifying promising forest management and forest product alternatives for a circular bio-economy. These GHG LCA's consist of several steps along a forest-to-disposal path: considering forest management and wood product utilization. Focusing on key components of advanced forest product GHG LCAs, we will present examples of recently published studies. Key components include i) assessment boundaries; ii) baseline and alternative future forest management assumptions as new wood product supply chains, including bioenergy, come online; iii) uncertainty analysis including stochastic events affecting forest carbon stocks (wildfire, pests, climate change, etc.); iv) wood product substitution benefits including dynamic baseline assumptions for alternative energy generation (e.g., sliding grid electricity emission profiles); v) inclusion of a wider range of climate-relevant impact metrics (different GHGs, albedo effects, etc.); vi) temporal considerations including dynamic accounting that considers GHG specific half-lifes; and vii) GHG emission discounting to explore near-term GHG benefits.

These components can be accommodated in a host of GHG LCA accounting frameworks for attributional or consequential in forest management or (forest) product centered life cycle assessments (e.g., Buchholz et al., 2015; Buchholz, Kifalu, et al., 2017; Buchholz & Nepal, 2023). Applications can range from jurisdictional climate action plans (e.g., Maritato et al., 2021), state-wide (forest management) strategies for nature-based climate solutions, to product specific LCAs such as wood-based high-rise buildings. We will further pull from previous research into state-level forest sector analytics (e.g., Canham et al., 2013; Gunn & Buchholz, 2018) and scenario specific assessments (e.g., Gunn et al., 2020; Timmons et al., 2016) as well as integrating risk and sensitivity analysis into these LCAs (e.g. Buchholz et al., 2022;) and extensive management scenario analysis (e.g., Gunn & Buchholz, 2018).

To identify key levers for decision makers, accounting elements need to be reported separately to disaggregate carbon impacts and associated uncertainties by category (stocks, products in use, post use, energy, substitution energy, substitution products) and allocate uncertainty factors separately by accounting element.

This presentation provides the audience with an overview on state-of-the-art GHG LCA analysis and how to translate results into actionable climate policies.

Innovative investment, ownership concentration and corporate financial performance – evidence from the Chinese forest products firms

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Yijing Zhang[1]
Chaochao Jiang[1], Qinxin Ma[1], Wen Luo[2]
[1] South China Agricultural University, College of Economics & Management, Guangzhou, China
[2] Zhongkai University of Agriculture and Engineering, College of Management, Guangzhou, China

Abstract: Forestry product firms shoulder the dual missions of economic development and ecological protection. Therefore, analyzing firms' performance is conducive to improving firm-level operations and country-level green development. This paper uses the fixed-effect model with panel data for 102 listed forest product firms from 2014 to 2020 in China to explore the relationship between innovative corporate investment, ownership concentration, and performance. In addition, further analysis was conducted based on different industrial segments (pulp and paper, wood-based panels, and other forest products firms) and ownership property (state-owned and non-state-owned). The results are drawn as follows: (1) There is a positive relationship between innovative investment and corporate performance of forest product firms but a negative relationship between ownership concentration and performance. (2) Ownership concentration negatively moderates the relationship between innovative investment and corporate performance. (3) Innovative investment has a more considerable impact on the performance of pulp and paper than wood-based panel firms; similarly, ownership concentration has a severe impact on the performance of pulp and paper and other forest products firms than wood-based panel firms. (4) Innovative investment has a more significant impact on the performance of state-owned firms than non-state-owned firms. However, ownership concentration only significantly impacts the performance of non-state-owned firms. Therefore, this paper concludes that forest product firms should enhance the awareness of innovation, increase innovative investment and moderately adjust the ownership structure to establish an effective ownership balance mechanism. Moreover, the government should provide stable and supportive policies and regulations to encourage innovative corporate operations.

Interdisciplinary life cycle assessment model for ecosystem services evaluation to achieve resilient, circular economy

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Swati Mishra[1, 2]
Ramachandran Sundararaj[1], A. Muthu Kumar[1, 2]
[1] Institute of Wood Science and Technology (IWST)-ICFRE
[2] Indian Council for Research and Education (ICFRE)

Abstract: Life cycle assessment (LCA) has proven to be beneficial for economic development and reduced climate burden, and in the last few decades, it has significantly addressed social and technological issues. However, the current analytical LCA approaches are still not able to assess the impacts of anthropogenic metabolism on the ecosystem and its services. The lack of knowledge and data obstruct the interlinkage of the different disciplines to facilitate a more tailored approach to address the complex issues of quantifying ecosystem services and learning the microscopic units of the ecological system to mitigate climate change impacts. It hinders the transition of the Global South from an anthropocentric approach to a greener, more resilient circular economy.

The use of an interdisciplinary model of life cycle assessment (LCA) could advance the analysis of ecosystem services (ES) delivered by nature-based solutions (NBS). This paper highlights the plethora of models and guidelines for selecting suitable models, structures, and frameworks concerning spatio-temporal changes and biological systems. It views LCA beyond the human visual system and calls attention to a dynamic and viable system model for resilient landscapes. It includes additional functions like data, structure for controlled and autonomous systems, critical systems of acoustic and visual systems, perception, and depth. It has evolved from a model to an interdisciplinary integration framework addressing knowledge and socio-technical gaps.

The research stresses the significance of the flow of material and energy, sustainable management rules, and environmental consequences that don’t exceed marginal benefits, but also talks about governance and social aspects. It goes beyond the assumption of fixed coefficients in production and gives rise to a solution for the knife-edge problems of sustainable and resilient forest-based economies.

Nature-based solutions as innovations to enhance sustainability change in the built environment – A literature review

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Katja Lähtinen[1]
Atte Koskivaara[1]
[1] Natural Resources Institute Finland (Luke)

Abstract: Bio-based circular economy has been presented as a solution to manage global human-induced problems related to climate change and decline in ecosystem carrying capacity. Nature biodiversity provide well-being benefits for humankind through ecosystem services. Abreast with ecosystem services acquired directly in natural environments (e.g., recreation, collection of berries and mushrooms), ecosystem services may also bring benefits in the built infrastructures through innovations in nature-based solutions. For example, as innovations they may substitute the existing technologies in cooling of buildings or purification of air.

Yet, so far, according to a preliminary literature review on the topic, the interconnections between ecosystem services as sources for nature-based solutions in the built environment and business development in the bio-based circular economy have not gained much of attention in academic research. By employing literature on ecosystem services, innovations and business models as an analytical framework, the overall purpose of this study is to provide information on the existing nature-based solutions, which as innovations may substitute the existing technologies and enhance sustainability change in the built environment. The material of the study is based on peer-reviewed studies, which are collected with systematic review approach and snowball methodology. As methods of analysis, qualitative approaches (e.g., thematization) is being used.

To fill in the void in the existing academic knowledge on the theme, the first aim of the study is to provide information on the current knowledge on the nature-based solutions to enhance sustainability change in the built environment. The second aim of the study is to identify the availability of different types of nature-based solutions in the markets. The third aim of the study is to assess the potential of different types of nature-based solutions in the built environment to create sustainable value for different societal stakeholders (e.g., their potential to substitute the existing technologies). The results of the study will provide new insights on the potential and barriers of nature-based solutions to become established product-service offerings in the markets, which could bring sustainable value for multiple societal stakeholders in the built environment.

Promoting forest-based circular bioeconomy business on marginal lands: Climate impacts and financial profitability

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Miika Marttila[1]
Lauri Leppäkoski[1], Jukka Luhas[1], Mirja Mikkilä[2]
[1] Department of Sustainability Science | LUT School of Energy Systems Yliopistonkatu 34 P.O.box 836 53850 LUT University
[2] Department of Forest Sciences | Faculty of Agriculture and Forestry Latokartanonkaari 7 P.O. Box 27 00014 University of Helsinki

Abstract: Forest-based bioeconomy actors are urged to respond to challenges that require climate change mitigation, biodiversity conservation, and the overarching need to understand and promote the overall sustainability of operations. A transition to a more sustainable forest-based bioeconomy necessitates the exploration of resilient and socially just solutions that can simultaneously address these challenges, ensuring environmental integrity, equitable outcomes, and long-term viability for all stakeholders involved. This calls for initiatives that address both climate and financial goals while promoting sustainable rural development.

We present an integrated model for circular bioeconomy business focusing on utilization of marginal land area in Finland. The integrated model comprises short rotation cultivation, wood-based biochar production, and a greenhouse, with integration achieved following circular bioeconomy principles. By leveraging wood and by-product utilization among these actors, we seek to maximize resource efficiency and create a synergistic relationship within the system. To evaluate the integrated model from multiple perspectives, we employ a combination of life cycle assessment and financial analysis, allowing us to gain insights into the design of an integrated circular bioeconomy model that enhances both financial viability and climate change mitigation.

Our model is assessed based on climate impact and financial profitability, comparing the impacts to a non-integrated business-as-usual (BAU) model. The impacts will be addressed from the perspective of each actor separately to understand the equitability of the outcomes too. As such, our research emphasizes the need for more holistic approaches that not only deliver financial viability but also foster social and environmental resilience. This multi-method approach not only contributes to circular bioeconomy strategies for policymakers and offers a scalable case study for practitioners but also generates valuable insights for researchers seeking to explore the potential of other integrated models in the bioeconomy sector.

Regional wood-based construction policy networks: a case of Joensuu, Finland

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Md. Rayhanur Rahman[1]
Ida Wallin[2], Ritva Toivonen[1], Anne Toppinen[1]
[1] Department of Forest Sciences, University of Helsinki, Finland
[2] Department of Urban and Rural Development, Swedish University of Agricultural Sciences, Sweden

Abstract: Previous literature suggests that wood-based construction (WBC) policy networks confronts inadequate alignment and cooperation at a different level. Even though WBC is prominent for climate change mitigation and achieving global sustainability goals, there is limited understanding of the regional WBC policy network, which are however critical for adopting circular forest-based bioeconomy policies in Finland. This study represents an exploratory case on one frontrunner city in terms of carbon neutrality goal by 2025, Joensuu's regarding WBC, underpinning the policy network analysis theory. Since wooden structures in Joensuu are rapidly ascending, the current study aims to examine and better comprehend the characteristics of policy networks. This study accumulated data utilizing online survey from 2021 and used quantitative Social Network Analysis to investigate the policy network. Our results show that the WBC policy network of Joensuu is moderately dense and mainly consists of research, business, and government organizations. Some of the most commonly mentioned organizations are considered the most influential actors based on different centrality measures. Interestingly, a local hub Business Joensuu, although being a non-profit business and regional development organization, holds a central position in the network. Three groups—government and research, business and industry, and a mixed one—predominantly emerged as a result of the higher frequency of communication in the network. Scientific information and knowledge are the most common resources distributed among policy actors, indicating the network is primarily in the research and innovation phase. Considering the range of policy goal preferences, network actors are most concerned with the pressing issue of climate change mitigation measured by reducing carbon emissions from construction material flow. Future research could progress with comparative case analysis with other municipalities utilizing qualitative approach for value networks and their consequences on policy outcomes, and public procurement for securing circular bioeconomy, and forest-based business sustainability transitions.

Seeds of Transformative Forestry? An Exploration of Innovative Business Models Supporting Fast-Growing Broadleaf Forestry Value Chains

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Derek Garfield[1]
Vilis Brukas[1]
[1] The Swedish University of Agricultural Sciences, Southern Swedish Forest Research Centre, Sweden

Abstract: Forests are the focus of heated debates surrounding sustainability transitions in Sweden. Several streams of research on biodiversity and biomass production point to potential benefits for the Swedish bioeconomy through increasing the amount of fast-growing broadleaf species (FGBs) within the landscape. Efforts to transition this social-ecological system towards greater sustainability and resilience entails a complex interaction of anticipation and action by a diverse array of stakeholders. Such a process includes the development of new values, technologies, and networks to produce bio-based goods and services. Innovation and sustainable business models in the forest sector are crucial to this process, but how do actors come to see FBGs as a source of value for their business and what techniques make the realization of these values possible?

In this project, we interact with fifteen innovative firms across the forest sector, from forest owners to producers of value-added goods, in order to gain insight into how economic, social, and ecological values are ascribed to and produced in FGBs and how these are transmitted through the value chain. Through a series of semi-structured interviews, we conduct an analysis based on sustainable business model archetypes to describe rationales and motivations of innovators' selection of FGBs as a source for sustainable business practices. We discuss how these are operationalized into processes of economic production and how they are translated and transformed through network relationships along the value chain.

Our approach builds on theoretical assumptions about change processes within socio-technical systems from a multi-level perspective. We contribute a novel methodology for engaging with systems transitions from an actor perspective that implements qualitative analysis of business models as a means of exploring the complex processes of social learning within emerging niche-networks and gives insight into innovation diffusion and niche accumulation as driving forces for system transitions.

Seizing new business opportunities? Financial competitiveness and value creation in wood construction element value-chain

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Atte Koskivaara[1]
Katja Lähtinen[1], Anne Toppinen[2]
[1] Natural Resources Institute Finland (Luke)
[2] University of Helsinki

Abstract: The outlook of wood construction is widely regarded positive. This is largely reasoned with the various bioeconomy strategies that target to increase the use of wood in construction. Also, regardless of the materials used, industrialization of building processes in an urbanized society has long been considered a requirement for enabling better construction efficiency and competitiveness of construction industry businesses.

However, despite the positive outlook, the use of wood construction components has remained as a promising niche that has not met its full potential. Especially with the strong industrial ties between concrete industry and construction sector, wood construction element (WCE) value-chain needs competitive businesses to enable innovations, implementation of new solutions and to gain larger market share in a strongly competed construction sector. For wood product companies, the shift toward construction sector supply chains has resulted in product and process innovations together with business model development.

To assess the financial competitiveness and value creation in Finnish WCE value-chain, this study uses quantitative methods to analyse and compare annual financial reports of identified wood element manufacturers and sawmills over years 2012-2021. The two industries present important parts of wood construction and therefore their financial status gives indication about competitiveness of the value-chain. The companies in this study are mostly small and medium sized enterprises which were selected to present their corresponding industry. Therefore, for example sawmills with major secondary production were dismissed. This ensures that the companies truly present their part in the value-chain also enabling industry comparison.

The preliminary results suggest that although the financial competitiveness between the industries have been on similar levels, the development over ten-year period has had clear differences. Especially, the solvency and liquidity of sawmills have developed to a more favourable direction compared with WCE manufacturers. On the other hand, value creation reveals clear differences in the industries asset structures. More precisely, the WCE industry is more labour oriented, therefore requiring more employers leading to weaker labour productivity. However, the opposite is true when looking at the value-added by capital employed.

Sustainability as a market opportunity for the cross-laminated timber (CLT) – A literature review on multi-dimensional life-cycle impacts in building

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Katja Lähtinen[1]
Ritva Toivonen[2]
[1] Natural Resources Institute Finland (Luke)
[2] University of Helsinki, Faculty of Agriculture and Forestry, Finland

Abstract: Market diffusion of the wooden multi-storey construction (WMC) through utilization of engineered wood products (EWPs) brings opportunities to enhance transition towards sustainable circular bioeconomy. Especially the technological properties of the cross-laminated timber (CLT) make it a prominent alternative to concrete and steel used in traditional multi-storey building processes. Building with CLT may induce economic, environmental, social and technological (i.e., multi-dimensional) life-cycle benefits for several stakeholders. For instance, society may benefit from increase in carbon sequestration, businesses from industrialization of building processes, and citizens from more pleasant living environments.

The first objective of this study is to identify relevant information and gaps on understanding the multi-dimensional life-cycle sustainability of building with the CLT. The second aim is to compose a framework to evaluate and communicating the sustainability impacts for different stakeholders. The material of the study is composed of peer-reviewed articles published in international academic journals gathered and analyzed with a systematic literature review approach.

The preliminary results show building with the CLT to offer several benefits contributing to the transition towards sustainable circular bioeconomy. However, the existing research information is neither balanced from the perspective multi-dimensional sustainability assessments, nor in relation to different life-cycle phases of building with the CLT. For example, the existing information mostly addresses economic, environmental, and technological impacts of early life-cycle phases (i.e., material manufacturing and building processes), while information on social impacts and later life-cycle phases (i.e., usage of buildings and re-use, recycling, or disposal) is much scarcer. Yet, to develop new circular business models and create new value with customers by building with the CLT, more comprehensive life-cycle sustainability information would be required.

Key words: forest bioeconomy, circular economy, wooden multi-storey construction, innovations, business renewal

Sustainable value creation in the forest-based sector: a literature review

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Katri Rusanen[1]
Teppo Hujala[1], Jouni Pykäläinen[1]
[1] University of Eastern Finland

Abstract: Sustainability transitions such as the transition to circular bioeconomy challenges traditional forest-based sector and the way it operates. Specially, companies within the sector should contribute to climate change mitigation, biodiversity loss and societies' well-being while providing income to the shareholders. So far, the traditional forest-based sector has been considered path-dependent and locked-in to specific technologies which could hamper its ability to renew. Similarly, the sustainability of the sector is increasingly contested in science and public discussions despite the efforts to sustainability reporting and compliance with certifications. Hence, there is a need for new sustainable business models and value creation within the forest-based sector through which companies could increase the well-being of both ecological and social systems by sustaining business activities. So far there is a great amount of research regarding the sector's value creation, and a thorough picture is needed. Thus, the aim of this systematic literature review is to provide profound information on how sustainable value creation is considered in the diverse literature regarding forest-based sector. Our data consists of 73 peer-reviewed articles, book chapters and conference papers. The preliminary results indicate the economic dimension in value creation has dominated the literature whereas environmental and social dimensions have started to emerge within the past ten years. Three-dimensional perspective on sustainable value creation has been studied most in the past five years. The social dimension has been studied the least. Value creation is especially measured and monitored on monetary terms and the value of environmental and social dimensions are considered more on conceptual level. Based on our categorisation, business model, servitization and value chain are the three most used theoretical perspectives to consider value creation. Overall, more empirical research is needed to understand sustainable value creation and realisation of environmental and social values. Hence, a systemic perspective on value creation which includes aspects of social and environmental dimensions should be emphasized in future research. Furthermore, there is a need for inter-disciplinary approach in studying and assessing sustainable value creation and here several different theories, methods and tools could be applied to enhance the sector's contribution to sustainability transitions.

The Industrial Development of Forest Biomass Utilization for Bioenergy to Advance a Circular Forest Bio-economy: A Holistic Analysis Framework

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Xufeng Zhang[1, 2]
Jingxin Wang[2]
[1] School of Economics and Management, Beijing University of Technology, China
[2] School of Natural Resources, West Virginia University, USA

Abstract: Forest biomass utilization for bioenergy has been a critical part of the development of the circular forest bio-economy. A holistic analysis framework including forest-biomass facility siting, forest biomass supply chain optimization, techno-economic analysis and life cycle assessment of forest biomass utilization for bioenergy, was developed to aid in the industrial development of forest biomass utilization for bioenergy over the eastern United States. The results indicated that, 30 industrial sites were identified as the top priority sites for forest biomass-based bioenergy industry development in the high-suitable areas which accounted for 24.26% of the total area of the eastern U.S. The delivered cost of forest biomass to these identified sites ranges from $41.90 to $50.17 per dry Mg with an average of $44.77 per dry Mg, while the stumpage, harvesting, storage, preprocessing, and transportation accounted for 34.66%, 45.54%, 0.0004%, 5.58%, and 14.21% of the total delivered cost, respectively. Furthermore, for the forest biomass utilization for four alternative value-added bioenergy products in the eastern US, the minimum selling price is $177.82/Mg for pellet fuel, $110.24/MWh for biopower, $1059.4/Mg for biochar, and $4.98/Gallon for aviation fuel. The life-cycle Greenhouse Gas emissions are 149.80 kg CO_2 eq./Mg pellet fuel, 52.22 kg CO_2 eq./MWh biopower, 792.12 kg CO_2 eq./Mg biochar, and 2.13 kg CO_2 eq./Gallon aviation fuel, respectively. Considering the uncertainties, the 95% confidence intervals of minimum selling prices range from $164.77 to $190.97 /Mg for pellet fuel with an 81.85% probability to be profitable, from $100.20 to $120.21 /MWh for biopower with a 49.38% probability to be profitable, from $1000.91 to $1109.25/Mg for biochar with a 79.51% probability to be profitable, from $4.86 to $5.54/Gallon for aviation fuel with an 0.03% probability to be profitable. The minimum selling prices of pellet fuel and biochar are much less affected by market changes than those of biopower and aviation fuel. However, the production of biopower and aviation fuel has lower carbon intensities than that of pellet fuel and biochar. This study could comprehensively inform the decision-makers regarding the industrial development of forest biomass utilization for bioenergy to advance a circular forest bio-economy in the eastern U.S.

Tracking environmental performance using life-cycle assessment of hardwood product production

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Richard Bergman[1, 2]
Scott Bowe[2], Matthew Bumgardner[3], Poonam Khatri[1]
[1] U.S. Forest Service, Forest Products Laboratory, United States
[2] Forest and Wildlife Ecology, University of Wisconsin, United States
[3] U.S. Forest Service, Northern Research Station, United States

Abstract: In recent years, life cycle assessment (LCA) has become one of the most effective tools available for assessing and reducing the environmental impacts of products. This study used LCA to track the environmental performance of hardwood products produced in the U.S. The hardwood product sector in the United States has undergone major changes in the last two decades. These changes have negatively and positively affected the utilization of hardwoods. U.S. hardwood production has declined substantially because of both imported finished wood and nonwood products along with the cost competitiveness of domestic softwood species as replacement for industrial products like pallets. Contrarily, technology changes for hardwood product manufacturing have mostly improved the environmental footprint of these products. These environmental improvements have been quantified and tracked for two hardwood products (plane dried lumber and industry average pallets) using LCA. For cradle-to-gate production of planed dry hardwood lumber in the northeastern/north central and southeastern U.S., thermal energy consumption decreased from 5,800 to 3,876 and from 4,678 to 2,733 MJ/m^3, respectively while global warming (GW) impact decreased from 187 to 166 but unexpectedly increased from 134 to 209 kg CO_2e/m^3, respectively. For wood pallets, cradle-to-grave GW impact for new pallet production was 4.88 kg CO_2e per industry-average pallet compared to the value of 0.355 kg CO_2e for an industry-average repaired/remanufactured pallet. The reduction of GW impact for repairing wood pallets underlies a huge reduction of embodied carbon emissions which in part comes from lower requirements of raw materials such as roundwood while keeping current wood in circulation to the best extent possible.

Wooden elements for beauty, utility, and low carbon building stock – Co-creating sustainable innovation with four case municipalities of Finland

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Anne Viljanen[1]
Eliisa Kylkilahti[1], Vesa Kanninen[1], Katja Lähtinen[2], Liina Häyrinen[2], Juhani Marttila[2], Charlotta Harju[2], Mikko Kurttila[2], Atte Koskivaara[2], Anne Toppinen[1]
[1] University of Helsinki
[2] Natural Resouces Institute Finland

Abstract: Solutions nurturing low carbon building stock are urgently needed in the municipalities. Novel innovations emerge with wooden prefabricated elements, which offer new opportunities for a versatile, nature-based municipality landscapes to both new wooden multistory construction and retrofitting the existing multistory buildings. These new solutions with wood and with their high ambition level can have synergies with both saving natural resources and circular economy.

To co-create such transformative low carbon solutions, four case municipalities in Finland were involved in development processes. These included a municipality workshop series with altogether seven municipality workshops organized between 2021-2023. Simultaneously, this workshop process was enriched by expert suburban walks in which the local actors provided practical and contextual knowledge on developments made and planned with wooden elements. Research method is based on service design approach, innovation studies and a dash of futures studies. The study builds on innovation theories and human-centered, transformative service-design theories. The multi-actor co-design process involves researchers, practitioners and other stakeholders for a dual suburban/rural approach and seeks for holistic, feasible and acceptable carbon-wise housing solutions in case municipalities. The data consists of workshops and interrelated city walk discussions, i.e., documented in transcribes, posters, notes, and photos as well as background materials, such as consumer interviews, diaries, and municipality strategies.

Preliminary results indicate that instead of creating a wide pool of new service ideas, the process leads the way for ideas and solutions to intertwine supporting the systemic innovation uptake. When bringing the experimentations to practice, few pathways were favored. Some municipalities envisioned pathways relating to the reasonable retrofitting practices, which have synergies with novel innovations with wooden retrofits. One case municipality was keen on promoting intertwined information actor networks pathway and took steps to linking municipality land use zoning actors. Results can be used for more in-depth service development to foster sustainability among municipalities in Finland and beyond.

Woodshed Mapping: Assessing Feedstock Availability, Economic and Environmental Impacts, and Attracting Investment and Identifying Locations

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Raju Pokharel[1]
Emily Huff[1]
[1] Department of Forestry, Michigan State University

Abstract: Managers and decision makers are often tasked with accomplishing large landscape level goals with limited resources. While policy mechanisms like tax incentives and cost-sharing can accomplish landscape scale goals, it is also important for managers, decision makers, and the landowners themselves to understand market coverage and competitiveness for the harvested wood products available on the landscape. This is simply because they don't create revenue to help offset total project costs. The woodshed maps demonstrate where market 'hotspots' occur, highlights areas best suited to invest in, from both an industry, forestry professional, and policy perspective, and which wood products industries are most likely to succeed. It focuses on wood products and categorizes them into three main types: sawlogs, pulpwood, and biomass, and can be used for feedstock assessment, evaluating economic and environmental impacts, and optimizing the supply chain to support decision-making for management, investment, and policy formulation. Woodshed allows users to generate maps for different aspects of the market. A demonstration of the woodshed mapping tool and various applications will be highlighted. Current research application of woodshed maps includes feedstock assessment and economic impacts of increased biopower, biochar, and mass timber production in the Great Lake States. This approach also estimates the available wood in each logger's basket (service area), assesses competition and analyzes the logging sector. Finally, this approach will also be used to evaluate interstate forest product dependency and carbon leakage with varying policies between the adjoining states.

"Living with nature as the nearest neighbor" – Values related to nature in Finnish citizens' housing expectations

T2.14 Innovations and new business models towards more sustainable circular forest bio-economy, especially including life-cycle and techno-economic assessments

Charlotta Harju[1]
Liina Häyrinen[1], Katja Lähtinen[1], Anne Toppinen[2]
[1] Natural Resources Institute Finland (Luke)
[2] University of Helsinki

Abstract: Human-nature connections in the built environment have multiple benefits related to physical health and mental well-being, and proximity to nature has started to become more important also in defining citizens' housing preferences. People value nature in diverse ways, and in forest rich and scarcely populated Finland, nature has also always been a significant part of the citizens' national identity. Yet, there is still limited information on the values Finnish citizens attach to nature in relation to other housing attributes. This study investigates the conceptualization and the role of nature in citizens' housing expectations in Finland. The data were collected in 2022 with an online questionnaire sent to randomly sampled 10,000 people aged 18–80 living in Finland. In this study, an open-ended question related to sub-section of data on citizens' wishes and hopes for housing with 382 responses was utilized and analyzed with qualitative methods (e.g., thematization, content analysis).

The preliminary results show that having a home near nature is important to half of the respondents. They especially emphasize living near forests, lakes, and the coast. Furthermore, citizens attach different values to nature in their housing expectations, including intrinsic, instrumental, and relational values. Also, other types of values (e.g., emotional, social) are recognized. The results provide new information on the meaning of nature in Finnish citizens' housing expectations. Recognizing the importance and value of nature in housing also provides opportunities for new innovations, such as developing different nature-based solutions to substitute the existing technologies, e.g., in living milieus.

T2.15 Innovations to support sustainability in non-timber forest products value chains

"Inov'Açaí" - Co-construction of knowledge, Innovations and Public Policies for the Sustainability of Community Production in the Amazon Bioeconomy.

T2.15 Innovations to support sustainability in non-timber forest products value chains

Eliane Superti[1]

[4] Brazilian Agricultural Research Corporation (EMBRAPA)

Abstract: The açaí value chain in the Brazilian Amazon brings together a wide variety of local, national and global markets, articulating research and development institutions,gatherer families, informal entrepreneurs, artisanal and industrial entrepreneurs, around production and commercialization. Since 2017, açaí is the product with the highest production value in Brazil, in the subgroup of non-wood vegetable extraction foods. This article presents the research agenda and results of the "Inov'açaí" research group, organized on two fronts; political and technological. The studies focused on the community-based açaí chain in the Pará municipalities of Abaetetuba and Santa Luzia do Pará and, in the State of Amapá, in the municipality of Mazagão and in the Bailique Archipelago. The first front of analysis addressed public policies and international cooperation while the second collaboratively proposed intervention in production and commercialization processes through the use of technologies and social innovations. The objective was to promote the co-construction and transfer of knowledge and technologies between the public sector, international organizations and civil society, producers and researchers for the elaboration, execution and diffusion of innovations and strategies of nature-society interactions for a sustainable and inclusive development in the chain. The guiding questions were: What strategies, with a strong positive impact on the production, processing and community-based commercialization of açaí, have producers, their organizations and local governments been developing and how do international cooperation agreements and the implementation of the SDGs support them? How, based on the demands of cooperatives and community-based agroindustry, can technologies make production visible, add value to the product and maximize the use of waste? The actions on each front were organized into specific tasks based on the methodological approach of action research and quali-quanti techniques, in addition to laboratory research. The results already achieved were: mapping of action strategies within the scope of public policies - coordination, execution and bottlenecks - as well as in relation to international cooperation projects; identification and application of technologies and social innovations linked to the study of the forest collection and the productive capacity of the açai groves, as well as bio(technologies) for the reuse of açaí seeds.

25 years of non-timber forest product value chain and livelihoods interventions: Experiences, impacts and lessons from Cameroon

T2.15 Innovations to support sustainability in non-timber forest products value chains

Verina Ingram[1]
Rene Kaam[1, 2], Louis Ndumbe[3], Abdon Awono[4], Divine Tita Foundjem[4], Michele Danleu[5]

[2] INBAR
[3] University of Buea
[4] CIFOR-ICRAF
[5] GIZ

Abstract: Cameroon represents "Africa in miniature" with high levels of forest cover but increasing rates of deforestation, and variable but common use of forest products for multiple subsistence and commercial uses. Despite the national development situation moving from low to medium level development status, rural poverty remains high, particularly among marginalized societal and ethnic groups, and is associated with forest product use, dependence, commercialisation and social-ecological resilience.

Over 25 years of development, conservation and research interventions have sought to support "sustainable" commercialization, value chain development, alternative livelihoods, cultivation and domestication of non-timber forest products (NTFPs)in Cameroon. Over this period, narratives on NTFPs, value chain development, rural development, forest-people relationships, justifications of interventions and impact logics, measurements of impacts using top-down or science based-knowledge - have changed little. Indicators of the effectiveness of interventions, such as changes in prices, profits, value adding, harvesting practices, cultivation rates, resource availability, empowerment, deforestation and conservation have been mixed. This raises questions of what have been the legacy and impacts of such interventions in the long term? What has changed, for who and why? What's worked and not worked? What lessons can be learnt from evaluating successes and failures of intervention concerning NTFPs on livelihoods and ecosystems – looking at the (un)expected outcomes and impacts? and, what do these lessons imply for future policies, projects, programs and interventions?

This article examines the evidence by taking a long-term view identifying 10 projects/programs, and then involving the beneficiaries and implementers in evaluating long-term socio-economic, political (governance and policy) and ecological outcomes and impacts of these interventions. The discussion is conceptualized in terms of Sustainable Livelihoods Approach and Social-Ecological systems thinking (i.e. impacts on both livelihoods and -ecosystems of the landscapes where these products originate from) and taking a value chain approach to look at direct (and indirect) actors in NTFP value chains and interventions. Implications for scientific research, local knowledge and practices, and policy will be presented.

Boosting Forest Value with Non-Timber Forest Products and Extended Management: An Examination of South Korea's Practices

T2.15 Innovations to support sustainability in non-timber forest products value chains

Gihyun Park[1]
Gayoung Won[1], Eunjeong An[1], Hyungsik Jung[1], Hee Han[1, 2]
[1] Department of Agriculture, Forestry and Bioresources, Seoul National University, Republic of Korea
[2] Research Institute of Agriculture and Life Science, Seoul National University, Republic of Korea

Abstract: Despite South Korea's commendable green transition, the limitation of its forestry development lies in the low profitability of timber-focused practices. It's clear from Net Present Value (NPV) and Land Expectation Value (LEV) analyses that exclusive reliance on timber yields inadequate returns. However, the incorporation of the 2022 direct payment for forestry system and the exploration of non-timber forest products have shown significant potential to enhance forestry income. The direct payment system alone amplified the income derived from Japanese larch and Korean pine by five and nine times, respectively. Moreover, the inclusion of non-timber forest products lengthens the cultivation period, yielding a substantial increase in overall revenue. When cut at the optimal age of 70 years, the income from timber production of Japanese larch and Korean pine multiplies 40 times and 12 times, respectively. In addition, extended forest management periods amplify the public value of forests. By taking into account aspects such as direct payments, non-timber products, public value, and optimal cutting age, the economic value of Japanese larch and Korean pine forests skyrockets 48-fold and 29-fold, respectively. Overall, moving away from a strictly timber-oriented approach to a diversified production model, in conjunction with lengthier forest management durations, considerably augments profitability and enriches the non-market values of forests.

BOOSTING THE SUSTAINABILITY OF THE MONTESINHO NATURAL PARK OAK FOREST THROUGH INNOVATION AND VALORIZATION OF ACORN AND HONEYDEW

T2.15 Innovations to support sustainability in non-timber forest products value chains

Joana Amaral Paulo[1]
Ana Tomás[1], Antero Sousa[2], Ines Bento[1], Margarida Rios[1], Margarida Tomé[1], Susana Barreiro[1]
[1] Centro de Estudos Florestais / Instituto Superior de Agronomia
[2] Bota um cibo

Abstract: In the Montesinho Natural Park one of the most abundant and relevant types of habitat are oak forests dominated by Pyrenean oak. Current knowledge concerning this species mainly focuses tree growth, while there is a clear lack of research regarding acorn, a product with growing market demand for the production of flour and derivative products. Topics of interest cover yield, biology, edaphoclimatic drivers, and acorn abortion, the latest a limiting factor for both forest natural regeneration and development of new products. The Acorndew project aims at minimizing these knowledge gaps.

This work summarizes results obtained from the data collected between 2021 and 2023 in four monitoring sites (altitude varying from 600m to 1000m). The surrounding area was subject to forest and acorn inventory, showing a quite dense forest with 527 to 5858 trees.ha^{-1} (average 2905). The following research topics were addressed: i) acorn yield, availability and abortion rates quantification; ii) relationship between altitude, forest composition, forest structure and light availability and the variables in i). Light availability was characterized at tree level using the Clark index, which was then used to compute weighted stand variables.

Results show a large inter-annual variability of acorn availability, with 2021 (severe drought conditions) showing lower values compared to 2023. Significant inter-site variability was also observed: 0 kg.ha^{-1} to 896 kg.ha^{-1} (average 154 kg.ha^{-1}) considering only fully developed acorns in 2022, and 0 kg.ha^{-1} to 1230 kg.ha^{-1} (average 225 kg.ha^{-1}) considering all sampled acorns. The proportion of acorn abortion was found to vary between 74% and 90% out of the total number of sampled acorns, with phenology monitoring indicating abortion mainly occurred from mid-July to mid-August. Stand characteristics showed a weak correlation with the dependent variables considered, in particular due to the presence of three outliers in the data set. The correlation with these variables is higher considering only the acorns sampled in stages prior to full development, raising the hypothesis of mature acorn predation.

Future work focus on the study of the interaction between stand variables and light availability, and on the identification of pathogens possibly involved in the high percentage of acorn abortions.

Development of a science-based system of allocating Almaciga resin in the Philippines

T2.15 Innovations to support sustainability in non-timber forest products value chains

ANALYN CODILAN[1]
Lawrence Adolph Amada[1], John Louie Educado[1], Marlo Caña[2], Leonardo Barua[2], Angelito Cinco[3], Canesio Predo[1], Rogelio II Andrada[1], Kharmina Paola Evangelista[1], Vanessa Palma-Torres[1], Rose Jane Peras[4], Margaret Calderon[1]
[1] Institute of Renewable Natural Resources, College of Forestry and Natural Resources, University of the Philippines Los Baños, College, Laguna, Philippines
[2] Makiling Center for Mountain Ecosystems, College of Forestry and Natural Resources, University of the Philippines Los Baños, College, Laguna, Philippines
[3] Land Classification Division, Resource Data Analysis Branch, National Mapping and Resource Information Authority, Lawton Avenue, Fort Bonifacio, Taguig City, Metro Manila, Philippines
[4] Department of Social Forestry and Forest Governance, College of Forestry and Natural Resources, University of the Philippines Los Baños, College, Laguna, Philippines

Abstract: Harvesting of almaciga resin is a major source of livelihood for indigenous peoples in the Philippines. A permit is required prior to harvesting and it indicates the annual harvestable volume, which is based on an inventory and computation using operable area and average number of tappable trees per ha. Some tappers relayed that they harvest more resin than their annual allowable volume, suggesting an oversupply of resin. However, there is no baseline study that could support whether these claims are true. With these, the study investigated the tapping practices and resin yield of three (3) groups of tappers in Southern and Northern Palawan and Davao Oriental. A total of 281 trees were measured for location, diameter, height, crown width and frequency of harvest (3 and 6 months) and were subjected to a year-long monitoring of resin yield. For monitoring, local tappers were trained on how to properly weigh, record, document and report their resin harvests and local coordinators verify the reports. The tapping practices of the three groups were also documented and compared. Results of the study shows that tree diameter and frequency of tapping affect resin yield. In Davao Oriental, the average tree diameter is 37 cm with an average tree height of 16 m, growing at an elevation of 200 to 600 masl. In Northern Palawan, the elevation is between 400 to 700 masl and the average tree diameter and height is 56 cm and 20 m, respectively. Bigger trees can be found in Southern Palawan with a mean diameter of 91 cm and height of 19 m and are found in an elevation of 700 to 1000 masl. Resin yield for 3-months frequency harvest range from 0.72 to 4.58 kg per tree depending on the location and diameter size. On the other hand, resin yield for trees harvested every six months range from 1.99 to 8.92 kg per tree. These results could serve as baseline in determining the actual resin yield of Almaciga trees and will serve as significant input in developing a science-based determination of annual harvestable volume towards the sustainable production of Almaciga resin.

Forest ecosystem services conservation focusing on social-ecological dynamics of non-timber forest products in Japanese horse chestnut populations

T2.15 Innovations to support sustainability in non-timber forest products value chains

YOSHIHIKO IIDA[1]

[1] University of Tsukuba, Japan

Abstract: In order to develop conservation strategies for forest ecosystem services, this research aims to evaluate the conservation value of tree populations from an interdisciplinary perspective, focusing on the social-ecological dynamics of non-timber forest products (NTFPs) in Japanese horse chestnut populations (*Aesculus turbinata* Blume). First, based on the hypothesis that naturally variable forest ecosystem services are culturally and socially stabilized through the maintenance of populations, I systematize the sustainable conservation mechanisms of NTFPs and the local knowledge for conservation that has been newly developed by the private sector in recent years. Second, in order to quantitatively understand the conservation effects of the populations, I compare and evaluate the ecological-economical effects of harvesting or utilization of non-timber forest products, such as nuts gathering and honey production, with those of harvesting and utilization of woody materials such as wood craft and furniture. Third, to model and generalize conservation strategies for forest ecosystem services, I collect case studies of the social-ecological dynamics of Japanese horse chestnut populations on a national scale and conduct a comparative analysis of the commonalities and differences in population conservation.

Impact of commercialization, a serious drops in NTFP production from Natural Forest: Proposed Innovative Mechanism to reconcile the sustainability

T2.15 Innovations to support sustainability in non-timber forest products value chains

PRODYUT BHATTACHARYA[1]
Sanjoy Patnaik[2]
[1] University School of Environment Management ,GGS Indraprastha University, New Delhi-110078 India
[2] Freelance Consultant

Abstract: The contribution of non-timber forest products is highly precious for rural people.NTFP resources are considered as a pathway to achieve bio-economy and are much more relevant for developing countries. Our natural forests have some limited ability to supply products that are used for the supply of medicine, food, cosmetics, and various other purposes. In the South Asian region where population pressure is very high and rural poverty is rampant, the NTFP-based enterprise is considered as a popular model for rural livelihood development.

But in a recent NTFP-based livelihood generation project in India, the ground reality was different, the ecological security of the forest is under serious threat due to over and untimely harvesting of NTFPs, low regeneration of tree species, forest fire, weeds infestation,climate vulnerability, and limited rainfall. In the last five years, there is a reasonably big project in the name of the '*Van-Dhan'* (forest wealth) innovative scheme introduced by the central government in 20 states with a proposed layout of 200 billion rupees business in rural areas based on NTFP collection, processing and value addition. The creation of the new local institution of 1205 new*'Van Dhan Vikash Kendra* (NTFP development center), 18075 self-help group (SHG) with 3,61,500 members in the collection and processing network dealing with 55 products.

The current exploratory survey in 34 sites in 9 states of India, shows that such commercialization plan of NTFPs cannot be successful in the long run as there is no backup support for explicit resource base management. There is a dichotomy in the approach, only the maximum collection, processing, and value addition were focused on assuring minimum support price (MSP) to collectors. Such a forest-based scheme has no future, as the NTFP supply has reduced from most forest divisions(about 60-200%). The organic link between conservation and sustainable utilization is difficult due to a reduction in the volume of supply and one-sided planning. To address the above challenges, it is suggested that enrichment planting, assisted natural regeneration, rotational harvesting, creating the people's protected area (PPA) as well as application of certification may be useful for the sustainable flow of natural products.

Innovating in cone mechanical harvesting to boost Pinus pinea cropping

T2.15 Innovations to support sustainability in non-timber forest products value chains

Claudia Delard[1]
Veronica Loewe-Muñoz[1, 2], Ian Homer[3], Aldo Salinas[1], Rodrigo del Rio[2], Mónica Balzarini[4, 5]

[5] Universidad Nacional de Córdoba, Argentina

Abstract: Stone pine (*Pinus pinea* L.) is a Mediterranean species that produces the most expensive nut worldwide. In Chile, the species cropping is considered an emergent business, with over 4,000 hectares planted for pine nut production in the last years. In this country, stone pine trees show vigorous growth and high cone productivity, being relevant advancing in the efficiency of cone harvesting under different site conditions and plantation characteristics. Three harvesting trials were performed to evaluate mechanical and manual harvesting in one traditional 46-year-old plantation and in two grafted orchards (12 and 13 year-old) located in central Chile. Mechanical harvesting was run with an Orchard-Rite shaker (US) considering different levels of pump flow rates (38% to 65%) to avoid harvesting 1- and 2-year-old conelets developing simultaneously on the tree; and one and two vibrations of 3 second duration each; and constant 2,200 rpm. Manual harvesting was performed by a long- experienced Spanish professionist with poles from the ground and/or by climbing the trees. Tree size was measured before harvesting. Recorded variables included number of harvested 1-, 2- and 3-year-old cones, 3-year-old cones remaining on the trees (non-harvested), partial and total time of harvest per tree, and damage to branches, trunk and soil. In the traditional plantation, mechanical harvesting was significantly faster than the manual one; the percentage of mature harvested cones ranged from 60% to 100% of total cones. However, mechanical harvest is not feasible in all site conditions, including sandy soils. In grafted orchards, mechanical harvesting, a worldwide innovation, showed a good performance (70% to 100% of total mature cones harvested), without damaging the trees. Manual harvesting allows a complete tree harvesting (98% to 100% of total mature cones harvested). The obtained results contribute to the stone pine cropping intensification.

Reimagining Mayan Forest Gardens: Linking forest conservation to sustainable livelihoods through 'analog' forestry systems in the Yucatán of Mexico

T2.15 Innovations to support sustainability in non-timber forest products value chains

David W. MacFarlane[1]
J. Javier G. Quezada-Euán[2], Jorge A. Herrera-Silveira[3], Travis Gordon[4]

[4] Institute for Global Health, Michigan State University East Lansing, Michigan, USA

Abstract: The 10 million ha Mayan Forest ecosystem in the Yucatán of México is the second largest area of tropical forests in the Americas and home to Mesoamerica's largest indigenous population, sustaining thousands of indigenous families and farming communities. The Yucatán Peninsula is losing forest cover every year due expansion of intensive agriculture and coastal development, threatening biodiversity and traditional livelihoods. To address forest loss, government officials have set ambitious goals to achieve net zero deforestation, but innovative, science-based solutions are needed to address competing needs for forest conservation, sustainable agriculture and concerns about impacts on indigenous farming. Here, we describe new research on innovative 'analog' forest systems, which aim to strengthen rural communities, both socially and economically, by emphasizing conservation of forests through sustainable cultivation of high value, organic forest crops. These experimental analog forest systems are modeled after Mayan "forest gardens" with an initial focus on cultivating organic vanilla in natural forests and forest honey production in coastal mangrove systems. In both systems, pollination and honey production are derived from indigenous, forest-dependent bee species to investigate the potential to restore connections between forests, bees and human livelihoods. The experimental emphasizes the importance of community engagement and participation at each stage of the research process. Here, the community partners are women's groups interested in conservation, sustainable livelihoods, and equitable benefit sharing within communities. The possibility of communities obtaining additional income from forest carbon credits associated with forest gardens is also discussed.

The bark side of tree utilization

T2.15 Innovations to support sustainability in non-timber forest products value chains

Ferréol Berendt[1]
Charlett Wenig[2], Johanna Hehemeyer-Cürten[2], Michaela Eder[2], Tobias Cremer[1]
[1] Eberswalde University for Sustainable Development, Department of Forest Utilization and Timber Markets, Eberswalde, Germany
[2] Max Planck Institute of Colloids and Interfaces, Department of Biomaterials, Potsdam, Germany

Abstract: Bark protects trees against insects, browsing by game, forest fire and mechanical damage. In addition to its protective function, bark transports nutrients, stores carbon and reduces water evaporation and hence fulfils multiple functions.

During the processing of timber in wood industries, up to 170 million m³ of bark is produced annually worldwide and is considered a by-product or waste product: mostly for energy generation through incineration or as bark mulch. Due to these large quantities and the simultaneously low added value as well as its multifunctionality, bark is seen as a material with high potential to increase the raw material efficiency within a cascading utilisation. For this purpose, in-depth knowledge of the accumulating quantities, the composition and structure of bark and innovative utilisation options of bark from different tree species is indispensable.

Therefore, several studies on bark of native tree species (especially pine, oak, larch) were carried out. The investigations focused on 1) bark thickness, structure and bark volume, 2) carbon storage in bark, 3) processing techniques including weaving and flexibilisation of bark for design applications and 4) development of options for the production of binder-less bark panels.

The results have shown that 1) the bark thickness in pine pulpwood is very thin due to the high proportion of logs with mirror bark and 2) the carbon fraction in pine bark decreases with increasing tree height. Furthermore, 3) textile/ (design) applications, such as a jacket made of bark, were designed and 4) new approaches for the production of binder-free bark panels from bark pieces of different native tree species were conceived.

Both the resource availability of bark and the innovative possibilities for utilisation (in connection with long-term material utilisation and corresponding carbon sequestration) show the high potential of tree bark, which should be researched in more detail and thus exploited especially in times of a strongly growing bioeconomy.

The miracle mix of Moringa: Status of Moringa research and development in Malawi

T2.15 Innovations to support sustainability in non-timber forest products value chains

Willie Sagona[1]
Paxie Chirwa[2], Samson Sajidu[3]
[1] Forestry Research Institute of Malawi
[2] University of Pretoria
[3] University of Malawi, Chancellor College

Abstract: *Moringa oleifera* and *Moringa stenopetala* are grown in Malawi in different agro-ecological zones. *Moringa oleifera* is the most widely cultivated pan-tropical species of a monogeneric family, the Moringaceae, regarded as versatile because of its ability to provide edible food, oil and purify water for local communities. The tree is sometimes referred to as a "Miracle Tree" because of nutritional and pharmacological properties. Despite its great importance, *M. oleifera* is still not well exploited and hence considered as underutilized in Malawi. Natural distribution of *M. oleifera* in Malawi and elsewhere reveals rich variability in fruit types of semi-domesticated populations. Distribution pattern among others has had an influence on domestication trends in Malawi in terms of diversity. Despite the great variability of *M. oleifera*, there is no properly established genebank or database with either cultivated or spontaneous accessions in Malawi and elsewhere. Absence of elite varieties adapted to local conditions and use of seeds obtained through open pollination from planted plants are some of the major factors that limit productivity. In Malawi, there is limited knowledge of available genetic diversity present in Moringa species to warrant serious breeding programmes for meaningful scaling up. Furthermore, commercialization of *Moringa* products in Malawi is still very informal making it difficult to get reliable information of production volumes and prices thereby making it unattractive for scaling up. There is however a growing interest to upscale *Moringa* species distribution nationwide. *Moringa oleifera* is fairly distributed in specific agro-ecological zones of Malawi and easily adapted to new sites. This offers an opportunity to be planted much more widely by introducing the species within the existing farming systems as the species can also survive in degraded soils. As such, increased use of the species could have a positive impact on the nutritional and health status of people of Malawi.

T2.16 Innovative technologies for the development of bamboo and rattan products

A Multi-Faceted Net Zero Biorefinery for Production of Bamboo Pulp

T2.16 Innovative technologies for the development of bamboo and rattan products

Troy Wiseman[1]
David Winsness[2], Camille Rebelo[1]
[1] EcoPlanet Bamboo
[2] Comstock Fuels

Abstract: Wood pulping technologies, invented in the1800s for paper and materials production, continue to be utilized today. These methods involve chemicals to dissolve a majority of the hemicellulose and lignin present in wood, generating the desired pulp product. While chemicals used in the process can be recycled, hemicellulose and lignin are typically burned during the chemical recovery phase.

Traditionally, there has been limited value in recovering the hemicellulose and lignin, making burning them the most practical and profitable approach. However, increasing energy prices and a growing demand for carbon-neutral fuels such as sustainable aviation fuels (SAF), are currently making the recovery and conversion of these materials highly desirable.

As market dynamics shift and interest in establishing biorefineries in developing nations increases, technologies have evolved to prioritize pulp production and the recovery of hemicellulose and lignin. This shift, accompanied by the transition from laboratory-scale experiments to commercially viable operations, necessitates multidisciplinary partnerships capable of maximizing value and streamlining complex supply chains.

EcoPlanet Bamboo, in collaboration with technology provider Comstock Fuels, is spearheading the development of bamboo-based biorefineries in Latin America, Africa, and Asia. EcoPlanet has established a resource base of climate-positive bamboo on degraded lands. Comstock's patented biorefinery technology leverages purpose-grown bamboo biomass to produce pure bamboo pulp and BioleumTM, a converted mixture of hemicellulose and lignin used as feedstocks for SAF production. The bamboo pulp has demonstrated properties comparable to the highest grade of Northern Bleached Softwood Kraft pulp, while BioleumTM can serve as a substitute for crude oil in refineries, enabling the production of carbon-neutral or even negative-emission transportation fuels.

The production of approximately 100 gallons of carbon-neutral transportation fuels is anticipated per ton of bamboo pulp (production yields are currently undergoing testing and confirmation). This increases revenue for the pulping operation and contributes significantly to advancing the journey towards a carbon-neutral economy.

This presentation will delve into the technology itself, outlining the plans for its implementation across our expanding portfolio of sustainable bamboo resources. Moreover, it will address the challenges that have been overcome to establish a platform capable of scaling and replicating this unique multidisciplinary partnership.

A novel mechanical kiln for bamboo molded charcoals manufacturing

T2.16 Innovative technologies for the development of bamboo and rattan products

Zhijia Liu[1]
[1] International Centre for Bamboo and Rattan

Abstract: To upgrade the industrial techniques of bamboo molded charcoals (BMCs), a novel mechanical kiln was designed with the new heating method, high pyrolysis efficiency, and reuse of self-release gaseous. In this research, BMC-1 and BMC-3 were produced by novel mechanical kiln with pyrolysis temperature 650 °C and 389°C. BMC-2 was produced by brick kiln with pyrolysis temperature 680 °C. Proximate analysis, kinetic parameters, Cone Calorimetry, and X-ray fluorescence were used to investigate the energy properties and ash fusion characteristics of BMCs. It was concluded that the efficiency of novel mechanical kiln was increased by 320.44%, compared with brick kiln. The physical and mechanical performs of BMCs were improved by novel mechanical kiln. The ash, fixed carbon and moisture content of BMC-1 and BMC-3 met the requirements of EN 1860-2:2005. All BMCs had a stable combustion process, but BMC-1 and BMC-3 owned a higher reactivity and a lower mean yield of CO (1.78 kg/kg) and CO_2 (15.12 kg/kg). In addition, the novel mechanical kiln increased the content of SiO_2 and reduced the content of alkali metal in ash samples, resulting in variation of fusion characteristics and reducing the risk of fouling. These findings will be helpful to provide a scientific guidance to optimize the manufacturing process of BMCs.

Advancements in Bamboo Products as Sustainable Substitutes for Plastic

T2.16 Innovative technologies for the development of bamboo and rattan products

Changhua Fang[1]
Yuting Yang[1], Menghong Jiang[1], Yu Luan[1]
[1] International Centre for Bamboo and Rattan, Beijing, China

Abstract: The alarming environmental issues caused by plastic pollution have garnered global attention. From 1950 to 2018, about 6.3 billion tons of plastics have been produced worldwide, 9% and 12% of which have been recycled and incinerated, respectively. More than 70% of the plastic products is accumulating in landfills or sloughing off in the natural environment as litter, at some point, much of it ends up in the oceans. By 2050, oceans might contain more plastics than fish in terms of weight. The accumulation of plastic waste in landfills and natural environments, including oceans, has reached unprecedented levels, highlighting the urgent need for sustainable alternatives. Bamboo, with its versatile properties and numerous applications, has emerged as a promising substitute for plastic products. This study provides a comprehensive overview of the recent developments in bamboo products as substitutes for plastic items. Various sectors, including industrial cooling towers, soil reinforcement, automotive parts, composite pipes, electrical appliances, sports equipment, medical products, and daily necessities, have witnessed significant progress in utilizing bamboo as a sustainable alternative. The wide range of bamboo-based products explored in this study has the potential to alleviate plastic pollution and contribute to a more sustainable future.

Analysis of International Trade Status and Potential of the Products Concerning "Bamboo as a Substitute for Plastic"

T2.16 Innovative technologies for the development of bamboo and rattan products

Gangqiang Yin[1]

[1] International Center for Bamboo and Rattan

Abstract: The global bamboo and rattan industry has developed rapidly over the past 20 years, with more and more bamboo and rattan products and application functions. As a kind of non-scarce environmental resources, the global flow of bamboo and rattan products is a good carrier for countries to balance economic benefits and environmental effects. The soil and Marine environment have been seriously polluted, and posed a serious threat to the earth ecology and human health due to the large use of disposable plastic products. The Chinese government and the International Bamboo and Rattan Organization jointly launched "The Bamboo as a Substitute for Plastics Initiative", which is a major strategic measure to deal with the global plastic crisis. The international trade of products concerning "Bamboo as a Substitute for Plastic" is an important impetus for this initiative. Products concerning "Bamboo as a Substitute for Plastic" in the international trade market have a new opportunity with great potential for development.

This study presents the current global situation of products concerning "Bamboo as a Substitute for Plastic" through the visual analysis of the data from the United Nations commodity trade database, including trade scale, trade market and trade structure. Moreover, this study compares and analyzes the global international trade of plastic products, and puts forward the international market opportunities. The results show that: the current global quantifiable trade value of products concerning "Bamboo as a Substitute for Plastic" has been growing rapidly, showing a strong international market demand. Asia, Europe and North America are the main trade areas, and China is the largest trading country of products concerning "Bamboo as a Substitute for Plastic". Bamboo articles of daily use, bamboo tableware and kitchenware and bamboo panels for construction are the most potential products in international trade concerning "the Bamboo as a Substitute for Plastics Initiative". At present, the global consumption of plastic products is high, and the demand for plastic replacement is large. The results can provide support for facilitating the development of international trade and strengthening international cooperation in the field of trade policy.

Analysis on the Development of World Bamboo Industry under the Framework of the One Belt and One Road Initiative

T2.16 Innovative technologies for the development of bamboo and rattan products

Enlong Xia[1]
[1] International Centre for Bamboo and Rattan

Abstract: The bamboo industry, as a recognized green sunrise industry in the 21st century, has received high attention from the international community. The bamboo industry plays an important role in increasing farmers' income, promoting targeted poverty alleviation, and transforming development methods. It also makes positive contributions to maintaining global ecological security, addressing climate change, and promoting green growth. China has set a positive example in the development of the bamboo industry, playing an important leading role in promoting the development of the world's bamboo industry. However, the development of the global bamboo industry still faces many difficulties that need to be addressed urgently.

The development of the global bamboo industry is still uneven, with relatively high levels of development in Asia, led by China. The development direction and product types of the bamboo industry in Latin America are relatively single, and Africa is just in the early stages of development, and there is an urgent need for improvement and improvement in all aspects. Different countries attach varying degrees of importance to the bamboo industry, and many countries have just realized the importance of bamboo industry development, and many policy documents have not yet been issued. The scientific research and development of bamboo in most countries are insufficient, and there is a shortage of professional researchers and skilled workers, which greatly restricts the development of the bamboo industry. Under the framework of the "the Belt and Road", bamboo producing countries can, with the help of international organization resources and projects, strengthen capacity building, promote the flow of bamboo resources and technology, formulate support policies, guide regional demonstration, drive scientific and technological innovation, and strengthen talent training, which is an effective way to promote the development of bamboo industry in countries along the "the Belt and Road".

Anatomical Changes in Bambusa spinosa Roxb. induced by Alpha–Naphthalene Acetic Acid

T2.16 Innovative technologies for the development of bamboo and rattan products

John Karlo C. Saddoy[1]
Marilyn S. Combalicer[1], Lerma S.J. Maldia[1], Vinjoe M. Aboc[1], Amelita C. Luna[2], Crusty E. Tinio[1], Armando M. Palijon[3], Ramon A. Razal[4]

[4] Department of Forest Products and Paper Science, College of Forestry and Natural Resources, UPLB

Abstract: Bamboo has been ascending as one of the alternative materials for economic, social, and environmental activities. Recently, the advancement of propagation methods with mining soil interventions is still developing and progressing in literature for possible bioremediation purposes. This paper highlights the leaf and root anatomical response of *Bambusa spinosa* Roxb. planted in a mined-out soil treated with Alpha-Naphthalene Acetic Acid (ANAA – 0 ppm, 100 ppm, and 200 ppm) in LNL Archipelago Minerals Incorporation, Zambales, Philippines. The 3rd leaf and average-sized root were collected from each treatment and underwent freehand sectioning using a stainless blade. A microscopic investigation was performed using a compound microscope (Olympus CX21FS1). The photomicrographs taken were analyzed in ImageJ (version 1.54b) to measure the anatomy of leaves and roots. R (version 4.2.3) was used for data analyses considering the 95% confidence interval. Results revealed that the treatments increased the leaf anatomy, such as the thickness of silica bodies and plicate cells and sizes of bulliform cells, xylem, phloem, and fusoid cells, excluding only the total epidermal thickness. It was also observed that treatments induced changes in root anatomy, including the increased thickness of the epidermis, sclerenchyma layer, cortical cells, endodermis, and pericycle, as well as the sizes of pith, phloem, protoxylem, and metaxylem. These results significantly contribute to the efficient and effective propagation method of bamboo in sites with heavy metals due to mining activities. This paper also entails the importance of *B. spinosa* as a bioremediation species and promotes thorough economic development of the bamboo industry in the country.

Keywords: *ANAA, bamboo, leaf anatomy, root anatomy, mining sites*

Bending and shear performance of a cross-laminated composite consisting of flattened bamboo board and Chinese fir lumber

T2.16 Innovative technologies for the development of bamboo and rattan products

Xiubiao Zhang[1]
Yan Yan[1], Benhua Fei[2]

[2] International Centre for Bamboo and Rattan, Beijing, China

Abstract: Bamboo-wood composites are effective for utilizing the mechanical properties of bamboo and fast-growing wood resources. Investigation the application of flattened bamboo in engineering structures provides added value to bamboo resources. This paper analyzes the flatwise bending and shear properties of cross-laminated bamboo and timber (CLBT) panels consisting of flattened bamboo boards and Chinese fir lumber. A three-layer cross-laminated timber (CLT) panel made from Chinese fir lumber was used for comparison. The mechanical properties of the CLBT and CLT panels in the major strength direction were obtained through experimental tests, and theoretical and finite element models were developed to predict the panels' bending stiffness and strength. The calculated values were compared with the experimental data. The results showed that the failure modes of the three groups of CLBT panels were similar to those of the CLT panel and were predominantly rolling shear and bonding delamination. The bending strength and modulus of the CLBT were higher than that of the CLT. Increasing the number of layers of the flattened bamboo board improved the maximum bending moment and bending stiffness of the CLBT. The bending stiffness and strength of the CLBT/CLT obtained from the finite element model were in better agreement with the static test values than the theoretical model values. The results of this study provie new information for future engineering applications and the structural design of CLBT.

Keywords: Cross-laminated bamboo and timber (CLBT); Flatwise bending performance; Shear performance; Flattened bamboo board; Chinese fir lumber.

Changes of cell wall structure and chemical components during biodegradation of moso bamboo

T2.16 Innovative technologies for the development of bamboo and rattan products

SHUMIN YANG[1]
ZIQIAO XUE[1], SHAN LI[1], BO ZHANG[1, 2], LILI SHANG[1], YANGAO WANG[2]

[2] College of Forestry, Sichuan Agricultural University

Abstract: Biological pretreatment of lignocellulosic plant cell wall gains increasing attention due to its advantages of being environmentally friendly, less energy consumption and fewer by-products. However, the mechanism of the biodegradation of cell walls is not fully understood. In order to explore the structure and chemical changes in moso bamboo (*Phyllostachys edulis*) due to microbial degradation, 4.5-year-old moso bamboo was degraded by brown rot fungi (*Gloeophyllum trabeum*) and white rot fungi (*Coriolus versicolor*). The structure and chemical composition were observed through high-resolution imaging and spectroscopy. The results show that during the same period of fungal degradation, the vessels were broken most seriously, followed by the parenchyma cells, while only a small number of mycelia perforation was found in the fiber cells in the later stage of degradation. Mycelia mainly spread between cells through pits, and at this time, the extracellular enzymes secreted by mycelia degrade the cell wall, resulting in the further enlargement of pits and the formation of perforation. The fungal degradation of cell walls is a complex process. The degradation of each chemical component by fungi is carried out simultaneously, but at different rates. After 16 weeks of biological pretreatment, the relative content of cellulose in the cell wall decreased less than that of hemicellulose, lignin and ethanol extraction. White rot fungi had a stronger degradation effect on lignin and preferentially degraded S lignin. During pretreatment, relative crystallinity changed with the degradation of crystalline cellulose and other amorphous substances by fungi. The crystallinity of bamboo treated with brown and white rot fungi increased after 16 weeks. This study characterized the chemical changes in moso bamboo due to biodegradation, which will provide a reference for the efficient utilization of lignocellulose and bioconversion.

Effect of temperature on the structure and properties of rattan carbon-encapsulated iron particles

T2.16 Innovative technologies for the development of bamboo and rattan products

Lili Shang[1, 2]
Xing'e Liu[1, 2], Shumin Yang[1, 2], Zehui Jiang[1, 2]
[1] Department of Biomaterials, International Center for Bamboo and Rattan, Beijing 100102, China
[2] Key Laboratory of National Forestry and Grassland Administration/Beijing for Bamboo & Rattan Science and Technology, Beijing 100102, China

Abstract: Biomass-based carbon encapsulated nanomaterials is the proposed new carbon material with potential for commercial development. The inherent pore structure of the rattan is more conducive to the direct penetration of the metal salt solution, which can create an effective combination of carbon and metal source. In this study, rattan carbon-encapsulated iron particles were prepared by one-step pyrolysis using *Plectocomia himalayana* Griff. rattan as carbon source and ferric nitrate as metal source, and the effects of six pyrolysis temperatures (600, 700, 800, 900, 1000, 1100 ºC) on the structure and properties of the carbon coated nanoparticles were investigated. The results showed that the core/shell boundary was obvious, and the particle size was uniform when the temperature was 1000 ºC. When the temperature was 600 ºC, no core/shell structure was formed and the product was a mixture of carbon and Fe_3O_4, and the core/shell structure of carbon encapsulated iron nanoparticles could be prepared when the temperature was 700 ºC and above. Meanwhile, the phase of the core was mainly α-Fe and Fe_3C at 700-900 ºC, while it was mainly α-Fe with the increase of temperature. When the temperature rose to 1100 °C, the hollow carbon shell increases, and the proportion of complete carbon cladding structure was less. The saturation magnetization as well as increased with the increase of temperature, and the coercivity decreased with the increase of temperature, showing a better ferromagnetism. The adsorption effect of methylene blue showed the best at 1000 ℃, the maximum adsorption capacity was 186.22 mg/g, corresponding to the specific surface area of $135.29 m^2 g^{-1}$. This study indicated that using rattan as the carbon sources prepared by in-situ one-step pyrolysis at the 1000 ℃ could obtain the carbon encapsulated nanoparticles with uniform size and structure. This study provides a way to development of high value-added products of low-quality rattan.

Engineering Bamboo lumbers and its Utilization in buildings

T2.16 Innovative technologies for the development of bamboo and rattan products

Huanrong Liu[1]
Zehui Jiang[1], Benhua Fei[1]
[1] International Center for Bamboo and Rattan

Abstract: Bamboo, fast-growing tree grasses, is a cultural and ecological feature of many countries in Asia, America, and Africa. Comparing with trees, bamboo has a faster growth, shorter rotation, bigger yield, higher strength and better fiber, besides, bamboo can be used renewably and is sustainable once planted, which can provide environmental, social, and economic benefits. At present, there are nearly 10,000 bamboo products constituting over 100 series now being used in more than 10 fields, such as architecture, decoration, furniture, papermaking, packaging, transportation, medicine, food, textile and chemical industry. In this study, we present the resource and distribution of bamboo resource, introduce bamboo mechanical qualities, bamboo based Engineering materials and utilizations, especially substituting bamboo for plastics. Aside from its economic benefits, Bamboo has enormous positive implications on environment – reduced deforestation, carbon emission reduction and other improved ecosystem services. The global applications of bamboo and its products have a sustainable and greener future.

Life Cycle Assessment of Structural Glued Laminated Bamboo Products

[5] ETH Zurich, Switzerland

Abstract: Since 2000s, engineered bamboo products have gradually gained commercial importance in the international market. Glued laminated bamboo products used for structural applications in buildings have been well demonstrated in China for many years while the development of international standards for structural uses of engineered bamboo has evolved steadily in recent years. Currently, no database includes data on environmental impacts of structural glued laminated bamboo. The aim of this study is to provide reliable life cycle inventory data based on current industrial practices in China and make them available to global users. This study was developed in collaboration with international IGO, universities, manufacturer and will be supported by ecoinvent with the goal of integrating the data within the ecoinvent database. The life cycle inventory data for production of structural glue laminated bamboo products, was analyzed using the impact assessment method of IPCC 2021. Further considerations for biogenic carbon storage were assessed using the method GWPbio. Several strategies for the reduction of environmental impacts during the production process were tested, showing that the carbon footprint of these products can be reduced without major changes to the current practice in the industry.

Micro-propagation and Development of high yielding new bamboo variety BFRI bamboo BB1 of Bangladesh.

T2.16 Innovative technologies for the development of bamboo and rattan products

[2] Senior Research Officer, Silviculture Genetics Division, Bangladesh Forest Research Institute, Bangladesh. waheeda_bfri@yahoo.com, waheeda1223@yahoo.com

Abstract: Abstract:

Bamboo is emerging as one of the most important 21st century crop, since it produces food and wood. It is one of the fastest growing, annually renewable and harvestable plants with highest productivity and short harvesting cycle. It has a great potential in poverty reduction, industrial and sustainable development in rural areas. It also playing important roles for preserving our environment i.e. soil conservation and flood control, soil health, river bank protection, wind break etc. Bangladesh has 37 bamboo species. Among them *Bambusa balcooa,* local name (Borak bans) is one of the important thick wall village bamboo.

Tissue culture protocol of *Bambusa balcooa* was developed from branch nodal bud culture and produced bamboo seedlings for mass propagation and wider distribution in 2002. *In vitro* multiple shoot production of a single shoot was optimized and observed a vigorous growth in culture media. Each shoot produced a mini clump within 2-3 weeks with maximum shoots in the culture vessels. The rooted shoots were transferred in soil for hardening under green house. The hardened plantlets were produced profuse multiple shoots and grew luxuriantly in polybags. Field trails were done at different locations of the country in 2005. Performance of the tissue culture produced bamboo seedlings was observed at different locations and it was found promising. A three years old clump of BFRI bamboo BB1 produced maximum number of culms which was recorded as 30.40 nos in the field. This value is at least three times higher than the rhizome produced clump of the parental stock. Average culm height and diameter was recorded as 19.30 m and 7.70 cm respectively which is also higher than the rhizome produced clump of the parental stock. With the proper management, each seedling formed a clump within 3-4 years of planting with maximum numbers of new bamboo. Seedling survivality in the field level was 100%. No infection of diseases was observed. Later on the developed bamboo variety was multiplied for mass production and wider distribution among the farmers. The new variety was conserved at BFRI bambusetum and farmers field as a source of germplasm for future use.

Multiscale analysis of bamboo viscoelasticity response due to partial hemicellulose removal treatment

T2.16 Innovative technologies for the development of bamboo and rattan products

Xinxin Ma[1]
[1] International center for bamboo and rattan

Abstract: Hemicellulose degradation can improve the dimensional stability but decrease the stiffness for nature materials. In order to restrain the cracking/deformation phenomenon of bamboo products, the viscoelasticity response that a critical role in nature material processing and applications, were analyzed after hemicellulose removal treatment. The gradient structure-viscoelasticity relationship of bamboo has been obtained. In addition, a better flexibility treated method for bamboo material also has been indicated. The bamboo stem was cut into three slices and treated with hot water, steam, and acid. The outer slice, i.e., bamboo green, had the best strength and flexural toughness. Middle slice had higher viscoelasticity and best flexibility. Inner slice, also called bamboo yellow, had the best anti creep property and bad strength or modulus. The flexural toughness and flexibility of all three treatment groups increased. The acid group had more viscoelasticity response, and the increased deformation mainly recovered over time, which increased the flexibility of cell walls of macro bamboo. The water group and steam group had more elasticity response, and the increased deformation mainly recovered immediately, especially for water groups. This paper could be a reasonable selection support of bamboo materials for stiffness or flexible products.

Nutritional assessment of bamboo shoots from selected species growing in Kenya

T2.16 Innovative technologies for the development of bamboo and rattan products

[3] International Bamboo and Rattan Organization (INBAR), Beijing, China

Abstract: Bamboo are among the fastest growing multi-purpose plants on the planet with over 10,000 documented uses. Bamboo shoots is one of these uses and are delicacies for numerous communities in Asia, Africa and Latin America. However, information on proximate and mineral composition of bamboo shoots is scanty despite being used as vegetables in some parts of Kenya. In this study nutrient levels of five selected exotic species were evaluated namely; *Dendrocalamus giganteus*, *Dendrocalamus membranaceus*, *Dendrocalamus asper, Oxytenanthera abyssinica* and *Bambusa vulgaris* growing in Kenya. It was hypothesized that bamboo shoots are rich in nutrients of importance to human health. The shoots were collected from Nyahera, Nguriunditu and Karura in Kisumu, Kiambu and Nairobi Counties respectively. The samples were analyzed for proximate composition, minerals, vitamin, moisture content and calorific values using standard procedures. The moisture content for the shoots ranged from 89.9% to 92.1%. Results expressed in dry weight basis showed that crude fiber ranged between 17.6% and 34.8 %, protein content between 18.9% to 38.7%, ash content between 9.3% and 12.8%. On wet weight basis, vitamin C ranged between 2.03 and 4.17mg/100g, riboflavin from 0.02mg/100g to 0.05/100g, niacin (B3) from 0.19mg/100 to 0.08mg/100g while in *O. abyssinica* was below the detection limit of the equipment (of 0.01mg/litre). The shoots further recorded the minerals on wet weight basis as follows: magnesium content ranged between 0.09mg/100g and 3.31mg/100g, aluminium between 28.27mg/100g and 47.34mg/100; calcium between 2.33mg/100g and 31.25mg/100 while in *O. abyssinica* was below detectable level. Iron ranged from 0.83mg/100g to 5.31mg/100, copper from 0.15/100 to 0.19mg/100g and zinc ranged from 0.10mg/100g to 1.95mg/100. The sodium content ranged between 4.49mg/100g and 9.51mg/100g, potassium between 1.77mg/100g and 236.73mg/100g. Their calorific values on dry weight basis ranged between 393.99Kcal/100g and 464.86Kcal/100g. The findings on the nutritional content in terms of fibre, protein and minerals make bamboo shoots a potential meal of consideration for Kenyan households.

Preparation and Characterization of Cellulose Nanofibrils from Bamboo Holocellulose and Its Usage as Reinforcement in Starch Nanocomposites

T2.16 Innovative technologies for the development of bamboo and rattan products

Korawit Chitbanyong[1]
Sarawood Sungkaew[2, 3], Sawitree Pisutpiched[1], Somwang Khantayanuwong[1], **Buapan Puangsin**[1, 2]

[2] Center of Excellence for Bamboos, Kasetsart University, Bangkok 10900, Thailand
[3] Department of Forest Biology, Faculty of Forestry, Kasetsart University, Bangkok 10900, Thailand

Abstract: The development of bio-based materials from renewable plant resources, crops, and their by-products can be done to circumvent environmental issues related to the use of petroleum-based products. Among the natural biopolymers, starch has been considered the most promising material due to its low cost, biodegradability, and renewability. Therefore, starch has been converted into a thermoplastic starch (TPS) by appropriately mixing with water or some plasticizer (e.g., glycerol, sorbitol). However, disadvantages attributed to the hydrophilic properties of TPS in starch-based nanocomposites lead to poor mechanical properties. To overcome such limitations, using mineral or cellulosic fillers (e.g., clay, glass fiber, cellulose nanofibrils) as reinforcing agents in TPS is an effective solution.

Bamboo belongs to the family of grasses and is considered an alternative source of non-wood raw materials due to its easy propagation, wide distribution, availability, fast-growing nature, short rotation, and high productivity. This work oxidized bamboo holocellulose by TEMPO-mediated oxidation system using the 2,2,6,6-tetramethylpiperidine-1-oxyl. Then the oxidized celluloses were converted to individual cellulose nanofibrils by mild mechanical treatment. After oxidation, the weight recovery ratio of TEMPO-oxidized bamboo holocellulose (TOBH) was 73%, with a carboxylate content of 0.65 mmol g-1. The water-insoluble TOBH was converted to an aqueous dispersion of bamboo TEMPO-oxidized cellulose nanofibrils (TOBCN) through mechanical defibrillation and centrifugation, with the nanofibrillation yield of around 90%. Transmission electron microscopy (TEM) indicated that the widths of TOBCN were estimated to be between 3 and 4 nm and lengths of several micrometers. The TOBCN dispersions had high light transparencies of 99% at a wavelength of 600 nm. These nanofibrils were used as reinforcing nanoparticles in thermoplastic starch (TPS) films. The TOBCN dispersions were added in dosages of 0, 0.3, 0.6, 0.9, 1.2, and 1.5 wt%. Glycerol was used as a plasticizer. Nanocomposite films were prepared through a solution-casting process. The TOBCN/TPS nanocomposite films exhibited high optical transparencies, and their tensile strength, Young’s modulus, elongation at break, and work of fracture increased compared to the TPS films without TOBCN. The presence of TOBCNs, at 1.5 wt%, improved moisture resistance. The work demonstrates the potential of using bamboo cellulose nanofibril as reinforcement in nanocomposite materials.

Research on high-yield clean pulping technology of bamboo

T2.16 Innovative technologies for the development of bamboo and rattan products

Ting Wu[1]
Guigan Fang[1]
[1] Institute of Chemical Industry of Forest Products, Chinese Academy of Forestry

Abstract: China is the country with the richest bamboo resources in the world, with a bamboo forest area of 7,562,700 hm^2, accounting for 1/3 of the world's total bamboo forest area, but 80% of which has not been effectively utilized. In order to develop a comprehensive utilization technology for bamboo pulping and papermaking with high utilization rate, low consumption, high added value and clean production process, the main bamboo species in China, moso bamboo and sinocalamus affinis, were selected as research objects. The unbleached chemi-mechanical pulp process was used to study the pulping performance of bamboo by appropriately increasing the amount of NaOH in the impregnation section. The results showed that after two stages of extrusion and two stages of impregnation of the chemi-mechanical pulping process, in the impregnation section of NaOH dosage of 10%-15%, the pulp yield was both about 80%, the yield of sinocalamus affinis was slightly higher than the yield of moso bamboo. The electricity consumption required to produce chemi-mechanical pulp with Canadian standard freeness(CSF) 300mL was both less than 350 kWh/BDT, and the bulk thickness was both between 2.1 and 2.5 cm^3/g, which showed that the softening effect of the fiber was good and the electricity consumption was relatively low with high chemical dosage. The strength performance of sinocalamus affinis pulp was much higher than that of moso bamboo pulp. When the amount of NaOH used for impregnation was 12%, the tensile strength of sinocalamus affinis pulp with the CSF of 300mL reached more than 28 N.m/g, and the tear strength was even better, up to more than 6.0$mN.m^2/g$, almost close to the tear strength of bamboo chemical pulp. The tensile strength of the corresponding moso bamboo pulp was only 12N.m/g and the tear strength was only 2.5$mN.m^2/g$. Corrugated base paper and household paper made from moso bamboo and sinocalamus affinis pulp can meet the requirements of the corresponding standards. With the development of bamboo pulping and papermaking technology, it is expected to alleviate the shortage of wood fiber in the paper industry.

The Bamboo City, a new urban architechture that brings back natural element

T2.16 Innovative technologies for the development of bamboo and rattan products

John Changzhuan Shao[1]
[1] Junke Xiang

Abstract: The bamboo city emphasis the relationship between human and nature, the buildings harmonizes with the surrounding natural environment. The construction focuses on sustainability and environmental protection, encouraging residents to interact with nature.

As the population of the world continues to grow, there is an increasing demand for new and innovative approaches to urban planning and development. One feasible approach is the construction of bamboo cities, which offer a sustainable and environmentally-friendly alternative to traditional building methods. The Bamboo City can provide a sustainable solution to the growing problem of urbanization and provides a healthier and more livable environment for residents. The concept includes urban large-scale public buildings and small-scale urban facilities such as public benches, garbage cans, street lamps etc., so as to replace steel or concrete instead. In addition, it can satisfy furniture and houseware function and household necessities, which can be fabricated with bamboo to some extent. Moreover, The Bamboo City could also rich in culture and be vibrant in trade, culture, and healthy lifestyle.

Bamboo is a fast-growing, renewable resource with good environmental properties, its related product could be widely used alongside modern city development, providing solutions for building a green and low-carbon urban and rural environment. In the future, cities around the world may use bamboo as an essential building material. By expanding the application of bamboo could boost the development of bamboo industry and increase employment.

One of the challenges in building bamboo cities, however, is the need for innovation and technology in building techniques. It is important to ensure that bamboo structures meet both safety and code standards without compromising its sustainability and environmental impact.

In conclusion, the bamboo city offers a sustainable and eco-friendly approach to urban development that has the potential to revolutionize the way we build our cities. And as innovation and technology continue to develop, we could explore new ways to create sustainable urban infrastructure and buildings that not only benefit the environment but also the health and well-being of their residents.

The Contribution of Bamboo to livelihood improvement in Cameroon

T2.16 Innovative technologies for the development of bamboo and rattan products

Rene Kaam[1]
Ingram Verina[2], Winkel Georg[2], Tchamba Martin[3]
[1] International Bamboo and Rattan Organisation (INBAR)nal
[2] Wageningen University & Research
[3] The University of Dschang

Abstract: Bamboo sequesters 1.33 times more carbon than trees. The global market value of bamboo products is around €50 billion. Cameroon has about 1.2M ha of bamboo, second largest area in Africa after Ethiopia, a mix of indigenous and species introduced in colonial times. Bamboo contributes to the livelihoods of c.31,000 people, earning on average €708 annually for harvesters, craftspeople and sellers albeit these incomes are generally below poverty benchmarks. The potential for this grass to contribute further to livelihoods and to mitigate climate change however is under-realised due to a lack of, and inappropriate policy, and insufficient data. This study investigates the socio-economic contribution of bamboo for value chain stakeholders. Using an adapted Poverty Environment Network questionnaire and the Sustainable Livelihoods framework, a total of 233 interviews were conducted (9 village surveys, 128 harvester households in major bamboo production areas, 41 processors and traders and 55 consumers). Quantitative data was analysed using descriptive statistics, aggregation and extrapolations to estimate the sector's importance to stakeholder's livelihoods and economy. An innovative framework coupling Social-Ecological Systems focusing on the resource system, resource units, governance system, users and outcomes, will be used to analyse socio-economic benefits for direct (and indirect) value chain stakeholders and interventions. This data will be presented and how it will be used to provide input to a sectoral policy to be co-developed with bamboo value chain stakeholders, which considers trade-offs between the goals of conservation and climate change mitigation and development. Implications for scientific research, local knowledge and practices, and policy will be presented.

The distribution characteristics of vascular bundle and bending mechanical properties of Dinochloa orenuda in Hainan Island

T2.16 Innovative technologies for the development of bamboo and rattan products

Yan Yan[1]
Xiubiao Zhang[1], Benhua Fei[2]
[1] International Centre for Bamboo and Rattan Sanya Research Base
[2] International Centre for Bamboo and Rattan

Abstract: *Dinochloa orenuda* is widely distributed in Hainan Island, China, climbing growth, the slender culms similar to rattan. To explore the feasibility of using it as furniture material, the density, vascular bundle morphology, bending strength and modulus of culms at different heights were investigated. The density of culms increased from the base to the tip, which was between 0.47~0.56g/cm^3. From outside to inside of the wall, four types vascular bundles of undifferentiated, semi-differentiated, broken waist and double broken waist were successively distributed, the distribution density and individual size gradually decreased and increased, respectively. With the increase of culms heights, the bending strength and modulus of each segment was slightly increased and relatively stable, respectively, which is different from the mechanical properties of some scattered bamboo. The stable modulus is due to the tiny axial variation of the vascular bundle distribution density and the wall thickness. The results show that *Dinochloa orenuda* has stable mechanical properties and cross-sectional dimensions, which is similar to the rattan and can be used as a new type of furniture material in its original form.

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

HARNESSING EMPERICAL AND INDIGENOUS KNOWLEDGE TO CONSERVE AFRICAN JUJU TREE, OKOUBAKA AUBRVELLEI PELLEGR. & NORMAND

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

EKeoba Matthew Isikhuemen[1]
Emmanuel John-Onyijen[2]
[1] Department of Forest Resources and Wildlife Management, Faculty of Agriculture, University of Benin, Benin City, NIGERIA.
[2] Department of Health Safety and Environment, Okomu Oil Company Plc, Okomu-Udo, Edo State, NIGERIA

Abstract: *Okoubaka aubrvellei* Pellegr. & Normand (African Juju tree) is a rare totemic and hemi-parasitic tropical rainforest tree endemic to the Guinea-Congolian region of West/Central Africa. This mono-generic, non-pioneer light demander – highly revered because of its reputation for killing neighbouring trees – is currently very rare in Nigeria. Following its classification as endangered species on the IUCN Red list in 2015, we conducted two diagnostic investigations (ecological/phyto-demographic and socio-economic) in seven Local Government Areas (LGAs) located in the rainforest region of Edo State, Nigeria. First, inventory of relic tree population was carried out in the wild while count of natural regeneration was done under a matured mother tree. For the socio-economic study, responses were elicited from primary participants (local field staff of the Edo State Ministry of Environment (n=21) using the snowball sampling technique alongside questionnaire and key informants' interview. Recommendations from the primary participants were used to assess/elicit information from secondary participants: herbal practitioners/users (n=76) in 14 local communities, and vendors (n=38) of *O. aubrevillei* products in five markets in a metropolitan Council Area. Data were analysed using descriptive statistics. The results of diagnostic inventory revealed 13 individuals with *ca.*70% carrying various degrees of harmful lacerations/scars on their boles. For natural regeneration, 11 juveniles were counted under a mature mother tree while *Myrianthus arboreus* was the only tree found in cohort within 12m radius of all the species encountered. The results of socio-economic study revealed 135, mostly male adult respondents (87%) with average age of 54 years. Majority of the respondents (94%) opined that the species possesses magical powers; and that the tree bark is most harvested owing to its high demand and use in ethnomedicine (68%). Participants attributed the accelerated decline of *O. aubrevillei* population to harvest pressure (43%) and habitat loss (48.1%). While the key outcome of the diagnostic study was the affirmation that the species regenerates *in situ;* most respondents (76%) asserted that the mystical powers and ecological idiosyncrasies of *O. aubrevillei* can sufficiently sustain its ultimate survival in the wild without human assistance.

Intangible benefits of the forests: local ecological knowledge of plants for cultural ecosystem services in Western Ukraine

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Nataliya Stryamets[1]
Giulia Mattalia[2, 3], Renata Sõukand[4]

[4] Ca' Foscari University of Venice, Department of Environmental Sciences, Informatics & Statistics, Venice, Italy

Abstract: The use of plants for cultural purposes is a little-covered corner of biocultural diversity that has developed through time within a complex socio-ecological system. Ukraine is rich in both biological and biocultural diversity. One of the ways to interact with nature is to use plants for rituals, while rituals are complex interactions between humans and biodiversity shaped by history, culture, and ethnic belonging. Yet, in Western Ukraine, such rituals have been forbidden for over 50 years (1939-1991). The current revival of rituals by rural inhabitants is an untapped reservoir of local ecological knowledge. The aim of the present study was to identify the use of wild and cultivated plants for cultural purposes in two regions of Western Ukraine, Bukovina, and Roztochya, and to compare the findings with historical data.

Forty-seven face-to-face semi-structured interviews were conducted in the summers of 2018 and 2019. We document the use of plants for various ritual purposes in two ethnic groups of Hutsuls in Bukovina and Ukrainians in Roztochya. Based on interviews we identify seven holidays for which people used the diversity of plants both wild and cultivated. Our results show the re-emerging of those local ecological practices.

Among Bukovinian Hutsuls, we documented the use of 26 plant taxa while in Roztochya we recorded the use of 58 plants in 7 festivities (of which two were celebrated differently in both communities). Plants were mainly used in bouquets, but also for decorating churches, houses, or fruit baskets. We discuss the attitude, importance, and knowledge sources of those practices.

The research was supported by the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 714874)

Local Ecological Knowledge of Rattan species for sustainable livelihoods and forest management: Empirical Evidence from Ngambe-Tikar, Central Cameroon

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Nyong Princely Awazi[1, 2]
Marie Louise Avana-Tientcheu[3, 4]

[4] African Forest Forum, Nairobi, Kenya

Abstract: Rattan is an important non-timber forest product (NTFP) supporting the livelihoods of millions of indigenous people in the tropics. In the West and Central African sub-regions, there are 22 rattan species, with Cameroon harbouring 19 of these 22 species. Local Ecological Knowledge (LEK) plays an important role in the harvesting, processing and trading of these rattan species in Cameroon. Despite the important role LEK is playing, limited research has been carried out to ascertain the importance of LEK of different rattan species to livelihoods and the sustainable forest management in Cameroon. This study fills this void. Data were collected mainly through a random survey of 120 households involved in rattan harvesting, processing and trading in Ngambe-Tikar, Centre Region of Cameroon. This was complemented by key informant interviews, focus group discussions and direct field observations. Findings reveal that LEK is used by the indigenous people to determine the different commercially important rattan species which are: *Eremospatha macrocarpa*, *Calamus deerratus*, *Laccosperma secundiflorum*, and *L. Robustum*. The maturity of the rattan species is determined by looking at the colour, size, thickness, and length of stems, as well as the presence/or not of thorns. Using these criteria for maturity ensures that only the well matured stems are harvested, thereby ensuring sustainability. LEK equally aids the indigenous people to know which species are more abundant and which species are experiencing dwindling supplies. LEK helps the communities to know that their forest is disappearing as scarcity of rattan is associated with forest loss. This motivates the local community to take measures towards limiting forest degradation notably by limiting slash and burn farming which is one of the main drivers of forest degradation in Ngambe-Tikar. LEK positively correlates with livelihood improvement and sustainable forest management as indigenous persons endowed with more LEK are involved in the sustainable harvesting, processing and trading of rattan products such as baskets, chairs, tables, caps, beds, sieves, TV stands, Couch/Sofa, cupboards, wardrobe, flower jars. Thus, LEK enhances understanding of the livelihood benefits derived from rattan species which pushes the community to conserve rattan and the forest from where the rattan is harvested.

Local knowledge of acorn collectors for sustainable management of oak forest ecosystems in Turkey

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Mehtap Koç[1]
Alen Mevlat[2], Abbas Şahin[3], Kenan Ok[1]
[1] Istanbul University-Cerrahpasa, Faculty of Forestry, Department of Forestry Economics
[2] Proje Evi Cooperative
[3] Marmara Forestry Research Institute, General Directorate of Forestry

Abstract: Oak forests in the Mediterranean basin is provider of various goods and services such as (1) biodiversity; (2) agroforestry and silvopasture systems for the production of fodder and pasture; (3) wood for materials and energy; (4) acorn-based foods and beverages; and (5) other uses such as the manufacture of drugs and extraction of tannins for the leather industry. The "Palamut" mountain, which takes its name from the “acorn” in Turkey, is the region where the existence of various oak species and closed stand forest forms are observed. Also, traditional acorn harvesting from *Quercus ithaburensis* still continues. The initial findings of the socio-economic research work package on acorn collection are as part of an ongoing project led by the Marmara Forestry Reseach Institute of General Directorate of Forestry. The social purpose of the project is to compile local information about acorn collecting and to investigate the basic motivations of the people living in the Palamut Mountain region for sustainable management of oak forests. Through face-to-face interviews with 384 local people, engagement in acorn collection, both presently and in the past was obtained. According to the findings, 16% of the participants are currently active acorn collectors. A significant proportion, 36.5%, have never been involved in acorn collection. Furthermore, 47.5% of the respondents indicated that they used to engage in acorn collection in the past but have since discontinued this activity. 30% of previous acorn collectors reported discontinuing their activities within the past five years. Participants primarily attributed the decline in acorn collection to two key factors: the lack of acorn buyers and buyers offering low purchase prices. Participants who had engaged in acorn collection on their privately-owned lands revealed that 83% of them opted to convert their lands into agricultural areas by felling oak trees after discontinuing their collection activities. Conversely, 17% of participants reported cutting down oak trees on their lands to create grazing areas for livestock, designating them as pasturelands. Additionally, the research examined the participants' views on agrosilvopastoral systems. It has been determined that the level of local knowledge does not adequately support integrated systems today.

Measurement and Influencing Factors of Willingness to Accept Compensation for Ecosystem Service Provision: A Case Study of a Leading Forest Farm

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Guo Tongfang[1]
Wu Shuirong[1], Zhang Xufeng[2]
[1] Research Institute of Forestry Policy and Information, Chinese Academy of Forestry
[2] School of Economics and Management, Beijing University of Technology

Abstract: The Saihanba Forest Farm as a leading planted forest enterprise is an essential ecosystem services provider for the Beijing-Tianjin-Hebei region in China, the efforts of which in successful afforestation and landscape restoration have been recognized internationally awarded with the Champion of the Earth by the UN. However, few studies have focused on the value of ecosystem services from the provider's perspective. Understanding the providers' attitudes towards ecosystem service and willingness to accept compensation is crucial as it might affect the quantity and quality of ecosystem services provided in the future. In this study, a questionnaire survey was conducted among the staff of the Saihanba Forest Farm, the contingent valuation method was applied to measure their willingness to accept compensation for providing forest ecosystem services. A two-hurdle regression model was applied to analyze the influencing factors, and a tobit model was used for validation. The result indicated that the mean willingness to accept compensation was CNY 9800.84 (USD 1458.28) per hectare per year. The expected compensation increased with the age, education status family size. The variables of the number of families employed and cognition of payment for ecosystem services were negatively associated with willingness to accept the value. Among respondents who opted willing to accept compensation, those who realized the concept of payment for ecosystem services bid lower compensation amounts. The findings are meaningful for quantifying forest ecosystem services and promoting payment for environmental services for landscape restoration.

Non-timber forest products (NTFPs) as safety net in the era of COVID-19: Evidence from Northern Ghana.

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Samuel Adeyanju[1]
Mathurin Zida[2], Terry Sunderland[1, 2]
[1] Faculty of Forestry, University of British Columbia, Vancouver, Canada.
[2] Center for International Forestry Research (CIFOR), Bogor 16115, Indonesia

Abstract: The role of non-timber forest products (NTFPs) as safety net for the rural poor who use and depend on forest resources is widely acknowledged. However, this acknowledgement is often in the context of risks induced by seasonality, climatic change and environmental degradation. The global COVID-19 pandemic and the associated public health measures taken by national governments adversely impacted both local and national economies and people across the globe. In the same vein, the pandemic has also shed light on the safety net function of NTFPs during severe and unexpected events. In this paper, we expand this understanding by drawing on literature on safety net function of natural resources (including NTFPS) and field data collected in Northern Ghana. Overall, we underscore the role of non-timber forest products as a source of livelihood and food security for rural dwellers during the pandemic in Northern Ghana. Our findings support and build on previous research to underscore the significance of non-timber forest products as shock-absorber in crises periods and highlight policy implications for stakeholders in the forest sector as the world continues to "build back better."

Review and documentation of plant natural products and indigenous knowledge in Eastern and Northern region of Kenya.

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Elyas Hassan Mohamed[1]
Mwalewa US[1], Magret M Kaigongi[1], Albert Luvanda[1], George Muthike[1], Joseph Githiomi[1]
[1] Kenya Forestry Research Institute

Abstract: The paper reviews and documents information on plant natural products and indigenous knowledge in Kenya. Reports on ethnobotanical studies of different communities in Kenya especially in the North Eastern parts of the country are meagre despite their extensive use. The threat of extinction of the knowledge on herbal medicine by factors such as deforestation, lack of proper regulation, over exploitation, land use tenure and changing socio-cultural issues warrants an urgent documentation of the information to preserve it. The study targeted the ASALs communities in Eastern and North-eastern of Kenya which include the Kambas, Somalis, Boranas and Rendilles. Data on various plants species, part of the plant used, natural products, uses, method of preparations and administration by these communities were gathered through desktop review of various journals, books, published theses and in different electronic databases including science direct, Medline, Google scholar, Web of Science, AJOL, Kenyan university websites and libraries. The data was tabulated and analyzed. The documentation contributes to safeguarding indigenous knowledge on medicinal and plants natural products in the study areas, which is useful for the development of data base in order to avoid the loss of this important knowledge. The paper recommends documentation of indigenous knowledge on medicinal and other natural products in the remaining Counties in the Northern Kenya, where there's limited information.

Key words: "medicinal", "spices", "food", "fodder", "pesticidal", "plants of Kenya", "ethnobotany of Kenyan communities", "traditional medicinal plants of Kenyan communities".

Rural communities' views on woodland benefits in Guinea-Bissau: the importance of wild edible plants

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Ana Leite[1]
Quintino Mbunhe[2]
[1] Department of International Environment and Development Studies (Noragric), Faculty of Landscape and Society, Norwegian University of Life Sciences (NMBU), P.O. Box 5003, N-1432 Ås, Norway
[2] Lusophone University of Guinea-Bissau, Rua Vitorino Costa 1, Bairro Bolola, Bissau, Guinea-Bissau

Abstract: The West African woodlands provide an immense range of benefits to the livelihoods of many rural households inhabiting the region, but they have been severely degraded due to various land use pressures and climatic changes. While many studies in West Africa have evaluated woodland goods and services, few studies explicitly make the diversity of local people's values the focal point of research, which has been deemed critical for planning sustainable management strategies.

Using a sociocultural approach that combines focus group discussions and walk-in-the-woods in 20 villages located in the north of Guinea-Bissau, our research investigates how rural communities of different ethnic groups value the nearby woodlands and perceive vegetation trends.

We found that Wild Edible Plants (WEPs) are an important woodland benefit for all ethnic groups, particularly in times of food shortages, and that all perceive their declining availability due to woodland clearance for the establishment of cashew orchards. Differences in the benefits cited as important were more evident between farmers (Manjack, Balanta, and Mandinka) and pastoralists (Fulani) groups. For example, all famer groups showed the symbolic connection with the woodlands linked with the existence of *irãs* which are spiritual entities that inhabited those places (not mentioned by the Fulani).

Fulani consume a higher diversity of WEPs, including more root tubers and leafy vegetables, but apart from the WEPs most traded in urban markets (which are also managed locally), an imminent dietary change was noted with reduced WEPs consumption in response to the increased availability of rice (the main staple in the country).

Our study highlights the need for further in-depth studies of local people perspectives and values surrounding the West African woodlands. This will allow a better understanding of the possible synergies and differences that can be further promoted to sustainably manage this ecosystem. Specifically, we argue for the urgent need of adapting woodland management to account for the provisioning of wild foods.

Significance of local ecological knowledge, experiences of non-timber forest products for sustainable forest management in Chilgoza forest, Pakistan

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Faizul Bari[1]
Faizul Bari[1]
[1] Food and Agricluture Organziaion(FAO)

Abstract: Non-timber forest products(NTFPs) are vital for subsistence and meeting the source of daily nutrition and household food security in Pakistan. In Chilgoza pine forest ecosystem more than 2300 NTFPs are harvested as the livelihood of million of poor is heavily dependent upon the utilization of NTFPs due limited other options of earning in the poverty affected rural areas. According to an estimate more than 85 percent of the population get the livelihoods from the Chilgoza Ecosystem.

Throughout the human history these products are being used for a variety of purposes including food, fodder,, fiber, traditional medicine and several other uses. In Covid 19, the NTFP provided additional income to the local people due to its high demand. The wildlife is also a key NTFP in the pine ecosystem.

Due to the high level of dependency of the local on the NTFPs, they have plenty of traditional ecological knowledge and experiences regarding the sustainable utilization of NTPs. The local female population is the main stakeholder and direct beneficiaries of NTFPs and they have the required ecological knowledge and best practices to cope with the changed situation resulted from the external factors like socio-economic condition, natural disasters and climate change.

Under the GEF Chilgoza Project" Reversing deforestation and degradation in high value Chilgoza pine forest in Pakistan" at the start of the project a comprehensive survey was conducted to know the status of the various NTFPs, the potential and opportunities for their scientific utilization. Some key NTFPs were identified including Chilgoza pine nuts, variety of medicinal plants and mushrooms. The project first organized the local communities in the form of NTFP conservation and Management Committees. They developed a community based NTFPs utilization and management strategy, where the local knowledge, experiences, and best practices have been incorporated. The project provided to these communities the required tools and training to better utilize the NTFPs for greater economic return. The market linkages were also established for better prices. The local community is registering this product (pine nuts) as Geographical Indication(GI) to protect this product for the local communities and get better prices in international markets.

Socio-economic drivers, intergenerational disconnect, lack of interactive governance & more: Addressing challenges in unsustainable harvesting of NWFP

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Shalini Dhyani[1, 2, 3]
Deepak Dhyani[3]
[1] CSIR National Environmental Engineering Research Institute, Gland Switzerland
[2] IUCN Commission on Ecosystems Management, Gland, Switzerland
[3] Society for Conserving Planet and Life, Dehradun Uttarakhand India

Abstract: The recently released IPBES assessment on Sustainable Use of Wild Species highlighted overexploitation as a major threat to many wild species and endorsed the need to integrate inclusive actions at multiple scales, employ participatory processes, build interactive governance approaches and support context-specific adaptive management. As a lead author for the assessment I propose this case study Central Himalayas where natural forests are a vital support to local subsistence providing diverse provisioning services. This includes food, fodder, leaf litter and crop support to local communities. Over generations harvesting of NWFP by the communities in the region was well supported by local and traditional knowledge systems that included informal calendars for harvesting dependent on seasonality of NWFP and also rotational harvesting to ensure sustainable use of wild species. However over the years enhanced commercial tourism, emmigration of local people for education and livelihood, reduced livelihood opportunities, socio-economic drivers, loss of intergenerational connect and deforestation have severely affected these practices. There is a disconnect observed between nature-people relations too because of loss of rights on their nearby forests that is widening. Present study provides an overview on NWFP harvesting that includes fodder, leaf litter and wild edibles by locals and their related temporal use calendars, taboos and the entire process supported by informal governance of women welfare groups that for ages ensured sustainable harvesting of NWFP in Garhwal part of Uttarakhand state in India. Study highlights with examples how the drivers of loss especially local socio-economics, migration from villages, intergenerational disconnect and lack of interactive governance approach that have resulted in loss of age old traditional practices has affected sustainable harvesting leading to loss of resources. Study will also highlight the relevance of NWFP based livelihood resource centres and community based seed banks especially for lesser known underutilised wild edibles for developing domestication models for future as potential future food, nutraceutical and medicinal support for human well-being. Temporal calendars needs to be preserved and can be a relevant contribution to NWFP policies that has so far been ignored but has the potential to help improve acceptance of these policies by local communities.

The argan (Argania spinosa (L.) Skeels) forest and the innovative use of its products for the sustainable development of rural communities in Morocco.

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Abstract: Argan tree is endemic of arid environments of Middle and Southwestern Morocco, where it forms natural forests, providing multiple socioeconomic and cultural benefits for the local communities since ancient times. Starting from 1980s, Argan oil has been appreciated by international cosmetic industry, becoming one of the most expensive vegetal oil, increasing the anthropic pressure on argan forest in addition to environmental shocks. The argan forest was declared a Biosphere Reserve by UNESCO in 1998, while in 2018, a part of it was included in the GIAHS (Globally Important Agricultural Heritage Systems) Programme by FAO. Although the socio-economic benefits of the argan oil are well known, a comprehensive assessment of the threats and opportunities related to the argan forest is limited. This systematic literature review identifies the main threats for the argan forest as well as opportunities related to innovative uses of argan non-wood forest products, with attention on its role for the sustainable development of rural communities.

Results show that the argan forests is facing high pressure from several human activities (overgrazing, growing demand for argan nuts, land degradation), combined with socio-economic inequalities and difficulties in argan tree propagation. However, innovative use and recycling of the waste deriving from argan nuts processing offer promising opportunities for supporting a local forest-based bio-economy. Argan press cake can integrate livestock feeding, produce nanocellulose for sudan dyes extraction, or innovative bioplastics. Argan nut shells among other benefits can be used to produce environment-friendly and low-cost purifying materials for a wide range of chemicals and pharmaceuticals and as a source of bioenergy. Argan pulp can be used for obtaining bioethanol or natural insect repellent, providing a product diversification to local women cooperatives by adding value to a by-product currently considered an agricultural waste.

Despite the promising opportunities, the impact of innovative uses in terms of socio-economic development and ecological preservation is still limited, because of lack of operational programs that stimulate applications of research results in local management and development strategies. Resilience empowerment of argan socio-ecosystem require inclusion of local population through integration of local ecological knowledge and science-based solutions in consistence with communities' values.

The Contribution of Non-Timber Forest Products to Local Livelihood and Forest Conservation in Neelum Valley, Pakistan

T2.17 Local ecological knowledge of non-wood forest products for sustainable forest management and human well-being in diverse contexts

Faiza Sarwar[1]
Kazuhiro Harada[1]
[1] Graduate School of Bioagricultural Sciences, Nagoya University

Abstract: Promoting the sustainable use of Non-Timber Forest Products (NTFPs) can create a mutually beneficial situation for poverty reduction and biodiversity conservation. In Azad Jammu and Kashmir, Pakistan, NTFPs collection and processing play a crucial role in the local economy. More than 5000 families in the region are engaged in these activities. NTFPs collectors are usually low-income households who pursue plant collection as their part-time activity besides farming and livestock. Hence, the study aims to investigate how much NTFPs contribute to the household income of forest-dependent communities and analyze their role in sustainable forest management. The research was conducted in three villages of Neelum Valley, AJK, in northern Pakistan. In March-April 2021, 90 respondents were interviewed through close-ended and open-ended questionnaires.

The study's findings reveal that most of the local population relies on small-scale farming for survival. At the same time, many individuals supplement their income by collecting and selling plant materials for use in herbal medicine. Furthermore, local communities utilize various plants for food, medicinal purposes, fuelwood, agriculture tools, and construction. Eighty-nine plant families were identified to be used in these three villages. Due to the remote location of the villages and economic constraints, they have limited access to commercially produced medicines and continue to depend on medicinal plants. The study identified 220 species used as a traditional medicine to treat 73 diseases. Notably, the study highlights that the benefits derived by these communities from NTFPs positively impact sustainable forest management. Therefore, it is recommended that the residents of Neelum Valley continue to use NTFPs for their daily needs. Local people in the three villages possess extensive knowledge about the specific plants and their respective parts that can be used for various purposes. This study concludes that the trade of medicinal plants can serve as an alternative livelihood opportunity for households with low to medium incomes in Neelum Valley. However, specific challenges threaten the availability of medicinal plants, including a need for more awareness regarding proper harvesting methods and post-harvest handling, unrestricted grazing, deforestation, and encroachments. Hence, this research emphasizes the importance of promoting sustainable practices using NTFPs.

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Synergies and trade-offs in climate mitigation and adaptation potential of tree species mixtures: a synthesis across tree diversity experiments

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Haben Blondeel[1]

[2] INRAE

Abstract: The global forest area is expected to increase in the future, in an effort to increase the land carbon sink and hence contribute to climate change mitigation via afforestation. Forest plantations will form a substantial part of this forest expansion and, from a climate mitigation perspective, a thoughtful selection of species and mixtures with high growth and carbon sequestration potential is beneficial for carbon drawdown. Simultaneously, planted forests need to be resilient against the future impacts of climate change – i.e. adaptation. Choosing between various tree species during afforestation is essentially a question of trade-offs and synergies for mitigation and adaptation potential, which has direct practical relevance for forest management. Recent collaborative research across multiple tree diversity experiments has gathered empirical data on mitigation and adaptation potential, of the same tree species and stands and using harmonized protocols. Here we present a synthesis of these data, analysing which combinations of species and functional traits determine the mitigation-adaptation trade-offs and/or synergies. From this functional perspective, it will become possible to develop guidelines for tree species selection of mixed plantations where adaptation to climate extremes is paramount, in order to achieve the climate change mitigation potential of planted forest on the long term.

Admixtures of European beech with conifers show higher ecosystem and economic multifunctionality than pure beech stands without compromising multidive

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Abstract: Forest management in Germany increasingly strives to achieve multi-purpose forestry on public lands, where ecological, recreational, structural, aesthetic, and other goals are as important as timber production. One of these practices refers to the establishment of mixed forests, which often show higher biodiversity (associated animal and fungi groups, for example) compared to single species stands as well as overall ecosystem functioning, but also lower profitability, particularly when mixtures consist of broadleaves with lower industry use and market value. Mixing European beech with non-native conifers could be a compromise solution to be explored, although research on the relationships between biodiversity, ecosystem functioning, and economic performance in German mixed forests has not been fully explored. Our main hypotheses are as follows: 1) there is an effect of forest type (single-species or mixed) on the overall functionality, biodiversity, and economic outcome, and 2) mixed stands show the highest performance for economic value, biodiversity and ecosystem functions compared to the pure stands. We studied pure and mixed forests of European beech, Douglas-fir, and Norway spruce in 40 plots of 0.25 ha located across the state of Lower Saxony, Germany. Data on biodiversity, ecosystem functions, and forest inventory were collected between 2017 and 2021. We simulated the plots' risk-free future growth for the next 30 years under the climate-change scenario RCP 8.5 and then estimated their mid-term economic potential. We used generalized linear mixed models to model the relationships between economic value and biodiversity and ecological functions. Additionally, we analyzed the effects of forest type on biodiversity, ecosystem functions, and socioeconomic indicators, and calculated the mean functionality, biodiversity and socioeconomic functionality. Our findings indicate that admixing beech with conifers increased the overall levels of biodiversity, functionality and economic outcomes in contrast with beech forests. Despite being a non-native species in Germany, Douglas fir´s inclusion in the portfolio of species, in small patches, had similar or even better ecological and economic effects than the European Norway spruce. Admixtures of deciduous species such as beech with conifers can be a nature-based solution to enable multi-purpose forestry in Germany and beyond.

Assessing tree diversity effect on tree resistance to drought through hydraulic safety margins

Abstract: Extreme droughts are increasing in frequency and intensity, leading to significant diebacks in forest ecosystems worldwide. Increasing species diversity in forests is often cited as a crucial factor in enhancing stand survival during droughts. Various processes, such as complementarity, facilitation, and competition release, could potentially alleviate water stress in individuals during drought events. However, there is limited available data, and existing data indirectly relate to water stress, with little consensus on this topic. Plant hydraulic ecophysiology provides a mechanistic understanding of how trees respond to drought. In this study, we relied on Tree Diversity Network experiments (i.e Experiments that manipulate woody plant diversity over wide diversity gradients and are designed to allow separation of diversity and identity effects) to explore the effect of species diversity on drought vulnerability of trees. We collected essential plant hydraulic traits related to water stress exposure (water potential) and vulnerability (vulnerability to cavitation) along diversity gradients during drought events. Our extensive measurement campaign took place between 2021 and 2023, primarily during the exceptional 2022 drought, at six network sites (Italy in 2021, France, Belgium, Austria, and Germany during the extreme drought of 2022, and Brazil in 2023). We analysed species richness and tree species composition using one-way ANOVA and observed a significant positive effect of species richness on HSM in approximately 25% of the studied species, which is concordant with existing literature. However, when considering species

composition of the stand instead of just species richness, more complex interspecific interactions emerged. This highlights the need for a deeper understanding of mechanisms that underlie tree interactions in such stressful dry conditions. By examining competition and diversity indices at the individual level, we gradually untangle the effects of individual neighbourhood structures on individual stress during drought events. Our findings indicate that species interactions, through yet-to-be-identify processes, or community size traits can better explain stress patterns than a species diversity index. This reinforces the notion that focal tree functional traits relative to neighbouring trees are key components in better understanding how mechanisms operate at the local neighbourhood scale in individual tree responses to drought.

Decision-makers' Perspectives of Mixed Tree Plantations in a Changing Climate

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Abstract: Forestry and forest restoration are promising activities to mitigate climate change, as forests have a high capacity to sequester carbon in a short period of time. Mixed tree plantations for sustainable timber production can be a viable and scalable strategy to reconcile economic and environmental benefits and reduce the vulnerability of plantations to climate change. However, despite scientific evidence on the advantages of mixed tree plantations, conventional monocultures still prevail globally. Expanding mixed plantations depends on the decision makers preferences, which requires more than ecological and scientifical evidence of plantation performance. Here, our aim was to analyze the main barriers and opportunities to expand more sustainable mixed plantations in southeastern Brazil and southwestern France. In order to support policies and incentives to adapt forestry to climate change and increasing environmental demands. We identified the factors that govern landowners and forest managers decisions about mixed plantations based on a qualitative research method, developed through semi-structured focal interviews to identify the main barriers and possible future solutions, based on their experiences. The main barriers identified were: Dealing with species competition/dominance effect; Need for a genetic improvement program; Higher operating costs; and lack of technical knowledge. And the solutions presented were divided into three levels of mixtures: Level 1: Mixtures of clones - more common where there are massive *Eucalyptus* plantations, level 2: Mosaics of different species (landscape level), and level 3: At least 2 species in the same plot. We provide a basis for potential alternatives to promote mixed planting of trees in forestry, thus increasing the resilience of forests to climate change, in addition to their ability to provide multiple benefits to nature and people.

Effect of Regeneration Timing on Competition in planted Norway spruce and Birch Mixtures

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Babatunde Dosumu[1]
Emma Holmstrom[1], Ulf Johansson[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences (SLU), SE-23053 Alnarp, Sweden

Abstract: Establishing mixed forests plantations is more complex than monocultures, it requires knowledge of the individual trees in the mixture. Pioneer species such as birch are light demanding and fast growing early in the rotation. Conversely, spruce is a shade tolerant late succession species that, dominates the forest canopy over time. In southern Sweden, studies have shown the need to give naturally regenerated birch an early start when the goal is to intermix with planted spruce. Allowing naturally regenerated birch to establish before planting decreases the competition with planted spruce later in the rotation. Since naturally regenerated birch has a relatively low productivity, the production gains of intermixing with spruce is minimal thus it might be interesting to establish spruce – birch mixtures using improved material of both species in the regeneration. The aim of this study is to:

-Establish mixed stands of birch – spruce on former agricultural land by planting

-Understand how birch species grow at different planting times relative to spruce in the same stand

The mixed species experiment was established between 1989 - 1990 at Alingsås in southern Sweden. There are four (4) blocks with three (3) treatments randomly assigned within each block. In the first treatment plot, birch and spruce were planted at the same time, 1989. Birch was planted one year after spruce in the second plot while spruce was planted one year after birch in the last treatment plot. Mixture proportion of individual species is 50/50.

Data collection was carried out autumn 2023 with analysis completed in spring 2024. The results highlighted how the regeneration timing has impacted development of the mixture after three decades.

Effects of single- vs mixed-species restoration planting on biodiversity: A systematic review.

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Klaus Kremer[1]
Trishna Dutta[2], Beng-Gunnar Jonsson[3], Juergen Bauhus[1]
[1] University of Freiburg
[2] European Forestry Institute
[3] Swedish University of Agricultural Sciences

Abstract: Tree planting is expected to play a major role in achieving the restoration goals set globally to mitigate the impacts of climate change and to promote biodiversity and ecosystem services provision. However, the effectiveness of tree planting can vary depending on the contexts and methods employed. While there is growing evidence supporting the benefits of mixed-species planting for biodiversity, a comprehensive quantitative analysis of this knowledge is currently lacking. Moreover, specific taxonomic groups may respond quite differently to tree diversity at different spatial scales. To address this knowledge gap, we are conducting a systematic review to examine the effects of mixed vs pure planting on biodiversity. Our aim is to identify both global and regional patterns in the response of biodiversity to mixed planting, considering overall biodiversity as well as specific taxonomic groups.

Through a systematic search employing several search engines, we initially retrieved 6,374 studies potentially addressing our research question. Based on title and abstract we preliminarily selected 178 relevant field studies. These publications will undergo further selection through full-text assessment, considering their experimental design, the type of analysis conducted, and the format of the data provided. From the final pool of studies, we will extract data that allow us to conduct meta-analyses of experimental comparisons between mixtures and monocultures. In addition to identifying overall patterns in biodiversity responses, we will examine variations across different regions, climates, and ecological and management conditions. These analyses will provide insights into the underlying processes that drive the effects of mixed planting on biodiversity, and will allow us to offer case-specific recommendations for management practices involving restoration planting.

Fourteen years of research on the effect of diversity on trees : the IDENT-Montreal experiment

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

[3] University of Vermont

Abstract: Exploring the relationship between tree diversity and ecosystem functioning (BEF) has been an important focus of forest ecology in recent years. In particular, understanding the impacts of tree diversity on productivity has received special attention. After three decades of intensive research, there is now a general consensus that tree diversity positively affects forest productivity. This research also revealed mechanisms and environmental factors that, together, can strongly influence such effects across space. However, how and why tree diversity effects on productivity vary over time along stand development remain elusive.

This communication relies on growth and mortality records (among others) from the IDENT-MTL experiment that covers the early stages of stand development: stand establishment, canopy closure, and self-thinning. The experiment was established in 2009 and includes close to fourteen thousand trees of nineteen tree species (twelve natives, which we will focus on) in monocultures and mixtures of two, four, and twelve species.

We will demonstrate that not only is complementarity strong in mixtures, but that is as increased steadily with time. Self-thinning, or the density of trees in relation to their size, played an important role with now over half of the trees having died due to competition. We will also demonstrate that in fact not all species and communities react positively to diversity, and that certain combination of species are favoured.

Finally, we will look at how these fit with other results from this and other forest diversity experiments, and what may be the new frontiers in BEF research with trees.

Higher species diversity would benefit the two commercially significant conifers in Sweden: A single species perspective on mixed species forestry

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Zsófia Réka Stangl[1]
Maja K. Sundqvist[1], Michael J. Gundale[1]
[1] Swedish University of Agricultural Sciences

Abstract: A majority of forests in the Nordic region are managed as even-aged monocultures of pine or spruce. However, standard management methods have come under considerable scrutiny as society is demanding greater complexity in ecosystem services. This is often seen as a trade-off by the industry, relative to managing forest for productivity. However, there is a large body of ecological literature on how resource use complementarity of different tree species can actually enhance productivity, which could make productivity and complexity goals synergistic. Few studies have yet addressed how Nordic tree species grow at the individual tree level, when grown in monocultures or mixtures. Using tree core data from the Swedish National Forest Inventory, we set out to explore the effect of species mixtures on the 10-year basal area increment (BAi_{10}) of pine, spruce and birch, against the backdrop of the large latitudinal and temperature gradient of Sweden. Using linear mixed-effects models, we modelled BAi_{10} as a function of tree size, climate and stand composition, with stand density, soil characteristics, and year of sampling as random effects. Spruce growth rates were similar in monocultures and mixtures with pine above 60° north, but were higher in monocultures in the south. In contrast, pine benefited slightly from growing in mixtures with spruce, especially towards the south. Growing in mixtures with deciduous trees was beneficial for pine across the country, while spruce benefited significantly in these mixtures above 60° north, and was either not affected, or somewhat negatively affected towards the south. Growing in mixtures with conifers had no significant effect on the growth rate of birch.

In contrast with conventional knowledge, our analysis reveals that pine benefits from growing in more diverse stands. The response of spruce was temperature dependent; it grows best in monocultures in the southernmost parts of the country, while towards the north, growing in mixtures with deciduous trees becomes highly beneficial, and growing with pine is mostly neutral. Overall, we conclude that higher proportion of deciduous trees would benefit the growth of commercially significant conifers, at the same time substantially increasing biodiversity in the currently conifer-dominated forests of Sweden.

Meta-Analysis on the benefits of mixed plantations compared to monoculture

Abstract: Species diversity in mixed forests can be one important means of mitigate climatic change effects. However, complex plant interactions changing resource availability and use, lead to controversial results in the overall comparison of mixed and pure plantations across published studies. Discovering communalities among them is crucial. This study aimed to identify the main benefits of mixed stands. First, we performed a literature review of the last five years to search published comparative studies between mixtures and monoculture for several traits. Fifty studies involving mixed and pure plantations measuring tree growth, soil physics, chemical and microbiological characteristics were found. *Eucalyptus, Populus*, *Pinus*, and *Quercus* were the species most frequently used in designing mixtures. Second, we performed a meta-analysis of the ratio of means (ROM) of mixed and pure plantations for each trait. Our results indicated that the highest benefit of the mixing of species is found in biomass stock and most traits related to tree growth (ROM: 1.30 to 4 in average). Increased diversity of predator insects and fungi community were reported under mixed plantations. There was no agreement among studies on the effects of mixing on timber quality and soil physical and chemical properties. Our results summarize and confirm published findings about key benefits of mixed plantations in increasing tree yield and resilience to climate change. Site-species specific designs would be necessary to enhance the potential benefits of mixed plantations.

Mixed forests of Quercus suber and Pinus pinea: Enhancing the ecological and economic value of rural Mediterranean regions

Abstract: Challenges imposed by climatic uncertainty and global economy require a paradigmatic approach for forest management, rendering the existence of large monospecific areas an increased risk. The concept of mixed forest is consequently gaining interest, but is difficult to implement given the limited comprehension of these systems. Forest mixtures are far less investigated than pure ones and there is a need to fill knowledge gaps, such as the species that will be benefited/put in disadvantage by mixed systems or how and when to conduct silvicultural interventions. Forests around the Mediterranean basin are known for the production of a vast range of non-wood forest products (NWFP), such as pine nuts and cork. Currently, in Portugal, the mixture of the broadleaved *Quercus suber* (producing cork) and the conifer *Pinus pinea* (producing pine nuts) is gaining the attention of landowners, because of the potentially higher economic revenues and lesser investment risk under erratic climatic scenarios. This renewed interest is essential to counteract rural population abandonment, and may positively impact the spreading control of pests and diseases, soil conservation and biodiversity maintenance.

However, an interdisciplinary approach is needed, bridging ecology, economical and societal questions. Taking *Quercus suber* x *Pinus pinea* mixtures as example, this study address important questions like: What are the advantages/disadvantages of mixing these species? Which combination can provide higher revenues? Which management practices contribute more to enhance NWFP and fire prevention? Which composition is more susceptible to pests? Which mixture can sustain higher levels of functional diversity and promote carbon sequestration? How do forest managers perceive change and innovation in silvicultural practices and what is their willingness to adopt and implement them?

During three years, a set of plots was established in a north-south ecological gradient in Portugal where natural regeneration forests and mixed plantations were intensively monitored, engaging forest managers and landhowners in the project development. Together with greenhouse

experiments, where the two species were grown isolated and in combination, the results provide valuable guidance for managers who want to carry out the transition from monospecific to forest mixtures, maintaining ecosystem services without losing economic income.

Possibilities for increasing spruce and birch mixtures in southern Sweden: Insights from a simulation study

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Babatunde Dosumu[1]
Jorge Aldea[2], Emma Holmstrom[1], Urban Nilsson[1]
[1] Southern Swedish Forest Research Centre, Swedish University of Agricultural Sciences (SLU), SE-23053 Alnarp, Sweden
[2] Instituto de Ciencias Forestales (ICIFOR) / Forest Science Institute Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria CONSEJO SUPERIOR DE INVESTIGACIONES CIENTÍFICAS

Abstract: Today most of the regenerations in Sweden have the potential to become mixed forests; however, Scots pine and Norway spruce monoculture dominates mature forest stands. The natural regeneration potential of birch species in southern Sweden presents opportunities to increase species diversity in planted Norway spruce stands. Nonetheless, much research is still required to effectively manage these mixtures and develop silvicultural guidelines. Other important aspects includes assessing productivity and economy of spruce-birch mixtures in relation to the business as usual scenario of growing spruce monoculture.

Inventory data after first pre-commercial thinning from well-replicated mixed species experiment composed of naturally regenerated birch and planted spruce were the starting values in Heureka decision support system (StandWise). These trials were established on high productivity sites in southern Sweden. The mixed stands, which had different initial species proportions B2S1 (66% Birch, 33% Spruce) and B1S2 (33% Birch, 66% Spruce) were managed following two pathways. First strategy involved thinning to maintain initial species proportion (_mix) until final felling while the second focused on removing the smallest trees of either species (_TFB). Thinning in the spruce monoculture was according to common silviculture of the species in Sweden (_mono). At the economically optimal rotation age, birch proportion (% basal area), growth (MAI_{max}), and profitability (LEV) of spruce-birch mixed stands were assessed in comparison to spruce monoculture.

Retaining 18 – 30% birch until the end of the rotation in the mixed stands provided similar and sometimes better growth (9.63 – 10.16 m^3 ha^{-1} yr^{-1}) compared to spruce monoculture (9.7 m^3 ha^{-1} yr^{-1}). These spruce dominated mixed stands were also more profitable than growing spruce monoculture. Conversely, mixed stands with a high birch proportion (c.a. 63% of basal area) had 14% less growth relative to spruce monoculture. Thinning out the smallest trees regardless of the tree species proved most effective in managing the mixed stands. Given the potential of birch regeneration in southern Sweden, this study indicates synergies between growing spruce-birch mixtures, optimizing growth and economic gain.

Potential areas for forest plantations with native species in the province of Talara-Piura

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Zoila Lasmit Cerón Cancharis[1]
Ethel Rubin De Celis Llanos[1]
[1] Universidad Nacional Agraria La Molina

Abstract: The study generated a model of potential areas to establish forest plantations with the native species Prosopis pallida and Colicodendron scabridum in the province of Talara, department of Piura, Peru, using Geographic Information Systems. The climatic, edaphic and topographic requirements of the site and of the aforementioned species were considered in the methodology, evaluating their aptitudes in the areas determined as potential for multipurpose plantations based on the model developed by the National Forestry and Wildlife Service, this input was validated with data collected in the field phase. To determine the potential areas for each native species, a Hierarchical Analysis Process was carried out. As a result of the research, areas with different degrees of suitability for both species were determined. For Prosopis pallida an area of 11 343.97 hectares with high aptitude and 10 478.44 hectares with medium aptitude was determined, and for Colicodendron scabridum an area of 7 634.17 hectares with high aptitude and 14 188.24 hectares with medium aptitude was determined. The results of this study show that there are potential areas not only for installing forestry plantations, but also that these can be carried out using native species through mixed plantations. Native species are better adapted to the terrain where they are installed because they meet the site conditions, having previously developed naturally in the area. Thus, plantations with native species are a proposed solution for mitigating and adapting to climate change.

Productivity and resources acquisition of Norway spruce and silver birch in monocultures and a mixed plantation in hemiboreal conditions

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Abstract: Establishing mixed forests instead of monocultures is considered to improve the ecosystems' resilience to climate change. Mixing suitable tree species should give a complementarity effect, due to the mixture being able to use available resources more efficiently in comparison with a monoculture. Therefore, it is expected that mixtures will overyield monocultures of the same species and contribute to a higher climate benefit through higher carbon uptake. However, several studies in Northern Europe do not approve of the production advantage of mixtures over monocultures. Thus, the mechanistic understanding about resources utilization in mixture and monocultures are needed to design productive and resilient forest ecosystems under climate change.

A dual labelling experiment was established in monocultures and a 50/50 planted mixture of Norway spruce (*Picea abies* (L.) H.Karst.) and silver birch (*Betula pendula* Roth) in hemiboreal Estonia on abandoned agricultural site at the age of ~20 years. A solution of $K^{15}NO_3$ and $^2H_2$-labeled water were used to describe the vertical and horizontal rooting area of trees for nitrogen and water acquisition. Annual aboveground measurements were carried out to estimate current annual production. The present study does not support the generalization of mixtures overyielding at the current stand age. After two decades, the most productive forest type by stem volume was the spruce monoculture followed by birch monoculture and then the mixture with 198, 152 and 146 m^3/ha^{-1}, respectively. Birch benefited from the reduced intraspecific competition in the mixture as the mean stem volume of a single tree was 121% of the mean single tree stem in the monoculture. Spruce suffered from the interspecific competition in a mixture as the mean stem volume was 40% of the mean single tree volume in the monoculture. The growth advantage of birch over spruce in the mixture in comparison with their monocultures indicates interspecific competition rather than niche complementarity for soil resources in mixture. Based on the results new recommendations on forest management and silvicultural practices could be made to improve the establishment of mixtures in Northern Europe.

The significance of tree species richness, structural diversity and functional diversity for forest productivity and stability under drought

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Abstract: The increasing intensity and frequency of droughts threaten the world's forests and their potential to mitigate climate change. Mixed forest plantations may foster productivity and ecological stability compared to monospecific plantations under drought. However, the determinants, direction and drivers of tree diversity effects on productivity and stability remain elusive. Using a combination of dendroecological, inventory- and trait-based approaches, we examined if diversification in terms of tree species, structures, and drought-tolerance traits promotes the productivity and stability of forest plantations. With this aim, we studied diversity-productivity and diversity-stability relationships across spatiotemporal scales in both the tropical Sardinilla and the subtropical BEF-China tree diversity experiments located in Panama and China, respectively. Both experiments compare monocultures with mixtures of increasing tree species richness ranging from 1–5 species in the Sardinilla and 1–24 species in the BEF-China experiment. We found that tree species richness consistently increased productivity and stability. This effect was strongest at the highest levels of diversity. Disentangling the contributions of different diversity facets highlighted that structural diversity promoted productivity but was unrelated to stability. In contrast, diversity in functional traits related to drought tolerance fostered stability but not productivity. Studying drought-tolerance traits appears crucial for understanding the effect of species richness on tree responses to drought. Drought-sensitive species – those with traits indicative of low resistance to cavitation and a water-spending stomatal control – profited most from species richness under drought. Positive tree diversity effects on productivity scaled up from the local tree neighbourhood to the stand level, while positive diversity effects on stability were an emergent stand-level property. Species richness increased stand-level stability via asynchronous, trait-driven species responses to dry and wet years. Importantly, functional diversity and not functional identity in drought-tolerance traits increased stand-level stability. Overall, our experimental findings emphasize that promoting forest plantations diverse in species, structures, and functional traits can foster high productivity and stability and, thereby, their climate change adaptation and mitigation potential.

Tree diversity and functional traits as predictors of stand productivity

Abstract: Forests need to be resilient and adaptive in the face of global environmental change and mixed species forestry is a critical strategy for achieving this goal. It has been shown in many studies that mixed species forests can be more productive, more resilient to stress and disturbance while also providing a broader range of ecosystem services relative to mono-specific forests, yet the underlying mechanisms are not clear. Contrasting inter-specific functional trait expression and increased structural heterogeneity in mixtures may enhance community resource utilization, which could help explain synergistic effects on tree growth. Here, we conducted a meta-analysis of data from 21 tree diversity experiments across 5 continents to determine the extent to which mixed forestry can promote increased growth as measured by stand-level basal area and height mean annual increment. We then used structural-equation modeling to quantify the strength of linkages between species diversity and growth via vertical and horizontal structural heterogeneity, functional trait diversity, and functional stand composition. We will discuss our findings in terms of general growth trends identified, and potential mechanistic diversity-productivity pathways in tree species mixtures. The results can contribute to informing policy-makers and forest managers about the overall effectiveness of mixed forestry.

Tree diversity can improve forest resistance to insect pests at multiple spatial scales

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Hervé Jactel[1]
Bastien Castagneyrol[1], Inge van Halder[1], Nattan Plat[1]
[1] INRAE, umr BIOGECO, 33612 Cestas, France

Abstract: Faced with the spectacular increase in damage caused by forest pests as a result of global change, and with public opinion becoming increasingly demanding in terms of nature conservation, forest managers are looking for effective control methods that are also environmentally friendly. Converging results have shown that the diversity of tree species can improve the resistance of forests to attacks by insect pests. But this nature-based solution is not widely adopted by foresters because of the complexity of managing mixed forests. A recurring question is therefore how to mix tree species, and in particular at what spatial scale this diversity should be organised. Using the pine processionary moth as a case study, we studied the effect of mixing coniferous and deciduous trees at different spatial scales, from intimate mixing between trees, by juxtaposing plots of different compositions, to heterogeneous landscape compositions. We consistently found more pine processionary attacks in pine monocultures than in mixtures at the three spatial scales studied, but the effect of diversity varied according to the composition and structure of heterogeneous stands and landscapes. These results can be explained by the underlying mechanisms of associational resistance, both the bottom-up effects of host resource concentration and disruption of host tree finding processes, and the top-down effects of control by natural enemies, which also operate at different scales. This study opens the way to taking greater account of the diversity of trees in the design and management of forest plantations and landscapes to improve their resistance to increasing biotic hazards.

Tree growth responses to the Central European 2018-2020 drought as modulated by diversity, mycorrhizal type, and drought-tolerance traits

T2.18 Mixed forest plantations as natured-based solutions for climate change mitigation and adaptation

Abstract: Climate change scenarios predict an increasing frequency of consecutive drought years, likely having negative impacts on tree growth in Central European forests. Although mixing tree species has been found to increase the temporal stability of growth in tree communities, the results of different studies are still inconsistent with respect to extreme drought events. Recent studies show that besides climatic conditions, it is the biotic context, i.e. the traits of focal trees and their local neighbors, that modulates biodiversity–ecosystem functioning (BEF) relationships. However, it is not yet clear if functional trait identity and/or diversity can mitigate the impacts of extreme drought events. Here, we studied how tree growth in experimental forest plantations is influenced by tree diversity before, during, and after the Central European 2018-2020 drought. In addition, we explored how these relationships are modulated by mycorrhizal association types and other functional traits. We used annual growth data (2015-2022) of 5,120 tree individuals growing in a young tree diversity experiment in Germany (MyDiv) and measured functional traits related to drought tolerance and resource use of 10 broad-leaved tree species to model BEF relationships under drought. We found a positive response of individual tree growth to diversity in the pre-drought period and the first drought years. Nevertheless, this relationship reversed in the last drought yearnd the early post-drought period. Further, these relationships were modulated by the mycorrhizal type of the tree species; most strongly in the post-drought period. Tree species' drought-tolerance traits and traits related to resource use formed a joint trait syndrome. We found two axes of trait variation mainly driven by cavitation resistance and stomatal control, respectively. Analyses on the modulation of diversity–productivity relationships by these trait syndromes are ongoing. Overall, this study contributes toward understanding the biotic context dependency of BEF relationships under drought and provides a functional basis for designing tree species mixtures able to cope with climate change.

T2.19 Non-timber forest products and the bioeconomy

A Study on the Situational Analysis of NTFPs in Asian Region for Selected Commodities: Enhancing Community Livelihoods and Sustainable Value Chains

T2.19 Non-timber forest products and the bioeconomy

Junghwan Park[1]
YoungJu Han[1], Andaya Emmanuelle[2], Crissy Guerrero[2]
[1] Asian Forest Cooperation Organization (AFoCO)
[2] NTFP-EP Asia

Abstract: This study addresses the challenges and opportunities associated with non-timber forest products (NTFPs) in Asia, focusing on enhancing community benefits and promoting sustainable value chains. The livelihoods of rural communities, including indigenous peoples and women, heavily rely on NTFPs. However, accessibility, sustainability, and development of NTFP value chains vary among countries.

In order to address these challenges, the study examines NTFP sectors in 12 Asian countries: Bhutan, Cambodia, Indonesia, Kazakhstan, Kyrgyzstan, Laos, Mongolia, Myanmar, Philippines, Thailand, Timor-Leste, and Vietnam. By conducting a comprehensive analysis, including the identification of community-based enterprises, resource management practices, market dynamics, policy frameworks, expert opinions, and case studies of selected commodities, the study provides strategies to enhance community benefits and promote sustainable NTFP value chains, and valuable insights for interventions at the country level.

Four strategies Identified are as follows:

1. Resource Sustainability/Enhancement: The study emphasizes securing and enhancing NTFP supplies through sustainable harvesting, plant management, and cultivation. Collaboration and knowledge exchange among participating countries can optimize resource utilization.

2. Market-Responsive Product and Service Development: Standardization, certification, and product diversification are crucial for increasing community benefits. Market research should guide the development of high-value NTFP products, such as crafts, bamboo-based goods, medicinal plants, and nature-based tourism.
3. Research and Knowledge Building: A regional research agenda is proposed, covering baseline development, sustainable resource management, harvesting methods, and market research. Knowledge creation and exchange support the transition to a knowledge-based NTFP sector.
4. Innovation and Inclusive Approach: Adopting an innovative approach to NTFP sector development and defining competitive edges for each country can enhance community livelihoods and contribute to national economic goals. Building an entrepreneurial ecosystem for community-based NTFP enterprises is crucial for long-term success.

Interventions at the country level should prioritize resource management, value addition, market research, community enterprise formation, and partnerships with stakeholders to maximize NTFP benefits. Developing policies and strategies through a roadmap will enable the NTFP sector to

thrive, benefiting communities and sustainable development goals. By adopting a regional approach, knowledge sharing, experimentation, and collaboration among countries can lead to resilient and inclusive NTFP value chains in Asia.

Application of Tea Buffer Zones for Prevention of Forest Encroachment and Livelihood Improvement in Forest Reserves

T2.19 Non-timber forest products and the bioeconomy

Mercy Rutto[1]
Leila Ndalilo[1], Samson Okoth[1]
[1] Kenya Forestry Research Institute

Abstract: Forest encroachment in indigenous natural forests in Kenya has been one of the major contributors to forest deforestation. Kenya lost about 50% of its forest covering about 300,000 hectares between 1980 and 2000 due to extensive logging, charcoal burning, and extensive clearing of forested regions for food crops plantations. Various strategies have been employed to stop and reverse this negative trend, Forest buffer zones using tea crop has been one of the approaches implemented over the years through the Nyayo Tea Zones Development Corporation. This study investigated the effectiveness of the 100-meter tea buffer zones as a management strategy for the prevention of forest encroachment and livelihood improvement in Kakamega forest reserve Kenya. Geographical Information Systems (GIS) was used to map the extent of protection attributed to the tea buffer zones between the period 1985 - 2022. The household survey and Focus Group Discussions were conducted among 108 forest-adjacent communities to obtain their views on the importance of the tea buffer zones and their perception of forest conservation. The results from GIS indicate that along the tea buffer zones, 4.5% of forest ecosystem recovery was realized between 2005 and 2022. Socioeconomic results indicate that 30% of the forest adjacent communities were employed on the buffers tea farms, additionally, the communities rated the forest as a very important natural resource (69.7%) as it provided them with key benefits including the source of food and medicine (31.2%), provision of firewood (24.8%), environment conservation (14.7%) and preservation of cultural sites (7.3%). Based on their opinions the communities rated the forest buffer contribution to forest conservation moderately at 43.1%. These outcomes show a perfect association between forest conservation strategies and livelihood improvement. The decision to place tea buffers along the forest reserves proved to be an effective tool in preventing forest encroachment and improving the livelihoods of the forest-adjacent communities through the provision of alternative income.

ARE NON-TIMBER FOREST PRODUCTS CONCENTRATED AT REGIONAL AND STATE LEVEL IN BRAZIL?

T2.19 Non-timber forest products and the bioeconomy

Felipe Corrêa Ribeiro[1]
Sebastião Renato Valverde[1], Carlos Moreira Miquelino Eleto Torres[1], Lucas Abreu Kerkoff[1]
[1] Departamento de Engenharia Florestal, Universidade Federal de Viçosa, Brasil

Abstract: Brazil is the country with the largest tropical forest in the world and second in forest cover. The conscious use of natural forests permeates plant extraction of non-timber forest products (NTFP). The vast national territory, the diversity of the population and the forests mean that different products are produced, with a great variability of use. Understanding where it is produced, and the quantity allows us to indicate improvements and advances to encourage and increase their production in the country. Thus, the objective of the work is to determine the degree of concentration of production of the main PFNM between the years 1991, 2001, 2011 and 2021. they are: Açaí, Yerba mate, Brazil nut, Carnaúba (powder) and Babaçu (almond). The data was obtained from the survey of the production of vegetal extraction and forestry (PEVS) in Brazil. Two indices were used, the adapted concentration ratio (CR1) and the Herfindahl-Hirschman index (IHH). Both present results in percentage, where 100% indicates higher concentration. Concentration at regional/state level was analyzed. The 5 products are highly concentrated at a regional level (>85%), with emphasis on the North region, which produces Açai and Brazil nuts, and the Northeast, with carnauba and babassu. Carnaúba and yerba mate are 100% produced in a single region, Northeast and South, respectively. At state level, only Açaí and Brazil nut are deconcentrating their production, increasing production in different states of the region. Yerba mate and Babaçu are considered of high concentration (>75%) at state level, Paraná and Piauí, respectively. Only Yerba mate and Brazil nuts changed the dominant state in production between 1991 and 2001. The main NTFPs in Brazil are highly regional, due to the immense Brazilian diversity and phytophysiognomies, and largely concentrated even at the state level. Cases such as Açaí and Brazil nuts are becoming less concentrated at the state level, thanks to national recognition. As these are the products with the highest production, it is important to encourage their expansion, especially in the states of the domain region.

Assessing harvesting and postharvest handling practices of Strychnos cocculoides fruit in the Kavango West Region of Namibia.

T2.19 Non-timber forest products and the bioeconomy

Selma Ndemutila Elago[1]
[1] Directorate of Forestry. Okahandja Forestry Research Centre, Namibia

Abstract: The purpose of this study was to asses harvesting and postharvest handling practices of *Strychnos cocculoides* fruit in relation to the quality of the fruit in two study sites namely: Kaguni and Mile 20 in Kavango West Region; Namibia. The study identified existing harvesting and postharvest handling practices. It assessed the level of postharvest losses of *S. cocculoides* fruit at different handling practices and consumer preferences by evaluating Total Soluble Solids (TSS), taste, size, and weight when harvested at different maturity stages (fully mature, half mature and just mature). Semi structured questionnaires, focus group discussion and direct observations were employed for data collection. The findings indicate that fruits are harvested by women and children for consumption and income generation. Fruit were harvested fully mature, half mature and just mature. Climbing the tree and using the stick method to dislodge fruit were the two methods used for harvesting. Vehicle, donkey/oxen cart, head load or public trucks were used to transport fruit from the field and to other towns within Namibia. Poor harvesting and post-harvest handling practices were observed in both study sites. Community farmers lack knowledge of proper harvesting and postharvest handling practices. The maturity stages at which the fruit were harvested had no significant effect on fruit weight, size and TSS as well as taste in terms of consumer preferences. Fruit damage due to cracks bruises, rotting during harvesting, transportation, storage and marketing was the main challenges caused by poor harvesting and handling practices. Fruit were reported to be deteriorating resulting in short shelf life. The poor harvesting handling practices can have a negative impact on the income generated from the sale of the harvested fruit. Recommendations are made on how to improve on the existing fruit handling practices.

Ecological envelopes for species producing non-timber forest products in Portugal

T2.19 Non-timber forest products and the bioeconomy

Abstract: The Portuguese forest ought to correspond to the main forestry and industrial sectors' needs, and an increase in the area covered with Mediterranean species has to be undertaken, also mitigating climate change effects. This study aimed at predicting the spatial distribution of species producing non-timber products (chestnut, cork oak, and stone pine) and to understand the future spatial changes expected in emission change scenarios. The ecological envelope methodology (assessing each species' ecological requirements) was applied to infer those species' potential area, in both present and future, in two Shared Socioeconomic Pathways (SSP2-4.5 and SSP5-8.5), and two slice-time periods (2050 and 2090). The bioclimatic data downloaded from WorldClim 2.1 and the elevation from the Shuttle Radar Topography Mission, with a spatial resolution of 1 km, were used for modelling in the present. For the future, we used the Model EC-Earth3-Veg and the Shared Socioeconomic Pathways SSP3-7 from the CMIP6 (Coupled Model Intercomparison Project Phase 6). The ecological envelope methodology used ecological variables temperature and precipitation-related, and elevation. To evaluate the produced model for each species, we used two maps algebra methods: i) the Boolean method, where the species' area was obtained by multiplying the resulting variables reclassified with the Boolean approach (0-Inadequate, 1-Adequate), and ii) the additive model, where a final map is classified in five ranks: (4) excellent, (3) good, (2) fair, (1) marginal and (0) inadequate, by summing the environmental variables binary maps. The maps produced with the Boolean method were tested with the Integrated Aptitude for Mainland Portugal maps for the studied species (available on *EPIC WebGIS*), through a performance indicator (F) ranging from 0.30 to 0.70. Maps made with the additive model were evaluated by the spatial join with the National Forest Inventory points and a match of 72% to 99% was verified in the classes (4) excellent for the present. The chestnut area will drop from the current 45% area to nearly 9% in the best-case scenario and to 1% in the worst-case scenario. The results will help in planning these species' afforestation under climate change scenarios. This project was funded by CULTIVAR (CENTRO-01-0145-FEDER-000020), and also by FCT projects CERNAS-IPCB (UIDB/00681/2020), MED (UIDB/05183/2020), and CEF (UIDB/00239/2020).

Economic and Ecological Potentials of Non-timber Forest Products in Chure Landscape (Siwalik Hills) of Nepal

T2.19 Non-timber forest products and the bioeconomy

Yadav Uprety[1]
Ram C Poudel[2], Dipesh Pyakurel[3]
[1] Central Department of Botany, Tribhuvan University, Kathmandu, Nepal
[2] Nepal Academy of Science and Technology
[3] Resources Himalaya, Kathmandu

Abstract: Non-timber Forest Products (NTFPs) contribute significantly to maintaining rural livelihoods in most parts of the developing world. Primarily, NTFPs are the source of subsistence but are often the source of regular cash income and also serve as a safety net in times of crisis. Recently, studies are also directed toward understanding the role of NTFPs to enhance the adaptive capacity of households in the context of climate stresses. The Chure landscape, the longest and largest landscape of Nepal, in the outer foothills of the Nepal Himalayas is one of the most fragile and vulnerable landscapes because of its weak geological formation and pressure from anthropogenic factors. The conservation sensitivity and needs of the landscape are the concerns of the authorities for the last two decades. NTFPs are an important source of income for the local people in Chure-Terai Madhesh. The Master Plan of Chure-Terai Madhesh Conservation and Management has identified a number of potential species for marketing and livelihood. In this paper, we analyzed the NTFP harvest and trade data for the last fifteen years from landscape and prioritized the species having the potential for trade and soil protection based on a number of variables. Fifty-seven species traded from the Chure-Terai and additional three species having the potential of soil protection were subjected to priority ranking. Based on the prioritization criteria 17 species are identified as high priority species, another 17 species as medium priority species and 26 species are prioritized as low priority species. We argue that the promotion and/or management of these NTFPs in the landscape help achieve the dual objectives of economic development and ecological protection and restoration of the landscape.

Examining New and Developing Value Chains of Ecosystem Services: A Comprehensive Analysis

T2.19 Non-timber forest products and the bioeconomy

Paula Horne[1]
Airi Matila[2]
[1] Pellervo Economic Research PTT
[2] Tapio oy

Abstract: This paper presents an examination of selected new and developing value chains of ecosystem services that are not yet established in the market or whose value creation is poorly understood. Our study focuses on value chains from diverse ecosystems, namely forests, agricultural lands, and water bodies. While the focus is on cultural services, some less developed value chains of production services, such as non-wood forest products, were included in the analysis.

To gain a comprehensive understanding of the overall development of value added in the bioeconomy, we analyze the relationship between newly developed ecosystem service value chains and the more established bioeconomy value chains. Through this analysis, we identify complementary, neutral, and rivalrous dynamics, particularly in terms of land use.

Furthermore, we conduct an in-depth examination of the key players involved in the value chains and their contribution to value-added formation within the selected ecosystem services. Additionally, we investigate the demand and distribution of value and costs along the value chain.

Finally, our study assesses the bottlenecks that hinder the realization of the full value potential of ecosystem services. We propose possible solutions to overcome these challenges and suggest strategies for increasing the value added of ecosystem services.

This research contributes to the understanding of emerging value chains within the bioeconomy and sheds light on the opportunities and constraints associated with the development and commercialization of ecosystem services. The findings provide valuable insights for policymakers, businesses, and stakeholders seeking to capitalize on the untapped potential of ecosystem services in creating sustainable and economically viable solutions.

Non-Wood Forest Products' related habits of Spanish households shaping bioeconomy demand: consumption and harvesting factors and trends

T2.19 Non-timber forest products and the bioeconomy

Elena Górriz-Mifsud[1]
Valentino Marini Govigli[2], **Guillem Castellano-Durán**[1], José Antonio Bonet[1, 3], Marko Lovrić[4], Irina Prokofieva[1], Riccardo Da Re[5, 6], Enrico Vidale[5, 6], Davide Pettenella[5], Jenny Wong[7], Robert Mavsar[4]

[7] Wild Resources Ltd., Bangor, UK

Abstract: Non-Wood Forest Products (NWFP) represent a substantial resource for recreational and commercial activities in forest areas. According to Lovrić et al. (2020), 26% of European households collect NWFP, mainly for self-consumption. This share indicates the high, often underestimated, bioeconomy potential of these forest resources. However, the existence of marked between-country differences regarding the harvesting of non-animal NWFP by households makes it necessary to focus on country-level patterns to get further insights into the use and harvesting of NWFP. In this contribution, we zoom into Spanish data on harvesting and consumption patterns of NWFP with the aim of understanding their main predictors.

We hypothesized that variables such as the presence of children in the household, household size and income, municipality population, urban/rural self-identification, surrounding forest area, and the purchase of NWFP could be potential determinants for being a picker household.

Descriptive and logistic regression analyses were conducted to check the influence of these variables, for all NWFPs altogether and for each NWFP category separately. Our results show that 18.4% of the households in Spain pick yearly some type of NWFP. Otherwise, 93.5% households buy, at least, one of this. Specifically, 13.4% pick wild nuts, 12% wild mushrooms, 11.8% wild plants, 10.3% wild berries, 8% decorative plant materials and 1.1% pick truffles. These figures reflect the degree of technical and physical accessibility to the resources.

Also, households with higher incomes and municipal forest area, purchasing NWFP, living in a less population municipalities and auto-perceived themselves as them who live in rural areas are more likely to (mostly non-commercially) pick NWFPs. Interestingly, the exposition to forests (with different buffer areas) only contributed significantly to explaining NWFP-picking patterns for a wild plants and wild berries.

These figures reveal the actual gathering practices and consequent socio-ecological pressures and bioeconomic potential, which contrast with their typical invisibility within official statistics. Policies facilitating the organisation of these dispersed activities would allow for checking their sustainable

practice. Besides, facilitating the health and fiscal requirements for commercialization could boost more regular marketing in rural areas.

Opportunities and Constraints in Green Economy within the Forestry Sector among Western Kenya Counties

T2.19 Non-timber forest products and the bioeconomy

Stella Gatama[1]
[1] Kenya Forestry Research Institute, Lake Victoria Eco-region Research Programme P.O Box 5199-40108 Kisumu, Kenya. Stella Gatama1, Samson Ojung`a1,George Etindi1, Bernard Odit1. Email Addresses: sgatama@kefri.org and sojunga@kefri.org

Abstract: Green Economy dates back to 1989 when David Pearce et al., gave a report on green economy "Blue Print for Green Economy" that was commissioned by the UK Government. Green Economy focuses on sustainable use of renewable resources, sustainable agriculture and forestry among others. Ecosystems are facing risks due to increasing rates of depletion in natural resources to satisfy human needs and wants. Hence, a robust and regulatory framework is therefore important for effective implementation and management of green economy policies that will lead to the improvement of well-being. This research work looks at opportunities in green economy development in the forestry sector among stakeholders as well as challenges that hinder the attainment of green economy development.

Diverse stakeholders from 63 organizations in 9 Counties within the Lake Victoria Basin, were evaluated on how best to reverse unsustainable forestry related activities to promote sustainable development in production and consumption of forestry goods and services. The results indicate that women constitute approximately 78.7% of the persons involved in initiation and planning of green economy activities. The main funding sources are from organization's internal budgets (36.5%), businesses (19.1%) and contributions from family and women groups (12.7%). The stakeholders viewed green economy as an opportunity for job creation (50%), gender empowerment (35%) and for forest ecosystem services (15%). However, barriers that hinder the development of green economy include but not limited to; high dependence on forestry resources, inadequate funding and high cost of implementing initiatives. There is need for social inclusion and adoption of improved technology that will lead to the achievement of green economy within the country. The research work concludes that there is need for further assessment on the impacts of forestry green economy bio-enterprises and interlink forestry green economy practices with blue economy.

Resource Assessment and Marketing of Caterpillar Fungus (Ophiocordyceps sinensis) in the Buffer Zone of Makalu Barun National Park, Nepal

T2.19 Non-timber forest products and the bioeconomy

Damodar Gaire[1]
[1] Tribhuvan University,Institute of Forestry, Hetauda, Nepal

Abstract: Yarsagumba *(Ophiocordycecps sinensis)* is one of the highly expensive and potential medicinal mushrooms in the world. Owing to the herb's high efficacy and potency in curing various diseases, it is well known as an important nourishing tonic. The study has attempted to gather information regarding Yarsagumba, its associated species, various medicinal uses, and marketing channel. Out of 15 plots, only 3 plots were recorded the Yarsagumba with a frequency of 0.2 which was very low compared to other medicinal plants. We randomly recorded the Yarsagumba with a density of 833 (No)/ha equal to 0.5 kg/ha in the effective area. There was an imbalance between the population of moths and the spores of Caterpillar fungus. There were increasing trends in *Cordyceps sinensis* market, heavily dependent on Chinese buyers. The Chinese companies send agents to collect Yarsagumba directly from the fields. And they pay US$ 10/piece to villagers (according to the latest field study, June 2019). China is the largest producer of Yarsagumba and meets 95 percent of the world's demand. Nepal is the second largest supplier of fungus. Expansion of marketing channel is essential for getting more benefits focusing on local Yarsagumba collectors. It was observed that only 14.51 percent of men participated to collect the Yarsagumba because the majority of men migrated to India and overseas for searching jobs. Therefore, women would play a vital role in the sustainable harvesting of Yarsagumba. Different pharmacological actions such as antiasthma, antineoplastic, and antibacterial as well as actions on the heart and blood vessels, and on the smooth muscles of the intestine and uterus have been reported. The government of Nepal should prepare a national Yarsagumba management policy and local Yarsagumba management guidelines to address conflicts by clearly defining the roles, responsibilities, and rights of local institutions and actors. The Makalu Barun National Park should also prepare a separate management plan for sustainable harvesting so that local people would enhance their income, and the government would also increase income through royalties.

Keywords: Yarsagumba; Production; Collection; Sustainable Harvesting; Marketing, Policy

Rock rose produces potential non-timber forest products

Abstract: Global warming predictably will affect inland areas in the Mediterranean region, already distressed by extensive summers and severe drought. The rockrose (*Cistus ladanifer* L.), a shrub widely distributed in the Iberian Peninsula and North Africa, produces valued metabolites (e.g., labdanum resin), and could further be explored for biomass production, and as a food and feed source. Shrublands play an important role in the atmospheric CO_2 uptake, helping in global warming mitigation, since they act as carbon sinks. This makes the species a natural resource target in Mediterranean areas.

A rock rose common garden experiment installed in central Portugal, inland, was established by the end of October (2021) using 5 individuals (half-sibs with the same mother plant) from 5 different families (mother plants) collected from ten populations spanning the entire range of the species, in a randomized compact-family block experimental design. The common garden objectives are: 1) to establish a non-destructive method to estimate biomass production, 2) to estimate biomass production variability among and within populations and families, 3) to rank the populations, families, and individuals for biomass production, and 4) to select the best-suited rockrose lines to produce secondary metabolites. The first and second measurements were made 116 and 254 days after the plantation. The mean of crossed diameters and total height were used to calculate the cover area (circle) and the plant volume (inverted cone), to compare individuals' growth. In the 1st assessment, the differences between provenances were significant for the growth traits (height, canopy area, and volume). The provenance PG (Penha Garcia, Portugal), a local provenance, had always the highest growth traits, followed by a nearby located Spanish provenance, EVC

(Valdecaballeros, Spain). The PSV (São Vicente, Spain, subspecies *sulcatus*) and ESP (Sierra Palmitera, Southern Spain) had the worst growth traits performances. The mortality, in the 2nd measurement, was higher for the PBR, a northern provenance, followed by MKE and ESP, southern provenances. PAL (Alentejo, Portugal) had the lowest mortality. The populations and families will be further evaluated for biomass and metabolite productivity and profile, using the destructive analysis approach. This research was supported both by the CULTIVAR project (CENTRO-01-0145-FEDER-000020), and by Fundação para a Ciência e Tecnologia, projects CERNAS-IPCB (UIDB/00681/2020) and CEF (UIDB/00239/2020).

The hunting market - the market hunt: wild meat trade by indigenous communities in the Peruvian Amazon

T2.19 Non-timber forest products and the bioeconomy

Diego Shoobridge[1]
Zoila Cruz[2], Waldemar Mercado[1], Thomas Valqui[2], Ademar Ribeiro[3], Raymundo Mogollón[1], Jaime Porras[1]

[2] National Agrarian University La Molina Peru - Forestry Program
[3] Universidade Estadual de Campinas, Brazil – Program of Economics

Abstract: Little is known how bushmeat markets operate in the Peruvian Amazon and the influence they have on levels of extraction for food and commercial purposes. This paper analyzes the relationship between hunting intensity and the supply-demand interaction of bushmeat in the market in the central Peruvian Amazon region. It analyzes how the price of bushmeat relates to the intensity of hunting in native communities and to the demand for bushmeat in the market.

Price plays an important role in the use and trade of bushmeat. In the markets, bushmeat adopts supply and demand mechanisms, self-regulating. However, in the urban sector much of the bushmeat that reaches the city is sold outside the markets, which does not guarantee an efficient formal market.

The research confirms that the extraction, trade and use of bushmeat in the native communities of the Ucayali River near the city of Pucallpa are related to the commercialization of the resource in the city. The amount of meat shared, meat sold, and the average price are related to the total amount of meat hunted. The three elements interact influencing each other.

It is recommended to promote the legal sale of bushmeat of managed species in formal markets so that it can be subject to greater control, and allow prices to achieve a sustainable equilibrium level in the extraction and sale of bushmeat. Provider legalization should be promoted through registration requirements, management plans, and payment of fees and taxes. This guarantees greater monitoring of the flow of bushmeat to formal markets, allowing a price structure to be managed whose balance maintains supply and demand at levels that do not impose an increase in the quantities of meat hunted.

THE POTENTIAL OF NON-TIMBER FOREST PRODUCTS FOR THE BIOECONOMY IN LATIN AMERICA AND CARIBBEAN

T2.19 Non-timber forest products and the bioeconomy

Sandra Regina Afonso[1]
Janaina Deane de Abreu Sá Diniz[2], Ana Margarida Euler[3], Max Yamauchi[4], Maria de Fátima B. Lima[1], Roger Villalobos[4], Prado Fabiana[5], Neluce Soares[5], Kolbe Soares[6], Evelyn Cháves[4], Bruna De Vita Silva Santos[7], Mauro Luis Ruffino[8]

Abstract: South America is estimated to account for 21% of the world's forests. The countries of Latin America and the Caribbean (LAC) are the most biologically diverse in the world. South America alone is home to half of the Earth's biodiversity. Furthermore, biodiversity is embedded in the foundations of the cultures that have inhabited LAC. Within this context are non-timber forest products (NTFP), which have gained prominence in the last decade with the spread of the concept of bioeconomy in several countries. However, little attention is still being given to the potential of the bioeconomy associated with forests, given that it is not yet widespread and more in-depth discussions about its scope and challenges are needed. In this scenario, a forum has been organized with the aim of debating the bioeconomy of NTFPs used in the region. The BioForestALC – 1st Virtual Forum on the Potential of Non-Timber Forest Products for a Latin American and Caribbean Bioeconomy – through a set of events held between the end of 2021 and the beginning of 2022, brought together 350 participants from 20 countries, including civil society and government representatives, who discussed and formulated 142 action proposals to unblock the bioeconomy of NTFPs in Latin America. These proposals were systematized and grouped into 6 major lines of actions that should serve as the basis to guide future dialogues, activities and public strategies: (1) Capacity building considering the integration of different knowledge and the Food Security-Bioeconomy-Forest nexus; (2) Strengthening the commercialization, markets and value chains of the bioeconomy; (3) Inclusion of restoration in bioeconomy strategies; (4) Public/private promotion of research considering different types of knowledge and involving the various actors in society; (5) Promotion of financial mechanisms to develop bioeconomy chains; (6) Articulation for the elaboration, regulation and implementation of public policies. Although more discussions are needed, these action lines represent an important step and an opportunity to advance the promotion of a bioeconomy that is concerned to conserve forests and strengthen the livelihoods of populations in Latin America and the Caribbean, since NTFPs have been a fundamental part of hundreds of ancestral cultures.

Traditional knowledge, geographical indications and non-timber forest products towards a bioeconomy in community-based agroforestry systems

T2.19 Non-timber forest products and the bioeconomy

Ryo Kohsaka[1]
Yoshitaka Miyake[2]
[1] The University of Tokyo, Graduate School of Agricultural and Life Sciences, Japan
[2] Ministry of Agriculture, Forestry and Fisheries, Policy Research Institute, Japan

Abstract: Non-timber forest products and Geographical Indications: Will high quality be justified in era of climate change and population shrinkage in east Asia?

The production of non-timber forest products, such as shiitake, charcoal, and urushi (lacquer for wood products), in east Asia face multiple challenges from shrinkage of populations and climate change. To address these challenges, policy support instruments were introduced; Geographical Indications (GIs) at product level, Globally Important Agricultural Heritage Systems (GIAHS) at area designations or official instruments such as ordinance or notification including the one by Agency of Cultural Affairs for urushi. Such instruments frequently refer to the quality advantage of such products based on the domestic environment or terrior. The literature has separately discussed the effects of such instruments. Here we comparatively discuss and examine synergy and trade-offs of these policies and landscape management instruments for NTFPs.

There are three items of NTFP that are analyzed here to compare and evaluate the "taxonomy of support instruments."

Kunisaki City belongs to the Kunisaki Peninsula in eastern Kyushu Island. The Peninsula is part of Kunisaki Usa GIAHS. Log-cultivated shiitake production contributes to cyclical use of sawtooth oaks (Quercus acutissima). The government of Kunisaki City has been providing financial support on the purchase of spawn blocks. The city adopts a higher rate to purchase blocks of low-temperature varieties. Global warming destabilizes the production of these low-temperature varieties. Some government promotion now includes branding of mid-temperature varieties.

The Iwate Charcoal Association has made efforts to increase and standardize the quality for more than a century. This increased the carbonation level of charcoal. Because of these developed and shared production methods, the association applied for GIs hoping the price increase.

Joboji Urushi, Japanese lacquer of Joboji, increased its demand since 2015. The Agency of Cultural Affairs has demanded the use of domestic urushi for the preservation of cultural properties. Reacting to the increased demand, the city government of Ninohe started the preliminary resource management measure to map available urushi trees (Toxicodendron vernicifluum). Furthermore, the Joboji Urushi Association registered for GIs for the counterfeit prevention and the stable price. Historical production justified the registration.

Transition pathway for wild-simulated ginseng to forest-based bioeconomy

T2.19 Non-timber forest products and the bioeconomy

Mi Sun Park[1]
Hansol Lee[2]
[1] Seoul National University
[2] Asian Forest Cooperation Organization

Abstract: Non-timber forest products are useful foods and products, frequently vital income sources for forest communities. Wild-simulated ginseng is a non-timber forest product that has received attention for promoting the livelihoods of mountain villages and providing healthy foods. This study examined transition pathways to forest-based bioeconomy focusing on the wild-simulated ginseng industry in the Republic of Korea. Policy discourse on non-timber forest products has transited from quantity-oriented to quality-oriented, focusing on food safety in the Republic of Korea. This change in policy discourse on non-timber forest products supports the high value of wild-simulated ginseng in the market. The Korea Forest Service has adopted a quality management system targeting wild-simulated ginseng. Centralized governance mode controls food safety in cultivating and trading wild-simulated ginseng in the Republic of Korea. This research focused on adding values to non-timber forest products and developing strategies to enhance the wild-simulated ginseng industry for integration into the forest-based bioeconomy. This research proposes a pathway to revitalize the wild-simulated ginseng industry and transit to a forest-based bioeconomy. A biotechnology-based industry for wild-simulated ginseng can be developed focusing on specialization, technological innovation, and transparent governance to transit to a forest-based bioeconomy. The case of wild-simulated ginseng can be a model of biotechnology-based bioeconomy in the non-timber forest product industry.

Understanding the illegalities in the trade of central Himalayan medicinal plants

T2.19 Non-timber forest products and the bioeconomy

Dipesh Pyakurel[1]
Carsten Smith-Hall[2], Mariève Pouliot[2]
[1] Resources Himalaya Foundation, Nepal
[2] University of Copenhagen, Department of Food and Resource Economics, Denmark

Abstract: The increase in global demand for medicinal plants contributes to the bioeconomy at local, national, and regional scales but premature and over-harvesting, and illegal trade are posing threats to the survival of wild medicinal plants. Taking the case from Humla district of Western Nepal, this paper analyses the nature and scale of corruption in the trade of medicinal plants. Empirical trade data were obtained in two time periods: 2014-15 and 2021-22 using semi-structured and open-ended questionnaires. While the number of traders won't change in two time periods; 21 in 2014-15 and 23 in 2021-22; the volume of trade increased from 133.34 tons to 402.67 tons over two time periods. Concurrently, the value of trade increased from USD 1.39 million in 2014-15 to USD 1.94 million in 2021-22. The volume of jatamansi (*Nardostachys jatamansi*) records a massive increment: from 85.8 tons in 2014-15 to 224 tons in 2021-22 followed by Kutki (*Picrorhiza scrophulariiflora*): 35.5 tons to 48.8 tons in two time periods. Interestingly trade of setakchini (*Polygonatum cirrhifolium* and *P. verticillatum*) was unrecorded in 2014-15 but the volume of trade reached 107.8 tons in 2021-22, showing how the overseas demand shapes the trade. The trade is associated with different forms of illegalities like harvesters not receiving the collection permits, harvesting beyond the allocated quotas, premature harvesting, use of alternative names to save royalty, and rent-seeking from government officials. While there are not any shortcuts to deal with illegalities, the study proposes to transfer the management rights to local governments and adoption of cost-effective yet scientific methods (e.g., environmental niche modeling) for quota allocation to minimize the illegalities.

Keywords: Environmental products, Humla, Nepal, Premature and over-harvesting, Quota allocation, Rent-seeking

T2.20 Novel treatments for wood and biobased products

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

A Data-Driven Holistic Analysis Framework for Economic Impacts Assessment of Forest Biomass for Bioenergy

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Xufeng Zhang[1, 2]
Jingxin Wang[2]
[1] School of Economics and Management, Beijing University of Technology, China
[2] School of Natural Resources, West Virginia University, USA

Abstract: A data-driven holistic analysis framework was developed to aid the industrial development of forest biomass for bioenergy to promote the regional bioeconomy. Leveraging the existing but fragmented multi-source data, four components of industrial bioenergy development were integrated into the framework including spatial statistical analysis of biomass feedstock and bioenergy production, machine learning-based suitability assessment, bioenergy plant sites identification and ranking, and socio-economic impacts assessment. A case study was conducted for forest biomass to pellet fuel in the U.S. Mid-Atlantic region. Our results indicate that the great potential of forest biomass with high variation at the county level is primarily clustered in western Pennsylvania and eastern North Carolina. Integrating the datasets of biomass feedstock, road conditions, employment status, income status, population, and current bioenergy production, the machine-learning model demonstrates good performance for bioenergy industry suitability assessment, with the high-suitable areas accounting for 19.76%, medium-suitable areas for 34.74%, and low-suitable areas for 54.49% in the region. Forest biomass availability and distance to major roads are the two top factors affecting bioenergy industry development. We identified 65 industrial sites within the suitable areas and their rankings were derived as a reference of the bioenergy development priority. The socio-economic impacts assessment indicates that the one-year construction of a medium-size pellet fuel facility (75,000 dry tons/year) could create 127 jobs, $8.78 million of labor income, while the operation could create 202 jobs, $10.52 million of labor income, $14.66 million of value-added, and $33.61 million of output in total per year for the state-level economy.

Keywords: Forest biomass; Bioenergy; Holistic framework; Machine learning; Suitability assessment; Economic impacts.

A multi-criteria decision support system for the optimum provision of forest ecosystem services in a forest-based bioeconomy

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Martin Brunsmeier[1]
Sandra Krommes[1], Veronika Auer[1]
[1] Rosenheim University of Applied Sciences

Abstract: Forest ecosystems and therefore also the forest-based bioeconomy are affected by rapidly changing climatic and market conditions. Climate change makes it essential to increase the resilience of forests to protect them from storms, fires, pests and drought. At the same time, forests should serve as the basis for a sustainable and circular bioeconomy: for carbon sequestration and water retention, ensure a sustainable supply of wood and non-wood products, and serve for recreation and tourism. The complexity of stakeholder demands, as well as the natural influence of the changing climatic conditions, make it difficult to decide on sustainable forest management for the optimum provision of forest ecosystem services towards a forest-based bioeconomy while strengthening the resilience of forests.

The EU Horizon 2020 project ONEforest presents a multi-criteria decision support system that provides stakeholders of the complete forest-wood value chain with information for decision-making. Partially contradictory ecological, social and economic objectives of stakeholders in the forestry and wood industry are assessed, and synergies and trade-offs between different forest ecosystem services and their effects are simulated over the next decades.

In four case study regions representing different climatic and geographical regions (boreal, alpine, Mediterranean and continental climate), different forest management options and their impacts on forest ecosystem services are analysed. In an interdisciplinary approach involving stakeholders, the decision support system is based on forest growth models and combines them with a multi-criteria optimisation approach to reflect stakeholders' demands on the forest-wood value chain. The corresponding impacts on the wood industry are presented with an additional system dynamics model. This system dynamics model is based on material flow analyses and (social) life cycle assessments. Using a scenario technique, future developments in the political, technological, environmental, economic and social fields are considered. The multi-criteria decision support system serves as a blueprint for other European regions to balance forest ecosystem services taking into account the impacts of climate change and the regional situation. Stakeholders (from e.g. forestry, industry, politics and NGOs) can use this support system to optimize their decisions towards a sustainable and circular forest-based bioeconomy.

Assessing the circularity and cascading resource use of Danish wood flows using national material flow accounts

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Niclas Scott Bentsen[1]
Huntley Brownell[1], Bogomil Iliev[2]
[1] University of Copenhagen, Department of Geosciences and Natural Resource Management
[2] University of Copenhagen, Department of Food Science

Abstract: Understanding how wood is used has important implications for forest management, economic policy, and climate action. While individual wood streams are documented by various sources, a comprehensive, economy-wide mapping of wood use, its circularity and cascading has been lacking in Denmark.

Our study presents a comprehensive national wood flow analysis for all wood products, to include harvest, import, export, and domestic flows through the economy, as well as to assess the level of circular and cascading wood resource use.

The analysis builds on Physical Supply-Use Tables compiled by Statistics Denmark in combination with other sources to construct wood flows including documented and undocumented harvest, import, export, flows between industries and to final consumption, as well as residues and waste. We estimated total Danish use of wood fibre in 2018 to be around 17,747,000 m^3 Solid Wood Equivalents (SWE), of which more than 15 million m^3 was used for energy production. Most wood used in Denmark is imported, with a net import of more than 11 million m^3 SWE.

Based on Eurostat's Circular Material Use rate indicator, 8.4% of wood used is recycled and reused domestically. The overall cascading factor for wood in the Danish economy was calculated to be 1.44, indicating that wood is used almost one and a half times before oxidation or final consumption.

By using simple mass balancing principles, we identified significant undocumented flows of wood into the economy which are currently used for energy purposes, representing more than 1 million m^3 SWE per year from 2015 to 2021.

Ongoing monitoring of wood flows in national economies is paramount in supporting and documenting a transition to a circular bioeconomy and to increase environmental and climate benefits of wood products and materials.

Assessment of the sustainability of apiculture, a forest-based enterprise for improved livelihoods and provision of ecosystem services in Kenya

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Mercy Gichora[1]
Jonah Kiprop[2], Anthony Macharia[3]
[1] Kenya Forestry Research Institute, Forest Productivity and Improvement Theme
[2] Kenya Forestry Research Institute, Socio-economics, Policy and Governance Theme
[3] Ministry of Environment, Climate Change and Forestry, Kenya

Abstract: Studies were carried out in 2020 to document the status of beekeeping in Kenya's arid and semi-arid lands (ASALs) where rain-fed agriculture is quite limited but opportunities may be explored for non-wood forest products. The baseline survey was complemented by a value chain analysis of beekeeping enterprises in Kajiado, Tana River and Siaya Counties of Kenya. These Counties were until recently sparsely populated and naturally endowed with honey bees and appropriate bee forage plants. The studies incorporated the random administration of questionnaires, key informant interviews and focus group discussions (FGDs) amongst diverse value chain actors. A gross margin analysis was thereafter undertaken to assess the potential and profitability of the beekeeping enterprise. It pointed out an average profitability of USD 88 and USD 13 for crude and refined honey/year per hive respectively, in all three counties. Traditional lifestyles were reportedly facing increasing pressure from land use changes occasioned by human migration and an increasing local population, conversion of rangelands to crop production, livestock overstocking of animals and deforestation for charcoal production. The studies revealed several barriers that limit the commercialization of the sector. They included poor enforcement of laws and quality standards (policy), inadequate knowledge of production, harvesting and processing methods (technical), perceived high initial cost of inputs for setting up apiaries (financial), marketing limitations and taboos that forbid women to participate in apiculture or its association with witchcraft and poverty (cultural). There was little local appreciation of the ecological services offered by bees. The apiculture value chain was thus not fully functional as a forest-based bio-economy in the selected counties, which could reflect the situation nationally. Kenya, therefore, remains dependent on imports to meet a deficit in quality honey and hive products. We recommended the development of comprehensive beekeeping policies incorporating capacity building of actors along the value chain for improved household income and enhanced supply of ecosystem services at the county level. The apparent need to adopt and strengthen enforcement of national and global standards to improve the quality and value of hive products should be addressed.

Key words: Case study, bioeconomy, beekeeping, policies

Açai: Success story of integrating a global product through informal markets with marginal indigenous and local communities

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Abstract: In the last decade, açai (*Euterpe oleracea*) has become part of a global chain, with growing markets mainly in the United States and Europe. At the same time, it represents a staple food for a large part of the Amazonian population, including indigenous and traditional communities. Until today, the coexistence of local informal circuits has been possible with the structures of global chains. In our research, we sought to understand how indigenous and local communities participate in the açai chain, both in local marketing circuits and in national and international supply chains. Data on the açai value chain were collected from official documents, interviews and observations during field missions in the Brazilian states of Amapá and Pará. The greatest production and consumption are found in the state of Pará, but the largest exporters are companies in the state of São Paulo. Informal circuits are important to guarantee the food and nutritional security of the local population; however, they are not yet being contemplated by public support although these markets need to improve transport, storage, processing, marketing and communication infrastructure. In global circuits, purchasing companies depend strongly on local communities regarding fruits supply. In this sense, producers coordinating through associations, cooperatives or collective brands makes possible to group larger supplying volumes, as well as requirements for different types of certifications. Challenges arise for both local and global markets, mainly in terms of logistics infrastructure, communication and training of actors, not to mention the variation in production between harvests as it is a predominantly gathering product, and the decrease in supply during the off-season. Fruits providers and enterprises commitments may also enhance natural and social production factors, such has forest management – to avoid process of açaization (increase in the density of açai groves with biodiversity loss) and gathering labour conditions. The success story of açai, to be sustainable, needs to maintain the participation of local actors in the production and marketing activities, as well as local consumers since the fruit is the main food for Amazonian communities and generates thousands of jobs in the Amazon urban centers.

Bioenergy and landscape restoration in Indonesia

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Himlal Baral[1]
Ahmad Dermawan[1], Budi Leksono[2]
[1] Center for International Forestry Research and World Agroforestry (CIFOR-ICRAF)
[2] National Research and Innovation Agency (BRIN) Indonesia

Abstract: Land degradation is becoming a global challenge, with Indonesia being no exception. Rising populations and their associated food and biomaterial demands have accelerated the conversion of forests for other land uses; a trend that persists in many parts of the world. Forest landscape restoration (FLR) is being promoted as a means for reversing land degradation while providing multiple products and services, including bioenergy. FLR using biofuel-friendly trees under climate smart agroforestry practices and utilizing fruits, nuts and biomass for energy could solve multiple issues by turning unproductive degraded lands into productive landscapes; preventing further conversion of natural vegetation for other uses; compensating for the high initial investments required for FLR; and providing multiple ecosystem services, including climate regulation. This talk highlights multiple issues associated with FLR and bioenergy, such as policy analysis, geospatial assessment for identifying land suitability, farmers' perceptions and species-specific details useful for land managers, planners and policymakers.

Climate and energy policies and forest bioeconomy

Markku Ollikainen[1]
[1] University of Helsinki, Finland

Abstract: This paper examines how climate policy impacts the use of wood and allocation of side streams between energy production and higher valued biochemical products in forest bioeconomy. The starting point is the European Union's (EU) climate policy, where burning wood-based side streams for energy is treated as carbon neutral, because emissions from harvesting are calculated in the land-use sector. This policy is compared to an alternative, where burning biomass or use of wood is taxed according to their carbon dioxide (CO_2) content. Emissions trading hits not only direct CO_2 emissions but also increases the price of electricity. We demonstrate that emissions trading favors energy production instead of biochemical production and cascading use of wood, and green certificates may slightly increase use of fossil fuels. As an alternative policy, a carbon tax on harvested wood does not change incentives concerning allocating side streams between energy and bioproducts but a carbon tax levied on burned side stream decreases use of side streams in energy production, thus, promoting cascading use of wood-based side streams.

Does forest contribute to food security? Insights from a study case among small-scale farmers from the northern Peruvian Amazon.

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Karin Begazo Curie
Liesbet Vranken[1]
[1] KU Leuven, Department of Earth and Environmental Sciences, Division of Bio-economics, Celestijnenlaan 200E, 3001 Heverlee, Belgium.

Abstract: Forests have a decisive role for achieving SDGs, including those related to livelihoods and food security. A body of literature has illustrated that forests can support food security in some settings, however, this contribution is still not well understood, underestimated and not sufficiently included in policy decisions. The present study attempts to fill this gap by focusing on the forest direct contribution (provision of food and cost-saving) and indirect contribution (sale of forest products) to food security, by measuring the subsistence and cash income of a wide range of forest products and its contribution to the household income. For doing so, quantitative socio-economic data were collected from 400 households (HHs) located in fifty villages from two districts in the Department of Loreto. The research area comprises contrasting districts regarding tenure regimes, levels of remoteness and deforestation. We used the Household Food Insecurity Access Scale (HFIAS) to investigate the degree of food insecurity (access) and the Coping Strategy Index (CSI) to identify the most utilized coping strategies by the households. Our findings evidence that forests play a significant subsistence function on the livelihoods of rural households, particularly in poor and remote settings. The contribution of forests to food security is mainly through the provision of wild food and indirectly through the cost-saving from the use of fuelwood, NTFP (e.g., medicine and construction materials) and timber. We found that forest products such as NTFP and game are important sources of food, particularly for remote and poor households, lacking of alternative incomes. These products are also important coping strategies when HHs cannot access enough food. Even if cash income has a minor contribution to food security, NTFP such as fruits are important cash income sources while providing food for subsistence. Differences were found between tenure regimes and levels of remoteness regarding food insecurity. Our findings evidence the essential contribution of forest to food security (provision of food and subsistence goods) and should call the attention of policy makers and user managers for forest conservation and the sustainable use of forest products, especially in areas affected by deforestation and lacking of alternative income sources.

Efficient utilization of waste wood in a Circular Bioeconomy: Potentials and barriers

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Arbnore Cakaj[1]
Jan Luedtke[1]
[1] Thünen Institut of Wood Research, Leuschnerstrasse 91c, 21031 Hamburg, Germany

Abstract: This abstract focuses on circularity in forest-based bioeconomy and its contribution to achieving sustainability by integrating the economy, environment, and social dimensions. The circular bioeconomy concept is augmenting the academic and political interest since it aligns with the eleven Sustainable Development Goals of the UN 2030 Agenda, where it can contribute to a broader range beyond biomass production. The research comprises a comprehensive literature review on wood waste as a biomass affiliated with a forest-based bioeconomy, explicitly focusing on Germany. The evaluation of the wood waste position in the forest-based bioeconomy examines the integration of the frameworks for policies, initiatives, and influential projects and the most effectively used practices in German territories.

The outcome presents several recognitions of the forest-based bioeconomy benefits beyond the biomass potential. It stimulates research innovation, development, and job opportunities in the economic dimension. Advancing environmentally fosters ecosystem services and improves biodiversity conservation through sustainable forest management. In terms of the social dimension, it empowers the communities with public involvement to feel included and to bring awareness, knowledge, and benefits to society.

This research marks the value of the circular approach in the bioeconomy with a particular emphasis on the Forest sector, the importance of moving beyond the wood biomass perspectives, and the appreciation of the multi-dimensional benefits of forest-based bioeconomy. By adopting circularity in the forest sector, Germany and Europe, in general, can encourage forest-based resource efficiency to reduce environmental impacts and boost economic growth. To unlock the circular economy potential within the bioeconomy, it is crucial to embrace the cooperation of all the stakeholders throughout the whole value chain, involving the policymakers, the research institutions, and the industries. Embracing the cooperation of all these stakeholders throughout the whole value chain not only creates a path for a prosperous future but also emphasizes the significance of a holistic and circular path to a forest-based bioeconomy.

Empirical facts about forest-based production and product transformation on a global level: A stages approach

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

La Thi Tham[1, 2]
Tran Van Hiep[3, 4], Kendisha Soekardjo Hintz[5], Eckhard Auch[5], Jürgen Pretzsch[5], Dietrich Darr[6]

[5] Technische Universität Dresden, Faculty of Environmental Sciences, Institute of International Forestry and Forest Products, Chair of Tropical and International Forestry, Tharandt, Germany
[6] Faculty of Life Sciences, Rhine-Waal University of Applied Sciences, Kleve, Germany

Abstract: Global resources and potentials for wood biomass and other forest products are declining, while the demand is increasing rapidly and the numerous positive effects for people and the planet are well documented. The use of forest products on a global level is hardly investigated from a meta-perspective of a bioeconomy. There is a need for the implementation of efficient forest resource production and use systems. In the context of the Sustainable Development Goal (SDG) 12, especially target 12.2, a far-reaching application of mechanisms of a bioeconomy and technological innovation which provide ample opportunities to optimize the value chain and resource use efficiency is essential.

The global normative system of optimally resource efficient use is contrasted by specific local contexts of socio-cultural, political and socio-economic realities, technological standards, level of development and environmental conditions. These often do not allow the instant shift and implementation of technologically optimal solutions and, therefore, the realization of the bioeconomy.

A stages approach is proposed to characterize contexts and to initiate changes towards improved resource use efficiency and value chain upgrading, thereby leading to bioeconomy transformation strategies. Three exemplary stages, demonstrating the sequence from low to high utilization intensity, are described by case studies: (1) fuelwood production for cooking and heating in Ethiopia, (2) the transition from Acacia wood chips to furniture in Vietnam and (3) steps towards the integrative use of bamboo in Southeast Asia. The lessons drawn from these cases are further discussed using some instruments to enhance utilization efficiency - vertical cooperation among actors across different value chains, innovative financing mechanisms, and the implementation of Participative Innovation Platforms, a recently developed and tested instrument that is used to induce innovation.

Forest-based Sector and SDGs- How this relationship have been measured?

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Renata Aguayo Lopes Da Silva[1]
Renato Cesar Gonçalves Robert[2], Thomas Purfürst[1]
[1] University of Freiburg
[2] Federal University of Paraná (UFPR)

Abstract: Established by the United Nations in 2015, the Sustainable Development Goals (SDGs) are a collection of 17 objectives that must be accomplished globally by 2030. The SDGs aim to reduce hunger, increase gender equality, assist sustainable production and consumption, promote decent work, and improve life on land and below water. Forest-based bioeconomy emerges as a significant lead in combating climate change and advancing sustainable initiatives. The SDGs are a well-known acronym, but studies that quantify and delve deeper into this connection are still lacking when it comes to the forest sector's contribution to them. It is essential to understand how the link between forests and the SDGs has been explored in order to fully understand its synergies and trade-offs. In order to identify the approaches that have been employed, a review of methods to measure the Forest sector's contribution to the SDGs was performed. Articles from popular databases were analyzed according to inclusion and exclusion criteria, and 83 articles were chosen for investigation. Studies from 2015 to 2022, written in English, from different geographic regions, were grouped into eight methods categories, named: content analysis, personal perceptions, interpretative analysis, frameworks, models, impact analysis, time series data, and SDG Indicators. Along the studies, common approaches include Earth observations, remote sensing, the iSDG model, literature reviews, systematic reviews, SWOT analyses, case studies, the Delphi approach, online surveys, critical and theoretical analysis, macroeconomic modeling framework, Life cycle assessment (LCA), satellite image processing, SDG 15 targets, nature-based solutions, among others. The study aimed to encourage more research by providing an overview of approaches that have been used to address the issue. However, having a broad range of measurements available to address the SDGs can be challenging, since a large variety of methods applied also leads to difficulties in comparing, analyzing, and tracking them. In conclusion, future opportunities will demand more holistic approaches that should be used in order to understand all aspects involved in this context and more dynamic and systemic approaches must be further investigated.

Forestry beyond growth: Natural disturbance, degrowth, and the forest carbon sink

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Logan Robert Bingham[1]
Felix Bastit[2], Thomas Knoke[1]
[1] Technical University of Munich
[2] INRAE

Abstract: Economic growth is a major driver of climate change and biodiversity loss. Proposals to avert catastrophic climate change by downscaling economic growth (i.e., degrowth) are hotly debated, but the implications for forests remain largely unexplored. This presentation aims to introduce degrowth to forestry and forestry to degrowth. We show that previously-identified degrowth trajectories consistent with 2°C can generate negative Ramsey discount rates, complicating the use of the standard Faustmann formula. To address this, we derive an inclining rate schedule for the degrowth to steady-state transition and use it to explore how optimal management under disturbance risk might be altered by the expectation of a sustained economic contraction. To our knowledge, this is the first microeconomic analysis proposing a potential link between degrowth and forest composition. It suggests that even bioeconomy sectors which are not directly targeted for degrowth might be impacted by discount rate effects, including changing carbon dynamics and disturbance vulnerabilities. It also highlights that by simplifying their treatment of forest carbon dynamics, past efforts to model degrowth pathways may have neglected an important feedback: forest managers' expectations about the economic future.

From branch to beam: The resource-smart transformation of low-quality tree assortments into structural building materials

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Tobias Nenning[1]
Andreas Tockner[2], Michael Grabner[1], Christian Hansmann[1, 3], Wolfgang Gindl-Altmutter[1], Johannes Konnerth[1], Maximilian Pramreiter[1]
[1] University of Natural Resources and Life Sciences, Vienna, Institute of Wood Technology and Renewable Materials, Austria
[2] University of Natural Resources and Life Sciences, Vienna, Institute of Forest Growth, Austria
[3] Wood K plus – Competence Centre for Wood Composites and Wood Chemistry, Tulln an der Donau, Austria

Abstract: Defossilization efforts in the construction sector require the increased use of modern engineered wood products, which are mainly produced from conifers at present. But, in the face of climate change adaptation, Europe's vegetation shifts towards potentially more resilient hardwood and mixed forests. Since hardwoods differ fundamentally in their habitus and mechanical-technological properties, new approaches are urgently needed to increase efficient hardwood utilization. Indeed, bridging forestry and the wood processing sector is essential for mastering this challenge.

Therefore, the presented utilization concept starts in the forest, where deciduous trees including *Fagus sylvatica, Quercus petraea* and *Populus alba* were inventoried in their entirety using Personal Laser Scanning (PLS). Thereby, information on branch volume, diameter, length and inclination is collected since this assortment, together with the stem top, accounts for up to 50% of the aboveground biomass in deciduous trees.

The PLS data allows efficient sorting and breakdown of the non-uniform assortments into easy-to-transport dimensions. Furthermore, the PLS data can partially enhance our understanding of branch wood's variability in mechanical material properties.

Downstream processing is carried out using a technology, whereby the wood segments are processed in longitudinal - radial direction and split into elongated macro-fibres. Compared to traditional sawmilling a higher yield can be achieved with this technology. At the same time, the natural wood structure, which is important for the final mechanical properties, can be retained. In the final step, the fibre elements are further processed into structural beams and panel products relevant to construction.

This highly material-efficient utilisation concept for low-value hardwood is expected to enable a high proportion of forest product utilisation also in the future, contributing to a resource-smart use of biomass in the emerging bioeconomy.

From Neglect to Opportunity: Exploring the Potential of Non-Wood Forest Products in Europe's Bioeconomy through Innovation Cases

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Alice Ludvig[1]
Gerhard Weiss[1], Ivana Živojinović[1]
[1] University of Natural Resources and Life Sciences (BOKU), Vienna and EFI-FRPN

Abstract: The contribution examines the overlooked potential of non-wood forest products (NWFPs) in the context of forest-related bioeconomy research and policy. Taking an innovation system perspective, the study identifies barriers to NWFP development and proposes strategies for their support. By analyzing 20 innovation cases in Europe through document analysis and semi-structured interviews with experts, the research reveals that there is no singular innovation system dedicated to supporting NWFPs. Instead, sporadic support is provided through specific programs within different sectoral or regional innovation systems such as forestry, agriculture, nature conservation, rural, or regional development. Unfortunately, the institutional system exhibits a notable neglect towards NWFPs, resulting in a lack of statistical data, research, educational programs, training initiatives, and focused support structures. This study uncovers significant potential for NWFPs in the forest bioeconomy, particularly for private forest owners and producers. These opportunities range from subsistence-based NWFP collection to collectively organized production that benefits rural areas. The identified activities primarily involve product innovations, with some instances of service or social innovations, and a few cases combining multiple types of innovations. Drawing from successful examples, the study proposes suggestions to enhance innovation support structures

How to define and measure substitution effects in bioeconomy: A scoping review

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Fernando Gordillo[1]
Holger Weimar[1]
[1] Thuenen Institute of Forestry

Abstract: The substitution of bio-based resources instead of fossil-based ones is an important goal of the bioeconomy. Reviews and methodological approaches already exist on this topic; however, such existing scientific basis encompasses a wide diversity of definitions and quantification methods. Identifying how substitution effects are defined and what methods are used for their quantification will serve as the basis for the development of a framework concept for the evaluation of bio-based resources usage. This review, following the PRISMA extension for scoping reviews, documents the working definitions and quantification methods of substitution effects within bioeconomy. Appropriate peer-reviewed literature was searched for using databases from SCOPUS and Web of Science. Following an iterative identification process, selected articles for review included a mention of the term “substitution effect”, the type of biomass (agricultural, woody, fish), and the type of substitution (for material use or energy conversion). The resulting selection of articles was limited to publications in which a definition for substitution effects has been provided and a corresponding quantification method has been explained. From the selected articles we extracted information on methods applied for quantification of substitution effects, biomass types used for substituting fossil-based products, as well as on bio-based products and sectors. Preliminary results show that life cycle assessment methods are predominantly used and that a significant number of articles focused on the substitution of wood-related products for non-wood products. The findings of the full review will be used to develop an assessment of substitution effects within the German Bioeconomy Monitoring in order to identify more efficient and sustainable uses of bio-based resources.

Investigation of a Set of Indicators to Support the Establishment of Wood Biomass Heat Supply Projects: A Case Study in Japan

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Masaru Watanabe[1]
Koji Harashina[1, 2], Megumi Sasaki[3], Masashi Saito[2, 4]
[1] The United Graduate School of Agricultural Sciences, Iwate University
[2] Agri-Innovation Center, Iwate University
[3] Shiwa Green Energy Co., Ltd
[4] Faculty of Agriculture, Iwate University

Abstract: The demand for woody biomass energy in the region creates market value for small diameter wood and low quality wood. This will increase production opportunities for the main product, wood, from an economic standpoint, resulting in a synergy that improves the supply and stability of woody biomass as a by-product, contributing to the sustainability of forest resource use. Therefore, the promotion of appropriate woody biomass energy use is an important factor for sustaining a forest-based bioeconomy. Avoiding the risk of feedstock shortages is important for the establishment of woody biomass energy use. On the other hand, it is necessary to stably procure a certain amount of woody biomass to ensure the sustainability of the energy business. Therefore, an accurate evaluation of the amount of available woody biomass and improvement of its supply potential are required. Promising measures to increase the supply potential include higher purchase prices, subsidy policies, and infrastructure development, but there is a cost trade-off. On the other hand, the use of biomass energy has multifaceted benefits such as ensuring energy security, revitalizing local economies, and reducing GHG emissions. Therefore, in order to support and evaluate the energy use of woody biomass, it is important to present a comprehensive set of indicators such as the amount of available energy, the possibility of improving the supply potential and its cost, and the benefits to be obtained. In this study, these indicators are calculated for Shiwa Town, Iwate Prefecture, which is an advanced case study site for wood biomass heat supply in Japan. The town is currently planning to further expand the scale of heat supply, and this study examines the feasibility and necessary measures for this expansion.

Less grey more green, less concrete more wood? Construction material narratives toward sustainability

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Pipiet Larasatie[1]
Eric Hansen[2]
[1] University of Arkansas at Monticello, USA
[2] Oregon State University

Abstract: Purpose: Given historical developments in the construction sector and the path dependencies inherent in current practice, this study aims to capture the rhetoric amidst construction industry (wood vs concrete). We focus on the competing narratives employed by supporters on both sides of this “material warfare” and specifically investigate their advantage and disadvantage arguments.

Design/methodology/approach: To meet our objective, we looked at news articles through Google search tool using keywords “wood vs concrete building construction”.

Findings: The articles are published as early as 2006, and along the years, the competing conversations are more prominent with the “birth” of mass timber. The topic is also becoming an interest for specific audiences such as the architects, engineers, and insurance companies. Through inductive thematic analysis of 100 articles, we find that cost and sustainability are two dominant factors in the narratives.

Originality/value: Each sector claims to be more cost effective and sustainable than the others, typically sniping at each other. This rhetoric, we argue, will not be beneficial for society and environmental sustainability. A sustainable built environment requires cross sector collaboration between wood and concrete companies to handle difficulties that they cannot address successfully within their own sector.

Monitoring public perceptions of forest-based business in the drive towards the bioeconomy

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Karen Bayne[1]
Andrea Grant[1]
[1] Scion (New Zealand Forest Research Institute Limited), Christchurch, New Zealand

Abstract: *The pathway to a forest-based bioeconomy requires a higher level of interest and investment in forest-based business, including the need for increased propagation, planting, forestry operations, processing and consumer use of wood and fibre products. Each stage presents risk due to lock-in of existing production flows and industry investment. An inherent risk is that of public acceptability of new bioeconomy production, circularity, and desired consumer behaviour.*

This research has been underpinned by a gap in knowledge about public perspectives of forestry and forest management practices, as well as growing awareness of the cost of losing social licence or resistance to new forestry developments. As many national bioeconomies are heavily reliant on forest sector strength, and others look to increase their forestry plantings and investments, we need a better understanding of forestry's social licence. Industry-level support from publics is needed for forest bioeconomies to thrive. Policy makers need to be confident that developments to meet circular and biobased production goals are not shut down by societal concern, and investment returns are not undermined by unforeseen developments in the consumer marketplace.

A segmentation survey revealed five clusters of typologies based on concerns for plantation forest practices, values, worldviews and environmental identity, levels of trust in forestry and support for commercial forestry. Clusters also showed differences in degrees of agreement with social, cultural environmental and economic values; different orientations to scientific, western and indigenous worldviews; and a characteristic tendency towards specific demographics associated with some clusters.

Identifying public views that lie outside of dominant media voices or opinion leaders creates a baseline from which future changes in social licence can be measured, anticipated and responded to. Social reactions can be monitored, and proposed solutions provided to address negative reactions before they become an issue. In addition, the range of personas present within these typologies supports targeted messaging towards certain public groups, identifying segments of society that may require specific social impact assessment, or personas that will be more likely to give support to forestry-based bioeconomy initiatives, particularly those large in scale or that may change the landscape or social fabric within communities.

Novel natural capital approach to value creation in the development of forest-based business: resilient and socially just economies

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Mirja Mikkilä[1]
Ritva Toivonen[1], Anne Toppinen[1]
[1] Department of Forest Sciences | Faculty of Agriculture and Forestry Latokartanonkaari 7 P.O. Box 27 00014 University of Helsinki

Abstract: Natural Capital refers the world's stocks of natural assets which include geology, soil, air, water and all living things. The natural capital provides a wide range of raw materials, products and ecosystem services making human life possible. In this, the Planetary Boundaries set the safe operation space for humanity (Steiffen et al., 2015). Especially two of the global challenges, climate change and biodiversity loss, influence directly on the natural capital-based bioeconomy. The changing operation environment, such as awareness of environmental pressures, EU policy regulation, and regional policy targets related to, for example, energy security, industrial policy, and just living call for 1) strengthening the resilience of the natural capital business models and 2) innovating new businesses for integrated value creations based on climate and biodiversity wise solutions.

The novel natural capital business challenges the prevailing silo-structures of the natural capital sub-sectors, such as agriculture, forestry, renewable energy, mining. In this the recent cases indicate both financial profitability and environmental sustainability of integrated agri-forest-environment business models, e.g. from Indonesian forest-plantation context (Mikkilä et al. 2021) and circular bioeconomy models in Southern Finland (Leppäkoski et al., 2021; Luhas et al. 2022). Furthermore, the Forest Biodiversity Program for Southern Finland (METSO) shows the voluntary forest protection by landowners based on public-private partnership. The program enhances biodiversity by developing permanent and temporary protection agreements and compensating a part of the commercial value of forest and land to landowners (https://mmm.fi/en/forests/biodiversity-and-protection/metso-programme).

Novel approaches integrating more holistically natural capital related sub-sectors and operations needs to be addressed in research and economic development to turn the grand challenges to opportunities in novel natural capital business. The scale of the solutions can vary from micro to global ones, but the sustainability of the models should lay on the strengthening of the resilience and social justice of societies. To address the need for new natural capital business, we model in this paper, employing a literature review, 1) what active management and productizing of forest nature values (specific ecosystems) is, 2) how pricing and trading models can be developed, and 3) how the required banking model is outlined.

Opportunities for a sustainable and circular development of the wood sector in Wallonia

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Sophie Trachte[1]
Tom De Mil[2]
[1] Faculté d'Architecture, Unité de Recherche en Architecture (URA), ULiège, B-4020 Liège, Belgium
[2] Forest is Life, TERRA Teaching and Research Centre, Gembloux Agro Bio-Tech, University of Liège, Passage des Deportés 2, 5030 Gembloux, Belgium

Abstract: In the framework of its strategy for smart, sustainable, and inclusive growth, the European Commission has introduced the concept of Smart Specialisation Strategy (S3) with the objective to enable Members States to adopt new regional strategies for scientific research and industrial innovation. The Walloon Government adapted its Strategy S3, for the period 2021-2027. Its objective is creating new and robust ecosystems of innovative "academic and industrial research" around five main strategic areas, amongst others circular materials. Wood can be a circular material, and within this framework, the initiative "VALorisation du BOis en WALlonie - VALBOWAL", leaded by the University of Liège and supported by other Walloon Universities and organizations/companies, has been accepted with the goal to support Walloon circular economy development while diversifying the Walloon forests, strengthening their resilience to climate change and increasing their carbon storage, whilst stimulating the local economic development of the wood sector, and optimizing the carbon storage in wood products. Three research axes, completed by a transversal axis focusing on professional training and wood promotion, have been proposed, to encourage fundamental developments in three major fields:

- **Resilient and diversified Walloon forests** with the objective to rethink the constitution of regional forests with more diversified, more dispersed and multiple ages species, while striving to make it more productive and relying on digital technologies (inventory, resource mobilization and traceability).
- **First and second transformation of wood from Wallonia** with the objective to strengthen the use of hardwoods, underexploited in Wallonia, and the recovery of wood waste in the development of structural elements and by-products for construction and green chemistry.
- **Valorisation of local Walloon wood in building sector** with the goal to encourage the use of innovative and circular wood products, to achieve the objectives of carbon neutrality and circular economy in the building sector

This contribution will present and discuss the first research results and its action plan for research and innovation and the role of this initiative within a European context for the coming years.

Potential mismatches between forest management and relevant targets of global sustainability

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Matteo Vizzarri[1]
Lorenzo Rossi[1], Roberto Pilli[2], Guido Ceccherini[3], Simone Rossi[2], Giorgio Vacchiano[1]
[1] Università degli Studi di Milano, Milano, Italy
[2] Consultant, Joint Research Centre, European Commission, Ispra, Italy
[3] Joint Research Centre, European Commission, Ispra, Italy

Abstract: Global climate and biodiversity crises pose imminent challenges to meeting global targets for sustainable development in 2030. Forests are essential components of the Earth system as they contribute to local communities' wellbeing and social-economic development through e.g. mitigation and adaptation, biodiversity conservation, energy and material supply. Efforts in global decision making for ensuring short term sustainable development targets have been made so far, but downscaling remains largely uncertain. The way forests are currently managed determines whether the contribution of these key ecosystems to sustainable development goals will be met in the near future. By further developing UN stats at global scale, we evaluate the country-based correlation between forest management intensity and the most relevant indicators of sustainable development targets. To refine the indicators' set and improve their scientific soundness and replicability, we gap-fill the information with remote sensing data. By global region, we find that forest management positively correlates with most of production and economy-related targets under investigation, but negatively with targets dealing with reducing the human impact on environment, including the resulting risks for local populations. Also, the historical signatures of these correlations do not show a linear increasing or decreasing trend, likely due to the complexity of processes at stake. Based on our findings, we argue that: correlation between forest management and sustainability targets should involve multi-sectoral analysis to be fully explained; our analysis is a primer addressing this correlation, but the complementary causation can only be disentangled with more specific studies; the indicators currently used for sustainability targets can be improved by including impact and response functions. In conclusion, our study sets the stage of the current correlation between the intensity in use of global forest resources and the variation of sustainable development targets in a broad context. Our findings stimulate the multi-scale monitoring of forest resources and the assessment of the contribution of forests and forest management to reaching sustainable development from global to national scale.

Preparation of Oleocanthal and Oleacein from Canarium oleosum Based on CPC Technology and Their Antioxidant Activities

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Chengzhang Wang[1]
hao zhou[1]
[1] Institute of Chemical Industry of Forest Products, Chinese Academy of Forestry

Abstract: Olive oil, as an important part of the Mediterranean diet, can prevent type 2 diabetes, cancer, neurodegenerative diseases and cardiovascular disease, which is mainly attributed to its rich monounsaturated fatty acids (C18:1,55%~83%), as well as alcohol, sterols, hydrocarbons, phenolic compounds, especially phenolic alcohol and cyclic ene ether derivatives. Total polyphenol extract (TPF) in olive oil is a complex mixture, including simple phenols, lignins, flavonoids, terpenoids, and triterpene acids, among which the most characterized components are hydroxytyrosol, tyrosol, oleuroside, OLEO (common name stimulating aldehyde), OLEA (common name oil essence), etc. OLEO is a nonsteroidal anti-inflammatory drug with stronger activity than ibuprofen, and also has strong antioxidant, neuroprotective, anticancer, and bacteriostatic effects. OLEA also has strong antioxidant, anti-cancer, bacteriostasis and other functions, and also prevents and suppresses cardiovascular diseases and cellular aging. However, the yield and quality of olive oil polyphenols are seriously affected by genotype, environment and processing technology, resulting in the separation and purification of OLEO and OLEA are very difficult.

Based on centrifugal partition chromatography (CPC) and supported by thin-layer chromatography, preparative chromatography or other purification methods, the total polyphenol extract (TPF) of olive oil extracted from extra virgin olive oil was used as raw material to separate and prepare oleocanthal (OLEO) and oleacein (OLEA) quickly in forms of monomer compounds, then characterized their structures by ^{1}H NMR and their antioxidant activities were also investigated. The results showed that 9 g of extract dissolved in 20 mL of methanol, and 14 fractions were obtained during the process of CPC with a solvent system of n-hexane/ethyl acetate/ethanol/water volume ratio of 3:2:3:2. After purification, OLEO of 422.3 mg and OLEA of 163 mg with a purity of above 95% were gotten respectively; the antioxidant activities of OLEO and OLEA at different concentrations (0~1 g/L) evaluated by their free radical scavenging capacity on $ABTS^{+}\cdot$, DPPH· and T-AOC total antioxidant capacity, it indicated OLEA had stronger antioxidant activity than OLEO, and the IC50 values of OLEO and OLEA for DPPH· were 0.029 and 1.85×10^{-11} g/L, respectively, and their total antioxidant capacities reached the highest of 0.1571 and 0.6462 mmol/L $FeSO_4\cdot7H_2O$, respectively.

QUALITY CRITERIA FOR INDICATORS MEASURING SUSTAINABILITY OF FOREST USES

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Abstract: Assessing and enhancing the sustainability of forest use practices is a key element in transition towards more sustainable bioeconomy. Climate change and biodiversity loss are increasing the risk for severe disturbances and imbalance in key earth system processes. Transition to more sustainable consumption and land use are needed to avoid more losses in health and wealth of humankind and to conserve viable ecosystems and biodiversity. Forests and the ways we utilise them play an essential role in achieving this transition.

Being able to verify the effects of forest management to sustainability requires measuring it in a way that is reliable, cost-effective and acceptable for stakeholders. Hence developing such criteria and indicators to prove the sustainability of forest use is of great importance for forest-based bioeconomy's social acceptance and economic viability. With shared understanding about how to measure changes in sustainability the decision-making about the use of natural resources can be founded on widely accepted knowledge.

Based on literature review we created a set of six quality criteria for sustainability criteria and indicators to help decide which criteria and indicators are appropriate for practical decision situations. We tested the quality criteria in a process of developing sustainability criteria and indicators for measuring the sustainability changes of forest use in Finland.

We collected suggestions for sustainability criteria from a selected group of stakeholders in a series of workshops during autumn 2021. The workshop process followed a collaborative "joint fact finding" approach. We thematised the collected data and tested the created criteria and indicators against the quality criteria. Instead of the widely used categories of economic, ecological, and social-cultural sustainability we created six main categories for relevant indicators that can support the decision-making. The tested set of criteria was then discussed again with stakeholders and other researchers and amended accordingly.

Our study advances the methodology of measuring sustainability of the use of natural resources,

especially forests. In our presentation we discuss the selected six quality criteria and their use as well as the six main categories of sustainability criteria.

Shaping the bioeconomy: Challenges in aligning the German National Bioeconomy and the German National Biomass Strategy

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Tilman Schachtsiek[1]

[1] German Federal Ministry of Food and Agriculture

Abstract: At the beginning of 2020, the German Federal Government adopted the National Bioeconomy Strategy. For the Federal Government, the bioeconomy encompasses the production, development and use of biological resources, processes and systems in order to provide all sectors with products, processes and services within the scope of a viable economic system. The aim of the National Bioeconomy Strategy is to develop bioeconomic solutions for the sustainability agenda, recognise and harness the potentials of the bioeconomy within ecological limits, expand biological knowledge and turn Germany into a leading research and innovation site of the bioeconomy.

The German National Biomass Strategy compliments the German National Bioeconomy Strategy. It provides clear political guiding principles and specific policy tools for the management of biogenic material streams against the background of climate protection, biodiversity conservation and food security, as well as to aid producers and users of biomass with regard to the sustainable, efficient and climate-friendly production and use of biomass.

This presentation discusses the challenges in aligning the two strategies; it highlights the task of sustainable bioeconomy policy to shape the political framework conditions in such a way that biomass is provided and used sustainably and where it is most effective; it reflects the role of science in providing information about sustainability and effective use of biomass and finally, it points to the areas where further research is needed to shape a sustainable bioeconomy.

Sharing economy in the forest-based sector

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Petra Palátová[1]
Radek Rinn[1], Hubert Paluš[2], Roman Dudík[1], Ratna C. Purwestri[1], Vilém Jarský[1]
[1] Czech University of Life Sciences Prague/Department of Forestry and Wood Economics, Czechia
[2] Technical University in Zvolen/Department of Marketing, Trade and World Forestry, Slovakia

Abstract: The potential of sharing economy has been investigated in various fields of economy, but not yet in detail in the forest-based sector, although the principles of sharing economy are in line with sustainable bioeconomy. Because current economic situation is rather turbulent and societal preferences have been changing too, information efficiency and costs saving remains crucial for decision-making in all companies, irrespective of their legal form and size. Economic benefit is one of the main reasons for adopting sharing economy by companies. The main aim of the contribution is to answer questions of potential and future utilization of sharing economy principles in companies along forest-based value chain. The methodological approach consists of two main methods, questionnaire surveys among Czech and Slovak companies in the forest-based sector and semi-structured interviews with representatives of these companies with decision-making power (mostly management bodies of these companies). Selected results obtained from the surveys are processed statistically to provide relevant conclusions. The findings indicate potential for utilization of sharing economy principles in the forest-based value chain, however there are also important limiting factors, e.g., time and regional factors and information deficiency. Findings of the research are important primarily for management of the companies in the forest-based value chain, mostly in Czechia and Slovakia, but the findings are potentially applicable to all companies in the above-mentioned value chain in central Europe.

Shedding light on the obstacles in the way of doubling the Finnish forest bioeconomy

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Matti Valonen[1]
Jani Laturi[1], Olli Korhonen[1]
[1] Pellervo Economic Research, Forest and Environmental Economics Research Group, Finland

Abstract: The forest industry's contribution to the value added of the Finnish national economy per cubic meter of wood has decreased markedly since the heyday of paper production. Finland's bioeconomy strategy aims at doubling the value added of its bioeconomy by 2035, and thus also doubling the value added of the forest bioeconomy. This would improve the industry's global competitiveness and ability to pay for wood while strengthening the Finnish national economy. The achieved increase in the overall wealth of Finland would help in balancing the downsides of growth and finance the necessary changes the ambitious target requires.

Doubling the value added of the forest sector requires extensive changes in the value chain and ramped up production of novel higher value products based on the principles of the circular bioeconomy without increasing wood usage and causing environmental harm. There are obstacles and bottlenecks in the way of the changes this transformation requires. Shedding light on these is necessary to direct public resources efficiently and sustainably. In this project commissioned by the Finnish Prime Ministers Office, the aim is to produce quantitative information on the potential of increasing the value added of the bioeconomy and the obstacles in its way.

This research will focus on the obstacles and bottlenecks for increasing the value added of the forest-based bioeconomy. The research will be conducted by carrying out a literature review in autumn 2023 and interviewing companies in the forest bioeconomy sector in the beginning of 2024. The literature review will focus on the past 5-7 years to guarantee its topicality. The interviews will focus on the obstacles and bottlenecks inhibiting or slowing down the scaling up of the company's production and value chains. The interviewees will also be asked for suggestions on how to get rid of these obstacles and bottlenecks or ease their effect.

Stakeholder perception of climate change adaptation measures along the forest value chain

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Annechien Dirkje Hoeben[1]
Tobias Stern[1]
[1] Institute of Environmental Systems Sciences at the University of Graz, Austria

Abstract: Context: Climate change poses a growing threat to the resilience of European forests due to the increasing frequency and severity of natural disturbances on an increasingly larger scale. As a result, the wood value chain is subject to periods of under- and oversupply. Efforts to enhance the adaptive capacity in the wood value chain are often not streamlined between forest management and the processing industry.

Specific topic of the study: In our study, we aim to find out how different stakeholders along the wood value chain perceive different climate adaptation measures, regarding their feasibility and effectiveness over time and on a spatial scale. By the feasibility of a measure, we understand how difficult it is to implement a measure regarding financial, human and time constraints. By the effectiveness of a measure, we understand the success of a measure to cope with climate change-related disturbances.

Methods: We are conducting an online survey from May-August 2023 with a sample of stakeholders working along the wood value chain or in governing authorities in Europe. We focus on nine regions: The New Forest (UK), Catalonia (ES), Bauges, (FR), Galicia (ES), Finland, Ireland, Istria (HR), Kostelec (CZ), and Upper Rhine valley (DE). However, stakeholders from other regions are also welcomed to participate.

Preliminary results: We expect that stakeholders along the wood value chain assess it to be more important to take adaptation measures in the future than at present time. This effect is expected to be stronger for the processing industry than for forest management. Furthermore, we hypothesize that stakeholders along the wood value chain assess it as more important that an adaptation measure is feasible than effective. Lastly, we expect that stakeholders in regions with a high frequency and severity of forest disturbances consider adaptation measures more important.

Conclusions: In the end, we hope to point out adaptation measures that lead to synergies between forest management and the processing industry. Subsequently, we would like to formulate an advice to improve communication and strengthen resilience in the growing bioeconomy. At the time of the IUFRO Stockholm 2024, we will present the final results.

Towards a sustainable forest-based bioeconomy in Germany– socioeconomic indicators and resource productivity

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Susanne Iost[1]
Holger Weimar[1]
[1] Thünen Institute of Forestry

Abstract: The monitoring of socioeconomic indicators of the forest-based sector in Germany was initiated as part of the Charter for Wood initiative in 2004. The objective was to increase the per capita use of wood and wood products from sustainable production. At this time, sustainability referred to sustainable forest management and production of wood and wooden products, climate change mitigation effect through increased CO_2-storage, and the creation of jobs and value added. To monitor these goals, wood use and socioeconomic development of the forestry and timber cluster have been quantified on an annual basis in wood balances and cluster statistics. These approaches provide data on jobs, turnover, and gross value added of forestry-based economic activities as well as on total supply and use of wood and wood-based products.

Since its initiation, the German Charter for Wood has evolved and is dealing with more sustainability aspects. In today's circular bioeconomy approach CO_2-storage in wood-based products remains an important aspect, as does employment. However, the transformation of fossil-based towards bio-based economies is bringing the obvious limits in availability of wood and biomass in general to the front. Circularity aspects for a sustainable use of biomass are becoming increasingly important.

However, circularity still remains an ambiguous concept covering a range of approaches. Two main approaches are the operationalization of circularity within the existing economic system and the transformation of the socio-economic structures. The forestry and timber cluster is not yet characterized by fully closed production loops, and efficient material use of wood, i.e. reducing, reusing and recycling, needs to be further implemented in wood-processing value chains. In 2020, gross value added of the German forestry and timber cluster was approx. 60 billion Euros and a total of almost 126 Mio. m³ of woody resources (including roundwood, wood residues, and post-consumer wood) were used. To link outcome of wood processing to resource use we calculate resource productivity and use available data on wood material flows and socioeconomic output indicators. We present disaggregated results and discuss implications for reducing, reusing and recycling woody resources in the forestry and timber cluster on its way to circularity.

Unlock Potentials of Forest Sector in Bioeconomy Development: Case of China

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Xiaoqian CHEN[1]
Wenhui CHEN[1]
[1] Beijing Forestry University School of Economics and Management

Abstract: China by far is the largest producing and consuming country on concrete and steel, coal, paper and paper board, fossil fuel based products like polyester fiber and plastic (PVC). Since 2000, China speeded up the swift from traditional economy development model to green economy development with increased demand on bio-based technologies, materials and products. In 2021, China National Development and Reform Commission issued the 14th Five-Year (2021-2025) Plan for the Development of Bioeconomy", pledged again China's commitment on promoting bioeconomy development since it's first National Bioeconomy Strategy was published in 2007. Forest sector could play curial role in bioeconomy development given by replacing the fossil fuel based raw material with renewable forest resource based products. 231 million hectares forest, 19.5 billion m3 forest stock, and the forest sector with total output value over 100 billion USD annually provided a solid foundation for forest bioeconomy development in China. However, the external challenges still along with the numerous opportunities. We first reviewed bioeconomy strategy development China, summarized the forest bioeconomy development history, current situation and challenges, then using PEST model to analyze impacting factors from political, economic, social and technological angel. In the end, we provided recommendations on how to improve the policy support, leverage successful business model and better unlock the forest sector's potentials in China's bioeconomy development.

Unlocking the bioeconomy of NTFP in the northern Amazon of Bolivia

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Daniel Marcelo Larrea-Alcázar[1]
Luis Leonardo Arteaga Borth[1], Marcos Fernando Terán Valenzuela[1]
[1] Asociación Boliviana para la Investigación y Conservación de Ecosistemas Andino-Amazónicos (Conservación Amazónica-ACEAA)

Abstract: Despite its great potential, the contribution of Brazil nuts (*Bertholletia excelsa*) to Bolivia's Gross Domestic Product (GDP) is low (close to 1-2%). However, it was not always so. The economy based on the harvesting of non-timber forest products (NTFP) is part of northern Bolivia's history and recent past. The fall of the quinine economy, which occurred towards the end of the 19th century, was followed by the exploitation of rubber (*Hevea brasiliensis*). The challenge was to transport the rubber up the river, to the Andes. Everything would change with the discovery that the Mamoré and Beni rivers flowed into the Madeira River and that before they converged at a junction, which was called Cachuela Esperanza. The activity of rubber promoted the establishment of the so-called "barracks", along with the often-forced migration of indigenous people. It is estimated that rubber exports fluctuated between 8 and 12% at the beginning of the 20th century and after booms and busts it reached its final collapse towards the end of the 80s. The history of the Brazil nut begins in the 1920s, but it was during the 1960s that it would reach its first peak with around 5-6 million tons of exports, a volume that was maintained until the early 1980s, when the conformation of beneficiary companies in Bolivia northern would consolidate a processing capacity that would end up taking off the industry as we know it today (20-25 millions of t exported per year). The geography of the Brazil nut in the north of Bolivia is a legacy of that of the rubber, with important participation of barracks, today, private properties. The big difference is in the presence of local communities' owner of these forests, who has undertaken another colossal challenge, to be the cornerstone of another resource, the harvest and sale of the pulp of açaí berry (*Euterpe precatoria*). This process is supported by the creation of sub-national protected areas and other effective area-based conservation measures (OECMs). How this revival of NTFP can get to participate in Bolivia's GDP is an open question.

Where does the wood come from? A physical accounting model to trace the origin of wood-based products

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Matthias Bösch[1]
Hermann Englert[1], Holger Weimar[1], Matthias Dieter[1]
[1] Thünen Institute of Forestry

Abstract: In today's globalized world wood-based products are often imported from countries other than those where the wood was grown. Bilateral trade statistics are thus only of limited help for getting a better understanding of how production-related environmental impacts are caused by consumption elsewhere. This study presents a novel physical accounting model that allows flows of wood-based products to be traced along international supply chains, therefore making it possible to consistently relate the consumption of wood-based products to the origin of roundwood. In comparison to previous studies, the proposed method covers entire supply chains, including finished wood and paper products, such as furniture and printed matter, and also accounts for flows of processing residues and recovered paper. The main results of the accounting model are detailed country-by-country matrices indicating the locations of origin of the products consumed in a given nation. For instance, it is revealed that out of the finished wood products consumed in the USA in 2018, 75.6% originated domestically, 10.7% from neighbouring Canada and the remaining 13.7% from other countries.

Wood construction and pulp and paper – two examples of circularity - in a long-lived wood products value chain and a commodity with short life span

T2.21 Pathways towards sustainable and circular forest-based bioeconomies: Advances in research to address challenges and realize opportunities

Alicja Kacprzak[1]
[1] Food and Agriculture Organisation of the United Nations (UNECE/FAO Forestry and Timber Section)

Abstract: The forest sector is naturally situated both in the biological and the technical cycles of sustainable and circular bioeconomies. Wood itself, as a natural raw material has several advantages over other materials circulating in economies. It is therefore well fitted to embrace a bio-based economic model of the future. This paper analyzes how circularity concepts can be applied in two key forest-based industries: the wood construction as an example of long-lived wood products value chain, and the pulp and paper industry as an example of wood-based commodity with a short life span.

The paper analyses circularity and sustainability in at different stages of these two value chains, including, for the wood construction, the impact of different material development technologies (CLT, LSL, LVL, OSL, PSL) and building methods (mass timber, panelized construction, modular construction, off-site construction). It also looks at the circularity aspects of the retrofitting and demolition of existing buildings and the need for increased recovery and reuse of wood. For the pulp and paper industry, the focus is made at the sustainability and circularity of pulp production, different types of paper products, and industry processes using pulp to obtain end products with different qualities and applications, such as printing, packaging, and hygiene papers.

Whether or not evaluated practices are sustainable has been assessed taking into consideration on three pillars: environmental protection, economic viability, and social equity. The evidence and information reviewed comes from desk research, and an examination of scientific literature. Additional information has been provided from official government sources available to general public and supported by case studies and examples of good practice.

The conclusions in both wood construction and pulp and paper point out to the potential laying in improved design, innovation and the increased recovery and reuse of residues, in particular the post-consumer streams. Some measures, such as those related to extending the life of products, including reuse, recycling, and energy recovery, are known in the industry practice, while others, including waste management, need further promotion and mainstreaming wherever and whenever economically, socially, and environmentally viable.

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Analysis of Forest Landscape Attraction Based on Machine Learning of Photo Content – A Case Study of Yulong Snow Mountain National Geopark in China.

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Ling Wang[1]
Jiahui Ding[1], George Frantz[2]
[1] School of Design, Shanghai Jiao Tong University, China
[2] College of Architecture, Art and Planning, Cornell, USA

Abstract: Forests are renowned for their unique landscape, ecological and health values, attracting numerous tourists annually. Conducting perception research on forests can aid in unveiling their cultural and social significance. Recent research on environmental perception and aesthetic preferences has focused more on user-generated photos posted online, which employ machine learning to explore landscape features that attract visitors. To this end, this present study focuses on Yulong Snow Mountain in Yunnan, China, a national geopark, whose mountainous forests and Tibetan culture are popular tourist attractions. Over the years, the local government has invested heavily in infrastructure development to cater to tourists. This study draws from three data sources: 1) a set of photographs taken by botanist, Joseph Rock, almost a century ago; 2) photos token by researchers during site investigation ; 3) and photos posted by tourists on Twitter and Flickr. The photos are labeled by employing image recognition technology, followed by a clustering algorithm that leverages word-vector models to identify landscape elements, including tourism infrastructure, and the interaction among elements in forest imagery. Through photo content analysis, this research accomplishes three main goals. Firstly, it employs a comparative approach to reveal the transformation of Yulong Snow Mountain forest landscape in the past century. Secondly, it delves into the appeal of the forest landscape to tourists, exploring their perceptions and preferences. Finally, it uses photo content to discuss the influence of tourism infrastructure development on tourism.

ARF@Pt creating free easy-access economic analysis for Portuguese forests

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Susana Barreiro[1]
Marta Baptista Coelho[1], António Henrique Correia[1], Margarida Tomé[1]
[1] Forest Research Centre, School of Agriculture, University of Lisbon

Abstract: Forest profitability has long been debated in Portugal. However, the few studies carried out over the years have always been scrutinized and criticized for not accurately representing reality. Controversial opinions regarding the management practices and silvicultural operation costs considered in these studies have been some of the reasons behind the discredit in the conclusion that forests are little to not profitable. The ARF@Pt is a task force created to tackle the limitations recurrently pointed in these studies. Coordinated by academia and involving stakeholders representing different groups (academia, public administration, research institutes, forest owners' associations, industrial and private owners, industries) the task force meets to discuss perceptions and knowledge sharing.

On a first stage, the participatory process allowed setting a common ground for preparing the inputs to be used to running forest growth simulations and economic analysis. These simulations intend to cover a range of tree species and site productivities, considering difficult and easy terrain conditions in combination with alternative management approaches, characterized by commonly agreed silvicultural operations' schedules, operation costs and stumpage prices. Once the simulations were run by academia, a second round of meetings was scheduled, where simulation results with integrated economic analysis, were presented and discussed with the group. Simulations were re-run whenever readjustments were required.

The ARF@Pt ultimate objectives are providing available analysis to stakeholders in a free easy-access dynamic web platform while contributing also with sound-results for the definition of appropriate governance measures that can properly assist the sustainable role of forests in bio-economy.

Climate change perceptions and environmental values in forest bioeconomy: the case of public preference for forest management in Norway and Sweden

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Do-hun Kim[1]
Hanne K. Sjølie[2], Francisco X. Aguilar[1]
[1] Swedish University of Agricultural Sciences
[2] Inland Norway University of Applied Sciences

Abstract: Forests deliver multiple ecosystem services fundamental to human well-being. As forests and derived industries play a pivotal role in bioeconomy, the pressure on forests to supply both wood and non-wood products and services increases together. Climate mitigation and adaptation, and preservation of habitats stand out as the main overall aims alongside wood production in the Nordic countries. Provision of these ecosystem services is strongly modified by forest management, and understanding public preferences for forest management strategies helps create effective and socially acceptable policies. We implemented a binary discrete choice experiment through surveys conducted in Norway and Sweden to elicit public preferences to changes from the *status quo* in key forest management attributes – increased set-aside area, proportion of uneven-aged tree stands, and number and type of tree species, within privately-owned production forests. These changes represent adding more weight to non-wood forest values than the current regular management and are named as *alternative forest management strategy*. Willingness-to-pay (WTP) estimates for the selected attributes were assessed using a binary random-effect logit model. Particularly, we tested whether climate change perceptions – represented by psychological distance to climate change – and environmental values are significantly associated with preferences. The Norwegian public preferred larger set-asides and diversification of tree species but was indifferent to tree age distribution, while the Swedish public favored changes in all three attributes. Norwegian and Swedish public commonly attached the highest WTP to increasing set-aside areas but had much lower WTP for other attributes. Noticeably, we found that psychological distance to climate change and environmental values were significantly associated with preferences. Greater psychological distance to climate change was a strong determinant of preferring the *status quo,* while greater biospheric values had a significant relationship with preference for *alternative forest management strategy* in both countries. Our results imply unequivocal support for increasing set-aside areas in Norway and Sweden. It showcases an important example of incorporating behavioral approach in designing forest bioeconomy models.

Keywords: Ecosystem services, forest management, climate change perceptions, environmental values, public preference, willingness-to-pay.

Consumer acceptance of circular construction materials: Attitudes of building users towards reuse of wood

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Shumaila Khatri[1]
Hanne Sjølie[1], Francisco Aguilar[2], Anders Nyrud[3]
[1] Inland Norway University of Applied Sciences
[2] Swedish University of Agricultural Sciences
[3] Norwegian University of Life Sciences

Abstract: The built environment is associated with a high carbon footprint owing to the large amounts of resource utilization as well as waste generation. Reusing construction materials, especially low-carbon material such as wood, can help in reducing the carbon emissions of the building sector. Norway has a long tradition of using wood as a construction material due to its durability, lightweight and aesthetic qualities. Despite that, the reuse of wood is far from being a mainstream practice in Norway, and therefore, the bottlenecks for the use of circular construction materials need to be investigated.

Several research studies have focused on exploring consumer attitudes towards residing in wood buildings, however they focus on virgin wood. This study aims to gauge building dwellers' attitudes and acceptance towards residing in buildings made from used wood. By applying Roger's Diffusion of Innovation Theory, five variables of Relative advantage, Compatibility, Complexity, Trialability and Observability, affecting adoption of used material in their built environment are investigated. An online survey was distributed to residents in Norway, using a consumer panel at Norstat. We collected 1000 completed surveys which captured the representativeness of Norway demography and allowed further analysis with comparison of different demographic groups. The collected survey data were analysed via Confirmatory Factor Analysis (CFA) and Structural Equation Modeling (SEM) to examine relationships of the aforementioned five independent variables with the dependent variable of Adoption (i.e. acceptance of used material in their buildings). These relationships revealed the readiness of the consumer markets to adopt the innovation of circular construction materials, and the distribution of adopter categories (innovators, early adopters, early/late majority and laggards) was determined.

The study findings provide a snapshot of current consumer acceptance of circularity in the construction sector and indicate triggers and barriers that can be scaled up and counteracted in the favor of more wood circularity in the built environment.

Forest Stewardship Council (FSC) developing solutions for circularity

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Loa Dalgaard Worm[1]
Anand Punja[2], Marion Karmann[3]
[1] FSC Denmark Strategy and Development Director
[2] FSC International Chief Engagement and Partnerships Officer
[3] FSC International, Adenauerallee 134, 53113 Bonn, Germany

Abstract: In its Global Strategy FSC recognizes the need to shift towards bio-based and low-carbon circular economies (CE). However, the current requirements for verification of FSC-certified products along the value chain from forest to end-users are basically based on linear business models. There is a need for the FSC system to accommodate, incentivize, encourage, and support a cascading use of forest-based fibers beyond the existing option of FSC recycled certification, which only caters for one of the five dominant circular business models.

To rethink the FSC system to enable circular use of fiber on large scale, we have conducted surveys and in-depth interviews to understand our stakeholders' current and future needs for such transition. Internal and external datapoints related to FSC, market potentials and risks for FSC in transition to CE were analyzed.

The shift towards supporting a CE for forest based fibers will require innovation of the FSC normative framework and certification infrastructure to enable and encourage reuse of fibers/ material and products and enable circular business models at scale. This includes exploring new areas beyond the existing FSC system such as how FSC can support the use of alternative fiber streams, such as agricultural waste streams, to minimize bio-product demand pressures for virgin forest-based fibers and maximize the value of ecosystems services from the same forest. It also includes putting safeguards in place for worker's rights throughout the supply chains – including currently not covered waste material gathering and sorting facilities. And it includes exploring how FSC can incentivize the use of fibers at the optimal point in the fiber cascade to ensure longest possible carbon sequestration.

It also requires partnerships with leading organizations, members, and stakeholders to scale the market and demand for circular use of fibers. And it requires for FSC to institute market incentives for uptake of circular use.

We discuss options and activities that contribute to the transformation of FSC systems towards CE, as well as the perspectives of FSC membership. We show how and when the research community can efficiently engage in the development of further improved requirements for more circularity in this sector.

Future pathways of forest ecosystem services – a stakeholder analysis in four European regions

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Camilla Widmark[1]
[1] Swedish university of agricultural sciences

Abstract: Forests provide a wide array of services, and a sustainable use of forest ecosystem services (FES) is essential for achievement of sustainable development goals. However, as humans face climate change, societal and environmental challenges, fundamental changes are needed to ensure future prosperity in the growing bioeconomy and circular economy transformation. This transformation depends on both technical and social innovations together with societies adapting to a bio-based sustainable future. In policymaking, synergies need to be realised and trade-offs evaluated and addressed in forest management in general to support continuous provision of FES.

In this study, organisations that has an interest in FES was approached within ONEforest research case study regions; Catalonia (Spain), Estonia, Grisons (Switzerland), and Hesse/Thuringia (Germany). The purpose of the study was to identify key determinants of the use of forest ecosystem services and the effect of these factors on the provision of FES, and the downstream wood value chain. Interacting with stakeholders in a collaborative learning approach, a scenario-based technique further used PESTEL frame to identify key determinants to discuss future pathways for the societal use benefits of forest ecosystem services.

The results indicate that forest stakeholders identify different conflicts between FES, e.g., between timber production and recreation, or between timber production and carbon storage. However, the identified conflicts are context dependent. Stakeholders further identified decision-making and management challenges regarding FES. Finally, the study notes that prioritization of FES provision may become necessary due to increasing demand and potential conflicts. Overall, the result of stakeholder analysis FES help to inform more effective and inclusive forest management and governance including the needs and interests of stakeholders, which will contribute to a more successful policy implementation.

Government and industry perceptions of Bioeconomy: A Comparative Study of nine European Regions

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Siebe Briers[1]
Inazio Martinez de Arano[1]
[1] European Forest Institute, Finland

Abstract: The bioeconomy has gained significant attention as a viable solution to address complex global challenges, such as resource scarcity, climate change, and sustainable development. The European Commission's Bioeconomy Strategy provides a framework for advancing the bioeconomy in Europe. However, the successful implementation of the bioeconomy in Europe largely depends on the engagement and priorities of individual regions and regional stakeholders.

Government and industry are key actor groups in driving a sustainable future, with a paramount influence on the trajectory of the bioeconomy. Governments have the power to shape the future of the bioeconomy through strategies, policies, and regulations. They can also facilitate an enabling environment by removing bureaucratic burdens and creating favourable conditions. Meanwhile, the private sector contributes to the bioeconomy through direct business choices and investments, driving innovation and market implementation.

This study explores the perceptions of government and industry in nine European regions regarding the bioeconomy, shedding light on their unique perspectives and priorities. The study is based on an online survey launched in nine European regions, in the regional language, gathering a total of 713 responses.

Preliminary results indicate very positive attitudes towards the bioeconomy. It is perceived as highly related to sustainable land management and circular economy. Respondents perceive both socio-economic and environmental benefits of the bioeconomy, although the vast majority perceives environmental benefits as more important. When asked about most promising sectors, bioenergy emerges in first or second place, even though it may not be the sector with greatest positive environmental impact. Access to investment and scientific information are perceived as the main drivers for bioeconomy development; limited co-operation among different stakeholders and lack of supportive policy & legislative environment are identified as key barriers.

Government, and even more so industry respondents show high willingness to develop the bioeconomy, with greater willingness among those that feel more familiar with the concept (r^2=0.403). Interestingly, across regions, both government and industry actors seem to attribute a greater responsibility to the public sector in i) advancing in social awareness and communication, ii) ensuring positive environmental and social impacts, and iii) investing in the bioeconomy.

Insights Into Life-Science Students' Views on Bioeconomy Entrepreneurship

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Fredric Mosley[1]
Venla Wallius[1], Siebe Briers[1], José Rodrigo Mendes e Chagas[1], Petra Palátová[2], Radek Rinn[2], Inazio Martinez de Arano[1]
[1] European Forest Institute (EFI), Finland
[2] Czech University of Life Sciences Prague (CZU), Department of Forestry and Wood Economics, Czech Republic

Abstract: Societies are in the midst of a transition away from the linear fossil-based economy model, with much uncertainty about what will replace it. In Europe, the Green Deal provides a roadmap for action through its underpinning policy initiatives and strategies, such as the Bioeconomy Strategy. The greening of jobs is an important element across these initiatives, and entrepreneurship plays an enabling role.

Entrepreneurship in the field of bioeconomy varies between countries and regions, and there are different approaches for promoting it. Common measures include creating a favourable regulatory environment, improving access to finance, enhancing support structures and promoting education. In the end, the decision to pursue business opportunities depends on personal preferences, which is influenced by specific social, cultural, political, and economic contexts. Research on individuals' perceptions of environmental entrepreneurship can provide insights, revealing differences and similarities between regions and countries. This can then enable policymakers to address issues to ensure successful policy outcomes.

The objective of this study was to understand life-science students' perceptions of bioeconomy, and their experience with and interest in pursuing entrepreneurial activities in that 'solution space'. To this end, a survey targeting life science students in European institutes of higher education was conducted, gathering 764 responses.

Our preliminary results show that students' familiarity with bioeconomy and related concepts varies, but most respondents associate bioeconomy with nature-based solutions, ecosystem services, and circular use of resources. Moreover, entrepreneurship raises high interest among students, but it may be that many ideas do not get tested, as there are barriers that prevent the pursuit of business opportunities. Interest is driven by the chance of reducing environmental impacts and creating positive impacts on the life quality of communities, as well as the positive impact on personal life quality. In this work, we will propose ways to overcome the perceived barriers to entrepreneurship in the field of bioeconomy to support the greening of jobs.

Perception of Silver birch and the possibilities of its use in the framework of adaptation to climate change in the Czech Republic

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Roman Dudík[1]
Petra Palátová[1], Marcel Riedl[1]
[1] Czech University of Life Sciences Prague/Department of Forestry and Wood Economics, Czech Republic

Abstract: Central Europe, especially the Czech Republic, has been affected by high temperatures and low precipitation since 2015. This has caused the decline of stands, in particular spruce. The result has been an increasing share of salvage fellings, culminating in 2020 with the felling volume of 35.75 million cubic metres (salvage fellings 95%). Of this volume, 96.5% was coniferous timber. The volume of timber logged in 2020 was more than 100% higher than in 2015. The impacts of the progressing calamity on the regions and local wood-processing industries were important. Large volumes of salvage logging started to occur in the north-east part of the country, with the calamity moving westwards through the regions with a higher share of spruce. High logging led to a significant increase in the formation of clearings and thus to an enormous extent of afforestation of these clearings. In view of these effects of climate change, previously less-used tree species have been sought for afforestation. One such example is the Silver birch (Betula pendula Roth), which was previously considered as a weed tree species harmful to the main economic tree species in the country (spruce, pine, beech, oak). Birch wood was mainly used as fuelwood. To motivate forest owners to use birch in regeneration, it was necessary to analyze the economic aspect of birch management in Czechia. This analysis reflected 3 types of soil stands: acidic, fertile, water influenced. It was also necessary to inform the forest owners about other possibilities of birch utilization, which lead to higher monetization of birch wood on the market. Results of the national research led to the conclusion that the economic efficiency of birch plantations is significantly enhanced by increasing share of natural regeneration. In birch wood utilization, marketing analysis of the concept testing phase was carried out to investigate the attractiveness of birch wood and thermally treated birch wood products to a sample of potential customers. Based on the experience from other countries (mainly Scandinavian countries) and the results of the national research, it was possible to recommend forest owners to use birch to an increased extent in forest regeneration.

Residents' experience of living in newly built wooden apartment buildings in urban context

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Jaakko Jussila[1]
Ritva Toivonen[1]
[1] Department of Forest Sciences, PO Box 27, 00014 University of Helsinki, Finland

Abstract: This research examines experiences of residents purchasing and living in newly built wooden multi-storey apartments in Finland and Sweden. Wooden multi-storey construction (WMC) offers an alternative building solution for urban consumers seeking a low-carbon, sustainable lifestyle. This exploratory study develops an understanding about residents' views on sustainability of newly built wooden apartment buildings through thematic interviews in five cities across Finland and Sweden.

The study uses a qualitative approach involving in-depth interviews of residents and property managers in eight new wooden buildings conducted between January and June of 2022. While residents were generally satisfied with their living conditions, the study identifies main areas of concern for residents related to wood material. Issues such as material durability, ambiance of the building, costs of construction, and future maintenance requirements are discussed. Wood material was experienced as mainly positive and was assessed together with overall aesthetics, sustainability and durability aspects of the building. Residents trusted that the builders considered the apartment's sustainability criteria during construction (e.g., material durability and resistance to changing climate conditions).

The study concludes that while several prejudices related to wood material has been assessed, action is needed to ensure consistent quality in new wooden buildings. Furthermore, residents would benefit from better information available by the constructors on the unique features of wooden buildings.

REVIEW OF PELIS CONTRIBUTION TO PLANTATIONS DEVELOPMENT AND LIVELIHOODS IN KENYA

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Joram Kagombe[1]
David Maingi[2], Mercelyne Khalumba[3], Gerald Ngatia[4], Zipphora Toroitich[3], Louis Kiuma[3], Dominic Musango[3], Luke Njuguna[3], Anthony Tabot[3]
[1] Kenya Forestry Research Institute
[2] Forest Society of Kenya
[3] Kenya Forest Service
[4] National Association of Community Forest Associations

Abstract: Kenya Forest Service manages an area of 152,000 Ha set aside for industrial forest plantations. Community role was recognized vide the Forests Act, 2005 and consequently retained in current Forest Conservation and Management Act 2016. Plantation establishment have been raised over time through shamba system, non resident cultivation and currently Plantation Establishment and Livelihood improvement (PELIS). Performance of PELIS has had mixed reactions from different stakeholders that have resulted in previous bans followed by reorganization to improve the system. The study aimed at reviewing plantation establishment method to give recommendation of the way forward following an earlier proposal to phase out the system. Literature review was conducted followed by a field visit to sample forest station numbering 135 spread in 7 conservancies.Field study was carried through guided group discussions and administering of data and information collection tools. Results showed that the existing PELIS regulations and rules if implemented to the letter would be effective in realizing the desired plantation establishment goals with adherence to the rules at 69.1%. However PELIS rules should be reviewed to capture benefits beyond establishment, revise current permit rules to safeguard planted trees by farmers with punitive clauses at hand over, develop audit standards and means to achieve them. Tree planting in PELIS areas has been a success with farmers fully engaged resulting to a reduction in backlogs from 40,000 ha to 14000ha in the last 4 years with an average survival rate of 69.9% . Contribution to PELIS farmers' livelihoods was significant, at Ksh 109,997 per farmer per year. Externalities found to affect PELIS success were;Changes in population pressure on farm land, declining household income, Climate Change due to delayed, inadequate or rainfall failure that contributed to poor tree establishment and crop failures. Changes in policies, legislations and guidelines are sometimes perceived and implemented differently by both farmers and KFS causing farmers to loose trust on PELIS. Study recommended sustainability to be included in the PELIS agreement where farmers are entitled to future benefits from final plantation incomes. The team concluded that PELIS should be continued with reviews on its implementation rules and guidelines.

Sustainable value creation and collaborative business models in the future forest-based sector

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Annukka Näyhä[1]
Romana Rauter[2], Venla Wallius[1, 3]
[1] Jyväskylä University School of Business and Economics
[2] Institute of Environmental Systems Sciences, University of Graz
[3] European Forest Institute

Abstract: Human impacts to the Earth have been enormous in our era. Also forests ecosystems have been negatively affected by human-induced activities in numerous ways. Currently in many countries with plentiful forest resources (e.g. in Finland), the utilization of forests and development of new forest-based businesses are in focus for attaining a more sustainable, circular bioeconomy. Yet, there are not commonly accepted, widely applicable solutions to solve many of the key challenges -including the questions on what the environmentally sustainable uses and levels of harvesting are, and which modes of forest utilization should be supported and how. Widely applied organization-centric business models with focus on creating economic value for a certain company and its shareholders have limited potential to exert a positive influence on social or environmental sustainability and mitigate above-described complexities in forest utilization. Collaborative business models -leaning on the idea that businesses should incorporate sustainability perspectives, diverse needs of stakeholders and lead to shared and sustainable value for multiple players-could be enablers for such a sustainability transition. However, promoting shared value creation between different companies as well as between firms and diverse societal actors requires more knowledge on the involved actors, their views and relations.

This study aims to answer the question of how the sustainability transition in the Finnish forest-based sector could be facilitated by shared value creation. More specifically: What kind of collaborative business models and relations do already exist between involved firms and their stakeholders? Which factors promote or prevent shared value creation?

We conduct 65 semi-structured interviews with firms and their stakeholders in May–October 2023. Around 25 interviews will be conducted with the companies including as many different types of forest-based firms as possible; the firms will vary in terms of business models, maturity, size and networks. Around 40 interviews will be conducted with firms' societal stakeholders including forest owners, researchers, environmental NGOs, politicians, journalists, and interest organizations.

The interviews are ongoing, so the findings with in-depth views on shared value creation potential, collaborative business models and the involved actors will be presented at the conference.

ack: BuSuT-project funded by the Academy of Finland (340756)

Sustainable Wood for Thriving Cities and Forests: How cities can support thriving forests nearby and faraway through Conservation Timber

T2.22 Perception – Awareness – Choice. How forest bioeconomy becomes a reality

Scott Francisco[1]
Valeria Romano Lara[1, 2], Mack Phillips[1], Sarah Jane Wilson[1, 3]
[1] Pilot Projects Collaborative
[2] Universidad San Francisco de Quito
[3] University of Victoria

Abstract: Tropical forests are one of the world's most critical biospheres and assets for climate change mitigation (Roe et al. 2019) and continue to be at risk due to both natural disturbances and human-induced land-use changes (Curtis et al. 2018, Goldman et al. 2020, GFW 2022), representing 8-10 percent of global greenhouse gas (GHG) emissions annually (Harris et al. 2012, Seymour & Busch 2016). Furthermore, the discourse on sustainable and low-carbon construction often focuses on how to incorporate more wood into primary building systems and whether or not global forests can sustain a "timber transition" (Churkina et al. 2019). In balancing conservation and development interests, it is clear that supporting communities on the front lines of forest conservation is necessary, and that these connections and impacts be made evident to consumers through the wood products they specify.

Methods:

Case studies will be used to identify the systemic impacts of 2-3 conservation timber enterprises. Case studies will first collect primarily qualitative data using methods such as interviews, observations, and analysis of primary and secondary sources. Quantitative data will be collected from a wider range of conservation timber enterprises to determine the associated benefits to forest conservation, management , restoration, and forest communities.

Results:

Preliminary results and near-term projections will be presented from 2-3 programs in progress in conservation timber enterprises such as Bigi Poika (Suriname), Carmelita (Guatemala), Bambidié (Gabon), and Cheringoma (Mozambique). Long-term projections will also be presented to show potential environmental and social benefits of conservation timber.

Conclusions:

The methods underpinning the analyses of conservation timber enterprises present the opportunity to through engaging the complete value chain of wood products. Through these methods and metrics, the specification of sustainable, responsibly sourced wood can help to conserve forests, support community enterprises and lead to massive climate and biodiversity benefits.

T2.23 Planted Forests for Achieving a Sustainable Planet

Global economic, timber, and carbon implications of alternative forest plantation growth pathways

T2.23 Planted Forests for Achieving a Sustainable Planet

Adam Daigneault
Brent Sohngen[1], Justin Baker[2], Alice Favero[2]
[1] The Ohio State University
[2] North Carolina State University

Abstract: Forest-based natural climate solutions such as reforestation have been proposed as cost-effective options to achieve climate change mitigation goals. Recent studies have debated how much land is available for reforestation and what forest types (e.g., plantation, natural) should be utilized to help meet increasing timber and carbon sequestration demands. However, many studies lack analysis of how alternative reforestation pathways and constraints can affect economic indicators like timber prices and wood supply. We build upon these studies by: (1) identifying key forest-use and planting constraints proposed in the ecological literature, (2) developing 20 reforestation scenarios that promote or constrain the use of plantation and natural forests for meeting timber and carbon sequestration objectives in various regions of the globe (i.e., a land sharing vs. sparing approach), and (3) quantifying the economic (e.g., timber supply, prices) and biophysical impacts (e.g., forest area, carbon stocks) for each scenario at the global and regional level. We apply a dynamic forest sector model (Global Timber Model) that maximizes total welfare in timber markets over time across approximately 300 forest types by managing forest stand ages, compositions, management intensity, and acreage given production and land rental costs over 200-year simulations. We conclude that climate change mitigation and timber supply goals can both increase over the next century through a combination of more intensive management of existing forests and the expansion of forest area overall. We also find that these objectives can be met more efficiently if plantations are able to expand under less constrained policy conditions. For example, constraining the expansion of plantation forests can increase roundwood prices by \$3 – \$266/m3 compared to the unrestricted plantation growth scenario. Further, constraining plantation area to only expand in temperate, developed country forests can increase in the global roundwood prices by an average of 8%, while carbon sequestration is reduced by about 4% relative to the unconstrainted plantation case. Our analysis provides new insight on how plantations could play an increasing role in helping meet future carbon and timber supply objectives, although potential ecological tradeoffs and related policy constraints (e.g., EU Zero Deforestation/Degradation policies) could limit their growth.

Allometric model and Carbon Sequestration Rates in Paulownia tomentosa (Thumb.) Plantations at ICIMOD's Living Mountain Lab in central Himalaya

T2.23 Planted Forests for Achieving a Sustainable Planet

Nabin Raj Joshi[1]
Surendra Raj Joshi[2], Eriaca Udas[2], Bhaskar Karky[2], Ripu Mardhan Kunwar[3]
[1] 1 Asia Network for Sustainable Agriculture and Bioresources, P.O. Box 11035, Kathmandu, Nepal
[2] 2 International Centre for Integrated Mountain Development (ICIMOD), GPO Box 3226, Khumaltar, Kathmandu, Nepal
[3] 3Gandaki University, Mustang Chowk, Pokhara, Nepal

Abstract: Allometric equations are important for estimating species-specific tree and forest biomass and carbon stocks. *Paulownia tomentosa* (Thunb.) is a fast-growing tree species native to central and western China and Southeast Asia. This species has recently been introduced in Nepal for agroforestry systems, its allometric equations have not yet been developed. This study used a destructive sampling method to develop allometric equations considering seven tree components (Bole, Branches, Leaves, Twigs, Tap roots, Lateral roots and Fine roots) in the ICIMODs Living Mountain Lab representing the central Himalayan region. An equation for estimating total biomass as a best fit for tree was y=14.228xDBH -120.81, r^2=0.973. Using the allometric model we calculated the mean biomass 150.42 t ha^{-1} in 2014 and 429.81 t ha^{-1} in 2022. The mean carbon stock was found to be 149.81 tC ha^{-1} in 2014 and 202.01tC ha^{-1} in 2022. The carbon sequestration rate based on the annual increment rate in *Paulownia tomentosa* was found to be 5.87 tC $ha^{-1}yr^{-1}$. The allometric equations assisted to estimate the biomass and carbon sequestration rates which could be helpful to address global climate change through mitigation. The allometric equations have potential application to similar physiographic and climatic zones as well as to smallholders and communities who intend to participate in climate change mitigation programs.

Bamboo as a Nature-Based Solution (NbS): Assessing the Transformative Potential and Constraints for Climate Change Mitigation

T2.23 Planted Forests for Achieving a Sustainable Planet

Chunyu Pan[1, 2]
Guomo Zhou[2], Anil Shrestha[1], Guangyu Wang[1, 2]
[1] Faculty of Forestry, University of British Columbia
[2] State Key Laboratory of Subtropical Silviculture, Zhejiang A&F University

Abstract: Nature-Based Solutions (NbS) are gaining momentum as transformative responses to climate change and biodiversity crises. This study investigates bamboo, a fast-growing, woody grass, as a promising NbS in tropical forest landscapes. Through a systematic and comprehensive review of 91 articles, we reveal the potential and limitations of bamboo in climate change mitigation considering its role as a carbon sink in bamboo ecosystems, carbon storage in bamboo products, and carbon credits in bamboo projects. Our study illustrates that global bamboo forest ecosystems demonstrate significant carbon sequestration (up to 70 tCO_2/ha/yr) and storage capacity (up to 270 tC/ha), with abiotic factors and management strategies affecting carbon storage in bamboo biomass. Notably, research is predominantly Asia-centric (91%), underlining a pressing need for investigations in other pan-tropical zones like Africa (7%) and South America (1%). Additionally, bamboo forest ecosystems offer the potential for carbon storage through the production of durable goods. Our review suggests a net negative carbon life cycle of bamboo-based products compared to conventional industrial products. Yet, comprehensive assessments of product carbon pools from specific bamboo forests are lacking. Despite bamboo's considerable potential in carbon offset markets, the absence of internationally recognized methodologies constrains its wide global application. Recognizing these gaps, we propose developing inclusive methodologies and climate policies that recognize bamboo as an NbS. This study underscores the transformative potential of bamboo as an NbS, raising critical reflections on its role in promoting human well-being, social inclusion, power equality, and biodiversity benefits. Our findings offer insights into how science can integrate communities and stakeholder perspectives and resolve complex NbS project design and implementation trade-offs. Thus, bamboo presents a compelling case for incorporating multiple dimensions of NbS into complex governance contexts for effective climate change mitigation.

Business requirements for developing successful forest plantation projects

T2.23 Planted Forests for Achieving a Sustainable Planet

Jacek Siry[1]
Bob Izlar[1], Joe Parsons[1]
[1] University of Georgia

Abstract: Forest plantations play an important role in meeting our needs for wood products and environmental goods and services, and have emerged as a unique regulating Nature-based solution (NBS) for climate change adaptation and mitigation. Planted forests have been proposed as one of the most efficient and cost-effective means to store more atmospheric carbon. Consequently, increasing the area and productivity of planted forests is a crucial method to meet increasing timber and climate demands by capturing carbon in forests and subsequent wood products and providing short-run terrestrial energy. Increases in planted forests to achieve their promise for economic provisioning and climate regulating services mandate that a host of technical, research and policy issues must be resolved quickly. This presentation focuses on issues relevant to business success of forest plantation projects, including rural land tenure and rights, regulations promoting or limiting public and private forest land management, broadly defined infrastructure, policy implementation, investment opportunities, timber markets as well as markets for other forest products and services (e.g., forest carbon). We then address the opportunities, within the context of commercial plantations, for improving product quality, value added production, new product development, standardization, and a positive environmental perception of plantations in producing and consuming countries. Successfully addressing these issues can help bring much needed funds for plantations projects, while generating a range of benefits for producing regions.

Can public forest planning for private planted forests contribute to increased forest carbon sequestration? -The case of Japan

T2.23 Planted Forests for Achieving a Sustainable Planet

Keisuke Toyama[1]
[1] Iwate University

Abstract: Japan has a hierarchical public forest planning system, where prefectures and municipalities must develop plans for private forests. Forest owners or their agents can also voluntarily develop and submit plans. Every five years, each plan must indicate the expected amount of felling, planting and thinning, as mandated by the Forest Act.
This aligns with the obligations set forth internationally since the Kyoto Protocol, which, regardless of actual CO_2 absorption, requires the implementation of silvicultural tasks such as thinning, based on the definition of managed forests.
Conversely, while most logging targets coniferous planted forests, there has not been enough progress in promoting the reliable implementation of replanting after logging, or the selection of high CO_2 absorbing species.
Furthermore, the estimated CO_2 absorption is decreasing due to the aging of coniferous planted forests. Therefore, aging is often cited as a reason to justify clearcutting and increased timber production, but few plans intending to convert slow-growing species through harvesting have been found.
Therefore, it can be inferred that the current Japanese public forest plans fail to contribute directly and effectively toward enhancing the CO_2 absorption capacity of forests. The complexity of the system, coupled with the necessity for alignment with plans at other hierarchical levels, might inhibit the incorporation of effective initiatives within these plans. Future policy development would benefit from incorporating objective findings, such as scientific estimates of absorption on different scenarios. Such an approach would contribute to evidence-based policy making (EBPM) and the efficacy of the planning system.

Economic Analysis of Select Commercial Forestry Enterprises in Central Kenya, a profitability analysis.

T2.23 Planted Forests for Achieving a Sustainable Planet

Anthony Macharia[1]
Jonah Kiprop[1], Joram Kagombe[1]
[1] Kenya Forestry Research Institute

Abstract: Forestry is an important sector in Kenya due to the role it plays in supporting productive sectors of the economy such as manufacturing and construction as well as the supply of ecosystem services. Over the past years, the country has been heavily relying on public forests to supply over 70% of forest products. This has contributed to unsustainable extraction, destruction, and degradation of forests. There is a need to profile commercial forestry as a viable investment option that contributes to employment creation and income generation while supplementing the supply of forest products. There however exists limited information on the potential for commercial forestry as a competitive land use option in the country. Using a Cost Benefit Analysis approach, we undertook an investment appraisal for three forest-based enterprises, Eucalyptus (Transmission poles), Pine, and Cypress (sawn timber) to assess their viability and potential economic returns. Eucalyptus enterprise had the highest profitability with a net present value of USD 6,824.54, followed by Cypress at USD 6,006.07 and finally, pine at USD 3,872.74 per hectare, respectively. Eucalyptus production is getting much prominence in the country due to its ability to grow fast, its high demand, as well as its multiple uses. There has also been an increase in private companies applying modern seasoning technologies to produce high-quality eucalyptus furniture, doors, and flooring panels, thus increasing demand further. Cypress and pine were mainly preferred by the construction industry for making roof trusses as well as furniture. Increased training and awareness on species-to-site matching and appropriate silvicultural management practices are essential in improving earnings from commercial forestry enterprises in the country.

Key Words: Forest-based enterprises, commercial forestry, cost-benefit analysis, competitive land use option

Economic and environmental benefits of selected state forest sector development programs—sources of success and failure.

T2.23 Planted Forests for Achieving a Sustainable Planet

Virginia Morales Olmos[1]

[1] Departamento de Ciencias Económicas, Universidad de la República-Sede Tacuarembó, Tacuarembó, Uruguay.

Abstract: Several countries have developed their forest sectors based on policies that included the design of incentive programs. In the case of Latin America, some of the programs were designed with various objectives, including the use of commercial plantations. In South America, three relatively successful cases stand out: Brazil, Chile, and Uruguay. The case of Uruguay is the most recent development, with its Forestry Law passed in the late 1980s. The objective of this presentation is to analyze the components of the forest sector development programs of these three countries and their current challenges, with a particular focus on the case of Uruguay. It is observed that most of these programs had as a common characteristic the incentives to plantations and not so much to industries. The raw material was considered key for the development of the sector. Furthermore, increasing the forest area would generate environmental benefits, taking pressure off the use of natural resources, and providing ecosystem services. In recent decades, the discussion on the impacts of climate change on forests, as well as on their capacity to continue providing ecosystem services, has opened the discussion on the need to review forest sector development programs considering new scenarios and the lessons learned. In the case of Uruguay, there was recently a long discussion on the need to pass a new forestry law. While there was agreement on the need to make some changes, there was no agreement on the need for a new law. In the end, the latter position prevailed. At the same time, the government has taken initiatives that involve not only the forest sector but other sectors, such as the bond indexed to climate change indicators (BIICC) recently issued.

Global Forest Plantation Trends and Forest Product Markets and Forest Carbon Implications

T2.23 Planted Forests for Achieving a Sustainable Planet

Prakash Nepal[1]
Jaana Korhonen[2], Jeffrey Prestemon[3]
[1] USDA Forest Service Forest Products Laboratory
[2] ORISE/USDA Forest Service Southern Research Station
[3] USDA Forest Service Southern Research Station

Abstract: This presentation will discuss the projections of global planted forest area and what they imply for global forest products markets and forest carbon, 2015-2070. Projections are made under alternate socioeconomic futures, as represented by the Intergovernmental Panel on Climate Change-(IPCC) inspired shared socioeconomic Pathways (SSPs). Depending on the SSP and modeling approach, the analysis suggests increases in global planted forests of 9% to 46% under a scenario of low economic growth (SSP3) to 14% to 66% in a wealthier world (SSP5), relative to forest area observed in 2015. Aside from the global results, projected trends in planted forest area varied substantially across world regions, suggesting that regions with higher projected economic growth, such as Africa, Asia, and South America, would experience the largest expansion in planted forest area in the future. Incorporating such projections into a global forest sector model led to a projected global increase in forest stocks (and forest carbon), a decline in roundwood price, and an increase in consumption (and production), with wide variations in their projected effects on national and regional markets, relative to a reference scenario without a future increase in global planted forests.

How forest carbon standards in the United States are hindering carbon sequestration from southern pine plantations

T2.23 Planted Forests for Achieving a Sustainable Planet

Matthew Pelkki[1, 2, 3, 4]
Shaun Tanger[1, 2, 3], Bruno da Silva[5]
[1] Arkansas Center for Forest Business
[2] College of Forestry, Agriculture, and Natural Resources
[3] The University of Arkansas at Monticello
[4] The University of Arkansas System Division of Agriculture
[5] Mississippi State University College of Forest Resources

Abstract: In the United States, cellulosic carbon sequestration in forests has several characteristics of forest carbon that can be traded in offset markets. The first is the period of sequestration which for regulatory markets is typically 40 to 100 years. The second characteristic is that only live forest carbon is counted in a carbon account; forest products and forest residues are excluded from carbon accounting. Lastly is the requirement of additionality, which restricts "common practice" that funded through other mechanisms. Using the Forest Vegetation Simulator for loblolly pine plantations, we project forest carbon, wood products carbon, and carbon avoidance from wood used for energy under scenarios of common practice, maximum forest mean annual increment, and 100-year rotations to address the issues of period and carbon accounts. Examining economic equilibrium theory, we estimated the quantity additional CO_2e that would be stimulated by forest landowners responding to carbon revenue from common practices. Findings show that if wood products carbon is part of the tradable carbon pool from loblolly pine plantations, rotations of 40-44 years that maximize mean annual increment sequester the most carbon, followed by rotations that follow common practice that maximizes land expectation value. The lowest total sequestration occurs using a 100-year rotation. Equilibrium market economics finds that payment for carbon sequestered from common practices alone can increase region carbon removals by 2-4%. If reduction of atmospheric carbon is the objective or offset markets, they are missing opportunities from one of the largest global forestry sectors.

Implementation pathways, partnerships, and policy coherence for advancing ambitious global planted forest carbon goals

T2.23 Planted Forests for Achieving a Sustainable Planet

Kathleen McGinley[1]
[1] USDA FS International Institute of Tropical Forestry

Abstract: Planted forests have been proposed as one of the most efficient and cost-effective means to capture and store atmospheric carbon and reduce adverse impacts of climate change in the short- to medium-term. Innumerable tree planting programs have been established at local to global scales in recent years as part of a growing global movement promoting tree planting as a key component in proposed solutions for global climate change. Tree planting and reforestation efforts are primary components of many countries' commitments to the Paris Climate Agreement and are incorporated in targets for achieving the United Nations' Sustainable Development Goals, the New York Declaration on Forests, and the UN Decade on Ecosystem Restoration 2021–2030. Consequently, tree planting promises have received record and expanding financial, political, and societal support, yet myriad challenges exist in turning ambitious commitments into effective and enduring reforestation and restoration on the ground, planting 'the right trees in the right places', engaging and sustaining local stakeholder participation, and integrating tree planting policies and practices with other nature and non-nature based climate solutions. Effective implementation of major tree planting and reforestation campaigns can be particularly constrained where governance systems, institutional capacities, and financial architectures are limited and where the underlying causes of forest loss, degradation, and greenhouse gas emissions are not addressed or overlooked.

We examine major tree planting and reforestation initiatives in Brazil (Amazonia Sustainable Landscapes Reforestation Project), Philippines (National Greening Program), Tanzania (Kwimba Reforestation Project), United States (Appalachian Regional Reforestation Initiative), and other parts of the world, drawing on top-down/bottom-up perspectives on policy implementation to identify effective implementation strategies as well as key challenges and pitfalls. We provide insights into adaptive, effective implementation pathways at multiple, nested, and integrated scales for generating multiple measurable and enduring benefits from ambitious tree planting and reforestation initiatives for people and the environment.

Integrated Timber Investment Returns, Wood Fiber Stumpage Costs, and Forest Carbon Offset Costs for Global Planted Forests

Abstract: This presentation will discuss our research on integrated timber investment returns, wood stumpage costs, and forest carbon production costs in 2023 for a representative selection of about 15 countries and 45 planted species/ management regimes, using capital budgeting criteria, at a real discount rate of 8%, without land costs. Despite a large amount of disparate research, few if any studies have provided integrated estimates of investments, wood fiber costs, and forest carbon offset costs using fundamental primary data and production economics approaches. We will build on our prior research that estimated present values and internal rates of return for timber investments, using

average plantation forest growth and yield, input management costs, and timber products prices by selected country and species. From that production economics approach for forest management, we will extend the calculations to estimate average stumpage costs for wood fiber per cubic meter per rotation. In addition we will calculate the costs to produce forest carbon offsets in terms of the now traditional CO2e metric. These investment returns, wood fiber costs, and forest carbon storage equivalent costs will be compared with other existing timber investment, timber stumpage production costs, and forest carbon literature. This production economics primary data research approach will be compared with other secondary data research approaches for investments, wood fiber, and forest carbon. The results can be used for private, government, or nongovernment investments and for public policy intervention considerations.

Mixed success for carbon payments and subsidies in support of forest restoration in the neotropics

T2.23 Planted Forests for Achieving a Sustainable Planet

Abstract: Restoring forests in low- and middle-income countries (LMICs) may contribute to global carbon mitigation targets. However, upfront costs and inconsistent cashflows associated with forest restoration pose challenges for many landowners. Two proposed solutions include carbon payments and third-party cost-sharing to incentivize and alleviate the financial burden of restoration. However, empirical evidence to support these approaches, based on robust, dynamic field sampling is lacking. We use large, long-term datasets from Panama to assess the financial feasibility of three forest restoration methods, considering cost-sharing and carbon payment designs where income is generated through timber harvests. The results provide insights into necessary incentives for landholders in LMICs to adopt forest restoration.

We evaluated the growth and timber-derived revenue of secondary forests, native tree plantations, and enrichment plantations on low-nutrient soils. We compared three cost-sharing models derived from loan program analyses conducted in the region – *full* payments where all upfront and management costs were assumed by a third party, *half payments* where only 50% of the costs were covered, and a *no payments* option where no costs were covered. Lastly, we incorporated a carbon payment scenario into the different treatment and financial support scenarios.

We found that not all options are financially viable. Relying solely on timber revenue from secondary forests was not economically feasible without the support of third-party cost-sharing and carbon payments. While two high-value native plantation species (*Terminalia amazonia* and *Dalbergia retusa*) generated positive net present values (NPVs) on their own (US$7,474 ha^{-1} and

US$37 ha^{-1} at 7% interest rate (IR), respectively), enrichment plantations, on average, did not yield sufficient financial gains without cost-sharing and carbon payments. However, when cost-sharing and carbon payments are included, secondary forests became more profitable than the two native plantations (generating NPV > $US10,000 ha^{-1} with a 7% IR).

Incentivizing forest restoration of secondary forests in tropical regions will likely require both financial support and carbon payments. While native species plantations have the potential to generate revenue without subsidies, the high establishment costs (US$1,500 ha^{-1}) may still pose a significant barrier for small landowners. Therefore, financial support remains crucial in facilitating land-use transitions.

Optimizing plantation forest management in Southern Regional State of Ethiopia

T2.23 Planted Forests for Achieving a Sustainable Planet

Musse Gebre[1]

Abstract: Forest management strategies have significant effects on forest structures and functions. However, there is a lack of knowledge on the impacts of alternative management strategies on multipurpose forest ecosystem service in Ethiopia. This study aims to bridge this research gap by modeling the effects of various forest management prescriptions on the evolution of forest ecosystem services over time to select the most effective management strategy. Inventory data was collected from a total of 118 sample plots. These plots comprised 43 plots from Cupressus lusitanica, 70 plots from Eucalyptus globulus species, and 5 plots from mixed species. The collected data was organized and analyzed to generate a yield table and cash flows for a thirty-year planning horizon. Additionally, six different linear programming models were developed and analyzed to optimize single objectives. Furthermore, the Pareto Frontier tool was employed to assess trade-offs. The results of the study revealed that all plantation types, including Eucalyptus, Cupressus, and mixed species, yielded higher economic gains when higher thinning intensities and full harvest were applied, as opposed to lower thinning intensities. In unconstrained NPV maximization, the highest economic gain of up to 7.429 X 106 ETB/ha/year could be achieved with a thinning intensity of 37.5% in 2021 for Cupressus lusitanica, full harvest in 2025 for Eucalyptus globulus, and a thinning intensity of 37.5% in 2021 and full harvest in 2025 for mixed stands. To maintain tolerable annual soil loss and minimum carbon stock, out of the total area of 552.63 ha, 235 ha and 112.4 ha should be managed using lower thinning intensity. Furthermore, this study showcased the potential of the Pareto Frontier in analyzing trade-offs between ecosystem services in Ethiopian plantation forests. The findings indicated that maximizing NPV through forest harvesting comes at the expense of reduced aboveground carbon stock, the volume of ending inventory, and increased annual soil loss. The Pareto Frontier also provided multiple ideal points for decision-makers to select their preferred targets. This research can serve as a valuable reference for developing forest management plans that aim to maximize the diverse ecosystem services offered by plantation forests.

Optimizing tree planting to enhance China's afforestation carbon sequestration potential

T2.23 Planted Forests for Achieving a Sustainable Planet

Meinan Zhang[1]
Shirong Liu[1]
[1] Ecology and Nature Conservation Institute, Chinese Academy of Forestry, Beijing, China

Abstract: Tree planting is one of the cost-effective nature-based solutions to mitigate climate change impacts. It requires knowledge on where, which species, and when to plant, however, the knowledge remains largely elusive. Here, we assess China's afforestation potential by taking into account the local conditions of the ecosystems and the risks of future climate change, and develop a framework to optimize the afforestation plan, with the aim to maximize the carbon sequestration potential of afforested forests by 2060 to support China's net-zero commitment. Our results reveal a conservative estimate of 43.2 million hectares of land suitable for afforestation prior to 2060. With our optimized framework, we estimate a cumulated carbon sequestration of 2969.1 Tg C of afforested forests by 2060, with an average carbon sequestration rate of 84.8 Tg C/yr. Further, the age structure renewal can enhance their carbon sequestration potential, resulting in a 28.7% increase in carbon sequestration. Overall, we will plan 58.4 billion trees during the study period with, accumulated carbon sequestration of 3822.6 Tg C. Our findings underscore the importance of well-planned afforestation for enhancing carbon sequestration potential, and provide timely guidance to China afforestation and net-zero policies.

Restoring forests in a treeless land – challenges and opportunities

T2.23 Planted Forests for Achieving a Sustainable Planet

Edda Oddsdottir[1]
Brynjar Skúlason[2]
[1] Icelandic Forest Research, Mogilsa, IS-162 Reykjavík
[2] Land and Forest Iceland, Gömlu-Gróðrastöðinni, Krókeyri IS-600 Akureyri

Abstract: Iceland has a history of deforestation with the native birchwood reduced from estimated 25-40% of land cover around 870 AD to less than 1% around the mid 20th century. This was followed with severe soil erosion, resulting with large areas of barren areas.

Organized forestry is considered to have started in 1899 and following an early phase of experiments with exotic tree species, the focus was first on protecting birch woodland remnants. Since about 1950, emphasis has been on afforestation through planting trees, both the native birch and introduced tree species. Today, the forest cover is 2% of land area, with native birch woodland covering about 1.6% and cultivated forests the rest.

With large areas that can be afforested, opportunities for climate mitigation through afforestation are great and enhanced action in forestry is a vital part of Iceland's 2020 Climate Action Plan. However, climate change and afforestation for climate mitigation also proposes several challenges, including the selection of tree species, tree improvements, the effects on biodiversity and ecosystem function, adaption of existing forests to new insects and pathogens, and conflicts between forestry and other land use to mention some.

The formation of planted forest in Kyushu, Japan - Analysis using the 1960 and 1970 World Census of Agriculture and Forestry-

T2.23 Planted Forests for Achieving a Sustainable Planet

Ryudai Ueno[1]
Takahiro Fujiwara[2], Noriko Sato[2]
[1] Graduate school of Bioresourse and Bioenviromental Sciences
[2] Faculty of Agriculture, Kyushu University

Abstract: The forest landscape in the world changed completely in the Anthropocene when human activities transformed the ecosystem. Japan is an example that has shown a dramatic change in the landscape, especially in Kyushu, which is one of Japan's main islands.The rate of planted forest in Kyushu was about 54 percent in 2017. It is over the rate in Japan, which is about 46 percent. Nowadays there is more logging in Kyushu than in other areas in Japan. Thus, it is necessary to determine the land use after logging. Natural regeneration is chosen as a land use after harvesting planted forests. It is implied that the amount of residual buried seeds affects whether natural regeneration will succeed. The amount depends on the vegetation history of the planted forest. Therefore, natural regeneration requires understanding of its history. The study will provide essential information to achieve sustainable planted forests in Kyushu. In addition, it will analyse the current situation of logging planted forests afforested in the 1960s and 1970s in Kyushu by the statistics of Kyushu's forest and field survey.The study uses the 1960 and 1970 World Census of Agriculture and Forestry. They classify land of pre-afforestation uses into three categories: (i) natural forests, (ii)planted forests, and (iii)non-forest. The afforestation rate in each land was calculated for regions based on the digitised data. As a result, landscape changes in Kyushu are indicated as follows. Firstly, it is obvious that the planted rate of non-forest in Kyushu was the second highest in all of Japan's regions in 1960 and 1970. Secondly, the afforestation rate in natural forest harvest sites in kyushu was the third lowest in and the rate of afforestation in Kyushu was also the highest in Japan in 1960 and 1970. The result indicates that the major characteristic of the forest landscape change in Kyushu was the establishment of planted forests, and their scale was larger than that of other regions in Japan

Timberland investment management organizations and carbon credits in plantation forestry - state of the art and prospects

T2.23 Planted Forests for Achieving a Sustainable Planet

Rafal Chudy[1]
Christian Held[2], Timm Tennigkeit[2], Jonas Nacke[2]
[1] Forest Business Analytics, Łódź, Poland.
[2] Unique land use GmbH, Freiburg, Germany.

Abstract: Timberland investment management organizations (TIMOs) have established timberland as an asset class in mature markets. However, the growing number of TIMO investment vehicles is increasingly at a mismatch with the universe of investable assets in these marketplaces. As a result, TIMOs are facing growth limitations and declining revenue generation opportunities in established markets and are considering expanding the business to emerging forestry markets. This paper focuses on the state of the art of TIMO market potentials in emerging markets and carbon credits from forest plantations as an additional investment incentive and revenue driver. Key challenges and prospects for promoting forest investments in emerging markets are discussed. TIMOs invest in brownfield assets with stable and predictable timber flows, and other revenue streams (e.g., from carbon credits) are not yet of high relevance. Nevertheless, carbon credits can provide a crucial early cashflow for afforestation and reforestation activities in emerging economies, and carbon revenues may increase TIMO investors' appetite for greenfield projects. We conclude that market liquidity is critical but sufficient e.g. in countries like Brazil, Uruguay or Chile. Supportive interventions in less advanced emerging economies are needed to stimulate greenfield investments and forest sector development in these locations. Such interventions may include the promotion of sustainably produced timber, tax and incentive regimes for forest plantations, industries and infrastructure investments, and developing robust carbon market and land tenure regulations. From the geographical perspective, Latin America shows clear signs of maturing markets, while Sub-Sahara Africa and Southeast Asia still require external support, such as blended finance investments.

Tree planting vs. natural forest regeneration: relative cost-effectiveness at mitigating climate change

T2.23 Planted Forests for Achieving a Sustainable Planet

Abstract: Mitigating climate change cost-effectively requires identifying least-cost-per-ton greenhouse gas abatement methods. Here, we estimate and map the greenhouse-gas abatement cost ($/t$CO_2$) of the two most common reforestation methods: monoculture forest plantations and passive natural forest regeneration. We do so by combining 355 observations of implementation costs incurred by reforestation projects with new maps of opportunity cost, likely plantation genus, and carbon accumulation accounting for storage in harvested wood products. We find natural regeneration would be more cost-effective at mitigating climate change than plantations across two-thirds (68%) of the area considered suitable for reforestation across low- and middle-income countries. Using the more cost-effective method at every location, the 30-year, time-discounted abatement potential of reforestation at or below a cost of $50/t$CO_2$ is 24.6 GtCO_2 (15.4–27.9 GtCO_2 at or below $20-100/t$CO_2$)—13% more than natural regeneration alone, or 114% more than plantations alone. We find that reforestation offers more abatement at lower prices than previously estimated by the Intergovernmental Panel on Climate Change—more than six times as much abatement at or below $20/t$CO_2$, and more than twice as much abatement at or below $50/t$CO_2$.

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

An Integrated approach of risk assessment and insurance structures in forestry investments

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Quentin Voituron[1]
Luiz Galizia[1], Heloise Huyghues Despointes[1], Ariane Kaploun[1], Sylvain Coutu[1], Christelle Castet[1]
[1] AXA Climate

Abstract: It is a pivotal time for investment in forestry as this asset class is considered to behave very well for diversification with long term perspective. The multifunction forestry plan combining sustainable logging and conservation for climate and biodiversity purposes can provide ROI of 15%, much better that any other natural asset class. But climate risks can jeopardise this acceleration and risk-transfer options have to be associated with adaptation plan to insure the residual risks. We propose an innovative approach that combines mechanistic-based agent-based modelling with statistical change detection using satellite-based data to design new forest insurance products. This integrated approach enables to consider the climate adaptation measures and design products whose pricing will not only reflect the historical data but also future risks integrating adaptation plan.

A Study on the Establishment of Green Funds for National Park Conservation in China

T2.24 Scaling up investments and finance towards a responsible forest bioeconomy

Haiying Su[1]
[1] Professor,Chinese Academy of Forestry

Abstract: China is one of the world's most biodiversity-rich countries, hosting many of the world's most important national parks for preserving forest and wetland eco-systems, and habitats for rare and endangered species, such as the giant panda and tiger. Though the Chinese government has issued relevant policies and measures to support national park management, financing gap remains huge because national parks in China still highly rely on public funding from the central and provincial governments.

Aiming to provide recommendations on mobilizing private resources and setting up long-term financing mechanisms for national parks, this Study first analyzed the financing challenges that national parks face in China, including lack of clarity in the designation of financial powers and expenditure responsibilities; short of funding sources; low efficiency and lack of monitoring and supervision in fund use.

Based on the in-depth analysis of the models and experiences of national park financing in both the developed and developing countries, such as the US, Australia, Japan, South Africa and Indonesia, the Study suggested to adopt market approach to broaden the funding sources of national parks and expand the involvement of the general public and the private sector in conservation in China.

Besides biodiversity bonds or public donations, the Study specifically recommended establishing the National Park Green Funds which is in line with the Chinese government's guidelines on green financing and conservation.

Built on the reflection of the operation of existing green funds in China, the Study provided detailed suggestions on the fundamentals of the National Park Green Funds, which include: Participants of a variety of financial institutions at central and local level with the central government being the initiator; A two-tier fund leveraging mechanism to replenish the funding for both the Fund of Funds at the top and the sub-funds targeting specific national parks; Market-based management of the sub-funds and prioritization of conservation and the value-for-money principle in the decision making of Fund for Funds; Investments in eco-tourism, carbon sink to address climate change and co-management.

The Study concluded with risk management recommendations and policy support for the smooth operation of the National Park Green Funds.

A win-win for restorations and value chains: Evidence from initiatives in African and Mesoamerican countries and Small Island Developing States
